Introduction

The Ninth Conference on Machine Translation (WMT 2024) took place on Friday, November 15 and Saturday, November 16, 2024, immediately following the 2024 Conference on Empirical Methods in Natural Language Processing (EMNLP 2024) in Miami, Florida, USA.

This is the ninth time WMT has been held as a conference. The first time WMT was held as a conference was at ACL 2016 in Berlin, Germany, the second time at EMNLP 2017 in Copenhagen, Denmark, the third time at EMNLP 2028 in Brussels, Belgium, the fourth time at ACL 2019 in Florence, Italy, the fifth time at EMNLP-2020, which was held as an online event due to the COVID-19 pandemic, the sixth time at EMNLP 2021 at Punta Cana, Dominican Republic, the seventh time at EMNLP 2022 in Abu Dhabi, United Arab Emirates, and the eight time at EMNLP 2023 in Singapore. Prior to being a conference, WMT was held 10 times as a workshop. WMT was held for the first time at HLT-NAACL 2006 in New York City, USA. In the following years the Workshop on Statistical Machine Translation was held at ACL 2007 in Prague, Czech Republic, ACL 2008, Columbus, Ohio, USA, EACL 2009 in Athens, Greece, ACL 2010 in Uppsala, Sweden, EMNLP 2011 in Edinburgh, Scotland, NAACL 2012 in Montreal, Canada, ACL 2013 in Sofia, Bulgaria, ACL 2014 in Baltimore, USA, EMNLP 2015 in Lisbon, Portugal.

The focus of our conference is to bring together researchers from the area of machine translation and invite selected research papers to be presented at the conference.

Prior to the conference, in addition to soliciting relevant papers for review and possible presentation, we conducted 12 shared tasks. These consisted of 8 translation tasks: General Translation, Translation into Low-Resource Languages of Spain, Low-Resource Indic Language Translation, Chat Translation, Biomedical Translation, MultiIndic22MT, Non-Repetitive Translation, English-to-Lowres Multi-Modal Translation, three evaluation tasks: Metrics, MT Test Suites, Quality Estimation, and finally the Open Language Data Initiative.

The results of all shared tasks were announced at the conference, and these proceedings also include overview papers for the shared tasks, summarizing the results, as well as providing information about the data used and any procedures that were followed in conducting or scoring the tasks. In addition, there are short papers from each participating team that describe their underlying system in greater detail.

Like in previous years, we have received a far larger number of submissions than we could accept for presentation. WMT 2024 has received 54 full research paper submissions (not counting withdrawn submissions). In total, WMT 2024 featured 25 full research paper presentations and 96 shared task presentations.

The invited talk entitled “What makes MT research special in the LLM age?was given by Ricardo Rei and Nuno M. Guerreiro from Unbabel, Portugal.

We would like to thank the members of the Program Committee for their timely reviews. We also would like to thank the participants of the shared task and all the other volunteers who helped with the evaluations.

Barry Haddow, Tom Kocmi, Philipp Koehn, and Christof Monz

Co-Organizers

Organizing Committee

Chairs

Barry Haddow, University of Edinburgh
Tom Kocmi, Cohere
Philipp Koehn, Johns Hopkins University
Christof Monz, University of Amsterdam

Program Committee

Program Committee

Sadaf Abdul Rauf, Fatima Jinnah Women Unversity
Antonios Anastasopoulos, George Mason University
Duygu Ataman, New York University
Eleftherios Avramidis, German Research Center for Artificial Intelligence (DFKI)

Program

Friday, November 15, 2024

08:45 - 09:00 *Opening Remarks*

09:00 - 10:30 *Session 1 — Shared Task Overview Papers I*

Findings of the WMT24 General Machine Translation Shared Task: The LLM Era Is Here but MT Is Not Solved Yet
Tom Kocmi, Eleftherios Avramidis, Rachel Bawden, Ondřej Bojar, Anton Dvorkovich, Christian Federmann, Mark Fishel, Markus Freitag, Thamme Gowda, Roman Grundkiewicz, Barry Haddow, Marzena Karpinska, Philipp Koehn, Benjamin Marie, Christof Monz, Kenton Murray, Masaaki Nagata, Martin Popel, Maja Popović, Mariya Shmatova, Steinthór Steingrímsson and Vilém Zouhar

Are LLMs Breaking MT Metrics? Results of the WMT24 Metrics Shared Task
Markus Freitag, Nitika Mathur, Daniel Deutsch, Chi-Kiu Lo, Eleftherios Avramidis, Ricardo Rei, Brian Thompson, Frederic Blain, Tom Kocmi, Jiayi Wang, David Ifeoluwa Adelani, Marianna Buchicchio, Chrysoula Zerva and Alon Lavie

Findings of the Quality Estimation Shared Task at WMT 2024: Are LLMs Closing the Gap in QE?
Chrysoula Zerva, Frederic Blain, José G. C. De Souza, Diptesh Kanojia, Sourabh Deoghare, Nuno M. Guerreiro, Giuseppe Attanasio, Ricardo Rei, Constantin Orasan, Matteo Negri, Marco Turchi, Rajen Chatterjee, Pushpak Bhattacharyya, Markus Freitag and André Martins

Findings of the WMT 2024 Shared Task of the Open Language Data Initiative
Jean Maillard, Laurie Burchell, Antonios Anastasopoulos, Christian Federmann, Philipp Koehn and Skyler Wang

Results of the WAT/WMT 2024 Shared Task on Patent Translation
Shohei Higashiyama

Findings of the WMT 2024 Biomedical Translation Shared Task: Test Sets on Abstract Level
Mariana Neves, Cristian Grozea, Philippe Thomas, Roland Roller, Rachel Bawden, Aurélie Névéol, Steffen Castle, Vanessa Bonato, Giorgio Maria Di Nunzio, Federica Vezzani, Maika Vicente Navarro, Lana Yeganova and Antonio Jimeno Yepes

10:30 - 11:00 *Coffee Break*

11:00 - 12:00 *Session 1 — Shared Task Overview Papers I*

11:00 - 12:00 *General Translation Task*

MSLC24 Submissions to the General Machine Translation Task
Samuel Larkin, Chi-Kiu Lo and Rebecca Knowles

IOL Research Machine Translation Systems for WMT24 General Machine Translation Shared Task
Wenbo Zhang

Friday, November 15, 2024 (continued)

Choose the Final Translation from NMT and LLM Hypotheses Using MBR Decoding: HW-TSC's Submission to the WMT24 General MT Shared Task
Zhanglin Wu, Daimeng Wei, Zongyao Li, Hengchao Shang, Jiaxin Guo, Shaojun Li, Zhiqiang Rao, Yuanchang Luo, Ning Xie and Hao Yang

CycleGN: A Cycle Consistent Approach for Neural Machine Translation
Sören Dreano, Derek Molloy and Noel Murphy

UvA-MT's Participation in the WMT24 General Translation Shared Task
Shaomu Tan, David Stap, Seth Aycock, Christof Monz and Di Wu

Tower v2: Unbabel-IST 2024 Submission for the General MT Shared Task
Ricardo Rei, Jose Pombal, Nuno M. Guerreiro, João Alves, Pedro Henrique Martins, Patrick Fernandes, Helena Wu, Tania Vaz, Duarte Alves, Amin Farajian, Sweta Agrawal, Antonio Farinhas, José G. C. De Souza and André Martins

TSU HITS's Submissions to the WMT 2024 General Machine Translation Shared Task
Vladimir Mynka and Nikolay Mikhaylovskiy

Document-level Translation with LLM Reranking: Team-J at WMT 2024 General Translation Task
Keito Kudo, Hiroyuki Deguchi, Makoto Morishita, Ryo Fujii, Takumi Ito, Shintaro Ozaki, Koki Natsumi, Kai Sato, Kazuki Yano, Ryosuke Takahashi, Subaru Kimura, Tomomasa Hara, Yusuke Sakai and Jun Suzuki

DLUT and GTCOM's Neural Machine Translation Systems for WMT24
Hao Zong, Chao Bei, Huan Liu, Conghu Yuan, Wentao Chen and Degen Huang

CUNI at WMT24 General Translation Task: LLMs, (Q)LoRA, CPO and Model Merging
Miroslav Hrabal, Josef Jon, Martin Popel, Nam Luu, Danil Semin and Ondřej Bojar

From General LLM to Translation: How We Dramatically Improve Translation Quality Using Human Evaluation Data for LLM Finetuning
Denis Elshin, Nikolay Karpachev, Boris Gruzdev, Ilya Golovanov, Georgy Ivanov, Alexander Antonov, Nickolay Skachkov, Ekaterina Latypova, Vladimir Layner, Ekaterina Enikeeva, Dmitry Popov, Anton Chekashev, Vladislav Negodin, Vera Frantsuzova, Alexander Chernyshev and Kirill Denisov

Cogs in a Machine, Doing What They're Meant to Do – the AMI Submission to the WMT24 General Translation Task
Atli Jasonarson, Hinrik Hafsteinsson, Bjarki Ármannsson and Steinthór Steingrímsson

IKUN for WMT24 General MT Task: LLMs Are Here for Multilingual Machine Translation
Baohao Liao, Christian Herold, Shahram Khadivi and Christof Monz

NTTSU at WMT2024 General Translation Task
Minato Kondo, Ryo Fukuda, Xiaotian Wang, Katsuki Chousa, Masato Nishimura, Kosei Buma, Takatomo Kano and Takehito Utsuro

SCIR-MT's Submission for WMT24 General Machine Translation Task
Baohang Li, Zekai Ye, Yichong Huang, Xiaocheng Feng and Bing Qin

AIST AIRC Systems for the WMT 2024 Shared Tasks
Matiss Rikters and Makoto Miwa

Occiglot at WMT24: European Open-source Large Language Models Evaluated on Translation
Eleftherios Avramidis, Annika Grützner-Zahn, Manuel Brack, Patrick Schramowski, Pedro Ortiz Suarez, Malte Ostendorff, Fabio Barth, Shushen Manakhimova, Vivien Macketanz, Georg Rehm and Kristian Kersting

11:00 - 12:00 *Test Suites*

CoST of breaking the LLMs
Ananya Mukherjee, Saumitra Yadav and Manish Shrivastava

WMT24 Test Suite: Gender Resolution in Speaker-Listener Dialogue Roles
Hillary Dawkins, Isar Nejadgholi and Chi-Kiu Lo

The GenderQueer Test Suite
Steinunn Rut Friidhriksdóttir

Domain Dynamics: Evaluating Large Language Models in English-Hindi Translation
Soham Bhattacharjee, Baban Gain and Asif Ekbal

Investigating the Linguistic Performance of Large Language Models in Machine Translation
Shushen Manakhimova, Vivien Macketanz, Eleftherios Avramidis, Ekaterina Lapshinova-Koltunski, Sergei Bagdasarov and Sebastian Möller

IsoChronoMeter: A Simple and Effective Isochronic Translation Evaluation Metric
Nikolai Rozanov, Vikentiy Pankov, Dmitrii Mukhutdinov and Dima Vypirailenko

Friday, November 15, 2024 (continued)

A Test Suite of Prompt Injection Attacks for LLM-based Machine Translation
Antonio Valerio Miceli Barone and Zhifan Sun

Killing Two Flies with One Stone: An Attempt to Break LLMs Using English-Icelandic Idioms and Proper Names
Bjarki Ármannsson, Hinrik Hafsteinsson, Atli Jasonarson and Steinthor Steingrimsson

12:30 - 13:30 *Session 3 — Shared Task Posters II*

12:30 - 13:30 *Metrics Task*

MetaMetrics-MT: Tuning Meta-Metrics for Machine Translation via Human Preference Calibration
David Anugraha, Garry Kuwanto, Lucky Susanto, Derry Tanti Wijaya and Genta Winata

chrF-S: Semantics Is All You Need
Ananya Mukherjee and Manish Shrivastava

MSLC24: Further Challenges for Metrics on a Wide Landscape of Translation Quality
Rebecca Knowles, Samuel Larkin and Chi-Kiu Lo

MetricX-24: The Google Submission to the WMT 2024 Metrics Shared Task
Juraj Juraska, Daniel Deutsch, Mara Finkelstein and Markus Freitag

Evaluating WMT 2024 Metrics Shared Task Submissions on AfriMTE (the African Challenge Set)
Jiayi Wang, David Ifeoluwa Adelani and Pontus Stenetorp

Machine Translation Metrics Are Better in Evaluating Linguistic Errors on LLMs than on Encoder-Decoder Systems
Eleftherios Avramidis, Shushen Manakhimova, Vivien Macketanz and Sebastian Möller

12:30 - 13:30 *Quality Estimation Task*

TMU-HIT's Submission for the WMT24 Quality Estimation Shared Task: Is GPT-4 a Good Evaluator for Machine Translation?
Ayako Sato, Kyotaro Nakajima, Hwichan Kim, Zhousi Chen and Mamoru Komachi

HW-TSC 2024 Submission for the Quality Estimation Shared Task
Weiqiao Shan, Ming Zhu, Yuang Li, Mengyao Piao, Xiaofeng Zhao, Chang Su, Min Zhang, Hao Yang and Yanfei Jiang

HW-TSC's Participation in the WMT 2024 QEAPE Task
Jiawei Yu, Xiaofeng Zhao, Min Zhang, Zhao Yanqing, Yuang Li, Su Chang, Xiaosong Qiao, Ma Miaomiao and Hao Yang

12:30 - 13:30 *Open Language Data Initiative*

Expanding the FLORES+ Multilingual Benchmark with Translations for Aragonese, Aranese, Asturian, and Valencian
Juan Antonio Perez-Ortiz, Felipe Sánchez-Martínez, Víctor M. Sánchez-Cartagena, Miquel Esplà-Gomis, Aaron Galiano Jimenez, Antoni Oliver, Claudi Aventín-Boya, Alejandro Pardos, Cristina Valdés, Jusèp Loís Sans Socasau and Juan Pablo Martínez

The Bangla/Bengali Seed Dataset Submission to the WMT24 Open Language Data Initiative Shared Task
Firoz Ahmed, Nitin Venkateswaran and Sarah Moeller

A High-quality Seed Dataset for Italian Machine Translation
Edoardo Ferrante

Correcting FLORES Evaluation Dataset for Four African Languages
Idris Abdulmumin, Sthembiso Mkhwanazi, Mahlatse Mbooi, Shamsuddeen Hassan Muhammad, Ibrahim Said Ahmad, Neo Putini, Miehleketo Mathebula, Matimba Shingange, Tajuddeen Gwadabe and Vukosi Marivate

Expanding FLORES+ Benchmark for More Low-Resource Settings: Portuguese-Emakhuwa Machine Translation Evaluation
Felermino Dario Mario Ali, Henrique Lopes Cardoso and Rui Sousa-Silva

Enhancing Tuvan Language Resources through the FLORES Dataset
Ali Kuzhuget, Airana Mongush and Nachyn-Enkhedorzhu Oorzhak

Machine Translation Evaluation Benchmark for Wu Chinese: Workflow and Analysis
Hongjian Yu, Yiming Shi, Zherui Zhou and Christopher Haberland

Open Language Data Initiative: Advancing Low-Resource Machine Translation for Karakalpak
Mukhammadsaid Mamasaidov and Abror Shopulatov

Friday, November 15, 2024 (continued)

FLORES+ Translation and Machine Translation Evaluation for the Erzya Language
Isai Gordeev, Sergey Kuldin and David Dale

Spanish Corpus and Provenance with Computer-Aided Translation for the WMT24 OLDI Shared Task
Jose Cols

12:30 - 13:30 *Patent Translation Task*

Efficient Terminology Integration for LLM-based Translation in Specialized Domains
Sejoon Kim, Mingi Sung, Jeonghwan Lee, Hyunkuk Lim and Jorge Gimenez Perez

Rakuten's Participation in WMT 2024 Patent Translation Task
Ohnmar Htun and Alberto Poncelas

12:30 - 13:30 *Biomedical Translation Task*

The SETU-ADAPT Submission for WMT 24 Biomedical Shared Task
Antonio Castaldo, Maria Zafar, Prashanth Nayak, Rejwanul Haque, Andy Way and Johanna Monti

14:00 - 15:00 *Session 4 — Invited Talk by Ricardo Rei and Nuno M. Guerreiro. What Makes MT Research Special in the LLM Age?"*

15:00 - 15:30 *Coffee Break*

15:30 - 17:00 *Session 5 — Featured Research Papers Oral Presentations*

Translating Step-by-Step: Decomposing the Translation Process for Improved Translation Quality of Long-Form Texts
Eleftheria Briakou, Jiaming Luo, Colin Cherry and Markus Freitag

Is Preference Alignment Always the Best Option to Enhance LLM-Based Translation? An Empirical Analysis
Hippolyte Gisserot-Boukhlef, Ricardo Rei, Emmanuel Malherbe, Céline Hudelot, Pierre Colombo and Nuno M. Guerreiro

On Instruction-Finetuning Neural Machine Translation Models
Vikas Raunak, Roman Grundkiewicz and Marcin Junczys-Dowmunt

Saturday, November 16, 2024

09:00 - 10:30 *Session 6 — Shared Task Overview Papers II*

Findings of WMT 2024 Shared Task on Low-Resource Indic Languages Translation
Partha Pakray, Santanu Pal, Advaitha Vetagiri, Reddi Krishna, Arnab Kumar Maji, Sandeep Dash, Lenin Laitonjam, Lyngdoh Sarah and Riyanka Manna

Findings of WMT 2024's MultiIndic22MT Shared Task for Machine Translation of 22 Indian Languages
Raj Dabre and Anoop Kunchukuttan

Findings of WMT2024 English-to-Low Resource Multimodal Translation Task
Shantipriya Parida, Ondřej Bojar, Idris Abdulmumin, Shamsuddeen Hassan Muhammad and Ibrahim Said Ahmad

Findings of the WMT 2024 Shared Task Translation into Low-Resource Languages of Spain: Blending Rule-Based and Neural Systems
Felipe Sánchez-Martínez, Juan Antonio Perez-Ortiz, Aaron Galiano Jimenez and Antoni Oliver

Findings of the WMT 2024 Shared Task on Discourse-Level Literary Translation
Longyue Wang, Siyou Liu, Chenyang Lyu, Wenxiang Jiao, Xing Wang, Jiahao Xu, Zhaopeng Tu, Yan Gu, Weiyu Chen, Minghao Wu, Liting Zhou, Philipp Koehn, Andy Way and Yulin Yuan

Findings of the WMT 2024 Shared Task on Chat Translation
Wafaa Mohammed, Sweta Agrawal, Amin Farajian, Vera Cabarrão, Bryan Eikema, Ana C Farinha and José G. C. De Souza

Findings of the WMT 2024 Shared Task on Non-Repetitive Translation
Kazutaka Kinugawa, Hideya Mino, Isao Goto and Naoto Shirai

10:30 - 11:00 *Coffee Break*

11:00 - 12:00 *Session 7 — Shared Task Posters III*

11:00 - 12:00 *Low-Resource Indic Language Translation Task*

A3-108 Controlling Token Generation in Low Resource Machine Translation Systems
Saumitra Yadav, Ananya Mukherjee and Manish Shrivastava

Saturday, November 16, 2024 (continued)

Samsung R&D Institute Philippines @ WMT 2024 Indic MT Task
Matthew Theodore Roque, Carlos Rafael Catalan, Dan John Velasco, Manuel Antonio Rufino and Jan Christian Blaise Cruz

DLUT-NLP Machine Translation Systems for WMT24 Low-Resource Indic Language Translation
Chenfei Ju, Junpeng Liu, Kaiyu Huang and Degen Huang

SRIB-NMT's Submission to the Indic MT Shared Task in WMT 2024
Pranamya Patil, Raghavendra Hr, Aditya Raghuwanshi and Kushal Verma

MTNLP-IIITH: Machine Translation for Low-Resource Indic Languages
Abhinav P M, Ketaki Shetye and Parameswari Krishnamurthy

Exploration of the CycleGN Framework for Low-Resource Languages
Sören Dreano, Derek Molloy and Noel Murphy

The SETU-ADAPT Submissions to the WMT24 Low-Resource Indic Language Translation Task
Neha Gajakos, Prashanth Nayak, Rejwanul Haque and Andy Way

SPRING Lab IITM's Submission to Low Resource Indic Language Translation Shared Task
Advait Joglekar, Hamees Ul Hasan Sayed and Srinivasan Umesh

Machine Translation Advancements of Low-Resource Indian Languages by Transfer Learning
Bin Wei, Zheng Jiawei, Zongyao Li, Zhanglin Wu, Jiaxin Guo, Daimeng Wei, Zhiqiang Rao, Shaojun Li, Yuanchang Luo, Hengchao Shang, Jinlong Yang, Yuhao Xie and Hao Yang

NLIP_Lab-IITH Low-Resource MT System for WMT24 Indic MT Shared Task
Pramit Sahoo, Maharaj Brahma and Maunendra Sankar Desarkar

Yes-MT's Submission to the Low-Resource Indic Language Translation Shared Task in WMT 2024
Yash Bhaskar and Parameswari Krishnamurthy

11:00 - 12:00 *MultiIndic22MT Task*

Saturday, November 16, 2024 (continued)

System Description of BV-SLP for Sindhi-English Machine Translation in MultiIndic22MT 2024 Shared Task
Nisheeth Joshi, Pragya Katyayan, Palak Arora and Bharti Nathani

WMT24 System Description for the MultiIndic22MT Shared Task on Manipuri Language
Ningthoujam Justwant Singh, Kshetrimayum Boynao Singh, Ningthoujam Avichandra Singh, Sanjita Phijam and Thoudam Doren Singh

NLIP-Lab-IITH Multilingual MT System for WAT24 MT Shared Task
Maharaj Brahma, Pramit Sahoo and Maunendra Sankar Desarkar

11:00 - 12:00 *English-to-Lowres Multi-Modal Translation Task*

DCU ADAPT at WMT24: English to Low-resource Multi-Modal Translation Task
Sami Haq, Rudali Huidrom and Sheila Castilho

English-to-Low-Resource Translation: A Multimodal Approach for Hindi, Malayalam, Bengali, and Hausa
Ali Hatami, Shubhanker Banerjee, Mihael Arcan, Bharathi Chakravarthi, Paul Buitelaar and John Mccrae

OdiaGenAI's Participation in WMT2024 English-to-Low Resource Multimodal Translation Task
Shantipriya Parida, Shashikanta Sahoo, Sambit Sekhar, Upendra Jena, Sushovan Jena and Kusum Lata

Arewa NLP's Participation at WMT24
Mahmoud Ahmad, Auwal Khalid, Lukman Aliyu, Babangida Sani and Mariya Abdullahi

Multimodal Machine Translation for Low-Resource Indic Languages: A Chain-of-Thought Approach Using Large Language Models
Pawan Rajpoot, Nagaraj Bhat and Ashish Shrivastava

Chitranuvad: Adapting Multi-lingual LLMs for Multimodal Translation
Shaharukh Khan, Ayush Tarun, Ali Faraz, Palash Kamble, Vivek Dahiya, Praveen Pokala, Ashish Kulkarni, Chandra Khatri, Abhinav Ravi and Shubham Agarwal

Brotherhood at WMT 2024: Leveraging LLM-Generated Contextual Conversations for Cross-Lingual Image Captioning
Siddharth Betala and Ishan Chokshi

12:30 - 13:30 *Session 8 — Shared Task Posters IV*

12:30 - 13:30 *Translation into Low-Resource Languages of Spain Task*

TIM-UNIGE Translation into Low-Resource Languages of Spain for WMT24
Jonathan Mutal and Lucía Ormaechea

TAN-IBE Participation in the Shared Task: Translation into Low-Resource Languages of Spain
Antoni Oliver

Enhaced Apertium System: Translation into Low-Resource Languages of Spain Spanish–Asturian
Sofía García

Universitat d'Alacant's Submission to the WMT 2024 Shared Task on Translation into Low-Resource Languages of Spain
Aaron Galiano Jimenez, Víctor M. Sánchez-Cartagena, Juan Antonio Perez-Ortiz and Felipe Sánchez-Martínez

Samsung R&D Institute Philippines @ WMT 2024 Low-resource Languages of Spain Shared Task
Dan John Velasco, Manuel Antonio Rufino and Jan Christian Blaise Cruz

Back to the Stats: Rescuing Low Resource Neural Machine Translation with Statistical Methods
Menan Velayuthan, Dilith Jayakody, Nisansa De Silva, Aloka Fernando and Surangika Ranathunga

Hybrid Distillation from RBMT and NMT: Helsinki-NLP's Submission to the Shared Task on Translation into Low-Resource Languages of Spain
Ona De Gibert, Mikko Aulamo, Yves Scherrer and Jörg Tiedemann

Robustness of Fine-Tuned LLMs for Machine Translation with Varying Noise Levels: Insights for Asturian, Aragonese and Aranese
Martin Bär, Elisa Forcada Rodríguez and Maria Garcia-Abadillo

Training and Fine-Tuning NMT Models for Low-Resource Languages Using Apertium-Based Synthetic Corpora
Aleix Sant, Daniel Bardanca, José Ramom Pichel Campos, Francesca De Luca Fornaciari, Carlos Escolano, Javier Garcia Gilabert, Pablo Gamallo, Audrey Mash, Xixian Liao and Maite Melero

Vicomtech@WMT 2024: Shared Task on Translation into Low-Resource Languages of Spain
David Ponce, Harritxu Gete and Thierry Etchegoyhen

Saturday, November 16, 2024 (continued)

SJTU System Description for the WMT24 Low-Resource Languages of Spain Task
Tianxiang Hu, Haoxiang Sun, Ruize Gao, Jialong Tang, Pei Zhang, Baosong Yang and Rui Wang

Multilingual Transfer and Domain Adaptation for Low-Resource Languages of Spain
Yuanchang Luo, Zhanglin Wu, Daimeng Wei, Hengchao Shang, Zongyao Li, Jiaxin Guo, Zhiqiang Rao, Shaojun Li, Jinlong Yang, Yuhao Xie, Zheng Jiawei, Bin Wei and Hao Yang

TRIBBLE - TRanslating IBerian languages Based on Limited E-resources
Igor Kuzmin, Piotr Przybyła, Euan Mcgill and Horacio Saggion

12:30 - 13:30 *Discourse-Level Literary Translation Task*

CloudSheep System for WMT24 Discourse-Level Literary Translation
Lisa Liu, Ryan Liu, Angela Tsai and Jingbo Shang

Final Submission of SJTULoveFiction to Literary Task
Haoxiang Sun, Tianxiang Hu, Ruize Gao, Jialong Tang, Pei Zhang, Baosong Yang and Rui Wang

Context-aware and Style-related Incremental Decoding Framework for Discourse-Level Literary Translation
Yuanchang Luo, Jiaxin Guo, Daimeng Wei, Hengchao Shang, Zongyao Li, Zhanglin Wu, Zhiqiang Rao, Shaojun Li, Jinlong Yang and Hao Yang

NovelTrans: System for WMT24 Discourse-Level Literary Translation
Yuchen Liu, Yutong Yao, Runzhe Zhan, Yuchu Lin and Derek F. Wong

LinChance-NTU for Unconstrained WMT2024 Literary Translation
Kechen Li, Yaotian Tao, Hongyi Huang and Tianbo Ji

12:30 - 13:30 *Chat Translation Task*

Improving Context Usage for Translating Bilingual Customer Support Chat with Large Language Models
Jose Pombal, Sweta Agrawal and André Martins

Optimising LLM-Driven Machine Translation with Context-Aware Sliding Windows
Xinye Yang, Yida Mu, Kalina Bontcheva and Xingyi Song

Saturday, November 16, 2024 (continued)

Context-Aware LLM Translation System Using Conversation Summarization and Dialogue History
Mingi Sung, Seungmin Lee, Jiwon Kim and Sejoon Kim

Enhancing Translation Quality: A Comparative Study of Fine-Tuning and Prompt Engineering in Dialog-Oriented Machine Translation Systems. Insights from the MULTITAN-GML Team
Lichao Zhu, Maria Zimina, Behnoosh Namdarzadeh, Nicolas Ballier and Jean-Baptiste Yunès

The SETU-ADAPT Submissions to WMT 2024 Chat Translation Tasks
Maria Zafar, Antonio Castaldo, Prashanth Nayak, Rejwanul Haque and Andy Way

Exploring the Traditional NMT Model and Large Language Model for Chat Translation
Jinlong Yang, Hengchao Shang, Daimeng Wei, Jiaxin Guo, Zongyao Li, Zhanglin Wu, Zhiqiang Rao, Shaojun Li, Yuhao Xie, Yuanchang Luo, Zheng Jiawei, Bin Wei and Hao Yang

Graph Representations for Machine Translation in Dialogue Settings
Lea Krause, Selene Baez Santamaria and Jan-Christoph Kalo

12:30 - 13:30 *Non-Repetitive Translation Task*

Reducing Redundancy in Japanese-to-English Translation: A Multi-Pipeline Approach for Translating Repeated Elements in Japanese
Qiao Wang, Yixuan Huang and Zheng Yuan

SYSTRAN @ WMT24 Non-Repetitive Translation Task
Marko Avila and Josep Crego

14:00 - 15:30 *Session 9 — Research Paper Boaster Session*

15:30 - 16:30 *Session 10 — Research Paper Poster Session I*

Mitigating Metric Bias in Minimum Bayes Risk Decoding
Geza Kovacs, Daniel Deutsch and Markus Freitag

Beyond Human-Only: Evaluating Human-Machine Collaboration for Collecting High-Quality Translation Data
Zhongtao Liu, Parker Riley, Daniel Deutsch, Alison Lui, Mengmeng Niu, Apurva Shah and Markus Freitag

Saturday, November 16, 2024 (continued)

How Effective Are State Space Models for Machine Translation?
Hugo Pitorro, Pavlo Vasylenko, Marcos Treviso and André Martins

Evaluation and Large-scale Training for Contextual Machine Translation
Matt Post and Marcin Junczys-Dowmunt

A Multi-task Learning Framework for Evaluating Machine Translation of Emotion-loaded User-generated Content
Shenbin Qian, Constantin Orasan, Diptesh Kanojia and Félix Do Carmo

On Instruction-Finetuning Neural Machine Translation Models
Vikas Raunak, Roman Grundkiewicz and Marcin Junczys-Dowmunt

Benchmarking Visually-Situated Translation of Text in Natural Images
Elizabeth Salesky, Philipp Koehn and Matt Post

Analysing Translation Artifacts: A Comparative Study of LLMs, NMTs, and Human Translations
Fedor Sizov, Cristina España-Bonet, Josef Van Genabith, Roy Xie and Koel Dutta Chowdhury

How Grammatical Features Impact Machine Translation: A New Test Suite for Chinese-English MT Evaluation
Huacheng Song, Yi Li, Yiwen Wu, Yu Liu, Jingxia Lin and Hongzhi Xu

Abstract

This overview paper presents the results of the General Machine Translation Task organised as part of the 2024 Conference on Machine Translation (WMT). In the general MT task, participants were asked to build machine translation systems for any of 11 language pairs, to be evaluated on test sets consisting of three to five different domains. In addition to participating systems, we collected translations from 8 different large language models (LLMs) and 4 online translation providers. We evaluate system outputs with professional human annotators using a new protocol called Error Span Annotations (ESA).

1 Introduction

The Ninth Conference on Machine Translation (WMT24)[1] was held at EMNLP 2024 and hosted a number of shared tasks on various aspects of machine translation (MT). This conference built on 18 previous editions as a workshop or a conference (Koehn and Monz, 2006; Callison-Burch et al., 2007, 2008, 2009, 2010, 2011, 2012; Bojar et al., 2013, 2014, 2015, 2016, 2017, 2018; Barrault et al., 2019, 2020; Akhbardeh et al., 2021; Kocmi et al., 2022, 2023).

The goal of the General Machine Translation shared task is to explore the translation capabilities of current systems in diverse settings. We assess MT systems' ability to handle a broad range of translation and language use. How to test general MT performance is a research question in itself. Countless phenomena could be evaluated, the most important being:

- variety of domain (news, medicine, IT, patents, legal, social, gaming, etc.)
- style of text (formal or spoken language, fiction, technical reports, etc.)
- non-standard user-generated content (grammatical errors, code-switching, abbreviations, etc.)
- source modalities (text, speech, image)

Evaluating all phenomena is nearly impossible and creates numerous unforeseen problems. Therefore, we decided to simplify the problem and tackle only a selection of the phenomena.

We choose to evaluate different domains, this year focusing on the following ones: news, social/user-generated content, speech, literary, and educational. They were chosen to represent topics with different content styles and to be understandable for humans without specialist in-domain knowledge, thus not requiring specialized translators or human raters for evaluation. Due to limited access to monolingual data across all languages,

Proceedings of the Ninth Conference on Machine Translation, pages 1–46
November 15-16, 2024 ©2024 Association for Computational Linguistics

the test set for each language direction contains at most four of the domains (Czech-Ukrainian uses different domains).

We evaluate a diverse set of languages pairs:

Czech→Ukrainian,
Japanese→Chinese – *new*,
English→Chinese,
English→Czech,
English→German,
English→Hindi,
English→Icelandic – *new*,
English→Japanese,
English→Russian,
English→Spanish (Latin America) – *new*,
English→Ukrainian,

We newly test an audio modality as an additional source in the speech domain. Participants in this domain were provided with audio files and automatic speech recognized (ASR) text. Submission could use the original audio as an additional cleaner source modality instead of the provided ASR text.

In contrast to previous years, we adopt the Error Span Annotation protocol (Kocmi et al., 2024b), ESA for evaluation. This protocol, described in Section 6, combines aspects of DA (Graham et al., 2013) and MQM (Lommel et al., 2014).

In a shift towards document-level evaluation, we no longer provide source texts segmented into individual sentences. Instead, we keep all paragraphs intact and evaluated together.

Finally, this year's shared task included an increased number of test suites (Section 8) under the motto "Help us break the LLMs", focusing on revealing issues in the LLM translations from different perspectives, including a range of linguistic phenomena, idiomatic expressions and proper names, complex sentence structures, multiple domains, translation isochrony, speaker-listener gender resolution, prompt injection attacks, and gender-diverse, queer-inclusive content.

All General MT task submissions, sources, references and human judgements are available in the dedicated Github repository.[2] The interactive visualization and comparison of differences between systems can be browsed online on an interactive leaderboard[3] using MT-ComparEval (Klejch et al., 2015; Sudarikov et al., 2016).

The structure of the paper is as follows. We describe the process of collecting, cleaning and translating the test sets in Section 2 followed by a summary of the permitted training data and pretrained models for the constrained track in Section 3. We list all submitted systems in Section 4. Automatic evaluation is described in Section 5. The human evaluation approach of ESA is described in Section 6. The main results can be found in Section 7 and their extended version in Appendix D. Finally, Section 8 describes the test suites and summarises their conclusions.

Findings of the WMT2024 General MT Task Across the evaluation conditions, we observe the following:

- The best systems for English→Spanish produced close to flawless translations making it the easiest language pair (Section 6.4).

- The speech domain is the most challenging domain (likely due to the ASR) while the other three domains (news, literary, social) are similarly difficult (Section 6.4).

- Human references are in the winning cluster in 7 out of 11 language pairs. For one of the remaining 4 pairs (English→Hindi), we know the reference quality was suboptimal. This suggest that ESA protocol works well in our setting.

- ESA produced 37% more clusters than DA+SQM while using only half the number of human annotations (Section 6.5).

- The best performing system in the open and constrained system category is IOL-Research (wins 10 language pairs in this category). The best performing participating system is Unbabel-Tower70B, which wins in 8 language pairs. And the best performing system in general is Claude-3.5-Sonnet winning in 9 language pairs.

- Automatic scores are biased; although Unbabel-Tower70B placed first across all languages in automatic ranking it didn't perform as the winning system across the board of human evaluation. This is likely because we used the same metric (COMET) for automatic ranking as the system used during MBR highlighting the issue of hill-climbing on automatic metrics.

- We got a total of 28 participants, which nearly 50% more than last year. Most of the participants use an LLM as a part of their system, generally by fine-tuning it.

[2] github.com/wmt-conference/wmt24-news-systems
[3] wmt.ufal.cz

- Quality estimation metrics with fixed score for perfect translation and interpretable delta are promising for checking the quality of standalone human references.

2 Test Data

In this section, we describe the data collection process (Section 2.1), and the production of human reference translations (Section 2.3).

2.1 Collecting test data

As in previous years, the test sets consist of unseen translations created specifically for the shared task and released publicly to be used as translation benchmarks. Our aim was to collect public domain or open-licence source data covering a range of domains, and we also focused on using as recent data as possible to limit possible contamination (particularly relevant when using LLMs).

We chose four main domains from which to collect data (news, literary, speech and social), although we were not able to collect data in all domains for all three source languages (no social domain data is provided for Japanese→Chinese and Czech→Ukrainian data was collected separately, comprising news data and four other separate domains). For all language pairs, the test sets are "source-original", meaning that the text was originally written in the source language, which is then manually translated into the target languages. This is important to avoid "translationese" in the source texts, which can have a negative impact on evaluation accuracy (Toral et al., 2018; Freitag et al., 2019; Läubli et al., 2020; Graham et al., 2020). We aimed for a certain number of *tokens*[4] in each domain rather than a certain number of *sentences* (as in previous years) to better balance the domains and also because the document-level focus this year allowed avoid manual sentence splitting. We aimed for approximately 10,000 tokens per domain, adjusting this figure in cases where not all domains could be covered (this is notably the case for Japanese→Chinese, where the other domains are up-sampled to account for us not being able to provide data in the social domain). Basic statistics of each subdomain are given in Table 1.[5]

Note that by default, when languages are mentioned in this section, this refers to the source language of the texts.

News domain This domain contains data prepared in the same way as in previous years (Kocmi et al., 2023). We collected news articles from January 2024 extracted from online news sites, preserving document boundaries. We expect that news domain text will generally be of high quality.

For Japanese, the total amount of text data was determined by the number of characters since Japanese does not put spaces between words. Using the WMT23 Japanese test set and its translation into English, we found the ratio of the number of Japanese characters to English words was 2 to 1. Since the English news test set consisted of 8K words, we started making a Japanese news test set with a goal of 16K characters. After discovering that the Japanese social domain was unavailable, we set this goal to 24K characters.

Literary Domain The English source texts were manually selected from Archive of Our Own,[6] focusing on recent, high-quality stories.[7] The stories were divided into 1000-word segments, ensuring the preservation of entire paragraphs. In total, we obtained data from four stories (8K words).[8]

For the Japanese source texts, we selected five novels recently made public on Aozora Bunko,[9] a website that digitizes and publishes Japanese literary works whose copyright has expired. To maintain consistency with the English dataset, we tokenized the Japanese novels using MeCab (Kudo, 2005) and divided them into segments of up to 1000 tokens, while preserving paragraph boundaries. The final size of the Japanese literary test set was 15 chunks (22K characters).

Speech domain The speech data corpus was compiled from a diverse range of YouTube videos licensed under Creative Commons. These sources encompassed various domains, including documentaries, instructional (DIY) videos, tutorials, travel blogs, and film content. For this part of the test set, segments from 166 videos were selected and processed through automated speech recognition (ASR) systems. For the English-language source

[4] For Japanese source texts, we choose to use a certain number of characters, since words are not space-separated.

[5] Texts are sentence-segmented and tokenised using the language-specific Spacy models (Honnibal and Montani, 2017) optimised for accuracy where available. For Czech, we use the multilingual Spacy model, as a language-specific one is not available. Note that statistics, particularly for this language, are approximate.

[6] archiveofourown.org

[7] Texts were published between February and April 2024.

[8] For each, we select first two chunks of up to 1000 words.

Table 1: Basic statistics concerning the subdomains of each test set. Statistics are calculated on the source side. Sentence segmentation and tokenisation are carried out automatically as described in Footnote 5.

material, we used the proprietary Dubformer engine developed in-house. Japanese-language content was processed using the Whisper ASR system (Radford et al., 2022).

For Japanese, We selected 136 segments from 56 YouTube videos. They include both monologues and dialogues, as well as a variety of speakers, both men and women, adults and children. Video content includes press conferences, interviews, cooking recipes, travel vlogs, DIY videos, tutorials, product reviews, etc. We decided the total amount of speech data based on the number of characters transcribed. We started creating the data with a target of 16K characters and eventually ended up with 18K characters.

Social domain The social domain data is sourced using the Mastodon Social API.[10] Mastodon is a federated social network that is compatible with the W3C standard ActivityPub (Webber et al., 2018). Users publish short-form content known as "toots", with the possibility of replying to other toots to form threads. We decided to use the original server, `mastodon.social` because of its large community and publicly available toots.

We collected data in the first four months of 2024, using the reported language ID label to target the source languages of interest. Unfortunately, there were too few good quality posts for Czech and Japanese, and we therefore only release social domain data for English.

Given the document-level nature of the task this year, our aim was to collect threads comprising multiple toots. Our sourcing therefore involved regularly scraping random toots from the previous hour but also identifying and scraping any missing toots that made up threads only partially sourced (identified using the 'in_reply_to_id' attribute of already sourced toots). To avoid spam and uninformative toots, we removed empty toots, texts that appeared several times (probable spam), texts from accounts that produced a large number of toots overall (we set this to 100 for a total of 1.5M toots scraped) and from accounts we heuristically identified as being news outlets or bots (containing the keywords 'bot', 'news', 'weather', 'sports', 'feeds' or 'press' in their handle). We created threads from the individual toots and manually selected threads of interest from threads of minimum 2 and maximum 100 toots. Our selection was based on having a diverse range of topics and targeting those characteristic of non-standard user-generated content.

The selected documents contain between 5 and 76 segments of text, each segment corresponding either to a whole toot or a line of text within a toot (depending on whether the toot contained newlines, i.e. there is no distinction between newlines indi-

[10] mastodon.social/api/v1/timelines/public

cating a boundary between two toots and a newline within a toot). Each segment can therefore contain one or several sentences, depending on the original composition of the toots.

Czech and Ukrainian source texts Source texts for Czech→Ukrainian translation included the news domain as described above, Educational domain collected from online exercises and three domains (Personal, Official and Voice) from texts collected through Charles Translator.[11] The Charles Translator mobile app supports voice input, which is converted to text using Google ASR. The texts collected this way were marked as the Voice domain. The remaining Czech inputs from the Charles Translator service were classified either as Official (formal communication) or Personal (personal communication, usually between a Czech and Ukrainian speaker).

The texts were filtered and pseudonymized in the same way as in the last two years (Kocmi et al., 2022). For example we asked the annotators not to delete or fix noisy inputs as long as they are comprehensible. The only exception was the voice domain, where the source texts were post-edited to fix ASR errors, including punctuation and casing.

The Educational domain includes selected exercises from an online portal *Škola s nadhledem*[12] for elementary-school students from various subjects (chemistry, geography, Czech language, etc.). Some segments are not full sentences but short phrases. The reference translations for this domain were created by professional translators within the EdUKate project.

2.2 Comparison between Domains

Due to the change to document-level translation this year, for each language direction, we measured the amount of text per domain by counting tokens, aiming for approximately the same number of tokens per domain (see Table 1 for statistics of the different domains). In one sense, this means that the amount of textual content is roughly balanced per domain, as opposed to taking the same number of sentences per domain, which would result in domains with longer sentence lengths (e.g. news or literary) being over-represented with respect to domains with shorter sentences (e.g. social). However, it is worth noting that the nature of documents, in terms of their length and structure, differs greatly depending on the domain. This can be exemplified at its most extreme by a comparison between the literary, social and speech domains for from-English language directions.

The literary domain has only 8 documents, each one containing a large number of segments (25.8 on average), with each segment containing an average of 75.9 sentences. A document represents an extract from a longer literary text and each segment represents a paragraph of text.

The speech domain is represented by a larger number of documents (111), each one containing a single segment, composed of an average of 6.2 sentences. Each document in this case corresponds to a short dialogue, provided without segmentation into dialogue turns.

The social domain is represented by a fair number of documents (34 in total), but the composition is very different from the other domains, as we made a choice to preserve the structure of the initial posts (new-line separated text is represented by multiple segments) and of the thread itself (separate posts are separate segments). This has the advantage of preserving post boundaries and formatting choices, but has the disadvantage of creating a large number of individual segments (531 in total, compared to 206 for the literary domain and 111 for the speech domain), each containing few sentences. This has two main consequences: (i) if segments are handled individually by systems, most sentences will be handled with little context, since the other sentences appear in separate segments, (ii) in terms of the overall number of segments evaluated in the human evaluation (see Section 6), the social domain represents over half of the total number of evaluated segments (53.3% compared to 20% for the literary domain and only 11.1% for the speech domain). This has consequences for the calculation of macro-average scores when computing human rankings, as discussed in Section 7.1. The formatting choice could be rethought for future years, although would have to take into account the particularities of non-standard text in order to not introduce extra noise (e.g. concatenating newline-separated sentences would have to take into account the potential lack of end-of-sentence punctuation, but it would also have to take into account instances where newlines are used with a single sentence for purely visualisation purposes. A possible solution would be to allow a linebreak symbol such as `<br/>` to appear in the segments.

[11] translator.cuni.cz

[12] skolasnadhledem.cz

2.3 Human References

The test sets were translated by professional translation agencies, according to the translation brief shown in Appendix C. Different partners sponsored each language pair and various translation agencies were therefore used, which could affect the differences and quality of translations.

The quality of human references is critical especially for reference-based metrics (Freitag et al., 2023), and getting high quality translations is challenging despite the use of professional translators. Therefore, we propose to use a quality estimation metric to assess the quality of translation. We need a metric whose score is interpretable in an absolute way, i.e. a metric that generates a fixed score for perfect translations (such as 0) and has an understandable delta (for example -1 means a single minor error as in MQM-based metrics). For that reason, we chose a GPT-4-based implementation of GEMBA-MQM (Kocmi and Federmann, 2023).

Table 2 shows the GEMBA scores for individual domains together with the ESA human cluster that was obtained a few months later in our official manual evaluation.

The two target languages with the lowest GEMBA scores were Russian and Hindi. The vendor providing Russian translations improved the initial quality of translations after being presented with the GEMBA scores. On the other hand, the vendor providing Hindi translators claimed that the translations were flawless.

When we compare the average GEMBA score to human rank in Table 2, we can see that human reference is ranked in the top cluster for all languages except of Hindi, Ukrainian, and Chinese. While the GEMBA score did not reflect lower quality of Ukrainian, its low score for Hindi was confirmed by ESA. This shows that using quality estimation metrics is a possible way of assessing the quality of human translations, although better approaches needs to be developed.

2.4 Test Suites

In addition to the test sets of the regular domains, the test sets given to the system participants were augmented with several *test suites*, i.e. custom-made test sets focusing on particular aspects of MT translation. The test suites were contributed and evaluated by test suite providers as part of a decentralized sub-task, detailed in Section 8. Across all language pairs of the shared task, test suites contributed 718,598 source test segments (detailed numbers can be found in Table 9).

	Literary	News	Social	Speech	Avg.	Hum.
En.→Czech	-2.4	-2.0	-1.9	-1.8	-2.03	1
En.→German$_A$	-2.1	-2.0	-2.3	-2.3	-2.18	1
En.→German$_B$	-2.7	-0.8	-1.7	-2.0	-1.80	1
En.→Spanish	-1.1	-1.6	-1.2	-1.6	-1.38	1
En.→Hindi	-3.4	-4.5	-2.5	-2.9	-3.33	3
En.→Icelandic	-2.6	-0.8	-1.9	-1.4	-1.68	1
En.→Japanese	-1.7	-1.6	-1.7	-1.7	-1.68	1
En.→Russian	-2.6	-2.8	-2.5	-2.3	-2.55	1
En.→Ukrainian	-1.8	-1.0	-2.0	-2.3	-1.78	3
En.→Chinese	-3.1	-1.7	-2.8	-2.2	-2.45	2

Table 2: GEMBA-MQM score for human references. The first four columns are scores for individual domains, the fifth column is the average. The last column is the human cluster assigned with ESA protocol. Czech→Ukrainian is not included because of different domains and source data.

3 Training Data

Similar to the previous years, we provide a selection of parallel and monolingual corpora for model training. The provenance and statistics of the selected parallel datasets are provided in the appendix in Table 10 and Table 11. Specifically, our parallel data selection include large multilingual corpora such as Europarl-v10 (Koehn, 2005), Paracrawl-v9 (Bañón et al., 2020), CommonCrawl, NewsCommentary-v18.1, WikiTitles-v3, WikiMatrix (Schwenk et al., 2021), TildeCorpus (Rozis and Skadiņš, 2017), OPUS (Tiedemann, 2012), CCAligned (El-Kishky et al., 2020), UN Parallel Corpus (Ziemski et al., 2016), and language-specific corpora such as CzEng v2.0 (Kocmi et al., 2020), YandexCorpus,[13] ELRC EU Acts, JParaCrawl (Morishita et al., 2020), Japanese-English Subtitle Corpus (Pryzant et al., 2018), KFTT(Neubig, 2011), TED (Cettolo et al., 2012), and back-translated news.

Links for downloading these datasets were provided on the task web page. In addition, we have automated the data preparation pipeline using MTDATA (Gowda et al., 2021).[14] MTDATA downloads all the mentioned datasets, except CzEng v2.0, which required user authentication. This year's monolingual data include the following: News Crawl, News Discussions, News Commentary, CommonCrawl, Europarl-v10 (Koehn, 2005), Extended CommonCrawl (Conneau et al., 2020), Leipzig Corpora (Goldhahn et al., 2012), UberText and Legal Ukrainian.

Table 3: Participating submissions in the General MT shared task. The top section covers the externally contributed submissions, the middle section lists the language models added by us and the lower section covers the online systems. Online system translations were not submitted by their respective companies but were obtained by us, and are therefore anonymized in a fashion consistent with previous editions of the task. Row coloring shows closed-track (dark gray), open-track (light gray) and constrained (white background) submissions. The Architecture column shows whether the submission used decoder-only language models (dec), sequence-to-sequence (enc-dec), hybrid between dec and enc-dec or other architectures. The Strategy column shows the approach used to handling paragraph-level test data: sentence-level training and translation (sentence), paragraph-level training and translation (paragraph), hybrid between both (hybrid). Some values are unknown (–) due to missing information or submission papers.

4 System Submissions

This year, we received a total of 105 primary submissions from 28 participants. The increase in number of participants from last year's 19 can be explained by the shift in the field and the ease with which LLMs can be fine-tuned. The increased number of primary submissions can be explained by the fact that most submissions are multilingual and therefore cover many translation directions.

In the same manner as previous years, we also collected translations from online MT systems for all language pairs. Online system outputs come from four public MT services and were anonymized as ONLINE-{A,B,G,W}, which resulted in further 42 system outputs. Finally, we added contrastive translations by 8 LLMs, which included closed commercial products (such as GPT-4) and open models (such as Llama3). This resulted in 95 more submissions, with the total number of submissions being 242.

All participating systems are listed in Table 3. Appendix B provides more detailed short descriptions of the submitted systems, as provided by the authors at submission time. Section 4.1 discusses the general trends in chosen architectures and approaches to paragraph-level translation. Section 4.2 presents details on LLM benchmark usage in the task. Section 4.3 describes the different tracks to which participants could submit outputs: constrained, open and closed track. Section 4.4 describes the submission system setup.

4.1 Architectures and Strategies

In addition to a reference to a description paper (if one was provided), the submission name and the list of language pairs covered, Table 3 includes columns for the architecture and strategy used to approach the task of paragraph-level translation. If we compare the frequency of usage of different architectures between the external participants (i.e,. excluding benchmarking LLMs and online systems), we can see that:

- 11 participants train decoder-only language models (*dec* in Table 3)
- 7 participants train encoder-decoder seq2seq transformer models (*enc-dec*)
- 4 participants use a hybrid of the decoder-only and encoder-decoder architectures (*hybrid*)
- 3 alternative architectures were used: MEGA (Ma et al., 2023) in AIST-AIRC, CycleGAN (Zhu et al., 2017) in CycleL and discrete diffusion models in TSU-HITs.

Not all description papers specified the strategy used to translate the test set paragraphs. Of those who did, 5 submissions approached it by explicitly training paragraph-level translation systems, while 11 submissions translated single sentences after sentence-splitting the paragraph. 3 submissions described a hybrid approach of, for example, translating single sentences but automatically post-editing at the paragraph level. Several papers do not mention the strategy at all. We plan to address this lack of information in future WMT editions by requesting that the information be provided at submission time.

Interestingly, the paragraph-level approach is not limited to a single architecture: for instance, the CUNI-DocTransformer team uses an encoder-decoder approach, but trains it on paragraph-level parallel data, which includes synthetic data. There are examples to the contrary: several submissions fine-tune a decoder-only language model, but apply it to translate single sentences (IKUN, AIST-AIRC, several CUNI submissions).

Finally, almost all submissions used an LLM as a part of their setup. The most common use is fine-tuning of a pretrained model, most often LLama. Other uses of LLMs are for generating or cleaning up training data with an LLM (Jasonarson et al., 2024) or using an LLM for automatic post-editing (Tan et al., 2024).

4.2 LLM Benchmark

Over the last year, many new LLMs claimed multilingual and translation capabilities. However, there is no systematic and reliable MT evaluation of the most popular LLMs using the same setup on blind test sets. We therefore decided to collect the translations of LLMs ourselves.

We design unified code for collecting the translations in an identical setup for all LLMs. We used a 3-shot approach, where three fixed examples are taken from the past WMT test sets. We set the temperature to zero to avoid introducing randomness into the process.[15]

We evaluated most of the popular LLMs, both closed-source models and those with open

[15] The code for collecting translations is available at: github.com/wmt-conference/wmt-collect-translations

Language model	Input tok.	Output tok.	Cost
Aya23	4.4 M	0.7 M	4.1 $
Claude-3.5	5.5 M	1.0 M	31.9 $
CommandR-plus	4.4 M	0.7 M	23.4 $
Gemini-1.5-Pro	3.9 M	0.6 M	40.3 $
GPT-4	5.9 M	1.0 M	240.4 $
Llama3-70B	5.0 M	0.7 M	5.1 $
Mistral-Large	6.0 M	1.1 M	37.0 $
Phi-3-Medium	5.9 M	1.1 M	4.5 $

Table 4: Number of input and output tokens and estimated pricing for translating the full WMT24 test set without test suites. The Gemini model refused to translate Icelandic, and the estimate is therefore lower. Pricing for the open models Aya23 and Llama3 was estimated via together.ai.

weights. Specifically, we collect translations from Aya23, Claude-3.5-Sonnet, Command R+, GPT-4, Gemini-1.5-Pro, Llama3-70B, Mistral-Large, Nvidia-NeMo and Phi-3-Medium. As most of the models do not claim multilingual capabilities for all languages covered, we looked into the original reports for these LLMs to see which languages are claimed to be supported. We check if both source and target language are mentioned or evaluated in any of their multilingual settings. We mark LLMs that do not officially claim a support for a given language with the § symbol in the tables. However, to avoid selection bias, we collect translations for all languages for all LLMs, even those not officially claimed to be supported.

We collect all translations via the API of the respective services, and all data was collected during the submission week. Table 4 shows the number of input and output tokens as segmented via the models' internal tokenizers. The estimated cost is for the whole test set without test suites. Note that the prices for more recent GPT models are significantly lower.

4.3 Constrained, Open, and Closed Tracks

We distinguish three types of MT systems participating in the shared task: constrained, open and closed systems. The main idea is to level the field for different setups. For the constrained setup, we only allow specific training data and pretrained models from a specified list. Open systems are those developed using publicly available data or models. The final group of closed systems corresponds to all other systems that are built at least partly with a non-replicable setup.

- **Constrained systems** are those using only the specifically allowed training data (see Section 3) and the following pretrained models: Llama-2-7B, Llama-2-13B, Mistral-7B, mBART, BERT, RoBERTa, XLM-RoBERTa, sBERT, LaBSE. Constrained systems may use any publicly available metric that was evaluated in past WMT Metrics shared tasks (e.g. COMET or Bleurt) and any basic linguistic tools (e.g. taggers, parsers, morphology analyzers).
- **Open systems** (marked in tables with a light gray background) are limited to using software, data and models that are freely available for research purposes, so that the subsequent work could be replicated by a research group.
- **Closed systems** (marked with dark gray) correspond to all the remaining (fully automatic) systems, with no limitations imposed on their training data (all ONLINE systems and LLMs released without binaries fit into this category).

4.4 OCELoT

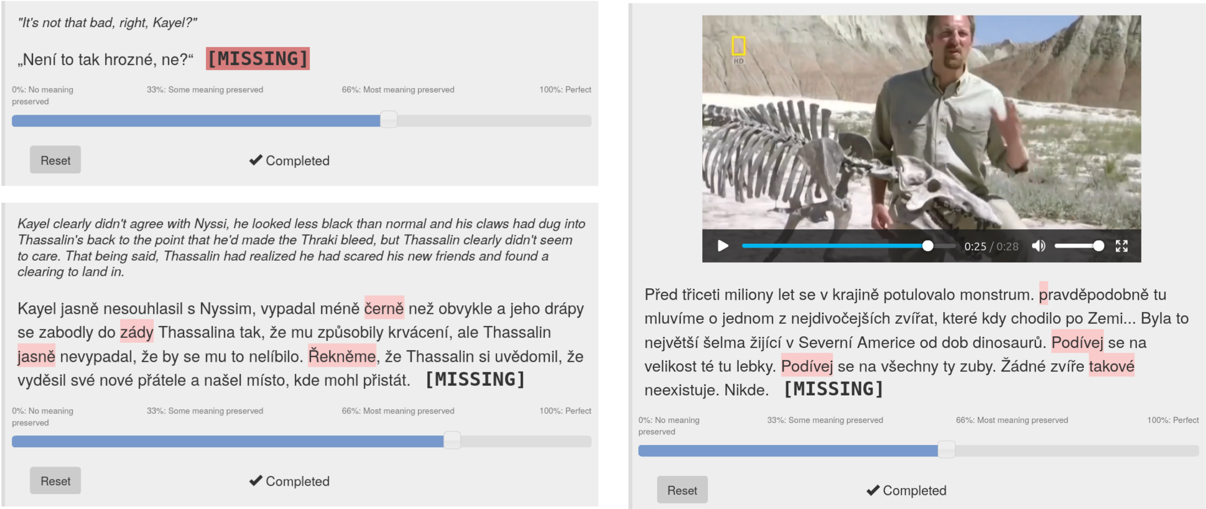
We used the open-source OCELoT platform[16] to collect system submissions again this year. As in previous years, only registered and verified teams with correct contact information were allowed to submit their system outputs and each verified team was limited to 7 submissions per test set. Submissions on leaderboards with BLEU (Papineni et al., 2002) and CHRF (Popović, 2015) scores from SacreBLEU (Post, 2018) were displayed anonymously to avoid publishing rankings based on automatic scores during the submission period. Until one week after the submission period, teams could select a single primary submission per test set, specify if the primary submission followed a constrained, open or closed system setting, and submit a system description paper abstract. These were mandatory for a system submission to be included in the human evaluation campaign.

5 Automatic Evaluation

This year, we received an unusually high number of submitted systems and we were not able to provide manual evaluation for all of them. Therefore, we decided to use automatic metrics to preselect the best performing systems with a method we call AutoRank, which is based on two different metrics:

- MetricX-23-XL (Juraska et al., 2023), a reference-based metric built on top of the mT5 model (Xue, 2020).

[16] github.com/AppraiseDev/OCELoT



"It's not that bad, right, Kayel?"

„Není to tak hrozné, ne?“ [MISSING]

Kayel clearly didn't agree with Nyssi, he looked less black than normal and his claws had dug into Thassalin's back to the point that he'd made the Thraki bleed, but Thassalin clearly didn't seem to care. That being said, Thassalin had realized he had scared his new friends and found a clearing to land in.

Kayel jasně nesouhlasil s Nyssim, vypadal méně černě než obvykle a jeho drápy se zabodly do zády Thassalina tak, že mu způsobily krvácení, ale Thassalin jasně nevypadal, že by se mu to nelíbilo. Řekněme, že Thassalin si uvědomil, že vyděsil své nové přátele a našel místo, kde mohl přistát. [MISSING]

Před třiceti miliony let se v krajině potulovalo monstrum. pravděpodobně tu mluvíme o jednom z nejdivočejších zvířat, které kdy chodilo po Zemi... Byla to největší šelma žijící v Severní Americe od dob dinosaurů. Podívej se na velikost té tu lebky. Podívej se na všechny ty zuby. Žádné zvíře takové neexistuje. Nikde. [MISSING]

(a) Excerpt of two segments from a larger document. In the first segment, the name *"Kayel"* is omitted which is a major error. In the second segment, there are many minor errors.

(b) Example of a video to text translation with several minor errors. The annotator can control the video player.

Figure 1: Two screenshots of ESA (Kocmi et al., 2024b) and the annotator instructions. ESA shows multiple segments within a document at once as well as video sources. After marking the individual error spans, the annotator assigns the final segment score from 0 to 100. The tool is implemented in Appraise (Federmann, 2018).

- CometKiwi-DA-XL (Rei et al., 2023), a quality estimation metric built on the XLM-R XL model (Conneau, 2019).

Both metrics are top performing metrics (Freitag et al., 2023), and we intentionally select two distinct metrics (different underlying pretrained systems and architectures) to minimize their bias and potential problems. Although quality estimation is on average slightly worse than reference-based evaluation, it helps us to avoid a potential reference bias when human references are suboptimal (Freitag et al., 2023). Multilingual quality estimation can be fooled when the translation is in the incorrect language, which the reference-based metric will penalize.

To compute MetricX, we used the official implementation[17] and the "google/metricx-23-xl-v2p0" model. MetricX produces scores at the segment level. To obtain scores at the system level, we averaged the segment scores. To compute CometKiwi scores, we used the official implementation[18] with the "Unbabel/wmt23-cometkiwi-da-xl" model, a reference-free model, taking the translation hypothesis and the source segment as inputs. COMET can produce system-level scores so we use them directly.

To merge the two metrics, we first linearly scale the scores of each metric to a range between 1 and the number of systems for a given language pair. We then average both normalized scores to reach the final automatic ranking, which we refer to as AutoRank. We provide a Jupyter notebook in the WMT24 repository to reproduce the scores.[19]

5.1 Selecting Systems for Human Evaluation

When selecting the systems for human evaluation, we prioritize open and constrained systems while penalizing closed systems. We select a subset of 10 to 15 systems per language pair based on AutoRank and following two rules. First, we exclude closed systems that are not among the first third of all systems and we exclude open systems that are not among the top two thirds of all systems. Second, motivated by several very low-performing systems, we also define a hard cutoff point. After this point we do not evaluate any system from any category. The cutoff point is selected as the first gap between two neighboring system's ranks larger than 1.5 of AutoRank. This decision was discussed and published in more detail in Kocmi et al. (2024a).

6 Human Evaluation

This year's human evaluation features Error Span Annotation (ESA; Kocmi et al., 2024b) for most languages. For Japanese→Chinese and

Language pairs	Annotators' profile	Tool
English→Chinese/Japanese/ Hindi/Spanish	Microsoft annotators — bilingual target-language native speakers, professional translators or linguists, experienced in machine translation evaluation.	Appraise ESA
Czech→Ukrainian English→Czech	ÚFAL Charles University annotators — linguists, annotators, researchers, and students who were native speakers in the target language and had a very high proficiency in English (for English→Czech) and good knowledge of Czech (for Czech→Ukrainian).	Appraise ESA
English→Ukrainian/ Russian/Spanish	Toloka AI paid expert crowd — Bilingual native target-language speakers who were high-performing on the platform.	Appraise ESA
English→Icelandic	The Árni Magnússon Institute for Icelandic Studies annotators — bilingual target-language native speakers, paid translators with 10–25 years of experience in Icelandic↔English translation.	Appraise ESA
English↔German Japanese→Chinese	Campaign managed by the 2024 metrics shared task.	Google MQM

Table 5: Annotators' profiles and annotation tools for each language pair in the human evaluation. English→Spanish was split between Microsoft and Toloka AI. All annotators were paid a fair wage in their respective countries.

English→German, we rely on the evaluation campaign from the metrics shared task 2024 (Freitag et al., 2024), which uses Multidimensional Quality Metrics (MQM; Lommel et al., 2014).

Annotation Protocol. ESA is based on highlighting/marking errors without classifying them into different error types (Kreutzer et al., 2020; Popović, 2020) and represents a compromise between overall scoring (such as direct assessment, DA; Graham et al. 2013) and error classification (such as MQM; Lommel et al. 2014).

The annotators (professional translators but not experts in MQM/ESA-style annotations) were asked to mark each error as well as its severity, "Minor" or "Major", as in Kocmi et al. (2024b); Popović (2020). In addition, the annotators were also asked to assign a score from 0 to 100, similar to DA, to the whole annotation segments (usually a sentence or a paragraph). However, the ESA score should be more robust than DA alone because the annotators are primed by the highlighted errors at the time of the scoring.

The interface is shown in Figure 1 with annotator instructions and other changes from the original implementation by Kocmi et al. (2024b) given in Appendix A. At the start of annotation, each annotator was exposed to an interactive tutorial where they were asked to interact with the system. The length of the context given to the annotators varies depending on the domain, ranging from one to ten sentences, as discussed in Section 6.1. The source for the speech domain is a video which is shown in a native HTML video player.

	Systems		Annotators	
Language pair		Duplication		Assess./system
Cs→Uk	11	1.0	14	1299
En→Czech	15	1.3	20	751
En→Spanish	13	1.0	14	370
En→Hindi	10	1.3	15	775
En→Icelandic	10	1.0	4	376
En→Japanese	12	1.5	14	1212
En→Russian	13	1.0	7	370
En→Ukrainian	10	1.0	8	376
En→Chinese	12	1.5	12	1217

Table 6: Number systems, annotators, and number of assessments per system in a language pair. Duplication of d means that each segment is annotated by d annotators. All language pairs had 649 segments over 170 documents except for Czech→Ukrainian which had 1954 segments over 302 documents. In total we collected 57k segment-level annotations. English→German and Japanese→Chinese are managed by the metrics shared task 2024.

The output of the ESA annotation is a list of errors and their severity (minor or major) and the final score from 0 to 100 for each segment.

Human Annotators Campaigns for different language pairs were managed by various vendors, as described in Table 6. In all cases, professional translators-cum-annotators are used. This is an increasingly strict requirement given the high quality of MT systems, which requires more expert annotators.

6.1 Data Preparation

Document Filtering. In our setup, all systems for a given language pair are evaluated on the same set of segments. On average, we start with 1092 lines per system, encompassing 184 documents. However, the distribution of document lengths is unbalanced. The majority of the documents (104) consist of just a single line, which is almost exclusively due to video translation segments (103), where each "document" contains strictly one segment. On average, 33 documents per language contain more than 10 segments. We limit these documents to the first 10 segments, motivated by the difficulty of annotating very long documents while maintaining relevant context in mind. After this adjustment, we arrive at an average of 744 lines per system. An overview is shown in Table 6.

Workload balancing We use the term "task" as a contained unit of 100 annotation segments. Each annotator is usually assigned to multiple tasks. This 100-segment constraint was kept for historical reasons and will be dropped in future iterations. In order to make it so that each task contains a comparable amount of work, we attempt to balance the number of words in each task to be as constant as possible.

For each task, we show a tutorial at the beginning consisting of 2 documents with 6 segments in total. The tutorial is for German→English translation but does not require any knowledge of German. Finally, we reserve 12 segments for quality control (Section 6.2) in each task. The resulting 82 segments are filled with full documents as much as possible. If that is not possible (i.e., because the next document is too long), a random document is drawn that is either duplicated or incomplete, in order to fill the 100 segments.

Annotation waves In order for a segment to be useful in the evaluation, we require that translations by all systems are evaluated. We therefore split (at the document level) the translated data for each language into two "waves", each of which covers a distinct set of source segments. The vendors are instructed to start the second campaign only after the first one is fully complete.

For some language pairs, the vendors finished early. In this case, we prepared an extra two waves, with a different coverage split of the same data, which they annotated afterwards. As a result, some language pairs have multiple annotations per source segment, was shown in Table 6. This is useful to compute inter-annotator agreement but also provides less noisy annotations.

6.2 Quality Control

Each task (100 segments) includes 12 quality control segments to ensure the high quality of the annotations. The tasks are created as follows:

1. The task (a maximum of 100 segments) is filled with machine-translated documents to be evaluated.
2. A random document is selected from the task.
3. Segments within the sampled document are perturbed.
4. The perturbed document is shuffled within the task at the document-level.
5. Steps 2-4 are repeated until 12 quality control segments are included in the task.

The segment perturbation is done by randomly sampling a span from the segment and replacing it with random text sampled from the entire corpus in the correct language. Since segment lengths vary and a single perturbation could be lost in a very large paragraph, we apply as many perturbations as there are sentences in the output. See Figure 2 for an example.

Source: *Sie haben gestern das Treffen wieder verschoben.*
Original: *He postponed the meeting again yesterday.*
Perturbed: *He postponed the meeting squirrels are never.*

Figure 2: An example of a perturbed translation based on the original system translation. In addition to the original error (the correct pronoun here is *They* and not *He*), we introduce the perturbed part.

After each task is completed, we check whether the perturbed segments received lower scores. Specifically, we compare the distribution of 12 original and 12 perturbed segments with a one-sided Mann-Whitney U test (Mann and Whitney, 1947). If the task fails to pass quality control (p>0.05), it is reset and reassigned to another annotator.[20] In the final data, 96% of perturbed segments have lower scores than their original counterparts.

6.3 Human Data Analysis

We briefly analyze the data from a broader perspective. The scores given by the annotators are largely concentrated near 100, with a small peak around 0 (see Figure 3). Most languages consistently had very few errors per segment, resulting in higher overall scores (see Table 7). For instance, for the Czech→Ukrainian, an average of 0.2 minor errors

[20] Task generation code: github.com/wmt-conference/ErrorSpanAnnotations/tree/main/preparation/wmt24

and 0.1 major errors per segment means there is approximately one minor error for every 5 segments and one major error for every 10 segments.

The annotation time, which is the primary focus of the analysis in Kocmi et al. (2024b), is similar across most languages with the exception of English→Icelandic. This could be caused either by more meticulous annotators or lower quality of submitted systems, which would require more annotation. The average time per segment is just 22 seconds (see Figure 4).

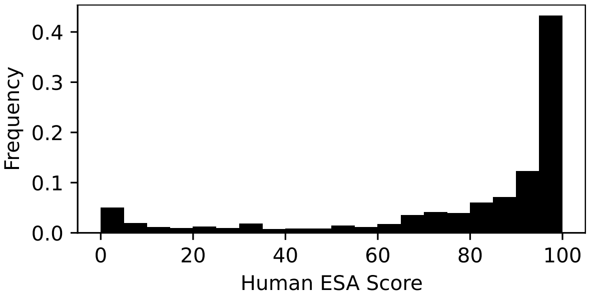

Figure 3: Distribution of final human segment-level scores. The ratings are dominated by the score close to 100.

Language pair	Minor	Major	Score	Time
Czech→Ukrainian	0.2	0.1	87.1	15.8s
English→Czech	0.6	0.2	86.2	25.3s
English→Spanish	0.7	0.4	87.1	22.0s
English→Hindi	0.5	0.2	87.3	25.7s
English→Icelandic	1.4	0.8	72.3	37.8s
English→Japanese	0.2	0.1	89.2	18.9s
English→Russian	0.5	0.3	83.4	23.0s
English→Ukrainian	0.4	0.3	84.4	21.8s
English→Chinese	0.2	0.1	87.6	16.8s

Table 7: Average number of minor and major errors per segment, average score and annotation time. Despite different annotation crowds, the statistics are balanced.

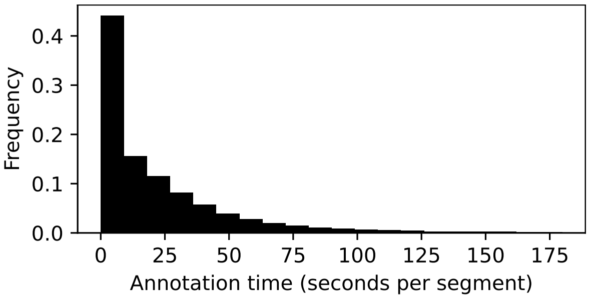

Figure 4: Distribution of annotation times per segment. The vast majority of segments is annotated under one minute.

	Literary	News	Social	Speech	Average
En.→Czech	93.1	94.9	93.3	92.1	93.3
En.→Spanish	96.3	96.2	95.5	94.1	95.5
En.→Hindi	95.4	93.6	91.3	88.3	92.2
En.→Icelandic	92.2	92.6	95.0	92.4	93.1
En.→Japanese	92.4	93.7	91.3	92.4	92.5
En.→Russian	94.1	93.1	92.1	86.6	91.5
En.→Ukrainian	93.2	93.9	94.3	85.9	91.8
En.→Chinese	92.0	92.5	90.7	88.4	90.9
Average	93.6	93.8	93.0	90.0	92.6

Table 8: Maximal obtained score per language and per domain across languages evaluated with the same source data (English).

6.4 Domain Difficulty across Languages

In Table 8 we present the maximal obtained score per domain per language. Although absolute scores are not comparable due to different sets of systems and different groups of annotators, we observe that, across the table, the speech domain obtains the lowest scores for nearly all language pairs suggesting it is the most difficult domain. This is reflected by the fact that the top-performing systems achieve lower scores in the speech domain compared to other domains. This difficulty likely arises from the reliance on ASR text rather than the original audio. This finding is consistent with MQM results from Freitag et al. (2024).

Secondly, we observe that the English→Spanish language pair receives the highest scores, suggesting that either the pair itself or the specific tested domains are relatively easy for top systems, which provide almost flawless translations. These results are consistent with the MQM results from Freitag et al. (2024) where the best system got only -0.12 MQM score, which is close to perfect, while the best German system got -1.58 MQM and the best Japanese-Chinese system an MQM score of -1.22.

Separate scores for each domain, system and language pair are presented in Appendix D.

6.5 Clustering of ESA compared to DA+SQM

This year, we revised the human evaluation protocol, ultimately moving from DA+SQM to ESA. In this section, we briefly compare several aspects of both methods. However, due to the absence of a direct head-to-head comparison on the same data and the many changes introduced since last year, this analysis cannot attribute all the improvements solely to the ESA protocol.

ESA produced 59 clusters across 114 systems. This compares to only 37 clusters produces by last year's DA+SQM approach for the same number of systems. In other words, ESA formed a cluster for every 1.9 systems, while DA+SQM created a cluster for every 3.1 systems. This increased clustering efficiency was achieved despite a decrease in the number of collected samples. With DA+SQM, we collected an average of 1400 annotations per system, whereas ESA required only an average of 750 annotations per system to achieve greater discriminative power.

7 Official Ranking Results

We now describe how we compute the final ranking, then discuss the final results and some potential issues with our ranking method. The results are shown on the following two pages in tabular form.

7.1 Human Ranking Computation

We calculate three different scores: the human ESA score, rank, and the cluster.

The **human ESA score** is the macro-average of the segment-level ESA scores grouped over the domains. This represents a change compared to previous years, since we used to calculate a simple average over all data. However, with the change towards paragraph-level test sets, the average number of segments per domain is imbalanced and the social domain represents almost half of all segments (see Table 1). To circumvent this imbalance, we use the macro-average as the main human score.

For the statistical analysis and **clustering**, we use the Wilcoxon signed-rank test, a paired non-parametric test (Wilcoxon, 1945), as suggested by Kocmi et al. (2024b). However, given the domain-level imbalanced distribution, we adapted our approach by combining the results from independent domain-level experiments via Stouffer's Z-score method (Stouffer et al., 1949), which combines p-values from individual domain-level Wilcoxon tests. The method produces almost identical clustering as if we had used Wilcoxon over the whole dataset whilst ignoring the imbalance.

Rank ranges indicate the number of systems a particular system underperforms or outperforms: the top end of the rank range is $l + 1$, where l is the number of losses, while the bottom is $n - w$, where n is the total number of systems and w is the number of systems against which the system in question significantly wins.

Systems are grouped into ranks that are separated by thick lines, such that systems within the same group do not strictly outperform other systems within the group. In other words, it is not possible to clearly say which system in the cluster is better than the all others. The ranks and clusters are computed with $p < 0.05$.

We say that a system is winning if it ranks in the first cluster, while ignoring the human reference.

The official rankings shown in Section 7.4 are generated on the basis of the ESA scores. Tables with head-to-head comparisons between all systems are included in Appendix E.

7.2 Verbosity of LLMs

As pointed out by Briakou et al. (2024), some LLMs produce verbose outputs, including an attempt to explain the translation or a refusal to translate. This creates an issue for both automatic and human evaluation of how to treat such outputs.

During the collection of LLM outputs, we asked the LLM to wrap the translation in a particular type of quotes (```) and post-edited LLM outputs removing all extra details outside of these quotes (keeping the whole answer if no quotes have been found). Therefore LLMs that did not follow the expected output format and produced additional output were not considered in the evaluation.

For future work, we should instruct humans to penalize verbose outputs and strengthen the prompt used for collecting LLM translations.

7.3 Human Ranking Discussion

When investigating the official results in Section 7.4, we can make several observations.

The best performing system in the open and constrained systems category is IOL-Research, winning 10 LPs in this category.

The Unbabel-Tower70B system is the best performing participating system winning in 8 LPs. In contrast, this system was ranked the first in all LPs in the automatic evaluation.This highlights that systems can overfit on automatic scores, especially when using Minimum Bayes Risk (MBR; Freitag et al., 2022) with testing metric.

Over all, the best performing system in general seems to be Claude-3.5-Sonnet (wins in 9 LPs); it even outperforms GPT-4 (wins in 5 LPs), which is much more expensive model. Human references are ranked in the first place for 5 language pairs and in the winning cluster for 8 language pairs, suggesting that the reference quality is high and ESA is robust to our setting.

For English→Icelandic, it was almost the case that each system belonged to its own statistically significant cluster. This could be put down to a greater diversity in the quality of systems (also highlighted by more diverse AutoRank scores).

7.4 Official Ranking Results Tables

Results tables legend

The human score is the macro-average of human judgements, grouped by domain. The rank takes into consideration head-to-head wins and losses. AutoRank is calculated from automatic metrics.
Ranking and clustering on human scores is done using Wilcoxon signed rank test for each domain separately and final p-value is combined via Stouffer's Z-score method to align with macro average for human score.
Systems are either constrained (white), open-track (light gray), or closed-track (dark gray).
LLMs that do not officially claim a support a language pair are marked with §.

8 Test Suites Sub-task: "Help us break LLMs"

The results in the previous tables indicate that the current evaluation methods, despite being more detailed and sophisticated, have difficulties in distinguishing MT output from human translations, or distinguishing the performance among different systems. Additionally, the appearance of LLMs has made it even more clear that generated translations, even those which seem to be fluent and surrounded by seemingly perfect content, can contain serious flaws. The increased interest in this new technology and the use of LLMs for translation, prompted us to set the theme of this year's test suite subtask as "Help us break LLMs". This was intended as a broader invitation to the NLP community to expose the weaknesses of LLM translations that are hidden behind the apparent overall high quality generation, but also to propose new innovative evaluation methods that may be of high interest for specific use cases. We are thrilled that this year's participation exceeded every precedent, with 11 test suites providing their valuable conclusions, which are presented below.

8.1 Setup of the sub-task

Each test suite is a customised extension of the standard test sets, focusing on specific aspects of the MT output. The evaluation of the MT output takes place in a decentralized manner, where test suite providers were invited to submit their customized test sets, following the setup introduced at the Third Conference on Machine Translation (Bojar et al., 2018). Each test suite provider submitted a source-side test set, which was appended by the organisers of the General MT Shared Task to its standard test sets. The corresponding outputs from the systems of the General MT Shared Task were returned to the test suite providers, who were responsible for carrying out the evaluation based on their own individual evaluation concept. The results of each test suite evaluation, together with the relevant analysis, appear in separate description papers, while a summary is given below.

This year's timeline gave the test suite contributors more time. We offered a pre-run in April, when test suite providers were given the opportunity to submit the current version of their corpus in order to receive translation output from online systems, which could help them to carry out the individual (often manual) evaluation in a more timely manner.

8.2 Submissions

The test suite sub-task received 11 submissions, out of which 9 completed the entire evaluation cycle. An overview of the test suites can be seen in Table 9. The descriptions of each submission and their main findings are given below.

Árni Magnússon Institute for Icelandic Studies (AMI; Ármannsson et al., 2024) The submission of the Árni Magnússon Institute's team to the WMT24 test suite subtask focuses on idiomatic expressions and proper names for the English→Icelandic translation direction. Intuitively and empirically, idioms and proper names are known to be a significant challenge for neural translation models. They create two different test suites. The first evaluates the competency of MT systems in translating common English idiomatic expressions, as well as testing whether systems can distinguish between those expressions and the same phrases when used in a literal context. The second test suite consists of place names that should be translated into their Icelandic exonyms (and correctly inflected) and pairs of Icelandic names that share a surface form between the male and female variants, so that incorrect translations impact meaning as well as readibility. The scores reported are relatively low, especially for idiomatic expressions and place names, and indicate considerable room for improvement.

Complex Sentence Structure Testset (CoST; vIIT_HYD; Mukherjee et al., 2024) This test suite presents an evaluation of 16 machine translation systems submitted to the Shared Task for the English-Hindi using our Complex Structures Test suite. Aligning with this year's test suite sub-task theme, "Help us break LLMs", the authors curated a comprehensive test suite encompassing diverse datasets across various categories, including autobiography, poetry, legal, conversation, play, narration, technical, and mixed genres. The evaluation reveals that all the systems struggle significantly with the archaic style of text like legal and technical writings or text with creative twist like conversation and poetry datasets, highlighting their weaknesses in handling complex linguistic structures and stylistic nuances inherent in these text types. This evaluation identifies the strengths and limitations of the models, pointing to specific areas where further research is needed to enhance their performance.[21]

Table 9: Overview of the participating test suites.

DFKI (Manakhimova et al., 2023b) This test suite offers a fine-grained linguistically motivated analysis of the shared task MT outputs for English–German and English–Russian, based on more than 11,500 manually devised test items, which cover up to 110 phenomena in 14 categories per language direction. Extending their previous test suite submissions (e.g. Avramidis et al., 2020; Macketanz et al., 2021, 2022; Manakhimova et al., 2023a), the submission of this year includes a considerable effort of manual linguistic annotation for the evaluation on 39 MT systems submitted at the Shared Task. Based on the results, LLMs are inferior to NMT in English–German when translating a few linguistic phenomena, though they show quite a competitive performance in English-Russian. Additionally, some LLMs generate very verbose or empty outputs, posing challenges to the evaluation process. Looking more closely at specific phenomena of English-German, LLMs seem to perform worse than the two best performing NMT systems in terms of punctuation, future verb tenses and stripping. For English-Russian, Yandex is weaker in named entities and terminology, Claude in function words, while Unbabel is weaker in verb valency. GPT-4 into Russian performs even worse than several commercial NMT-based systems.

Indian Institute of Technology Patna (IITP; domain dynamics; Bhattacharjee et al., 2024) LLMs have demonstrated impressive capabilities in machine translation, leveraging extensive pretraining on vast amounts of data. However, this generalist training often overlooks domain-specific nuances, leading to potential difficulties when translating specialized texts. This study presents a multi-domain dataset designed to challenge and evaluate the translation abilities of LLMs. The dataset encompasses diverse domains such as judicial, education, literature (specifically religious texts), and noisy user-generated content from online product reviews and forums like Reddit. Each domain consists of approximately 250–300 sentences, carefully curated and randomized in the final compilation. This English-to-Hindi dataset aims to evaluate and expose the limitations of LLM-based translation systems, offering valuable insights into areas requiring further research and development.

Inria (RoCS-MT; Bawden and Sagot, 2023), Robust Challenge Set for Machine Translation, is designed to test MT systems' ability to translate user-generated content with non-standard characteristics, such as spelling errors, devowelling, acronymisation, etc. The original English Reddit texts are associated with manual normalisations and translations in five languages (French, German, Czech, Ukrainian and Russian). RoCS-MT was first submitted to the 2023 task, showing that many non-standard phenomena still pose problems for most systems, although more common phenomena are better handled by the larger, closed-source models, presumably due to the large quantity of web-based seen during training. This year's version is largely the same as last year but with some improvements, including modifications to normalisations and to the annotation typology used (all modifications are documented in the GitHub repository).[22] Systems varied greatly in terms of their handling of

[22] github.com/rbawden/RoCS-MT

non-standard sentences, with marked differences depending on the type of system. Constrained systems inevitably struggling most, particularly with phenomena affecting the spelling of words (resulting in frequent copying of non-standard source words), a problem also affecting online systems. LLMs exhibited some of the best quality translations, although behaviour varied between translating standard and non-standard input, and additional issues such as refusal to translate and usage notes pose new technical challenges.

Isochrony Translation (Rask AI, Imperial College; Rozanov et al., 2024) MT has come a long way and is readily employed in production systems to serve millions of users daily. With the recent advances in generative AI, a new form of translation is becoming possible – video dubbing. This work motivates the importance of isochronic translation, especially in the context of automatic dubbing, and introduces 'IsoChronoMeter' (ICM). ICM is a simple yet effective metric to measure isochrony of translations in a scalable and resource efficient way without the need for gold data, based on state-of-the-art text-to-speech (TTS) duration predictors. The authors motivate IsoChronoMeter and demonstrate its effectiveness. Using ICM, they demonstrate the short-comings of state-of-the-art translation systems and show the need for new methods. The code has been released.

National Research Council Canada (Speaker-Listener Gender Resolution; gender-res; Dawkins et al., 2024) This test suite assesses the gender resolution tendencies of MT systems in literary dialogue settings. That is, each instance contains dialogue interleaved with additional meta-context. The spoken dialogue refers to either the speaker or listener such that the gender of the referent, if known, must be inferred from the meta-context and informs the correct translation. They find that stereotype factors within the meta-context, such as character descriptions and manner of speaking, affect the gender agreement choices of words within the dialogue. Regression analysis is performed to evaluate the relative influence of these contextual factors compared to structural factors and known stereotype influences (e.g., the internal gender stereotype of an adjective).

University of Edinburgh Prompt Injection, TruthfulQA (PIA; Miceli Barone and Sun, 2024) LLM-based systems typically work by embedding their input data into prompt templates which contain instructions and/or in-context examples, creating queries which are submitted to a LLM, then parse the LLM response in order to generate the system outputs. Prompt Injection Attacks (PIAs) are a type of subversion of these systems where a malicious user crafts special inputs which interfere with the prompt templates, causing the LLM to respond in ways unintended by the system designer. Recently, Sun and Miceli Barone (2024) proposed a class of PIAs against LLM-based machine translation. Specifically, the task is to translate questions from the TruthfulQA test suite, where an adversarial prompt is prepended to the questions, instructing the system to ignore the translation instruction and answer the questions instead. In this test suite, the authors extend this approach to all the language pairs of the WMT 2024 General Machine Translation task. Moreover, they include additional attack formats in addition to the one originally studied.

University of Iceland (GenderQueer; Friðriksdóttir, 2024) This paper introduces the GenderQueer Test Suite, a novel evaluation set for assessing MT systems' capabilities in handling gender-diverse and queer-inclusive content, focusing on English to Icelandic translation. As MT quality improves, there is an increasing need for specialized evaluation methods that address nuanced aspects of language and identity. The suite evaluates MT systems on various aspects of gender-inclusive translation, including pronoun and adjective agreement, LGBTQIA+ terminology accuracy, and the impact of explicit gender specifications. Its authors evaluated 18 MT systems submitted to the WMT24 English-Icelandic track. Key findings reveal significant performance differences between large language model-based systems and smaller models in handling context for gender agreement. Challenges in translating singular "they" were widespread, while most systems performed well in translating LGBTQIA+ terminology. Accuracy in adjective gender agreement varies, with some models struggling particularly with feminine forms. This evaluation set contributes to the ongoing discussion about inclusive language in MT and natural language processing. By providing a tool for assessing MT systems' handling of gender-diverse content, it aims to enhance the inclusivity of language technology. The methodology and evaluation scripts are made available for adaptation to other languages, promoting further research in this critical area.

9 Conclusions

The WMT 2024 General Machine Translation Task covered 11 translation pairs, two of which are non-English: Czech→Ukrainian and Japanese→Chinese. We introduced ESA (Error Span Annotations) as the main human protocol for assessing the translation quality, which enabled more efficient collection of human judgements than MQM while keeping high quality of annotations. In total, 108 human (semi-)professional annotators contributed more than 57,000 judgments.

We received 105 primary submissions from 28 participants, 4 online systems and 8 production large language models, which is a large increase from last year's task. The majority of participants already use LLMs in their systems.

The best performing open system is IOL-Research (wins 10 LPs in it's category), the best performing participating system is Unbabel-Tower70B (wins 8 LPs), and the best performing system in general is Claude-3.5-Sonnet (wins 9 LPs).

While the best performing system based on automatic metrics is Unbabel-Tower70B, it was not the winner across the board in the human evaluation, with the mismatch between the results likely due to metric bias (Kovacs et al., 2024) in MBR. This shows that human evaluation should be used as the final judge of translation quality.

Lastly, we showed promising results in the multimodal evaluation of the speech domain, proving to be a challenging domain for MT systems. On the opposite side, systems were able to produce near-perfect translations in English→Spanish, for the domains that we tested.

10 Limitations

We tested the general capabilities of MT systems. However, we have simplified this approach and only used three to five domains. Out of various modalities, we used audio and text.

Although we use human judgements as the gold standard, giving us more reliable signal than automatic metrics, we should mention that human annotations are noisy (Wei and Jia, 2021) and their performance is affected by the quality of other evaluated systems (Mathur et al., 2020). Lastly, different annotators use different ranking strategies, which may have an effect on the system ranking.

Some models may have used Comet or MetricX during their training, for example, using Minimum Bayes Risk. Our automatic evaluation of such models will be biased, giving them artificially higher scores.

Automatic metrics are limited and biased (Karpinska et al., 2022; Moghe et al., 2024), especially in novel domains (Zouhar et al., 2024a), which motivates them being superseded by human evaluation. Another potential problem may have been that test sets we use are paragraph-level; automatic metrics have usually been tested in a sentence-level scenario.

The ESA annotation interface implemented in Appraise is in English only with a tutorial in German→English. This caused difficulties to some of the Czech→Ukrainian annotators we hired, who could not understand English. One such annotator did not pass the initial tutorial and therefore did not participate in the annotation campaign. Next year, we plan to translate the annotation interface to either the source or target language for each translation direction.

11 Ethical Considerations

Inappropriate, controversial, and explicit content was filtered out prior to translation, keeping in mind the translators and not exposing them to such content or obliging them to translate it.

Human evaluation using Appraise for the collection of human judgements was fully anonymous. Automatically generated accounts associated with annotation tasks with single-sign-on URLs were distributed randomly among pools of annotators and we do not store any personal information. We do store the mapping between which annotator (with pseudonym) annotated which account. Annotators received standard professional translator's or evaluator's wage with respect to their countries.

Sentences in the Czech→Ukrainian dataset (in Personal, Official and Voice domains) were collected with users' opt-in consent, and any personal data related to people other than well-known people was pseudonymized (using random first names and surnames). Sentences where such pseudonymization would not be enough to preserve reasonable anonymity of the users (e.g., describing events uniquely identifying the persons involved) were not included in the test set.

Acknowledgments

This task would not have been possible without the partnership with Microsoft, Charles University, Dubformer, Toloka, NTT, Google, Árni Magnússon Institute for Icelandic Studies, Custom.mt, Cohere, Together.ai, Unbabel and the German Research Center for AI (DFKI).

Additionally, we would like to thank Nikolay Bogoychev, Konstantin Dranch and many others who provided help, feedback, and recommendations, as well as all shared task participants, for their participation and for providing their system descriptions for the paper.

We would also like to thank Toshiaki Nakazawa, Yoshimasa Tsuruoka, Jun Suzuki, and Takehito Utsuro for their help and recommendations in creating the Japanese test set.

Barry Haddow's participation was funded by UK Research and Innovation (UKRI) under the UK government's Horizon Europe funding guarantee [grant number 10052546 – HPLT].

Rachel Bawden's participation was funded by her chair position in the PRAIRIE institute funded by the French national agency ANR under the project MaTOS - "ANR-22-CE23-0033-03" and as part of the "Investissements d'avenir" programme under the reference ANR-19-P3IA-0001.

Maja Popović's participation was funded by the ADAPT SFI Centre for Digital Media Technology, funded by Science Foundation Ireland through the SFI Research Centres Programme and co-funded under the European Regional Development Fund (ERDF) through Grant 13/RC/2106.

Martin Popel's participation was funded by TAČR grant EdUKate (TQ01000458).

Ondřej Bojar acknowledges the support of the National Recovery Plan funded project MPO 60273/24/21300/21000 CEDMO 2.0 NPO. The manual evaluations were also supported by the InCroMin FSTP under the HE grant UTTER (101070631 – HE, 0039436 – UKRI).

This work has been using data and tools provided by the LINDAT/CLARIAH-CZ Research Infrastructure (https://lindat.cz), supported by the Ministry of Education, Youth and Sports of the Czech Republic (Project No. LM2023062).

A Error Span Annotation Miscellaneous

A.1 Annotation Guidelines

Higlighting errors: Highlight the text fragment where you have identified a translation error (drag or click start & end). Click repeatedly on the highlighted fragment to increase its severity level or to remove the selection.

- **Minor Severity:** Style/grammar/lexical choice could be better/more natural.
- **Major Severity:** Seriously changed meaning, difficult to read, decreases usability.

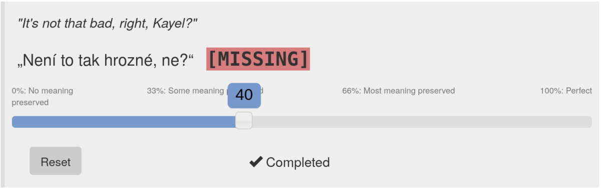
If something is missing from the text, mark it as an error on the **[MISSING]** word. The highlights do not have to have character-level precision. It's sufficient if you highlight the word or rough area where the error appears. Each error should have a separate highlight.

Score: After highlighting all errors, please set the overall segment translation scores. The quality levels associated with numerical scores on the slider:

- 0%: No meaning preserved: Nearly all information is lost in the translation.
- 33%: Some meaning preserved: Some of the meaning is preserved but significant parts are missing. The narrative is hard to follow due to errors. Grammar may be poor.
- 66%: Most meaning preserved and few grammar mistakes: The translation retains most of the meaning. It may have some grammar mistakes or minor inconsistencies.
- 100%: Perfect meaning and grammar: The meaning and grammar of the translation is completely consistent with the source.

A.2 Changes to Interface

Since the original study of Kocmi et al. (2024b), we used an updated version of the interface. Apart from minor quality of life changes, a noticeable change is the addition of a pop-up bubble that shows the exact score of the segment (see Figure 5). While it appears as a minor change, it might change the annotator behavior that prefer for example certain numbers, as annotators did in translation evaluation study of Zouhar et al. (2024b).



"It's not that bad, right, Kayel?"

„Není to tak hrozné, ne?“ [MISSING]

Figure 5: Interacting with the score slider shows the exact score to the annotator in the updated ESA interface.

B System Submission Summaries

This section lists all the submissions to the translation task and provides the authors' descriptions of their submission.

B.1 AIST-AIRC (Rikters and Miwa, 2024)

At WMT 2024 AIST AIRC participated in the General Machine Translation shared task and the Biomedical Translation task (Neves et al., 2024). We trained constrained track models for translation between English, German, and Japanese. Before training the final models, we first filtered the parallel data, then performed iterative back-translation as well as parallel data distillation. We experimented with training baseline Transformer models, Mega models, and fine-tuning open-source T5 and Gemma model checkpoints using the filtered parallel data. Our primary submissions contain translations from ensembles of two Mega model checkpoints and our contrastive submissions are generated by our fine-tuned T5 model checkpoints.

B.2 AMI (Jasonarson et al., 2024)

This paper presents the submission of the Arni Magnusson Institute's team to the WMT24 General translation task. We work on the English→Icelandic translation direction. Our system comprises four translation models and a grammar correction model. For training our systems we carefully curate our datasets, aggressively filtering out sentence pairs that may detrimentally affect the quality of our systems output. Some of our data are collected from human translations and some are synthetically generated. A part of the synthetic data is generated using an LLM, and we find that it increases the translation capability of our system significantly.

B.3 CUNI-DS (Semin and Bojar, 2024)

We present a naive transfer learning approach for English-to-Russian translation, leveraging English-to-Czech data within the constrained track of WMT24. Utilizing the Mistral-7B-0.1 model in its 4-bit quantized variant, we employ QLoRA adapter training. The approach involves two phases: first, training the adapters on the English-to-Czech CzEng 2.0 dataset, followed by fine-tuning the adapters further for English-to-Russian translation with additional corpora. The training spans a total of 48 hours. Evaluation is performed using WMT22 and WMT23 datasets, including the paragraph-level version of the latter.
Phase 1: Training on English-to-Czech Data
Dataset: CzEng 2.0, with examples packed into chunks of sequence length 2048.
Parameters: Warmup Steps: 20, Learning Rate: 2e-5, Weight Decay: 1e-2, Cumulative Batch Size: 32
Instructions: Alpaca-like instructions
Duration: 24 hours on a single A100 GPU, using the Unsloth library.
Phase 2: Fine-Tuning for English-to-Russian
Data: Yandex Corpus and News Commentary v18.1, with the latter divided into chunks of 10 sentences.
Regimen: Training with parameters similar to Phase 1.
Duration: An additional 24 hours, totaling 48 hours of training.

B.4 CUNI-{Transformer, DocTransformer, GA, MH, NL} (Hrabal et al., 2024)

This paper presents the contributions of Charles University teams to the WMT24 General Translation task (English to Czech, German and Russian, and Czech to Ukrainian), and the WMT24 Translation into Low-Resource Languages of Spain task.

Our most elaborate submission, CUNI-MH for English→Czech, is the result of fine-tuning Mistral 7B v0.1 for translation using a three-stage process: Supervised fine-tuning using QLoRA, Contrastive Preference Optimization, and merging of model checkpoints. We also describe the CUNI-GA, CUNI-Transformer and CUNI-DocTransformer submissions, which are based on our systems from the previous year.

Our en2ru system CUNI-DS uses a similar first stage as CUNI-MH (QLoRA for English→Czech) and follows with transferring to en2ru.

For en2de (CUNI-NL), we experimented with a LLM-based speech translation system, to translate without the speech input.

For the Translation into Low-Resource Languages of Spain task, we performed QLoRA fine-tuning of a large LLM on a small amount of synthetic (backtranslated) data.

B.5 CycleL and CycleL2 (Dreano et al., 2024)

CycleGN is a fully self-supervised Neural Machine Translation framework relying on the Transformer architecture that does not require parallel data. Its approach is similar to a Discriminator-less CycleGAN, hence the "non-adversarial" name, specifically tailored for non-parallel text datasets. The foundational concept of our research posits that in an ideal scenario, retro-translations of generated translations should revert to the original source sentences. Consequently, a pair of models can be trained using a Cycle Consistency Loss (CCL) only, with one model translating in one direction and the second model in the opposite direction.

In the context of this research, two sub-categories of non-parallel datasets are introduced. A "permuted" dataset is defined as a parallel dataset wherein the sentences of one language have been systematically rearranged. Consequently, this results in a non-parallel corpus where it is guaranteed that each sentence has a corresponding translation located at an unspecified index within the dataset. A "non-intersecting" dataset is a non-parallel dataset for which it is guaranteed that no sentence has an exact translation.

Masked Language Modeling (MLM) is a pre-training strategy implemented in BERT, where a specified proportion of the input tokens are substituted with a unique $mask$ token. The objective of the neural network under this paradigm is to accurately reconstruct the original sentence from this degraded input.

In inference mode, Transformers are able to generate sentences without labels. Thus, the first step is to generate pseudo-labels in inference, that are then used as labels during training. However, the models consistently converge towards a trivial solution in which the input, the generated pseudo-labels and the output are identical, achieving an optimal outcome on the CCL function, registering a value of zero. CycleGN demonstrates how MLM pre-training can be leveraged to move away from this trivial path and perform actual text translation.

As a contribution to the WMT24 challenge, this study explores the efficacy of the CycleGN architectural framework in learning translation tasks across eleven language pairs under the permuted condition and four under the non-intersecting condition.

Moreover, two additional language pairs from the previous WMT edition were trained and the evaluations demonstrate the robust adaptability of CycleGN in learning translation tasks.

B.6 DLUT-GTCOM (Zong et al., 2024)

This paper presents the submission from Global Tone Communication Co., Ltd. and Dalian University of Technology for the WMT24 shared general Machine Translation (MT) task at the Conference on Empirical Methods in Natural Language Processing (EMNLP). Our participation encompasses two language pairs: English to Japanese and Japanese to Chinese. The systems are developed without particular constraints or requirements, facilitating extensive research in machine translation. We emphasize back-translation, utilize multilingual translation models, and apply fine-tuning strategies to improve performance. Additionally, we integrate both human-generated and machine-generated data to fine-tune our models, leading to enhanced translation accuracy. The automatic evaluation results indicate that our system ranks first in terms of BLEU score for the Japanese to Chinese translation.

B.7 HW-TSC (Wu et al., 2024)

This paper presents the submission of Huawei Translate Services Center (HW-TSC) to the WMT24 general machine translation (MT) shared task, where we participate in the English to Chinese (en→zh) language pair. Similar to previous years' work, we use training strategies such as regularized dropout, bidirectional training, data diversification, forward translation, back translation, alternated training, curriculum learning, and transductive ensemble learning to train the neural machine translation (NMT) model based on the deep Transformer-big architecture. The difference is that we also use continue pre-training, supervised fine-tuning, and contrastive preference optimization to train the large language model (LLM) based MT model. By using Minimum Bayesian risk (MBR) decoding to select the final translation from multiple hypotheses for NMT and LLM-based MT models, our submission receives competitive results in the final evaluation.

B.8 IKUN and IKUN-C (Liao et al., 2024)

This paper introduces two multilingual systems, IKUN and IKUN-C, developed for the general machine translation task in WMT24. IKUN and IKUN-C represent an open system and a constrained system, respectively, built on Llama-3-8b and Mistral-7B-v0.3. Both systems are designed to handle all 11 language directions using a single model. According to automatic evaluation metrics, IKUN-C achieved 6 first-place and 3 second-place finishes among all constrained systems, while IKUN secured 1 first-place and 2 second-place finishes across both open and constrained systems. These encouraging results suggest that large language models (LLMs) are nearing the level of proficiency required for effective multilingual machine translation. The systems are based on a two-stage approach: first, continuous pre-training on monolingual data in 10 languages, followed by fine-tuning on high-quality parallel data for 11 language directions. The primary difference between IKUN and IKUN-C lies in their monolingual pre-training strategy. IKUN-C is pre-trained using constrained monolingual data, whereas IKUN leverages monolingual data from the OSCAR dataset. In the second phase, both systems are fine-tuned on parallel data sourced from NTREX, Flores, and WMT16-23 for all 11 language pairs.

B.9 IOL-Research (Zhang, 2024)

This paper illustrates the submission system of the IOL Research team for the WMT24 General Machine Translation shared task. We submitted translations for all translation directions in the general machine translation task. According to the official track categorization, our system qualifies as an open system due to the utilization of open-source resources in developing our machine translation model. With the growing prevalence of large language models (LLMs) as a conventional approach for managing diverse NLP tasks, we have developed our machine translation system by leveraging the capabilities of LLMs. Overall, We first performed continued pretraining using the open-source LLMs with tens of billions of parameters to enhance the model's multilingual capabilities. Subsequently, we employed open-source Large Language Models, equipped with hundreds of billions of parameters, to generate synthetic data. This data was then blended with a modest quantity of additional open-source data for precise supervised fine-tuning. In the final stage, we also used ensemble learning to improve translation quality.

B.10 MSLC (Larkin et al., 2024)

The MSLC (Metric Score Landscape Challenge) submissions for English–German, English–Spanish, and Japanese–Chinese are constrained systems built using Transformer models for the purpose of better evaluating metric performance in the WMT24 Metrics Task. They are intended to be representative of the performance of systems that can be built relatively simple using constrained data and with minimal modifications to the translation training pipeline.

B.11 NTTSU (Kondo et al., 2024)

The NTTSU team's submission leverages several large language models developed through a training procedure that includes continual pre-training and supervised fine-tuning. For paragraph-level translation, we generated synthetic paragraph-aligned data and utilized this data for training.

In the task of translating Japanese to Chinese, we particularly focused on the speech domain translation. Specifically, we built Whisper models for Japanese automatic speech recognition (ASR). We used YODAS dataset for Whisper training. Since this data contained many noisy data pairs, we combined the Whisper outputs using ROVER for polishing the transcriptions. Furthermore, to enhance the robustness of the translation model against errors in the transcriptions, we performed data augmentation by forward translation from audio, using both ASR and base translation models.

To select the best translation from multiple hypotheses of the models, we applied Minimum Bayes Risk decoding + reranking, incorporating scores such as COMET-QE, COMET, and cosine similarity by LaBSE.

B.12 Occiglot (Avramidis et al., 2024)

This document describes the submission of the very first version of the Occiglot open-source large language model to the General MT Shared Task of the 9th Conference of Machine Translation (WMT24). Occiglot is an open-source, community-based LLM based on Mistral-7B, which went through language-specific continual pre-training and subsequent instruction tuning, including instructions relevant to machine translation. We examine the automatic metric scores for translating the WMT24 test set and provide a detailed linguistically-motivated analysis.

Despite Occiglot performing worse than many of the other system submissions, we observe that it performs better than Mistral7B, which has been based upon, which indicates the positive effect of the language specific continual-pretraining and instruction tuning.

We see the submission of this very early version of the model as a motivation to unite community forces and pursue future LLM research on the translation task.

B.13 SCIR-MT (Li et al., 2024)

This paper introduces the submission of SCIR research center of Harbin Institute of Technology participating in the WMT24 machine translation evaluation task of constrained track for English to Czech. Our approach involved a rigorous process of cleaning and deduplicating both monolingual and bilingual data, followed by a three-stage model training recipe. During the testing phase, we used the beam serach decoding method to generate a large number of candidate translations. Furthermore, we employed COMET-MBR decoding to identify optimal translations.

B.14 Team-J (Kudo et al., 2024)

We participated in the constrained track for English-Japanese and Japanese-Chinese translations at the WMT 2024 General Machine Translation Task. Our approach was to generate a large number of sentence-level translation candidates and select the most probable translation using minimum Bayes risk (MBR) decoding and document-level large language model (LLM) re-ranking. We first generated hundreds of translation candidates from multiple translation models and retained the top 30 candidates using MBR decoding. In addition, we continually pre-trained LLMs on the target language corpora to leverage document-level information. We utilized LLMs to select the most probable sentence sequentially in context from the beginning of the document.

B.15 TranssionMT

Hyper-SNMT represents a cutting-edge approach in the field of machine translation. Hyper-SNMT is based on embedding sentences in a hyperbolic space, where distances naturally reflect language hierarchy and dependencies. This novel embedding space enables the model to achieve more accurate translations, especially for languages with complex grammatical structures and rich morphology. Both speed and accuracy are significantly improved compared to existing models. This submission is highlighting the portential of Hyper-SNMT to revolutionize the field of neural machine translation.

B.16 TSU-HITs (Mynka and Mikhaylovskiy, 2024)

This paper describes the TSU HITS team's submission system for the WMT'24 general translation task. We focused on exploring the capabilities of discrete diffusion models for the English-to-Russian, German, Czech, Spanish translation tasks in the constrained track. Our submission system consists of a set of discrete diffusion models for each language pair. The main advance is using a separate length regression model to determine the length of the output sequence more precisely.

B.17 Unbabel-Tower70B (Rei et al., 2024)

In this work, we present Tower v2, an improved iteration of the state-of-the-art open-weight Tower models, and the backbone of our submission to the WMT24 General Translation shared task. Tower v2 introduces key improvements including expanded language coverage, enhanced data quality, and increased model capacity up to 70B parameters. Our final submission combines these advancements with quality-aware decoding strategies, selecting translations based on multiple translation quality signals. The resulting system demonstrates significant improvement over previous versions, outperforming closed commercial systems like GPT-4o, Claude 3.5, and DeepL even at a smaller 7B scale.

B.18 UvA-MT (Tan et al., 2024)

Fine-tuning Large Language Models (FT-LLMs) with parallel data has emerged as a promising paradigm in recent machine translation research. In this paper, we explore the effectiveness of FT-LLMs and compare them to traditional encoder-decoder Neural Machine Translation (NMT) systems under the WMT24 general MT shared task across three high-resource directions: English to Chinese, English to Japanese, and Japanese to Chinese. We implement several techniques, including Quality Estimation (QE) data filtering, supervised fine-tuning, and post-editing that integrate NMT systems with LLMs. We demonstrate that fine-tuning LLaMA2 on a high-quality but relatively small bitext dataset (100K) yields COMET results comparable to much smaller encoder-decoder NMT systems trained on over 22 million bitexts. However, this approach largely underperforms on surface-level metrics like BLEU and ChrF. We further control the data quality using the COMET-based quality estimation method. Our experiments show that 1) filtering low COMET scores largely improves encoder-decoder systems, but 2) no clear gains are observed for LLMs when further refining the fine-tuning set. Finally, we show that combining NMT systems with LLMs via post-editing generally yields the best performance in our experiments.

B.19 Yandex (Elshin et al., 2024)

In this paper, we present the methodology employed by the NLP team at Yandex LLC for participating in the WMT 2024 General MT Translation track, focusing on English-to-Russian translation. Our approach involves training a YandexGPT LLM-based model for translation tasks using a multi-stage process to ensure high-quality and contextually accurate translations.

Initially, we utilize a pre-trained model, trained on a large corpus of high-quality monolingual texts in various languages, crawled from various open sources, not limited to English and Russian. This extensive pre-training allows the model to capture a broad spectrum of linguistic nuances and structures. Following this, the model is fine-tuned on a substantial parallel corpus of high-quality texts collected from diverse open sources, including websites, books, and subtitles. These texts are meticulously aligned at both the sentence and paragraph levels to enhance the model's contextual understanding and translation accuracy.

In the subsequent stage, we employ p-tuning on an internal high-quality corpus of paragraph-aligned data. This step ensures that the model is finely adjusted to handle complex paragraph-level translations with greater fluency and coherence.

Next, we apply the Contrastive Pretraining Objective (CPO) method, as described in the paper CPO, using a human-annotated translation corpus. This stage focuses on refining the model's performance based on metrics evaluated at the paragraph level, emphasizing both the accuracy of the translation and the fluency of the resulting texts. The CPO method helps the model to better distinguish between subtle contextual differences, thereby improving translation quality.

In the final stage, we address the importance of preserving the content structure in translations, which is crucial for the General MT test set. To achieve this, we introduce a synthetic corpus based on web pages and video subtitles, and use it during HE markup finetune training. This encourages the model to maintain the original text's tag structure. This step ensures that the translated output retains the structural integrity of the source web pages, providing a seamless user experience.

Our multi-stage approach, combining extensive pre-training, targeted fine-tuning, advanced p-tuning, and structure-preserving techniques, ensures that our model delivers high-quality, fluent, and structurally consistent translations suitable for practical applications and competitive benchmarks.

C Translator Brief

In this project we wish to translate data from several domains for use in evaluation of Machine Translation (MT). The translations produced by you will be compared against the translations produced by a variety of different MT systems. They will be released to the research community to provide a benchmark, or “gold-standard” measure for translation quality. The translation therefore needs to be a high-quality rendering of the source text into the target language, as if it was originally written directly in the target language. However, there are some constraints imposed by the intended usage:

- All translations must be “from scratch”, without post-editing from machine translation or usage of CAT tools. Using post-editing would bias the evaluation, so we need to avoid it. We can detect post-editing and will reject translations that are post-edited.
- Translation should preserve the paragraph boundaries but may change number of sentences per paragraph. The source texts contain one paragraph per line and the translations should be the same.
- Translators should avoid inserting parenthetical explanations into the translated text and obviously avoid losing any pieces of information from the source text. We will check the translations for quality and will reject translations that contain errors.
- If the original data contain errors, typos, or other problems, do not change the source sentences, instead try to prepare correct translation as if the error wouldn’t be in the source.
- The data contain several domains, each folder containing one domain source.

The source files will be delivered as text files (sometimes known as “notepad” files), with one paragraph per line. We need the translations to be returned in the same format. The translation file needs to have the same name as the original file.

Speech Domain The texts are the transcriptions of audio, edited by native speakers. Each file represents one segment of audio (you are also provided with correspondent audio in WAW format). Phrases said by different speakers are located on different lines. Audios correspond to different domains, they differ in formality, style, topics and number of speakers. The idea is to translate using the most similar language in the target language, matching as best as possible the characteristics of the source text.

Social domain The texts are from the social network Mastodon (similar to Twitter). Each file represents a thread or part of a thread from one or several users. Different posts within a thread are presented on different lines in the file, although individual posts can also span several lines. The sentences have been selected so that they do not contain offensive or sensitive content (hate speech, taking-drugs, suicide, politically sensitive topics, etc.). However, profanities were kept as they were taken to be illustrative of the sociolect of online language. If however, you do not feel comfortable with translating something, please leave the whole line blank and let us know that you have not translated it. The texts are particular in that they may contain spelling errors, slang, acronyms, marks of expressivity, etc. The idea is to translate using the most natural language in the target language, matching as best as possible the style and familiarity of the source text.

- Spelling mistakes should not be preserved in their translations, i.e. the translation should be spelt correctly
- Marks of expressivity (e.g. asterisks *wow*, capitals letters WOW) should be conserved as best as possible. However, we recommend not to attempt to reproduce repeated characters (e.g. woooow) in translation, as the choice as to which character to repeat is often arbitrary.
- There will be abbreviations and acronyms (e.g. btw -> by the way, fwiw -> for what it’s worse). These do not need to be translated using abbreviation or acronyms unless an abbreviation/acronym is the best translation choice in the target language.

- Users have been pseudo-anonymised (e.g. @user1, @user2). These should be left as they are, i.e. not translated.

- Platform-specific elements such as hashtags should be translated as hashtags, but the content should be translated as appropriate into the target language.

- Punctuation can be added if it necessary to avoid comprehension difficulties. Otherwise we recommend following the punctuation of the source text.

A file entitled README-social-domain-translation-notes.pdf has been distributed with the texts to translate. This file should not be translated. It contains some notes to provide additional context on the topic and terms used in some of the texts.

D Official Ranking Results (extends Section 7.4)

Results tables legend

The human score is the macro-average of human judgements, grouped by domain. The rank takes into consideration head-to-head wins and losses. AutoRank is calculated from automatic metrics.
Ranking and clustering on human scores is done using Wilcoxon signed rank test for each domain separately and final p-value is combined via Stouffer's Z-score method to align with macro average for human score.
Systems are either constrained (white), open-track (light gray), or closed-track (dark gray).
LLMs that do not officially claim a support a language pair are marked with §.

Human scores for individual domains are marked by an up arrow ↑ if their difference from the system domain score is larger than the standard deviation over all domains for given system (row) and down arrow ↓ indicates that the domain score is worse than the overall score.
Underlined domain scores indicate that the domain score is better than the domain score of system above it (of a better ranked system).

E Head to head comparisons

Following tables show differences in average human scores for each language pair. The number in each of cell shows the difference in average human scores for the systems in the column and row.

Because there are many systems and data conditions, the significance of each pairwise comparison needs to be quantified. We apply Wilcoxon signed-rank test to measure the likelihood that such differences could occur simply by chance. In the following tables ⋆ indicates statistical significance at $p < 0.05$, † indicates statistical significance at $p < 0.01$, and ‡ indicates statistical significance at $p < 0.001$.

Each table contains final rows showing the macro-average score achieved by that system and the rank range. Gray lines separate clusters based on non-overlapping rank ranges.

Abstract

The WMT24 Metrics Shared Task evaluated the performance of automatic metrics for machine translation (MT), with a major focus on LLM-based translations that were generated as part of the WMT24 General MT Shared Task. As LLMs become increasingly popular in MT, it is crucial to determine whether existing evaluation metrics can accurately assess the output of these systems.

To provide a robust benchmark for this evaluation, human assessments were collected using Multidimensional Quality Metrics (MQM), continuing the practice from recent years. Furthermore, building on the success of the previous year, a challenge set subtask was included, requiring participants to design contrastive test suites that specifically target a metric's ability to identify and penalize different types of translation errors.

Finally, the meta-evaluation procedure was refined to better reflect real-world usage of MT metrics, focusing on pairwise accuracy at both the system- and segment-levels.

We present an extensive analysis on how well metrics perform on three language pairs: English→Spanish (Latin America), Japanese→Chinese, and English→German. The results strongly confirm the results reported last year, that fine-tuned neural metrics continue to perform well, even when used to evaluate LLM-based translation systems.

Table 1: Official ranking of primary submissions to the WMT24 Metric Task. The final score is the weighted average correlation over 6 different tasks. Starred metrics are reference-free, and underlined metrics are baselines. See Table 14 for the pairwise comparisons from which the ranks were derived.

1 Introduction

The Metrics Shared Task[1] has been a key component of WMT since 2008, serving as a way to validate the use of automatic MT evaluation metrics and drive the development of new metrics. We evaluate reference-based automatic metrics that score MT output by comparing the translations with a reference translation generated by human translators, who are instructed to translate "from scratch" without post-editing from MT. In addition, we also invited submissions of reference-free metrics (quality estimation metrics or QE metrics) that compare MT outputs directly with the source segments. All metrics are evaluated based on their agreement with human ratings when scoring MT systems and human translations at the system and sentence level.

Proceedings of the Ninth Conference on Machine Translation, pages 47–81
November 15-16, 2024 ©2024 Association for Computational Linguistics

The final ranking of this year's submitted primary metrics is shown in Table 1. Below are some of the key details and changes implemented for this year's Metrics Shared Task:

- **Language Pairs**: For this year, we focus on three language pairs, all on the paragraph-level: (i) English→German (en→de), English→Spanish (Latin America) (en→es), and Japanese→Chinese (ja→zh).
- **Human Evaluation**: Like last year, we collected our own human quality ratings for our three language pairs leveraging professional translators performing MQM annotations (Lommel et al., 2014; Freitag et al., 2021). We released and uploaded[2] all MQM annotations, and we recommend using Marot[3] for looking into this data.
- **Meta Evaluation**: This year, we designed the meta-evaluation to evaluate metrics on how they are used in practice, by focusing on pairwise accuracy at the system- and segment-levels and removing Pearson correlation. At the system-level, we use a new statistic called soft pairwise accuracy (Thompson et al., 2024), and, like last year, we use pairwise accuracy with tie calibration (Deutsch et al., 2023) at the segment-level.
- **Challenge Sets Subtask**: The submission format of the challenge sets changed to provide for more flexibility on how the participants could challenge the metrics. In contrast to previous years, when the challenge items were evaluated in a rigid pairwise manner on whether the metric scores can distinguish between a good and a bad translation, this year's participants could provide single translations and then employ an evaluation concept of their own. This year's subtask features 4 submissions that test the ability of the metrics to evaluate MT outputs on African languages, the biomedical domain, on more than a hundred linguistically-motivated phenomena, as well as on low- to mid-quality outputs and specific challenges (empty strings, wrong/mixed language output and language variants).
- **Understand Magnitude of Score Difference**: Similar to last year, we include two analyses to understand the meaning of the score differences that metrics present with respect to the statistical significance of MT system rankings according to human annotations and metric scores. These analyses provide additional assistance for MT researchers to build an intuition on the relationship between the magnitude of metric score differences and the reliability of the improved translation quality.
- **MTME**: Similar to last year, all the data has been uploaded to MTME[4], and all results in this paper are calculated with this analysis tool. We encourage every metric developer to use MTME to calculate contrastive scores to enhance consistency and comparability going forward.

Our main findings are:

- Two metametrics (which are both ensemble metrics), MetricX-24-Hybrid and XCOMET, are the winners of the WMT24 Metrics Shared Task (Table 1);
- Fine-tuned neural metrics continue to be strong in performance and are effective quality estimators, even for LLM-based translations;
- Results from the challenge sets independently suggest that it is important for metric researchers to test the performance of metrics in diverse collections of linguistic phenomena, languages and domains, including low-resource languages, mixed languages and irregular outputs, and on a wide range of translation quality, in order to minimize anomalous and unexpected behaviours of metrics (Section 9).

The rest of the paper is organized as follows: Section 2 describes the test data. Section 3 presents an overview of the conducted expert-based human evaluation. Section 4 describes the metrics evaluated this year (baselines and participants). Section 5 describes the conducted meta-evaluation. Section 6 reports our main results. Section 7 interprets and evaluates metrics' scores beyond correlations. Section 8 summarizes our results for the WMT24 General MT Shared Task language-pairs based on their new ESA human evaluation methodology (Kocmi et al., 2024c). Section 9 presents a description of the submitted challenge sets along with their findings. Finally, Section 10 summarizes our most important conclusions.

2 Translation Systems

Similar to previous years' editions, the source, reference texts, and MT system outputs for the metrics task are mainly derived from the WMT24 General MT Shared Task (Kocmi et al., 2024a). The domains cover news, literary, speech, and social. We do not provide any sentence splitting, thus many segments contain multiple sentences. Each language pair contains a comparable number of sentences from each domain, resulting in reasonably balanced test sets. Data statistics can be seen in Table 2. The language pairs en→de and en→es have the same source segments; ja→zh consists of segments from only 3 different domains.

	news	literary	speech	social
	#tokens			
en→{de,es}	9,268	9,601	9,611	9,829
ja→zh	14,896	14,541	11,025	
	#docs (#segments/doc)			
en→{de,es}	17 (8.8)	8 (25.8)	111 (1.0)	34 (15.6)
ja→zh	45 (6.0)	15 (21.1)	136 (1.0)	
	#sents (#sents/doc)			
en→{de,es}	333 (19.6)	607 (75.9)	685 (6.2)	759 (22.3)
ja→zh	634 (14.1)	875 (58.3)	332 (2.4)	

Table 2: Test set statistics split by domain. Statistics are calculated on the source side.

The reference translations provided for the test sets are produced by professional translators.

For more details regarding the test sets, we refer the reader to the WMT24 General MT Shared Task findings paper (Kocmi et al., 2024a). All data has been released and can be downloaded[5].

3 MQM Human Evaluation

Automatic metrics are commonly evaluated by measuring correlations with corresponding human ratings. The quality of these human ratings is critical, and recent findings (Freitag et al., 2021) have shown that crowdsourced human ratings are not sufficiently reliable for evaluating high quality MT outputs. Furthermore, an evaluation schema based on MQM (Lommel et al., 2014), which requires explicit error annotation is more effective than an evaluation schema that only asks raters for a single scalar value per translation. Similar to last year, we decided to conduct our own MQM-based human evaluation on a subset of translation system submissions and language pairs which we believe are most interesting for evaluating current metrics. Instead of evaluating all MT system submissions, we restrict our human evaluation to the top scoring submissions, as determined based on baseline automatic scores. MQM is a general framework that provides a hierarchy of translation errors which can be tailored to specific applications. Google and Unbabel sponsored the human evaluation for this year's metrics task for a subset of language pairs using either professional translators (English→German, Japanese→Chinese) or trusted and trained raters (English→Spanish). The error annotation typology and guidelines used by Google's and Unbabel's annotators differ slightly and are described in the following two sections.

3.1 English→German & Japanese→Chinese

Annotations for en→de and ja→zh were sponsored and executed by Google, using 18 professional translators (10 for en→de, 8 for ja→zh) having access to the full document context. Each segment gets annotated by a single rater. Instead of assigning a scalar value to each translation, annotators were instructed to label error spans within each segment in a document, paying particular attention to document context. Each error was highlighted in the text, and labelled with an error category and a severity. Segments that are too badly garbled to permit reliable identification of individual errors are assigned a special *Non-translation* error. Error severities are assigned independent of category, and consist of *Major*, *Minor*, and *Neutral* levels, corresponding respectively to actual translation or grammatical errors, smaller imperfections and purely subjective opinions about the translation. Since we are ultimately interested in scoring segments, we adopt the weighting scheme shown in Table 3.

Severity	Category	Weight
Major	Non-translation all others	25 5
Minor	Fluency/Punctuation all others	0.1 1
Neutral	all	0

Table 3: Google's MQM error weighting.

Recent research demonstrated that rater assignment is crucial for reliable human evaluation and we adopted the suggested Pseudo-Side-by-Side

[5] https://github.com/wmt-conference/wmt24-news-systems

(pSxS) rater assignment as suggested in (Riley et al., 2024). For more details, exact annotator instructions and a list of error categories, we refer the reader to Freitag et al. (2021) as the exact same setup was used for the previous three metrics tasks.

3.2 English→Spanish (Latin America)

The annotations for the en→es (Latin America)[6] language pair were sourced from Unbabel, who engaged four professional native language annotators possessing extensive translation experience. Much like Google's approach, these annotators were provided with the full document context, comprising up to ten segments. Their task was to identify and classify errors by highlighting them, following Unbabel's MQM 3.0 typology[7].

The annotators were instructed to classify the errors based on severity, with Unbabel's classification encompassing not only "Minor" and "Major" error severities (analogous to Google's criteria) but also a "Critical" error severity. However, to ensure consistency in our evaluation process, we opted to align with the Google methodology outlined previously. Specifically, we treated all annotated "Critical" errors as "Major" errors, and we applied a weighting scheme for punctuation errors, as detailed in Table 3.

3.3 Human Evaluation Results

Due to the fact that we ran our own human evaluation, we were only able to evaluate a subset of the test segments. In Table 4, you can see the number of segments and documents for each language pair and test set that we used for human evaluation. In all cases, the MQM score for a segment is the sum of the scores for the errors in that segment, and the MQM score for a test set is the average of the MQM scores of the segments that were annotated.

The results of the MQM human evaluation can be seen in Table 5. It's important to note a non-intentional, but important difference in our human evaluation setting for the speech domain between the three language pairs. For English→German and English→Spanish, we asked human annotators to compare translations against the ASR output, which inadvertently disadvantaged participants who used audio input, including those providing human translations, as these translations rely on an error-free input. This is evident in the higher MQM scores for the speech domain for both language pairs for human translations and the dubformer system (which also utilizes audio input). However, for Japanese→Chinese, the human annotators compared against the cleaned human transcription. This mismatch was not intentional and we will discuss the impact on the correlation numbers in Section 6.

4 Baselines and Submissions

We computed scores for several baseline metrics in order to compare submissions against previous well-studied metrics. We will start by describing those baselines, and then we will describe the submissions from participating teams. An overview of the evaluated metrics can be seen in Table 6.

4.1 Baselines

SacreBLEU baselines We use the following metrics from SacreBLEU (Post, 2018) as baselines:

- **BLEU (Papineni et al., 2002)** is based on the precision of n-grams between the MT output and its reference, weighted by a brevity penalty. Using SacreBLEU we obtained sentence-BLEU values using the `sentence_bleu` Python function and for corpus-level BLEU we used `corpus_bleu` (both with default arguments[8]).

- **SPBLEU (NLLB Team et al., 2022)** are BLEU scores computed with subword tokenization by the standardized FLORES-200 Sentencepiece models. We used the command line SacreBLEU to compute the sentence level SPBLEU[9] and we averaged the segment-level scores to obtain a corpus-level score.

- **CHRF (Popović, 2015)** uses character n-grams instead of word n-grams to compare the MT output with the reference. For CHRF we used the SacreBLEU `sentence_chrf` function (with default arguments[10]) for segment-level scores and we average those scores to obtain a corpus-level score.

[6] Since the testset is for Spanish from Mexico rather than Spanish from Spain, the conducted annotations were collected taking that variant in consideration.

language	news	social	speech	literary
en→de	90/149 (17/17)	258/531 (34/34)	111/111 (1/1)	27/206 (8/8)
en→es	124/149 (14/17)	281/531 (20/34)	107/111 (1/1)	110/206 (5/8)
ja→zh	255/269 (45/45)	n/a	136/136 (1/1)	168/316 (15/15)

Table 4: Numbers of MQM-annotated segments per domain (number of docs in brackets).

BERTSCORE (Zhang et al., 2020) leverages contextual embeddings from pre-trained transformers to create soft-alignments between words in candidate and reference sentences using cosine similarity. Based on the alignment matrix, BERTSCORE returns a precision, recall and F1 score. We used F1 without TF-IDF weighting.

BLEURT (Sellam et al., 2020) is a learned metric fine-tuned on Direct Assessments (DA). Unlike COMET, BLEURT encodes the translation and the reference together and utilizes the `[CLS]` token as an embedding to represent the pair. We employed the BLEURT20 checkpoint (Pu et al., 2021), which was trained on top of RemBERT using DA data from previous shared tasks spanning from 2015 to 2019, along with additional synthetic data created from Wikipedia articles.

COMET-22 (Rei et al., 2022a) is a learned metric fine-tuned using DA from previous WMT Translation shared tasks. This metric relies on sentence embeddings from the source, translation, and reference to produce a final score. We utilized the default model `wmt22-comet-da` provided in version 2.0.2 of the `Unbabel/COMET` framework. This model employs XLM-R large as its backbone model and is trained on data from the 2017 to 2019 WMT shared tasks, in combination with the MLQE-PE corpus (Fomicheva et al., 2022).

COMETKIWI (Rei et al., 2022b) is a reference-free learned metric that functions similarly to BLEURT, but instead of encoding the translation along with its reference, it uses the source. We utilized the `wmt22-cometkiwi-da` model, which was a top-performing reference-free metric from the WMT22 shared task. This reference-free metric is fine-tuned on the same data as `wmt22-comet-da` using the version 2.0.2 of the `Unbabel/COMET` framework.

PRISMREFSMALL AND PRISMREFMEDIUM (Thompson and Post, 2020a,b) are both reference-based PRISM that uses a multilingual MT model in zero-shot paraphrase model to score the candidate translation conditioned on the reference, and the reference conditioned on the candidate translation, and averages the two scores. As LLMs have become quite capable multi-lingual MT models, we opted to use Llama3.1 (Llama Team, 2024) as the underlying MT model this year. PRISMREFSMALL corresponds to Llama3.1 8B and PRISMREFMEDIUM corresponds to Llama3.1 70B. The long context window of LLMs allows us to compute scores for entire documents, while still averaging scores for each sentence to produce sentence-level scores (Vernikos et al., 2022). We chunked longer documents into sub-documents of up to 10 sentences, and added a penalty for producing no output.

YISI-1 (Lo, 2019) is an MT evaluation metric that measures the semantic similarity between a machine translation and human references by aggregating the IDF-weighted lexical semantic similarities based on the contextual embeddings extracted from pre-trained language models (e.g. RoBERTa, CamemBERT, XLM-RoBERTa, etc.).

4.2 Metric Submissions

The rest of this section summarizes the participating metrics.

BLCOM_1 and BLCOM Unfortunately, we have no information about these submission.

BRIGHT-QE is a referenceless metric, which uses the XLM-XL encoder to perform multi-stage fine-tuning according to the XCOMET framework. In the first stage of training, we used DA 2017 2022 corpus, and gradually reduced the weight of REF-based loss with the idea of curriculum learning, trying to reduce the model's dependence on reference and better align the semantics of the translation and source text; in the second stage, we used batch softmax to normalize scores, and introduced KL divergence loss to learn to modify the minor rank error that MSE loss cannot solve, so as to obtain better Pearson correlation; finally, we further fine-tuned on high-quality MQM corpus to achieve better consistency with human expert MQM.

Table 5: MQM human evaluations for generalMT2024. Lower average error counts represent higher MT quality. Systems above any solid line are significantly better than those below, based on all domains with $p < 0.05$.

CHRFS (Mukherjee and Shrivastava, 2024) is an unsupervised reference-based metric, a semantic version of CHRF++ that integrates sentence embeddings to evaluate translation quality more comprehensively. By combining traditional character and word n-gram analysis with semantic information derived from embeddings, CHRFS captures both syntactic accuracy and sentence-level semantics.

DAMONMONLI and MONMONLI is a proof-of-concept of multiple ideas. A multi-lingual NLI model is used to extract embeddings for (mt, src) and (mt, ref) pairs, based on findings of Chen and Eger (2023). A multi-task learning approach is employed where different human annotations from WMT22 and WMT23 are used as different tasks. For each task, it uses a separate regression head that learns a monotonic function of the metric's score(Runje and Shankaranarayana, 2023). The main metric "DAMONMONLI" also includes a domain adversarial loss (Ganin and Lempitsky, 2015) to make metric representations robust against shifts in MT systems and language pairs.

GEMBA-ESA (Kocmi and Federmann, 2023) is an extension of previous work on an LLM-based metric, with an updated prompt to reflect the new human evaluation protocol ESA (Kocmi et al., 2024c) used at WMT General MT task. It contains a two-step approach where in the first step, MQM error spans are collected and in a second step, the final score is assigned.

MEE4 (Mukherjee and Shrivastava, 2023a) is an unsupervised, reference-based metric (an improved version of MEE) focusing on computing contextual and syntactic equivalences, along with lexical, morphological, and semantic similarity. The goal is to comprehensively evaluate the fluency and adequacy of MT outputs while also considering the surrounding context. Fluency is determined by analysing syntactic correlations, while context is evaluated by comparing sentence similarities using sentence embeddings. The ultimate score is derived from a weighted amalgamation of three distinct similarity measures: a) Syntactic similarity, which is established using a modified BLEU score. b) Lexical, morphological, and semantic similarity, quantified through explicit unigram matching. c) Contextual similarity, gauged by sentence similarity scores obtained from the Language-Agnostic BERT model.

METAMETRICS-MT (Anugraha et al., 2024; Winata et al., 2024) is a machine translation

Table 6: Baseline metrics and primary submissions for the metrics task. Supervised metrics are trained on MT evaluation data such as DA or MQM scores.

(MT) metric developed from our MetaMetrics (Winata et al., 2024), specifically designed to better align with human preferences using Bayesian optimization with Gaussian Processes (GP). By systematically integrating multiple existing metrics, we create a sparse allocation that only includes metrics enhancing the overall correlation score. We optimize this metric by maximizing Kendall scores from the WMT shared task (MQM) 2020-2022. MetaMetrics-MT achieves state-of-the-art performance for reference-based metrics, while its reference-free variant, MetaMetrics-MT-QE, demonstrates competitive correlation with human scores in the WMT24 metric shared task. By strategically assigning weights to combined metrics, MetaMetrics-MT aims to be as competitive as, if not superior to, any individual metric. To address missing values when reference data is unavailable, we propose a hybrid variant, MetaMetrics-MT-Hybrid, which utilizes both metrics to compensate for the absence of reference data in the reference-based setting.

MetricX-24 (Juraska et al., 2024) is a learned regression-based metric that builds on top of its predecessor from 2023. Similar to MetricX-23, it is based on the mT5-XXL pretrained language model, which is fine-tuned in two stages on DA and MQM scores from WMT 2015-22, and it implements three major design improvements. First, the training data in both stages is augmented with synthetic examples to make the metric more robust to several common failure modes, such as fluent but unrelated translation, or undertranslation. Second, a small proportion of DA data is mixed in during the second stage of fine-tuning in order to preserve the performance on non-MQM language pairs. Finally, the model's training is done on a mixture of examples that include the source only, the reference only, or both, which allows the model to operate in both a QE and a reference-based mode (and the latter either with or without the source included). Hence, both MetricX-24-Hybrid and MetricX-24-Hybrid-QE submission are in fact the exact same model, only with the references excluded from the input in the latter case.

sentinel-cand-mqm, sentinel-ref-mqm and sentinel-src-mqm (Perrella et al., 2024) are designed explicitly to scrutinize the accuracy, robustness, and fairness of the meta-evaluation process. The three sentinel metrics are trained only on the candidate, reference and source sentence respectively on DA and MQM data from WMT 2017 to 2022.

XCOMET and XCOMET-QE (Guerreiro et al., 2023) models are trained using both a sentence-level signal and span-level supervision coming from MQM data from previous years, along with some synthetic data that mimics hallucinations. We ensemble XCOMET-XXL and XCOMET-XL to give a single unified score.

XLsimMQM (Mukherjee and Shrivastava, 2023b) is an enhanced version of XLsim, a supervised reference-based evaluation metric, which we have transformed into a reference-free model to improve its applicability across multiple language pairs. Unlike the original XLsim, which was limited to the English-German language pair, XLsimMQM is trained on a filtered comprehensive dataset curated from WMT-MQM (2020-22), ensuring broader applicability and robustness. The filtered datasets (train, dev and test) contains uniform distribution across good, medium and poor-quality sentences; this careful balancing of the dataset leads to a better, reliable and robust metric.

5 Meta Evaluation

The goal of metric meta-evaluation is to quantify how well automatic metrics agree with human ratings of translation quality. There are a multitude of ways to approach this problem, as evidenced by the variety of solutions proposed by previous years' editions of the shared task. For instance—to name just a few possible design decisions—the agreement can be measured at the system or segment level; the agreement function can be Pearson, Spearman, Kendall, pairwise agreement, or L_2 loss; the agreement can be computed per domain or on the full dataset. None of these approaches are necessarily right or wrong, but rather each method evaluates a different property of the metric.

Because there is no one way to evaluate a metric, the past two iterations of the Metrics Shared Task defined a variety of "tasks" (or different configurations of meta-evaluations) that evaluated some aspect of a metric, then calculated an overall quality score by averaging the individual task scores. Implicitly, this approach defines a "high-quality" metric as one that performs well across the tasks on average. In 2022, there were 201 tasks that varied along dimensions such as language pair, domain, correlation granularity, correlation statistic, etc. In

2023, the number of tasks was reduced to 10, measuring only pairwise accuracy and Pearson at both the system and segment levels.

For this year's meta-evaluation, we follow the same approach of averaging performance across tasks, but focus the tasks to better align with how evaluation metrics are used in practice. The two main use cases that we targeted were using metrics to rank a set of MT systems and using a metric to rank a set of translations for the same source segment. The former setting is widely used by academics and practitioners in industry to determine whether one model produces better translations than another, and the latter setting has applications in Minimum Bayes Risk Decoding and Quality Estimation Reranking either directly as decoding method (Fernandes et al., 2022; Freitag et al., 2022) or to further fine-tune models (Finkelstein and Freitag, 2024; Finkelstein et al., 2024). The latter one is getting more popular and can introduce metric biases (Kovacs et al., 2024) that is an emerging challenge for metrics. As such, we defined one task to quantify how well metrics work for each of these two use cases separately for all three language pairs, resulting in a total of six tasks.

At the system-level, we use the recently proposed metric called soft pairwise accuracy, or SPA (Thompson et al., 2024). One of the drawbacks of standard pairwise accuracy (or the very related Kendall's τ) that has been used in previous years' shared tasks is that it does not account for the uncertainty of the system ranking. For example, if the human ranking of two systems is almost arbitrary (e.g, a statistical tie) but the metric ranking is quite certain, standard pairwise accuracy will either reward or penalize the metric nearly randomly. The reverse case—a certain human ranking and uncertain metric ranking—also nearly arbitrarily rewards or penalizes metrics. If both rankings are uncertain, the metric will again be rewarded nearly randomly, and the penalty for an incorrect ranking is equal to when the metric was very certain but also wrong.

SPA addresses this problem by using p-values as a proxy for certainty, calculating p-values between two systems using both the metric and human scores, then taking 1.0 minus the absolute difference between the two p-values as the metric's score for that pair. This rewards metrics that result in the same statistical conclusion as the human scores. Now, statistical ties do not randomly reward or penalize metrics, but instead the score is proportional to whether or not the metric and human have the same level of certainty in the ranking.

language	ref used	scored ref
en→de	B	A
en→es	A	–
ja→zh	A	–

Table 7: Use of reference translations.

task	lang	level	correlation	wt
1	en→de	system	SPA	1
2	en→de	segment	acc^*_{eq}	1
3	en→es	system	SPA	1
4	en→es	segment	acc^*_{eq}	1
5	ja→zh	system	SPA	1
6	ja→zh	segment	acc^*_{eq}	1

Table 8: For each language pair, soft pairwise accuracy (SPA) was used at the system-level and acc^*_{eq} at the segment-level. Each task was given equal weight in the overall average. See §5 for explanations of SPA and acc^*_{eq}.

At the segment-level, we follow last year's meta-evaluation and meta-evaluate metrics using "group-by-item" segment-level accuracy with tie calibration (Deutsch et al., 2023) denoted acc^*_{eq}.

The six tasks (shown in Table 8) receive equal weighting in the overall average, which is the final score for the metric.

Removing Pearson's Correlation: Notably, the meta-evaluation this year only focuses on evaluating rankings and does not include any correlation that evaluates the absolute value of the scores predicted by metrics, like Pearson's correlation. This decision was made because using metrics to rank systems or translations is much more common in practice than using a metric to approximate the absolute quality score as derived by humans, which is more similar to a Pearson correlation.

Limitations: Like previous years, we acknowledge that this approach is not perfect. One problem is that we need to combine correlations and accuracies that may have different dynamic ranges, which could result in certain tasks carrying more weight than others in the overall ranking. However, to simplify the implementation, we assigned equal weight to all tasks, which worked well in last year's evaluation.

5.1 Rank Assignment

For each task, we assign ranks to metrics based on their significance clusters in the same way that we did last year, detailed below.

We compare all pairs of metrics and determine whether the difference in their correlation scores is significant, according to the PERM-BOTH hypothesis test of Deutsch et al. (2021). We use 1000 resampling runs and set $p = 0.05$. As advocated by Wei et al. (2022), we divide the sample into blocks of 100, compute significance after each block (cumulative over all blocks sampled so far), and stop early if the p-value is < 0.02 or > 0.50.

The acc^*_{eq} statistic creates a problem for significance testing because it optimizes a latent tie threshold for each metric on each test set (just one threshold for all item-wise score vectors). Since the permutation test for comparing two metrics creates two new vectors by randomly swapping elements of the original vectors on each draw, this necessitates the very expensive step of finding two new tie thresholds for each draw. To reduce the expense, we used the following approximate procedure. First find an optimal threshold for each input metric on the current test set, then create all pairs of item-wise scores and assign a correct/incorrect status to each pair by examining whether the metric's ranking matches the human ranking. Then perform the permutation test on these pairwise status vectors rather than the original score vectors. This approximation has more degrees of freedom than the original test, and can sample pairs that would never result from swapping the original score vectors, but our experiments showed that it is a reasonable proxy for the correct procedure.

To compute overall p-values based on weighted average scores of two metrics across all tasks, we cache the results of the draws for the per-task significance tests. In all cases, these are vectors of K pairs of correlation or accuracy statistics. Where $K < 1000$ due to early stopping, we duplicate elements to get 1000 examples. Then for i in 1..1000 we compare the weighted average of the pairs from the ith draw across all tasks, and record the results to produce an overall p-value.

Clustering. Given significance results (p-values) for all pairs of metrics, we assign ranks as follows. Starting with the highest-scoring metric, we move down the list of metrics in descending order by score, and assign rank 1 to all metrics until we encounter the first metric that is significantly different from any that have been visited so far. That metric is assigned rank 2, and the process is repeated. This continues until all metrics have been assigned a rank. Note that this is a greedy algorithm, and hence it can place two metrics that are statistically indistinguishable in different clusters.

5.2 Implementation Details

The code for running the meta-evaluation is available in the MT Metrics Eval library.[11]

To calculate p-values for SPA, we use a paired permutation test (Noreen, 1989) with 1k resamples.

In previous years' shared tasks, tasks were categorized based on whether they included additional reference translations in the overall system ranking. Following last year's proposal, we always include the additional reference in the overall ranking. This year, this only applies to en→de which is the only language pair with more than one reference translation (see Table 7).

Out of all the submitted MT systems, MSLC consistently scores well below the other systems for all language pairs and was identified as an outlier and removed from the correlation calculation.

6 Main Results

As we have described in Section 5, the final statistic used to rank the metrics is defined as the average of the results from the six main tasks (system-level and segment-level tasks in different language pairs). Table 1 shows the official scores and rankings of all baselines and primary submissions. Table 9 shows the scores and rankings of each individual task at system level and segment level, respectively. Similar to last year's results, neural metrics perform significantly better than lexical metrics. Of the 26 evaluated metrics, BLEU, SPBLEU and CHRF are ranked 23rd, 22nd and 20th respectively. Fine-tuned neural metrics, like XCOMET and METRICX-23 are the highest ranked non-ensemble metrics. The ensemble submission METAMETRIC_MT is in the same significance cluster as XCOMET and METRICX-24-HYBRID, but relies heavily on the 2023 version of METRICX-24-HYBRID. Like last year, QE metrics perform very well, with METRICX-24-HYBRID-QE and GEMBA_ESA sharing the second significance cluster.

Figure 1 shows the correlation scores split by language pair. Interestingly, GEMBA_ESA is performing very well for en→es and ja→zh, while ranked below many metrics for en→de. GEMBA_ESA is

Table 9: Correlation results per task for the main language pairs. See §5 for descriptions of soft pairwise accuracy (SPA) and acc^*_{eq}. Rows are sorted by the overall average correlation across all 6 tasks (leftmost column). Starred metrics are reference-free, and underlined metrics are baselines.

a prompt-based metric and not fine-tuned for any metric task. Both en→es and ja→zh are new language pairs, and no fine-tuning data exists which might have played in disadvantage for all fine-tuned metrics.

We continue to be interested in metrics' abilities to generalise across domains. In Figure 2, we present the performance of each metric across different domains. Similar to last year, we observe that neural metrics perform better than lexical overlap metrics across all four domains. Figure 3 shows the average correlations of metrics when grouped separately by system-level and segment-level tasks. There is a high correlation between the rankings of both granularities.

7 Beyond accuracy and correlation

Last year, we conducted two additional analyses beyond correlation with human scores to find the threshold of metrics' score differences correspond to statistical significance of MT system rankings demonstrated by human annotators and the metrics themselves. Despite the better correlation with human judgements achieved by new neural metrics, BLEU remains as the most used metric in the MT research community. One of the reasons is that MT researchers have established some "shared understanding" about the relationship between BLEU and the actual translation quality, and similar intuitions about new metrics have yet to crystallize. Our analyses beyond correlation provided an interpretation of the metrics' score differences. Hence, we are continuing such analyses to support building an intuitive sense of metric score meanings and encourage broader adoption of new automatic MT evaluation metrics. As a reminder, our results should *NOT* be used as arguments to forego significance tests or appropriate human evaluation.

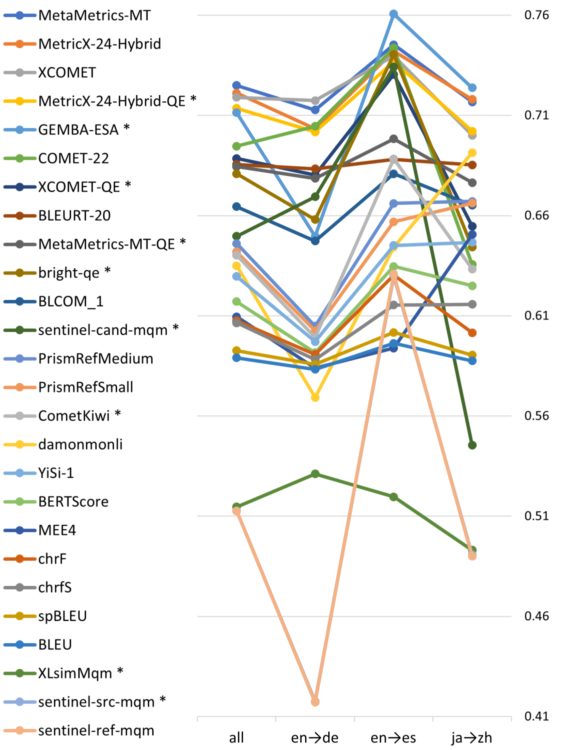

Figure 1: Average metrics' meta-evaluation scores in tasks grouped by language pair.

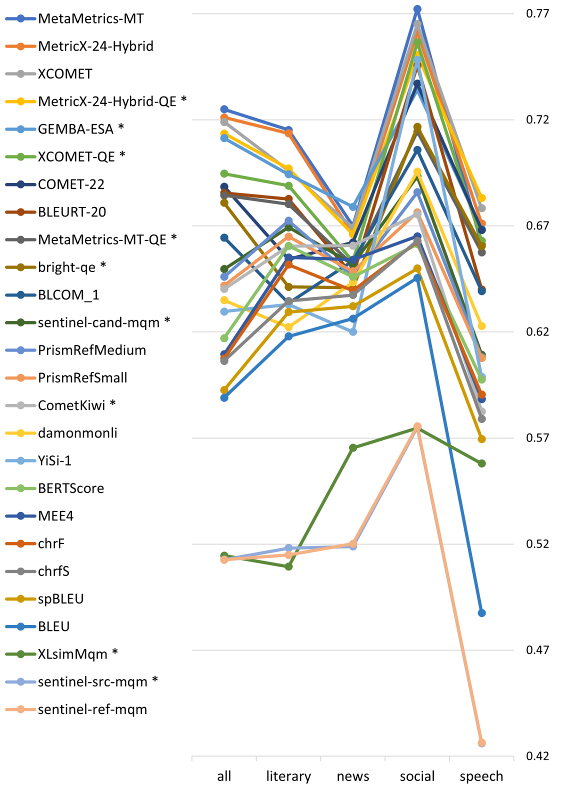

Figure 2: Average metrics' correlation with human in tasks grouped by domain.

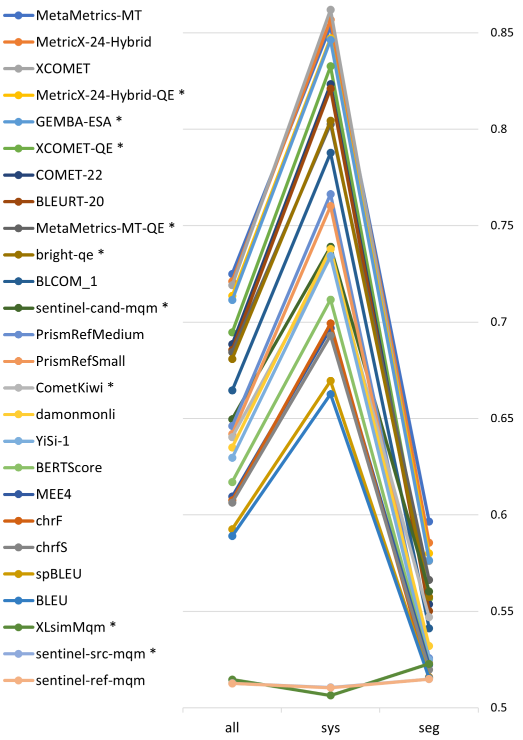

Figure 3: Average metrics' correlation with human in tasks grouped by granularity level.

7.1 Correspondence to MQM scores significance

We first study the relationship between statistically significant differences in human scores and the magnitude of metric differences as in Lo et al. (2023a). We run a two-sided paired t-test with an equal variance assumption for each system pair on segment-level MQM scores. After that, we fit the corresponding metric score differences and the p-values of the t-test on the MQM scores to an isotonic regression (Robertson et al., 1988), that predicts whether the human MQM score difference will be significant given the metric's score difference. Isotonic regression produces a non-decreasing function where the classifier output can be interpreted as a confidence level.[12] We set $p_{mqm} < 0.05$ as the significance level of MQM scores. Thus, the output of the isotonic regression function can be viewed as $Pr(p_{mqm} < 0.05|\Delta M)$ where p_{mqm} is the p-value of the t-test on the MQM scores for each system pair and ΔM is the metric score difference.

Figure 4 shows the (log) p-value of two-sided paired t-test on the MQM scores against the corre-

[12] https://scikit-learn.org/stable/modules/isotonic.html

sponding BLEU and COMET-22 score difference for each system pair in en→de. Figures 6-10 in appendix D, show the same analyses for all metrics and language pairs. For each metric, we can choose a particular level of confidence (i.e., a point along the y-axis on the right) to give metric score difference cut-offs (i.e., a point along the x-axis) that this metric difference reflects significant MQM score differences. Drawing a horizontal line from the confidence level, say 80%, to the red line enables us to find the minimum metric difference cut-off required at the corresponding x-value down from the red line, i.e. 5.4 for BLEU in Figure 4. Using this lookup method, Table 10 shows the cut-offs of ΔM when $Pr(p_{mqm} < 0.05|\Delta M) = 0.8$ for each metric and language pair.

We run the leave-one-system-out cross validation and Table 10 shows that the range of precision in the cross validation are consistently high across metrics, except for BLEU, BRIGHT-QE, COMETKIWI, MEE4, METAMETRICS_MT_MQM_QE_KENDALL.SEG.S, SPBLEU and XLSIMMQM. This means the metric cut-offs we find using the regression model are reliable.

Contrary to the shared understanding that 2 BLEU improvement represents "significant" or "notable by human" improvement in the actual translation quality, our analyses show that 5.4 BLEU improvement is required to be confident (80%) that the MQM scores would be different with statistical significance for en→de and that threshold would be as high as 11 BLEU for en→es. Table 10 serves as a reference between BLEU differences and differences in some of the modern metrics and assists metric users in understanding scores provided by modern metrics. For example, when evaluating ja→zh translation quality, we see that a BLEU difference of 1.4 corresponds to 80% confidence that the metric's ranking of the two MT systems will match the decision made by human annotators with a significant difference. Meanwhile, a COMET-22 score difference of 0.021 would have the same 80% chance of human judged significant difference.

7.2 Correspondence to metric scores significance

We run a study similar to that in the previous subsection but on the relations between statistically significant differences in metric scores and the magnitude of metric differences as inspired by Marie (2022). Instead of the two-sided t-test on MQM, the p-values are now obtained by running statistical significance tests with bootstrap resampling on the metric scores for each system pair. We fit the corresponding metric score differences and the p-values of the significance test to an isotonic regression for predicting whether the translation quality improvement as indicated by the metric will be significant given the metric score difference. We set $p_M < 0.05$ and thus, the output of the isotonic regression function is now $Pr(p_M < 0.05|\Delta M)$, where p_M is the p-value of the significance test on the metric scores for each system pair and ΔM is the metric score difference.

Figure 5 shows the (log) p-value of the significance test with bootstrap resampling on the metric scores for BLEU and COMET-22 score difference of each system pair in en→de. Additional figures (Figures 11-15 in appendix Appendix D) show the same analyses for all metrics and language pairs. Using the same lookup method described in the previous subsection, Table 11 shows the cut-offs of ΔM when $Pr(p_M < 0.05|\Delta M) = 0.8$ for each metric and language pair.

We run the leave-one-system-out cross validation, and Table 11 shows that the range of precision in the cross validation are consistently high across metrics. This means the metric cut-offs we find using the regression model are reliable.

Table 11 serves as a reference of metric differences that correspond to statistical significance with high confidence. For example, when evaluating en→de translation quality, we see that a BLEU difference of 0.97 corresponds to 80% confidence the difference is statistically significant. Meanwhile, a COMET-22 score difference of 0.0043 would have the same 80% chance of statistical significance. Our results, agreeing with Marie (2022), show that to claim significant differences ($p_M < 0.05$) in BLEU with high confidence (80%), the differences should be much higher than the shared understanding of 0.5 BLEU, ranging from 0.89 to 0.97 for the three language pairs.

Closely related to this analysis, Kocmi et al. (2024b) investigated the agreement between human evaluations and metric differences, employing pairwise accuracy as the meta-evaluation metric. Assuming an 80% agreement rate with human judgments, their findings align closely with ours for pretrained metrics but not for metrics such as BLEU or ChrF. For instance, COMET-22 requires a score difference of 0.0056 to achieve 80% accuracy with humans, compared to our range of 0.0043–0.0055. Similarly, CometKiwi requires a

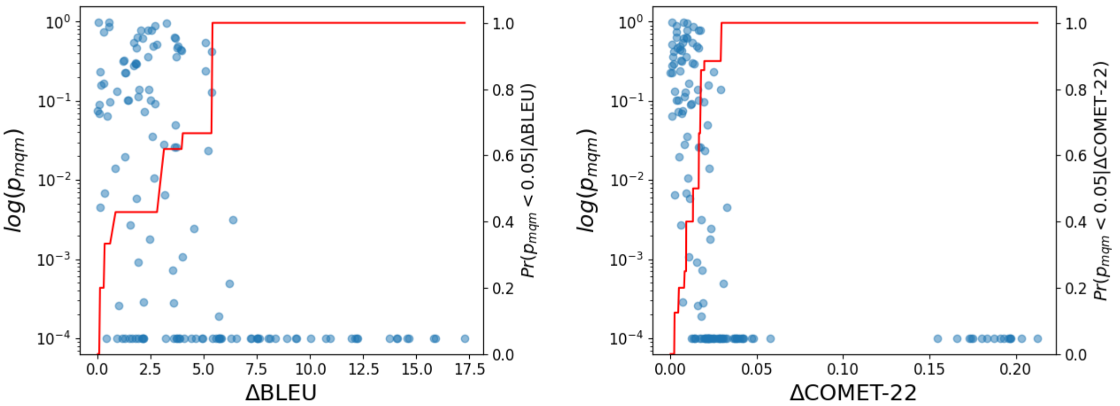

Figure 4: Log p-value of two-sided paired t-test on MQM scores (p_{mqm}) against the metric (left: Bleu, right: COMET-22) score difference for each system pair in en→de. The red line is the isotonic regression fit to all data points, representing $Pr(p_{mqm} < 0.05|\Delta M)$. Note: for readability, values of p_{mqm} are rounded up to 0.0001 when they are less than 0.0001.

Table 10: Minimum ΔM when $Pr(p_{mqm} < 0.05|\Delta M) = 0.8$ for each metric in different language pairs round to 2 significant figures, and the range of precision for the isotonic regression model in leave-one-system-out cross validation.

difference of 0.0053, while our results range from 0.0037 to 0.0056. Conversely, for Bleu, their analysis suggests an expected improvement of 2.34 Bleu points for 80% agreement, whereas our analysis indicates a need for an improvement of 0.89–0.97 Bleu points. However, it is important to note that we are comparing distinct metrics, and that confidence levels are not directly comparable to agreement rates.

We have to emphasize again that our result should *NOT* be interpreted as evidence to forego significance tests or appropriate human evaluation. Instead, we are only providing assistance to build an intuition on the meaning of the scores provided by the new metrics to encourage the transition away from lexical metrics towards more recent and stronger metrics.

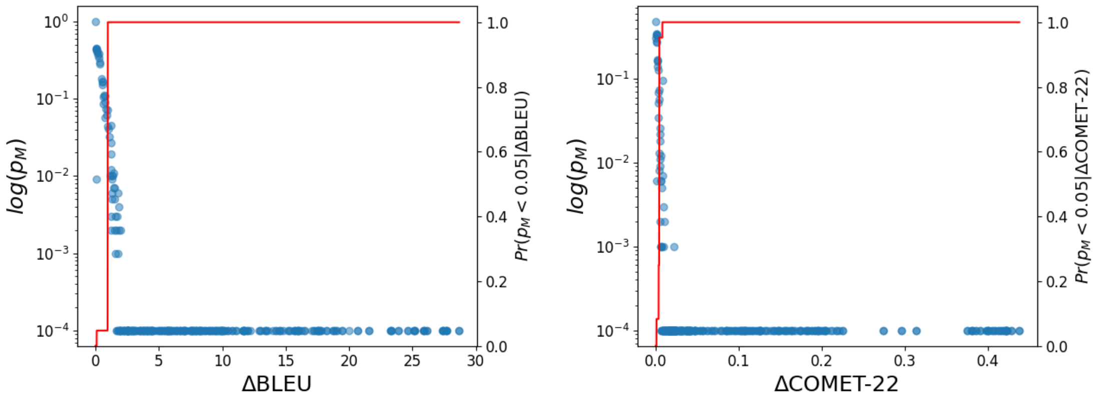

Figure 5: Log p-value of significance test with bootstrap resampling (p_M) on system-level metric scores against each metric (left: BLEU, right: COMET-22) score difference for each system pair in en→de. The red line is the isotonic regression fit to all data points, representing $Pr(p_M < 0.05|\Delta M)$. Note: for readability, values of p_M are rounded up to 0.0001 when they are less than 0.0001.

8 ESA Human Evaluation

In addition to our MQM annotations and as a contrastive evaluation to cover more language pairs, we look into the performance of metrics when compared to the human evaluation campaign conducted by the WMT24 General MT Shared Task (Kocmi et al., 2024a), which ran human evaluation for nine language pairs.

In contrast to previous years, WMT24 redefined their human evaluation process and developed a new method called Error Span Analysis (ESA, Kocmi et al. (2024c)), a method that simplifies MQM by asking annotators only to mark error spans and classify them either as minor or major severity. In addition to that, the annotator is asked to mark the whole segment with a score of 0–100 in the SQM fashion. As Kocmi et al. (2024c) claim, the method is cheaper than MQM to annotate, yet it produces closer human judgment to MQM annotations than the formerly used DA+SQM (Kocmi et al., 2023) due to being less affected by fluency.

We present system-level accuracy results for both MQM and ESA in Table 15. There are many factors that could affect the ranking. Apart from using a different human annotation protocol, MQM compares 3 language pairs whereas ESA compares 9 language pairs, containing also two low-resource pairs: Czech→Ukrainian and English→Icelandic. There is an overlap of only one language pair between the two: English→Spanish.

Most of the metrics have a similar ranking for both MQM and ESA; however, there are two metrics with largely different rankings: GEMBA_ESA and metametrics_mt_mqm_qe_kendall.seg.s, whose rankings are significantly lower under ESA than for MQM. The likely explanation for GEMBA_ESA is that ESA doesn't produce ties, in contrast to MQM, whereas GEMBA_ESA produces them regularly. As for the latter metric, we don't see any clear pattern except for having low performance for Czech→Ukrainian.

9 Challenge Sets Sub-task

For the third year, the Metrics Shared Task included a sub-task involving challenge sets. This sub-task is inspired by the *Build it or break it: The Language Edition* shared task (Ettinger et al., 2017) which aimed at testing the generalizability of NLP systems beyond the distributions of their training data. Whereas the standard evaluation of the shared task is conducted on test sets containing generic text from real-world content, the challenge set evaluation is based on test sets designed with the aim of revealing the abilities or the weaknesses of the metrics or evaluating particular translation phenomena. In order to shed light on different perspectives on evaluation, the sub-task takes place in a decentralized manner, since contrary to the main metric task, the test sets are not provided by the organizers but by different research teams, who are also responsible for analysing and presenting the results.

This subtask is made of three consecutive phases; 1) the *Breaking Round*, 2) the *Scoring Round* and 3) the *Analysis Round*:

1. In the *Breaking Round*, every challenge set participant (*Breaker*) submits their challenge set S composed of examples for different phenomena, where every example $(s, t, r) \in S$ contains one source sentence s, one translation hypothesis t and one reference r.

2. In the *Scoring Round*, The metrics participants from the main task (the *Builders*) are asked to score with their metrics the translations in the given test set. Also, in this phase, the metrics task organizers score all data with the baseline metrics.

3. Finally, after having gathered all metric scores, the organizers return the respective scored translations to the *Breakers* for the *Analysis round*, where they employ their own evaluation for the performance of the metrics with regard to the phenomena they intended to test.

This year there were 4 submissions, covering a wide range of phenomena and 23 different language pairs, which supersede the official language pairs of the Metrics Shared Task. An overview of the submitted challenge sets can be seen in Table 12. A short description of every submission follows:

AfriMTE Challenge Set The AFRIMTE challenge set (Wang et al., 2024b) aims to evaluate the capabilities of metrics for machine translation on low-resource languages, primarily assessing cross-lingual transfer learning and generalization across a wide range of under-resourced African languages. The challenge set concentrates on the subsets of the FLORES-200 dataset (NLLB-Team et al., 2022) and covers 13 language pairs. Specifically, there are Darija-French, English-Egyptian Arabic, English-French, English-Hausa, English-Igbo, English-Kikuyu, English-Luo, English-Somali, English-Swahili, English-Twi, English-isiXhosa, English-Yoruba, and Yoruba-English. Originally, AFRIMTE (Wang et al., 2024a) provides both fine-grained word-level error annotations and sentence-level Direct Assessment scoring for translation adequacy and fluency. For this year's challenge set sub-task, we utilize the translation adequacy test set from AFRIMTE as the African Challenge set to evaluate the sentence-level scoring performance of metrics. The analysis of the task submissions (Wang et al., 2024b) has yielded several insights. First, language-specific adaptation, cross-lingual transfer learning, and larger language model sizes significantly enhance metric performance. Second, moderately-sized supervised models can attain robust performance when augmented with language adaptation techniques tailored to

Challenge Set	Directions	Phenomena	Items	Citation	Link (https://github.com/)

BioMQM	11	biomedical domain	4,641	Zouhar et al. (2024)	thompsonb/bio-mqm-dataset
DFKI	2	linguistic phenomena	137,000	Avramidis et al. (2024)	DFKI-NLP/mt-testsuite
MSLC24	3	low quality MT	964	Knowles et al. (2024)	nrc-cnrc/MSLC

Table 12: Overview of the participation at the metrics challenge sets sub-task.

low-resource African languages during pretraining. Last, submissions demonstrate promising outcomes for language pairs such as Darija-French, English-Egyptian Arabic, and English-Swahili. However, considerable challenges remain for extremely low-resource languages like English-Luo and English-Twi, underscoring critical areas for future research and improvement in machine translation metrics for African languages.

BioMQM Recent work (Zouhar et al., 2024) has compared trained versus untrained metric performance on the WMT domains compared to the biomedical domain and shown that trained metrics appear to be over-fitting on the domains used in the WMT Metrics Shared Tasks. This is likely due to trained metrics using prior WMT metrics datasets, and then being evaluated on very similar data in the latest WMT Metrics Shared Task. Zouhar et al. (2024) released a biomedical dataset (BioMQM) consisting of source sentences and translations from Yeganova et al. (2021) along with new translations and MQM annotations. We produce scores on the BioMQM for the latest metrics (all those submitted to this Metrics Shared Task, plus the baseline metrics) and release them for future analysis.[13]

DFKI Challenge Set This year's submission by DFKI (Avramidis et al., 2024) expands the linguistically motivated challenge set of previous years (Avramidis et al., 2023; Avramidis and Macketanz, 2022), including 137,000 items in overall, extracted from 100 MT systems for the two language directions (en→de, en→ru), covering more than 100 linguistically-motivated phenomena organized in 14 linguistic categories. The metrics with the statistically significant best performance with regard to our linguistically motivated analysis are METRICX-24-HYBRID and METRICX-24 for en→de and METRICX-24 for en→ru, whereas METAMETRICS and XCOMET are in the next ranking positions in both language pairs. Metrics are more accurate in detecting linguistic errors among LLM translations than in translations based on the encoder-decoder NMT architecture. Some of the most difficult phenomena for the metrics to score are the transitive past progressive, the multiple connectors, the ditransitive simple future I for en→de and pseudogapping, contact clause and cleft sentences for en→ru. The LLM-based metric GEMBA, despite the overall low performance, has the best performance on scoring German negation errors.

MSLC24 Challenge Set Building on the Metric Score Landscape Challenge (MSLC23; Lo et al., 2023b), which aims to provide a view of metric performance on a broader range of MT quality, MSLC24 includes a collection of low- to medium-quality MT systems' output on the news portion of the WMT24 General MT Shared Task test set, as well as some specific phenomena that may result in unexpected behaviors from some metrics, such as empty strings in source/reference/hypothesis, wrong/mixed language output and different language variants. MSLC24 focuses on three language pairs (English→German, English→Spanish and Japanese→Chinese). The authors also submit the top system in this challenge set to the General Translation task in order to obtain human evaluation. Together with the high quality systems by other participants submitted to the General MT Shared Task, this enables better interpretation of metric scores across a range of different levels of translation quality and analyse metric characteristics beyond just correlation. The results of MSLC24 highlight the importance of examining real-word corner cases and issues of reproducibility in order to more responsibly introduce new metrics to the research community.

10 Conclusion

This paper summarizes the results of the WMT24 shared task on automated machine translation evaluation, the Metrics Shared Task. We presented an extensive analysis on how well metrics perform on

[13] https://github.com/thompsonb/bio-mqm-dataset/tree/main/data/WMT24_Metrics_ChallengeSet

our three main language pairs: English→German, English→Spanish and Japanese→Chinese. The results, based on 6 different tasks, confirm the superiority of neural-based learned metrics over overlap-based metrics like BLEU, SPBLEU or CHRF. These results are confirmed with ESA human judgement. Overall, we did not find any issues for neural fine-tuned metrics when evaluating LLM-based translations. In addition, we continued the challenge set subtask, where participants had to create contrastive test suites for evaluating metrics' ability to capture and penalise specific types of translation errors.

11 Ethical Considerations

MQM annotations in this paper are done by professional translators. They are all paid at professional rates.

Organizers from the National Research Council Canada, Unbabel have submitted to this task the frozen stable versions of their metrics (YiSi and COMET) dated before this year's shared task and publicly available. Newer versions of MetricX were developed without using any of the test set, test suite or challenge sets. We ensured that the metrics co-authored by Tom Kocmi were implemented without using any privileged test sets or insider information.

12 Acknowledgments

Results for this shared task would not be possible without tight collaboration with the organizers of the WMT24 General MT Shared Task. We are grateful to Google and Unbabel for sponsoring and overseeing the human evaluation.

Table 14: Results of pairwise metric significance tests for primary submissions using permutation resampling. Each value gives the 100 × estimated probability of the null hypothesis that the average correlation of the metric in the current row is ≤ the average correlation of the metric in the current column. Starred metrics are reference-free, and underlined metrics are baselines.

B Significance comparisons for main results

Table 14 contains the results of pairwise comparisons for the results in Table 1.

C Correlations with WMT ESA for all metrics

Table 15 shows the correlations of the metrics to the ESA scores (see Section 8 for which those scores are available). The overall ranking is sorted by the average correlation, which is the average over all tasks across all language pairs. Metrics that did not participate in all tasks do not have an average correlation, and are displayed at the end of the table.

The system-level ESA scores that were used to calculate SPA here differ slightly from those in the General MT Shared Task. Namely, the General Task calculates scores by macro-averaging over domains (each domain receives equal weight), whereas we perform a standard micro-average (each segment receives equal weight).

Table 15: Correlations of metrics to the ESA annotations that were collected as part of the General MT Shared Task. The metrics are sorted by the average correlation across all of the correlations and language pairs. Metrics in italics are contrastive submissions and underlined metrics are baselines. QE metrics are marked by an asterisk.

Abstract

We report the results of the WMT 2024 shared task on Quality Estimation, in which the challenge is to predict the quality of the output of neural machine translation systems without access to reference translations. In this edition, we continue to focus both on predicting sentence-level scores and on detecting error spans. Further, we expanded our scope to assess the potential for quality estimation to help in the correction of translated outputs, hence including an automated post-editing (APE) task.

We publish new test sets with human annotations that target two directions: providing new Multidimensional Quality Metrics (MQM) annotations for three multi-domain language pairs (English to German, Spanish and Hindi) and extending the annotations on Indic languages, providing direct assessments and post edits for translation from English into Hindi, Gujarati, Tamil and Telugu. We also perform a detailed analysis of the behaviour of different models with respect to different phenomena, including gender bias, idiomatic language, and numerical and entity perturbations. We received submissions based on both traditional encoder-based approaches and large language models (LLMs) and attempted to draw some comparisons in terms of performance and robustness to different phenomena.

1 Introduction

This edition of the shared task on Quality Estimation (QE) for machine translation builds upon previous iterations and findings, to further benchmark methods for estimating the quality of neural Machine Translation (MT) output at run-time, *i.e.* without relying on reference translations. The shared task introduces (sub)tasks that assess translation quality from multiple perspectives, examining errors both at a higher level (segment scores) and with a more fine-grained view (error spans). Additionally, we expand our scope to generating corrected outputs through Automatic Post-Editing (APE).

Recently we have observed a gradual shift in the QE paradigms and methodologies, enabled by the advancement of neural metrics as well as large language models. Specifically, we have seen consistently strong performance across different language pairs and setups at sentence-level QE (Specia et al., 2021; Zerva et al., 2022; Blain et al., 2023), alongside increased efforts towards more finer-grained, explainable, and actionable evaluation of translations that focusses on error identification and explanation (Blain et al., 2023; Fernandes et al., 2023b; Guerreiro et al., 2023). The proliferation of LLM applications has led to significant performance improvements in MT, elevating the importance of advancing methodologies for quality estimation, and at the same time, it has allowed for novel perspectives and tasks related to quality estimation (Fabbri et al., 2022).

In light of the above, in this edition, we emphasise –beyond multilingual quality estimation– the analysis of the behaviour and abilities of submitted models with respect to different linguistic phenomena as well as their robustness to different error types and biases. Furthermore, we attempt to explore the degree to which quality estimation signals can be leveraged to improve translation quality via downstream automatic post-editing (Chatterjee et al., 2018b; Deoghare et al., 2023). We thus **bring APE under the QE umbrella** to make it easier for participants to develop QE systems and explore different techniques to apply it in APE shared task. These considerations collectively contribute to progress toward trustworthy and dependable QE systems that could facilitate real-time, reliable assessments of translation quality, as well as inform APE systems towards generating a corrected trans-

lation.

In this edition of the shared task, we further expand the provided resources for sentence-level and fine-grained QE, providing new test sets and expanding to new language pairs. Following the previous editions, we provide annotations for *direct assessments* (DA; English-Tamil, English-Hindi, English-Telugu and English-Gujarati), *post-edits* (PE; English-Tamil and English-Hindi) and *Multidimensional Quality Metrics* (MQM; English-Hindi, English-Spanish and English-German) (Lommel et al., 2014). We describe in detail the annotation process and provide statistics for the new resources in Section 3.

Overall, in addition to advancing the state-of-the-art at all prediction levels, our main goals are:

- To extend the languages covered in our datasets and provide new test sets emphasising low- and medium-resource languages and zero-shot approaches;
- To continue investigating the potential of fine-grained quality estimation;
- To study the robustness of QE approaches to different linguistic phenomena, error types and biases;
- To continue monitoring the computational efficiency of proposed approaches for sustainability purposes; and
- To study whether we can leverage QE signals to improve translation quality via downstream APE task.

We thus designed three tasks this year:

Task 1 The core QE task, which consists of separate sentence-level sub-tasks for different language pairs (§**??**). The goal is to predict a quality score for each segment in a given test set, which can be a variant of DA (§3.2) or MQM (§3.3).

Task 2 The fine-grained error prediction task, where participants were asked to detect error spans alongside error severities (*Major* versus *Minor*) (§2.2).

Task 3 A newly introduced task, which requires participants to combine quality estimation and automatic post-editing in order to correct the output of machine translation. (§2.3).

The tasks make use of large datasets annotated by professional translators with either $0 - 100$ DA scoring, post-editing or MQM annotations. We provide new training, development and test data for Task 3 as well as fresh new test sets for Tasks 1 and 2. The datasets and models released are publicly available[1].

Besides the data made available through the QE shared task, participants were also allowed to explore any additional data and resources deemed relevant, across tasks. In addition, LLMs could also be used both to extend resources and to complement predictions.

The shared task uses *CodaBench* as a submission platform, where each sub-task corresponds to a separate competition instance. Participants (Section 5) could submit up to a total of 10 submissions per sub-task. Results for all tasks, evaluated according to standard metrics, are given in Section 6. Baseline systems were trained by the task organisers and entered into the platform to provide a basis for comparison (Section 4). We provide an additional evaluation focussed on robustness against different phenomena and biases in Section 7. A discussion on the main findings from this year's task is presented in Section 8.

2 Quality Estimation tasks

In what follows, we briefly describe each sub-task, including the datasets provided for them.

2.1 Task 1: Predicting translation quality

The ability to accurately estimate the quality of translations on-the-fly, i.e., without access to human references, is at the core of the QE shared task. This year, we focus on sentence-level quality, attempting to disentangle finer-grained analysis or post-edits that are tackled in Tasks 2 and 3.

Similar to the last edition, the data was produced as follows:

1. DA sentence level scores: The quality of each source-translation pair is annotated by at least 3 independent expert annotators, using DA on a scale 0-100.
2. MQM annotation: Each source-translation pair is evaluated by at least 1 expert annotator, and errors identified in texts are highlighted

[1] https://github.com/WMT-QE-Task/wmt-qe-2023-data

and classified in terms of severity (minor, major, critical) and type (grammar correctness, omission, style, mistranslation, among others).

The DA and MQM sentence level annotations were further processed to obtain normalised quality scores that have the same direction between high and low quality. We provide more details on the required pre-processing in §2.1.1.

2.1.1 Sentence-level quality prediction

Similarly to the previous year, we used a single competition instance both for DA and MQM-derived annotations aiming to motivate the submission of models that are robust to both annotation formats. Hence, we also aligned the scores by processing and normalising them as follows:

- For the **DA** scores we standardize the scores with respect to each annotator and then compute the mean average of standardized scores for each sentence.
- For the **MQM** scores we need to first compute the overall score from the individual errors. Hence for each annotator, we first compute the sentence-level score as:

  $$MQM^{sent}(hyp) = \frac{100 - \sum_{e \in hyp} severity(e)}{|hyp|}, \tag{1}$$

  where hyp is a hypothesis sentence represented as a sequence of tokens, e is an error annotated in that sentence and the $severity$ is computed but adding:

  + 1 point for minor errors
  + 5 points for major errors
  + 10 points for critical errors

  To align with DA annotations, we subtract the summed penalties from 100 (perfect score) and we then divide by the sentence length (computed as number of words). We then normalise per annotator as in the DA case and compute the mean average in the case of multiple annotators.

Regarding evaluation, systems in this task (both for DA and MQM) are **evaluated against the true z-normalised sentence scores using Spearman's rank correlation coefficient ρ as the primary metric**. This is what was used for ranking system submissions. Pearson's correlation coefficient, r, and Kendall τ were also computed as secondary metrics but not used for the final ranking of systems.

2.1.2 Finer-grained Evaluation and Challenge Sets

To assess the robustness and capabilities of automatic machine translation evaluation systems, we created a challenge set focusing on five different phenomena for the En-De and En-Es language pairs. Each category tests a particular aspect of translation quality that may have impact in real-world applications. The challenge set aims to determine whether evaluation systems can distinguish between correct translations—which we designate as hyp—and those containing subtle but relevant variations—which we designate as con.

Currency and date formatting This set tests the detection of format changes in currency symbols and date expressions. The hyp preserves the original source format (e.g., keeping "$100" or "MM/DD/YYYY"), while the con presents localized versions (e.g., "100 USD" or "DD/MM/YYYY"). Note that here it is the case that con is also a good-quality translation.

Word order This category examines the handling of word order variations. The hyp consists of monotonic translations that closely follow the source sentence order, while the con presents non-monotonic translations that rearrange words while preserving meaning. Evaluation models might have a preference towards one or the other, even though both preserve the meaning of the source.

Detached translations and omissions This set focuses on critical divergences from the source text. The hyp provides accurate and complete translations of the source. In contrast, the con includes examples where translations start correctly but then veer into unrelated topics or omit substantial portions of the source text. Evaluation systems are expected to detect these critical errors.

Idiomatic translations This category tests the handling of idiomatic expressions. The hyp presents idiomatic renderings that accurately convey the meaning in the target language, while the con offers literal word-for-word translations that may render the target text non-sensical. Evaluation systems should appropriately score translations that prioritize conveying the correct meaning over strict word-for-word translation.

We generated data for all the phenomena listed above using GPT-3.5 (`gpt-3.5-turbo-0125`) and GPT-4 (`gpt-4-1106-preview`). Then, we conducted a human annotation study to discard erroneous triples.

Gender Subset The gender subset of the challenge set aims to study QE metrics and gender inflection in grammatical gender languages.

Following Zaranis et al. (2024), we collected unmodified instances from the counterfactual subsets (Es and De) of MT-GenEval (Currey et al., 2022), an evaluation set for sentence-level gender bias in machine translation. In these examples, sources from English Wikipedia mention exactly one human entity and contain intra-sentence lexical clues that help disambiguate the entity's gender identity.[2] Each source is provided with a masculine (M) and a feminine (F) variant (e.g., "She/He is a graduate of Harvard, but rarely applies such skills."). Human references are included as well.

We compiled the gender subset by constructing contrastive pairs as follows. First, we sampled 150 instances from the original MT-GenEval's subset. Fifty unique sources have a female referent and fifty a male referent. From each instance, we created a triplet with the source, the reference with correct gender inflection used as hypothesis, and the reference with wrong gender inflection used as contrast. Then, to isolate the impact of the source content, we created two triplets for each of the remaining fifty instances. The source in the triples is identical except for the gender identity of the entity. This step yields 100 more examples. The gender subset hence counts 200 contrastive triplets in total.

2.2 Task 2: Fine-grained error detection

For this task, we focus on finer-grained quality predictions, taking advantage of the detailed information provided in the MQM annotation schema. Specifically, each error span is annotated with error severity (*minor*, *major*, *critical*) as well as error type (see also Figure 1). Following the findings of the previous edition, we focus on the severity annotations and do not use the other error categories annotated in the MQM schema. As a result, we aimed to (1) identify error spans and (2) classify said error spans as either *minor* or *major*. We note that we merge the critical and major categories, since in this edition we noticed particularly sparse occurrences of critical errors (even less than the previous year). Additionally, in this edition, the annotations included a *neutral* category, which was ignored as it was (1) not occurring for all language pairs and (2) they correspond to subjective opinions/preferences about translation. [3] We point readers to Figure 3 for some statistics on error severity distribution per language pair and domain.

The information used for this task consists of: *i*) start and end index positions for each error span; and *ii*) the simplified error severity. The error spans are identified as continuous sequences of characters within a target hypothesis, allowing for annotations of single white spaces and punctuation marks in order to account for omission and punctuation errors, respectively. Aiming to mimic the human annotations and simplify the task, overlapping error spans are allowed and count towards *recall* of different errors, but overlapping annotations are flattened for both gold and system annotations (see below). Figure 1 shows an example of annotations.

For the evaluation, the primary metric is the **F1-score**, computed on the character level and weighted to allow for half points for correctly identified span but misclassified severity. Precision and recall were also provided as complementary metrics. With respect to overlapping annotations, we allow for multiple character level annotations[4] and consider the best matching annotation per character position. As such, for each segment, we compute recall for the characters in gold annotation text spans by computing the ratio between the overlap with system error spans and the gold error span length and weighting severity mismatches by 0.5. Respectively, we compute precision with respect to the system error span length and apply the same weighting convention (down-weighting by 0.5 for mismatched error severities). Figure 1 and Table 1 show an example of the aforementioned process [5].

[2] We acknowledge a notion of gender identity beyond the binary. However, we include only masculine and feminine examples as they are provided in the original dataset.

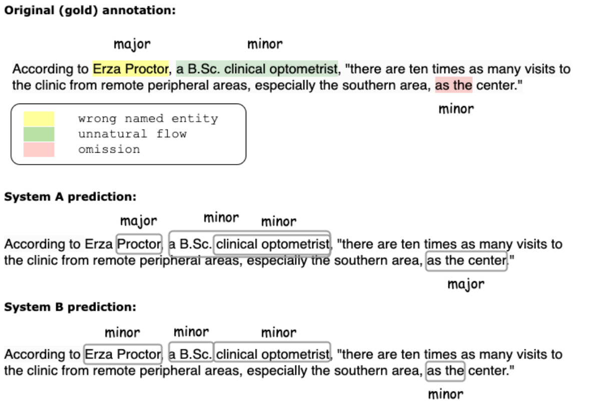
[3] Note that the neural errors are also not considered when computing an MQM score.

[4] The gold data was processed to remove identical segments that correspond to the same span but have different error categories, but it preserved any partially overlapping segments that correspond to different error categories and/or severities.

[5] The link to evaluation scripts can be found at: https://github.com/WMT-QE-Task/qe-eval-scripts/blob/main/wmt24/

Systems	Precision	Recall	F1-score
System A	$\frac{1*7+1*28+0.5*6}{7+28+13} = 0.79$	$\frac{1*7+1*28+0.5*6}{12+28+6} = 0.83$	0.81
System B	$\frac{0.5*12+1*28+0.5*6}{12+28+6} = 0.80$	$\frac{1*12+1*28+0.5*6}{12+28+6} = 0.80$	0.80

Table 1: Example of Precision and Recall computations for each annotation in the example of Figure 1.



Original (gold) annotation:

According to Erza Proctor, a B.Sc. clinical optometrist, "there are ten times as many visits to the clinic from remote peripheral areas, especially the southern area, as the center."

System A prediction:

According to Erza Proctor, a B.Sc. clinical optometrist, "there are ten times as many visits to the clinic from remote peripheral areas, especially the southern area, as the center."

System B prediction:

According to Erza Proctor, a B.Sc. clinical optometrist, "there are ten times as many visits to the clinic from remote peripheral areas, especially the southern area, as the center."

Figure 1: Example of gold annotations (MQM) for Task 2 (top) and respective prediction examples (bottom). Example taken from He-En test set.

2.3 Task 3: QE-informed APE

MT Automatic Post-Editing (APE) is the task of automatically correcting errors in a machine-translated text. As pointed out by Chatterjee et al. (2015), from the application point of view, the task is motivated by its possible uses to:

- Enhance MT output by harnessing information that is not available to the decoder or by conducting deeper text analysis, which may be prohibitively expensive during the decoding phase.
- Address systematic errors stemming from an MT system whose decoding process is inaccessible for focused modifications.
- Provide professional translators with improved MT output quality, thereby reducing the need for subsequent human post-editing.
- Tailor the output of a general-purpose MT system to align with the lexicon and style requirements of a specific application domain.

Building on the work of Chatterjee et al. (2018b); Deoghare et al. (2023), which demonstrated the potential of QE to enhance APE systems, this edition of the WMT QE shared task introduced the new QE-informed APE subtask. In this subtask, we focus on a unified *evaluation and correction* paradigm, taking advantage of the additional information provided by the human post-edits. Participants were encouraged to incorporate signals from QE systems to improve APE performance. The evaluation setup remained consistent with the previous rounds WMT APE shared tasks, requiring participants to automatically correct translations generated by a generic, domain-unadapted "black-box" NMT system. The training data consisted of human post-edits of translations produced by this system. While TER (Snover et al., 2006) and BLEU (Papineni et al., 2002) continued as the primary and secondary evaluation metrics, this year also introduced chrF (Popović, 2015) and COMET[6] for a more comprehensive automatic evaluation of the submitted APE systems.

For this year, English-Hindi and English-Tamil were the selected language pairs, with Hindi and Tamil as the target languages for post-editing. The training, development, and test data encompassed a wide range of domains, including education, legal, healthcare, culture, tourism, reviews, subtitles, and general/news.

3 Datasets

Below, we describe the datasets provided to participants for development and testing. Specifically, this year, we provided training data only for Task 3, which was newly introduced (see §3.4).

3.1 Training Resources

Overall, participants were encouraged to employ training data from a wide range of sources, including datasets from previous competitions, as well as synthetic or proprietary data.

Proposed training data for DA annotations, following the previous editions, includes the language pairs from the MLQE-PE dataset (Fomicheva et al., 2022), as well as the data from the previous QE editions (Zerva et al., 2022; Blain et al., 2023). Similarly, for the MQM data, we encouraged participants to refer to data from previous editions that

[6] https://github.com/Unbabel/COMET.

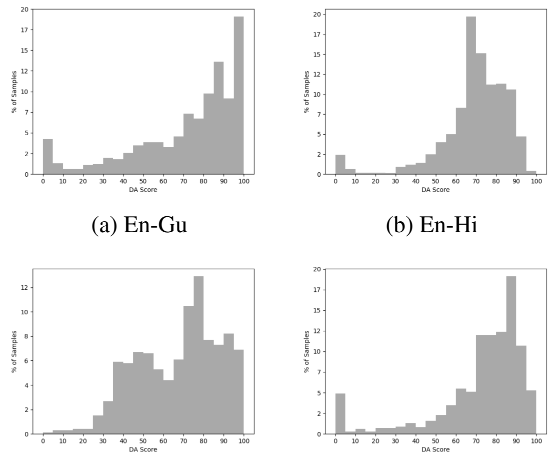
cover translation into German (En-De), Russian (En-Ru), Hebrew (En-He) and out of Chinese (Zh-En) (Freitag et al., 2021a,b), as well as the Indic-MT eval dataset (Sai B et al., 2023). However, we emphasise that in this edition, we introduce no new training data, treating the translations into Spanish (En-Es) and Hindi (En-Hi) as zero-shot tasks, and only En-De as supervised.

3.2 Direct Assessment (DA) Data

For all language pairs, the data provided is selected from publicly available resources.

We expand the Indic language pairs introduced in previous years, providing new unseen test sets of approx 1K segments each for Hindi (Hi; 1000 segments) and Gujarati (Gu; 1012 segments) as target languages from the Indo-Aryan language family as well as Tamil (Ta; 1000 segments) and Telugu (Te; 1000 segments) from the Dravidian language family. Following the previous edition, dataset curation and annotation were performed with the help of professional translators who were native speakers of the target language. The annotators were provided with guidelines which discussed DA score ranges with various error types. Additionally, parallel segments were curated from the following parallel corpora: *i*) *Anuvaad* parallel corpus[7] (General, Healthcare and Legal domain; *ii*) IITB English-Hindi parallel corpus[8] (Kunchukuttan et al., 2018) (Culture/Tourism domain), and parallel segments scraped from NPTEL[9]; and *iii*) SpokenTutorials[10] (Education domain). The curated segments were selected from the above-mentioned domains to ensure cross-domain impact and performance.

From the *Anuvaad* parallel corpus, we filter parallel segments using LaBSE, and select source sentences with varying token lengths, while the translation was obtained using $1.3B$ parameter NLLB model (Costa-jussà et al., 2022), as discussed in (Blain et al., 2023). During the annotation, weekly validation of randomly selected instances was performed by an unbiased native speaker who provided feedback to further improve annotations during the data curation. After all three annotators performed the DA annotations, we separated the data into training, development, and test sets while filtering for a balanced distribution of DA scores across all sets. We provide the distribution of DA scores for each language pair in Figure 2, where we can see that for all language pairs, we have similar distributions skewed towards high-quality scores. We can also observe that for Tamil, we have fewer segments of very low quality (DA $\leq$ 20), but instead, we have larger counts of segments of moderate quality (20 $\leq$ DA $\leq$ 60).



(a) En-Gu

(b) En-Hi

(c) En-Ta

(d) En-Te

Figure 2: Distribution of DA scores for the Indic language pairs.

3.3 MQM Data

As **test data**, we annotated new evaluation sets for three language directions: English-German (En-De), English-Spanish (En-Es) and English-Hindi (En-Hi). The evaluation sets were annotated by professional translators following a MQM typology (Burchardt, 2013) and specific guidelines[11].

The documents used for the evaluation sets are shared with the WMT General MT task and follow the same distribution of domains in that data (*e.g.*, news, social, literary and speech). The full documents were translated using the $54B$ parameters NLLB model (Team et al., 2022)[12] without sentence splitting. We subsequently split segments for annotation and annotated a total of 1511 segments for each translation direction.

The test data distribution according to error severities is shown in Figure 3. The NLLB model used to translate the evaluation sets is clearly stronger for En-De, with less than 100 major and minor errors for each content type. The distribu-

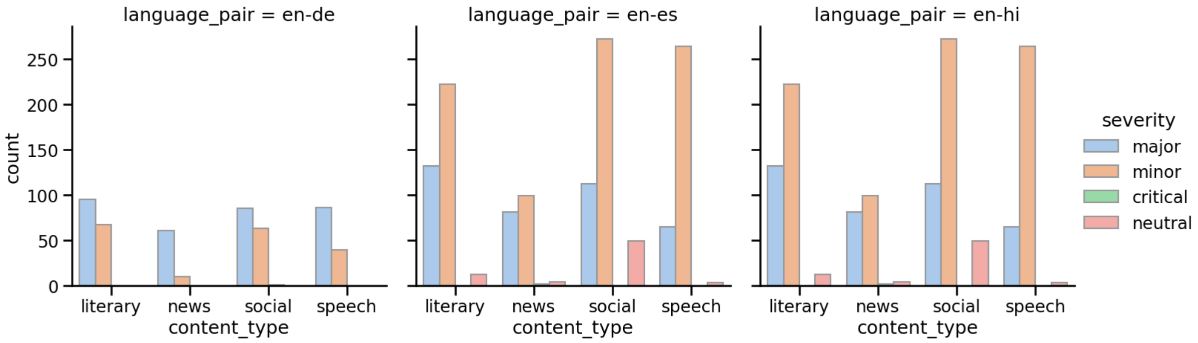

Figure 3: Distribution of error severities across language pairs and domains/content types.

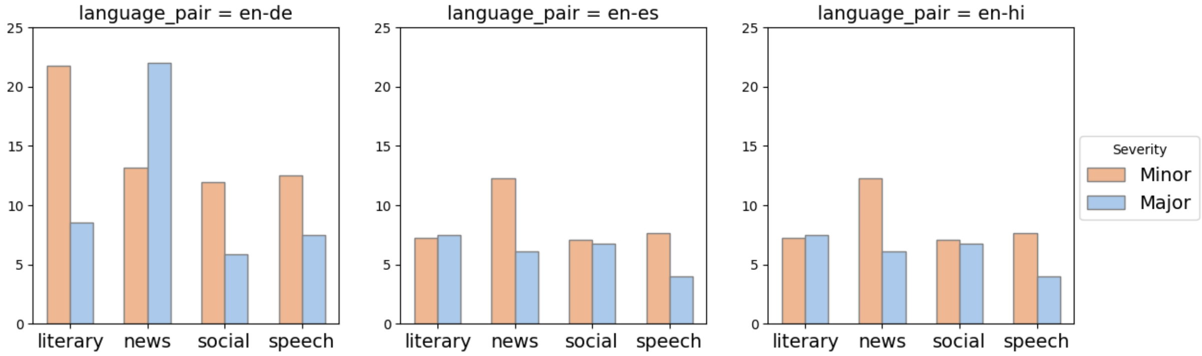

Figure 4: Distribution of average length (character count) for different severities across language pairs and domains/content types.

tion of major and minor errors changes drastically for En-Es and En-Hi, in particular the number of minor errors for the literary, social and speech domains, with more than 200 minor errors each. In addition, we can see that we have fewer errors for the news domain across all three language pairs, both in terms of minor and major errors. Contrary to frequency, however, Figure 4 shows that error spans identified for En-De are significantly longer on average for both identified error categories.

3.4 QE-APE Data

This year we introduce two new language pairs for the APE task: English-Hindi (*En-Hi*) and English-Tamil (*En-Ta*). For each language pair, the train, dev, and test sets respectively consist of $7,000$, $1,000$, and $1,000$ (*source*, *target*, *human post-edit*) triplets, where:

- The source (SRC) is an English sentence;
- The target (TGT) is a Hindi/Tamil translation of the source produced by a generic, black-box NMT system unknown to participants.
- The human post-edit (PE) is a manually revised version of the target, which was produced by native Hindi/Tamil speakers.

The English-Hindi train, dev, and test sets span culture, education, health, tourism, and general domains. Similarly, English-Tamil APE datasets contain sentences from legal, literacy, reviews, subtitles, news, health, and general domains.

We also provide a corpus of artificially generated data as additional training material. It consists of 2.5 million triplets for each language pair derived from the Anuvaad parallel corpus. Specifically, the source, target, and post-edit instances of this synthetic corpus are respectively obtained by combining: i) the original English source sentence from the Anuvaad corpus, ii) its automatic translation into Marathi, iii) the original Marathi target sentence from the Anuvaad corpus. Furthermore, we provide the DA scores for all samples in both train and dev sets. Additionally, the participants were encouraged to use the DA data released in the earlier iteration of the QE shared task for these language pairs.

To get an idea of the task difficulty, we focused on three aspects of the released data, which provided us with information about the possibility of learning useful correction patterns during APE

	Lang.	Domain	MT type	RR_src	RR_tgt	RR_pe	Basel. BLEU	Basel. TER	δ TER
2015	en-es	News	PBSMT	2.9	3.31	3.08	n/a	23.84	+0.31

Table 2: Basic information about the APE shared task data released since 2015- languages, domain, type of MT technology, repetition rate and initial translation quality (TER/BLEU of TGT). The last column (δ TER) indicates, for each evaluation round, the difference in TER between the baseline (*i.e.,* the "*do-nothing*" system) and the top-ranked official submission.

model training and successfully applying them at test time. These are: *i)* repetition rate, *ii)* MT quality, and *iii)* TER distribution in the test set. For the sake of comparison across the nine rounds of the APE task (2015–2023), Table 2 reports, for each dataset, information about the first two aspects. The third aspect, however, will be discussed by referring to Figure 5 and Figure 6.

3.4.1 Repetition Rate

The repetition rate (RR), measures the repetitiveness inside a text by looking at the rate of non-singleton n-gram types ($n = 1...4$) and combining them using the geometric mean. Larger values indicate a higher text repetitiveness that may suggest a higher chance of learning from the training set correction patterns that are also applicable to the test set. However, over the years, the influence of repetition rate in the data on system performance was found to be marginal.[13]

As shown in Table 2, in this edition, the RR for English-Hindi ranges between 2.7-3.3, and for English-Tamil RR ranges between 1.1-2.0. This difference may contribute to motivating the significantly different APE results observed for the two languages, as evidenced by a substantial TER reduction for English-Hindi (-19.29 "δ TER") compared to the "do-nothing" the baseline (see §4.3). Reviewing previous rounds of the APE task, however, suggests that RR remains only a partially informative indicator of task difficulty due to its variable correlation with final results, which may also depend on other factors or on the interaction of multiple factors that are yet to be fully understood.

3.4.2 MT Quality

Another complexity indicator is MT quality, which is the initial quality of the machine-translated (TGT) texts to be corrected. We measure it by computing the TER (↓) and BLEU (↑) scores (Basel. TER/BLEU rows in Table 2) using the human post-edits as reference. In principle, higher quality of the original translations leaves the APE systems with less room for improvement since they have, at the same time, less to learn during training and less to correct at the test stage. On one side, training on good (or near-perfect) automatic translations can drastically reduce the number of learned correction patterns. On the other side, testing on similarly good translations can *i)* drastically reduce the number of corrections required and the applicability of the learned patterns, and *ii)* increase the chance of introducing errors, especially when post-editing near-perfect translations. The findings of all previous rounds of the task support this observation, which is corroborated by the high correlation (>0.78) between the initial MT quality ("Basel. TER" in Table 2) and the TER difference between the baseline and the top-ranked submission ("δ TER" in Table 2).

As discussed in Section 6.3, this year seems to confirm the trends observed in the past. For English-Hindi, the baseline TER is quite high (46.36 points), leaving more room for improvement.

[13] The analyses carried out over the years produced mixed outcomes, with impressive final results obtained in spite of low repetition rates (Chatterjee et al., 2020) and vice-versa (Chatterjee et al., 2018a, 2019; Akhbardeh et al., 2021).

Whereas English-Tamil falls in medium-high difficulty (20.0<TER<25.0), making the task more challenging. The final gains ("δ TER" in Table 2) confirm the correlation between the quality of the initial translations and the actual potential of APE.

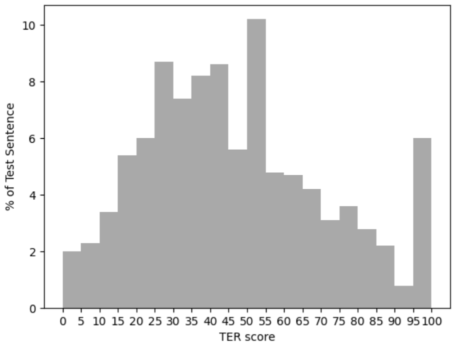

Figure 5: TER distribution in the APE 2024 English-Hindi test set.

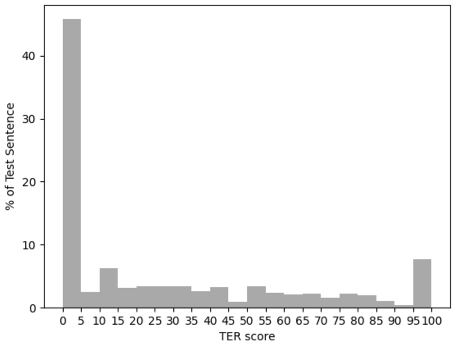

Figure 6: TER distribution in the APE 2024 English-Tamil test set.

3.4.3 TER Distribution

A third complexity indicator is the TER distribution (computed against human references) for the translations present in the test sets. Although TER distribution and MT quality can be seen as two sides of the same coin, it's worth remarking that, even at the same level of overall quality, more/less peaked distributions can result in very different testing conditions. Indeed, as shown by previous analyses, harder rounds of the task were typically characterised by TER distributions particularly skewed towards low values (*i.e.,* a larger percentage of test items having a TER between 0 and 10). On one side, the higher the proportion of (near-)perfect test instances requiring few edits or no corrections at all, the higher the probability that APE systems will perform unnecessary corrections penalised by automatic evaluation metrics. On the other side, less skewed distributions can be expected to be easier to handle as they give automatic systems larger room for improvement (*i.e.,* more test items requiring - at least minimal - revision). In the lack of more focused analyses on this aspect, we can hypothesise that in ideal conditions from the APE standpoint, the peak of the distribution would be observed for "post-editable" translations containing enough errors that leave some margin for focused corrections but not too many errors to be so unintelligible to require a whole re-translation from scratch.[14]

As shown in Figure 5, for English-Hindi the TER distribution follows more or less uniform distribution. The distribution is not too skewed towards near-perfect translation (which would have made it harder to further improve), nor towards the higher end of TER (which would have made it harder to learn error-correction patterns due to too noisy data). These characteristics make it easier to improve translation, which is reflected in the final evaluation results. On the other hand, as shown in Figure 6, for English-Tamil the TER distribution is highly skewed towards near-perfect translations. Around half of the test set falls in 0-5 TER points, making it prone to over-correction, which can be penalised by automatic evaluation metrics. This characteristic makes the English-Tamil test set much more challenging when it comes to gaining further translation quality improvements.

4 Baselines

In this edition, we opted to use publicly available, existing models without further tuning. Hence, we use a more unified architecture for Tasks 1 and 2, where all models use a large XLM-RoBERTa pretrained encoder without additional language tuning (see also Appendix A for hyperparameter details). The specific hyperparameters used are presented in Table 7. For Task 3, we opted for a simple "do nothing" approach as discussed in Section 4.3.

4.1 Task 1: Quality Estimation

For the **sentence-level** sub-task, we opted for using CometKiwi 2022 (Rei et al., 2022) which was trained on data from the Metrics and QE shared tasks (combining data from previous years up to

[14] For instance, based on the empirical findings reported in (Turchi et al., 2013), TER=0.4 is the threshold that, for human post-editors, separates the "post-editable" translations from those that require complete rewriting from scratch.

2022). Models are publicly available for download[15].

4.2 Task 2: Fine-grained Error Detection

For **Task 2** we also used a CometKiwi model, specifically one trained on the multi-task setting, to produce both sentence-level scores and word-level quality estimates. The model, trained on 2022 QE data is publicly available. [16] The word-level estimates are in the form of OK/BAD tags, and for this reason it is necessary to convert the original output to the one required by the Task 2 format. As such we process the word-level predictions as follows:

- Detokenize the sentence
- Annotate continuous BAD tokens as a single text span
- Assume all errors are major

4.3 Task 3: QE-informed APE

The official baseline results for **Task 3** are the TER/BLEU/chrF/COMET scores calculated by comparing the raw MT output with human post-edits. This corresponds to the score achieved by a "do-nothing" APE system that leaves all the test segments unmodified.

5 Participants

In this section, we present a brief system description gathered from each participant. For each team, we indicate the task(s) and sub-task(s) (*i.e.* language-pair(s)) they participated in, and point to relevant publications, if any.

Unbabel (T1; all): The submission for Task 1 follows their work from the previous competition (Rei et al., 2023), which corresponds to an ensemble of multiple checkpoints for the sentence-level subtask, using a weighted averaging of the predicted scores, optimised by language pair. The emphasis is on scaling the size of the pre-trained encoder from InfoXLM to XLM-R XL and XXL.

Pister Labs (T1; all): The team opted for an approach where they generated a set of reading comprehension questions and scored each hypothetical translation by evaluating how well it could answer the comprehension question when compared with the reference translation. The overall score for a hypothetical is then a simple average across the questions asked of it. Answers are generated by providing the question and the hypothetical translation to Llama3.1-8B (Dubey et al., 2024). The initial set of reading comprehension questions is generated through few-shot prompting of Llama3.1-70B, and evaluating results on a subsample of 100 training En-De translation pairs with Llama3.1-70B. The four questions with the highest Spearman correlation were then used for final testing. To improve question generation quality, they use techniques from OpenAI and Anthropic's prompting guides, as well as the self-consistency technique.

HW-TSC (T1; En-Hi, En-Ta, En-Te, En-Gu): The team employed the CROSS-QE approach (Li et al., 2023) as the basis for further tuning and opted for tuning separate models for each language pair. They used encoder-based models, experimenting with different encoders, which were trained on different combinations of source and translation vectors as input. They focused on improving model performance both in terms of training by employing different data augmentation methods and in terms of inference, exploring better strategies for ensembling checkpoints. In terms of data augmentation, they use a combination of LLMs with specific prompts to generate pseudo-data as well as text editing methods. [17]

HW-TSC (T2; all): The team employs a combination of LLMs, hypothesising that the reasoning abilities of large models may be helpful in the fine-grained task. They use the TowerInstruct-7B-v0.2 (Alves et al., 2024) model and the GPT-4o-mini (Islam and Moushi, 2024) model, using prompt engineering and in-context learning to obtain the predictions. Additionally, they employ data augmentation techniques mentioned for Task 1 and find that they can rely on pseudo-data for tuning the models. [18]

[16] https://huggingface.co/Unbabel/WMT24-QE-task2-baseline

[17] We consider submissions from users s50042889 and zhaoxf4 mentioned in the results page as one submission

[18] We consider submissions from users zhuming, zhaoxf4 and mengyao mentioned in the results page as one submission

TMU-HIT (T1; En-Hi, En-Ta, En-Te, En-Gu): The team submitted predictions that rely on LLMs, inspired by (Liu et al., 2023; Enomoto et al., 2024). They designed custom prompts for quality estimation and employed GPT-4o mini (Achiam et al., 2023) to sample assessment scores multiple times using the same prompt. They then experimented with combining the generated scores to compute the final score using either their average or their weighted sum, employing the generation probabilities as weights for the latter. They conducted evaluation experiments in both zero-shot and three-shot settings. Further, they also attempted fine-tuning GPT-4o mini using the training data released for the WMT23 Machine Translation task (Kocmi et al., 2023).

HW-TSC (T3; all): (Yu et al., 2024) The team explored two distinct approaches for developing APE systems. For the En-Hi pair, they leveraged the Llama3-8B-Instruct model through continual pre-training on the collected data and then supervised fine-tuning it on the real APE data. For the En-Ta pair, they trained a transformer model from scratch, first focusing on the MT (Machine Translation) task using web-collected data, followed by training on APE data. External MT candidates were incorporated during the training to boost performance further. To prevent overcorrection, Sentence-level QE models were employed to select between MT and APE outputs. Both users (**HW-TSC_yjwsss** and **HW-TSC_zhaoxf4**) from this team made the same submissions for En-Ta, but different submissions for En-Hi.

IT-Unbabel (T3; all): IT-Unbabel submission leveraged xTower (Treviso et al., 2024), a model built on top of TowerLLM (Alves et al., 2024), which is designed to provide free-text explanations for translation errors to guide the generation of an improved translation. The system was trained on material that includes the xTower dataset (GPT-4 generated explanations for translation correction), TowerBlocks, and additional training datasets provided by the WMT24[19] organizers for English-Hindi and English-Tamil, augmented with error span annotations from xCOMET (Guerreiro et al., 2023). A hybrid approach is used to dynamically select between the original translation and the corrected version produced by the xTower model using a quality estimation model.

6 Results

In this section, we present and discuss the results of our shared task. Please note that for all the three sub-tasks we used statistical significance testing with $p = 0.05$.

6.1 Task 1

As described in the Task 1 overview (§2.1.1), sentence-level submissions are evaluated against the true z-normalised sentence scores using Spearman's rank correlation coefficient ρ along with the following secondary metrics: Pearson's correlation coefficient, r, and Kendall's τ. Nonetheless, the final ranking between systems is calculated using the primary metric only (Spearman's ρ). Statistical significance was computed using William's test. The results are shown in Table 3.

Looking at the obtained scores, we observe an overall performance increase for the sentence-level scores compared to previous years for all language pairs (that have been previously tested) except for En-Ta, where we observe a small drop. We note, that while the domains and sources in the En-De MQM test-set are different, all DA test-sets are drawn from the same sources and observe similar score distributions to previous years, thus facilitating comparisons.

It should be noted that there is no clear winner across language pairs. Instead, different systems rank first for each language.

6.2 Task 2

For Task 2, the submissions are scored using the F1-score, computed at character level for the annotated error spans, as described in Section 2.2. Precision and Recall scores are also provided as complementary information to help contextualise the performance observed. Statistical significance was computed using randomisation tests (Yeh, 2000) with Bonferroni correction (Abdi, 2007) for each language pair. The results for Task 2 are described in Table 4.

This year, the fine-grained annotation task (Task 2) had a lower participation rate compared to the

previous edition, and we can also see that the obtained scores remained particularly low, indicating that the task remains challenging and difficult to address.

Specifically, if we focus on confusion matrices shown in Figure 7 for the submission received, we can see that the Baseline is over-predicting *Major* error spans, which gives a slight advantage regarding the F1 score since it leads to higher recall. This finding is consistent with higher precision obtained by HW-TSC submission as seen in the Appendix C, Table 17. We provide the confusion matrices for all language pairs in Appendix E.

Despite this, it is important to note that the methods submitted for Task 1 still seem to benefit from a multi-task approach that considers word-level information. Taking both these observations into account and looking towards future editions, it might be useful to redesign the task, aiming either at a different span representation that would perhaps attempt a better normalisation over different span lengths or deviate from the character level representation. Another alternative view would be to encourage methods that use error spans to support or interpret sentence-level quality (Leiter et al., 2023) or concentrate only on specific error types.

6.3 Task 3

6.3.1 Automatic Evaluation

Automatic Post-Editing evaluation results are shown in Table 5. The submitted runs are ranked based on the average TER (case-sensitive) computed using human post-edits of the MT segments as a reference, which is the APE task's primary evaluation metric. To provide a broader view of the systems' performance, BLEU, chrF, and COMET results computed using the same references are also reported. As can be seen from the table, all submissions for English-Hindi outperform the baseline by a significant margin across all metrics, with TER reductions that are always statistically significant. the baseline. The best system is able to improve trans-

		TER	BLEU	CHRF	COMET
En-Hi	IT-Unbabel	**27.08**	58.38	73.45	0.8646
	HW-TSC_yjwsss	**30.37**	54.50	71.06	0.8514
	HW-TSC_zhaoxf4	**31.32**	52.74	69.83	0.8517
	BASELINE (MT)	46.36	39.28	59.48	0.8084

	IT-Unbabel	24.54	70.05	82.30	0.9163
	BASELINE (MT)	24.71	70.16	81.80	0.9137

Table 5: Official results for the WMT24 Quality Estimation **Task 3 QE-informed APE** English-Hindi and English-Tamil shared task – average TER (↓), BLEU (↑), chrF (↑), COMET (↑). Statistical significance test is computed for the primary metric (TER) *wrt.* the baseline and the significant results are highlighted in bold. Baseline systems are highlighted in grey.

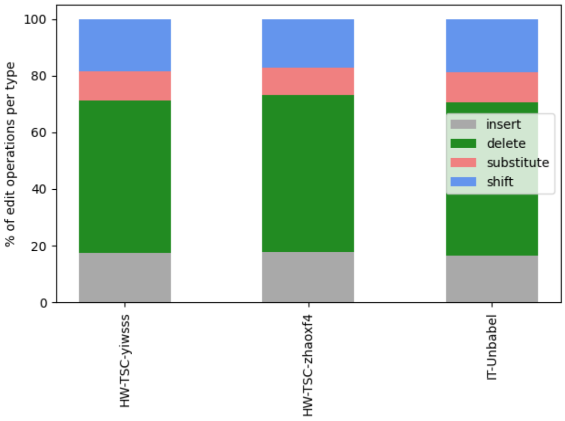

Figure 8: Distribution of edit operations (insertions, deletions, substitutions and shifts) performed by the three primary submissions to the WMT24 APE English-Hindi shared task.

lation quality by nearly 20.0 TER points. However, for English-Tamil, we observe that while all submissions performed slightly better than the baseline in terms of absolute scores across all metrics except BLEU, none of the systems show statistically significant gains compared to the baseline. As discussed in Section 3.4, this can be attributed to the combined effect of less repetitive data (between 1.1-2.0) compared to English-Hindi (between 2.7-3.3) and a stronger baseline (24.7 vs 46.4 TER), leaving less room for improvement.

6.3.2 Analysis: Systems' Behaviour

Modified, improved and deteriorated sentences. To better understand the behaviour of each APE system, we now turn toward the changes made by each system to the test instances. To this end, Table 6 shows, for each submitted run, the number of modified, improved and deteriorated sentences, as well as the overall system's precision (*i.e.,* the proportion of improved sentences out of the total number of modified instances for which improvement/deterioration is observed). It's worth noting that, as in the previous rounds, the number of sentences modified by each system is higher than the sum of the improved and the deteriorated ones. This difference is represented by modified sentences for which the corrections do not yield any TER variations.

As can be seen from Table 6, for English-Hindi, all submissions perform aggressive post-editing, with the top submission modifying 96.5% of the translations, where most of the modifications lead to improving the translation quality with a precision score of 84.56%. In contrast, for English-Tamil, all submissions adopt a conservative approach, limiting edits to 3.8%-4.8% of the test set. This aligns with our previous observations on task difficulty, driven by the higher MT baseline and the skewed TER distribution, with samples concentrated in the near-perfect translation range. In this challenging scenario, all submissions are able to improve the majority of modified translations with a precision score between 54%-59%.

Edit operations. Similar to previous rounds, we analysed systems' behaviour also in terms of the distribution of edit operations (insertions, deletions, substitutions and shifts) done by each system. This fine-grained analysis of how systems corrected the test set instances is obtained by computing the TER between the original MT output and the output of each primary submission taken as reference. As shown in Figures 8 and 9, similar to last year, differences in systems' behaviour are minimal. All of them are characterised by a large number of deletions, followed by insertions, shifts and substitutions. For English-Tamil, we observe a relatively lower proportion of shifts and substitutions compared to English-Hindi. This might indicate that English-Tamil might have more diverse APE outputs, which might be more challenging to evaluate with reference-based automatic metrics.

7 Evaluation on challenge sets

We received two submissions that we could evaluate on challenge sets: Pister Lab's submission, based on prompting Llama 3.1, and Unbabel's, based on CometKiwi. In Figure 10, we report the percentage of samples where the hyp translation is

	Systems	Modified	Improved	Deteriorated	Prec.
En-Hi	IT-Unbabel	965 (96.5%)	756 (78.35%)	138 (14.30%)	84.56
	HW-TSC_yjwsss	952 (95.2%)	688 (72.27%)	171 (17.96%)	80.09
	HW-TSC_zhaoxf4	665 (66.5%)	532 (80.00%)	85 (12.78%)	86.22
En-Ta	HW-TSC	48 (4.8%)	25 (52.08%)	18 (37.50%)	58.14
	IT-Unbabel	38 (3.8%)	19 (50.00%)	16 (42.11%)	54.29

Table 6: Number (raw and proportion) of test sentences modified, improved and deteriorated by each run submitted to the APE 2024 English-Hindi and English-Tamil sub-task. The "Prec." column shows systems' precision as the ratio between the number of improved sentences and the number of modified instances for which improvement/deterioration is observed (*i.e.,* Improved + Deteriorated).

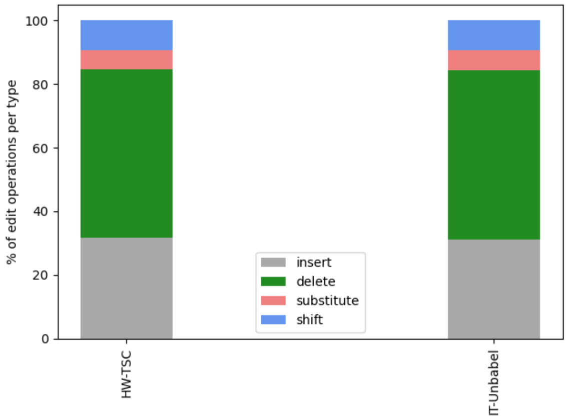

Figure 9: Distribution of edit operations (insertions, deletions, substitutions and shifts) performed by the three primary submissions to the WMT24 APE English-Tamil shared task.

scored higher, lower, or is tied to the con hypothesis.[20] Please refer to Section 2.2 for details on constructing these translation pairs for each phenomenon.

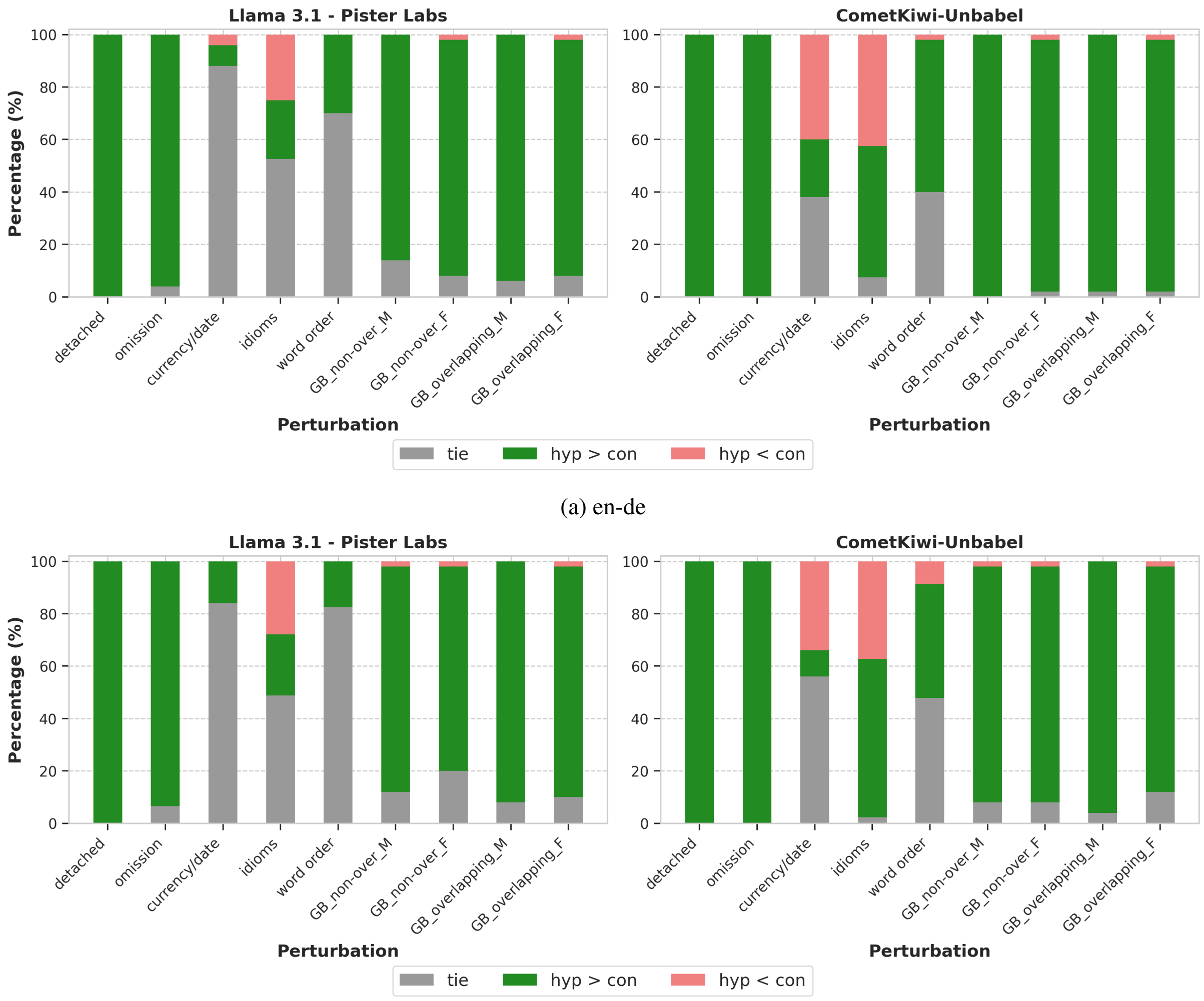
Detached translations and omissions Out of all the phenomena studied, these two constitute the most critical errors. It is thus highly encouraging that both models perform perfectly across the two language pairs in consistently scoring the correct hyp translation higher than the erroneous con translation.

Currency and date formatting This category reveals interesting differences between the two models. Llama 3.1 shows a high tie rate, indicating it often does not distinguish between original and localized formats. This suggests a more neutral stance towards formatting choices. In contrast, CometKiwi is more sensitive to these formats, behaving less predictably. Although, in most cases, it either prefers the source format or is indifferent to the localized format, there are some cases, in particular for en-es translations, where it does prefer the localized format that does not lexically match that found in the source text.

Idioms Llama 3.1 predominantly shows ties or a slight preference for non-literal, idiomatic renderings (hyp) that accurately convey the meaning in the target language. In contrast, CometKiwi's behavior is more varied and, perhaps surprisingly, often favors literal translations (con) even when they may not preserve the source text's meaning in the target language. This tendency towards literalness can be quite problematic in the context of idioms and other figurative texts, where meaning often diverges from word-for-word translations. One potential way to alleviate these trends is to train neural metrics with more diverse data that includes idiomatic and figurative language to improve their robustness.

Word order Here, Llama 3.1 shows a high rate of ties, suggesting that, similarly to what we found for the currency and date formatting phenomenon, it does not distinguish between monotonic translations that closely follow the source sentence order and non-monotonic translations that rearrange words while preserving meaning. This suggests that Llama 3.1's scoring may be more tied to the overall meaning of the translation. In contrast, CometKiwi demonstrates more preference for monotonic translations (hyp) across both language pairs, particularly for en-de. As such, CometKiwi appears to be more sensitive to word order, poten-

[20] Inspired by the analysis in Kocmi et al. (2024), we consider a tie with CometKiwi when the absolute difference between the scores of the hyp and con hypotheses is lower or equal to 0.1 points. For the Llama-based submission, for its more coarse-grained scoring range (more akin to a categorical distribution), we consider a tie when both translations receive the same score.



(a) en-de

(b) en-es

Figure 10: Share of instances in challenge sets where participant systems ranked the hypothesis translation higher than (green), lower than (salmon), or equal to (grey) the contrast. Results on en-de (top) and en-es (bottom).

tially favouring translations that maintain a structure closer to the source text. As a learned metric, this behaviour might be attributed to CometKiwi's training data, which may have contained more monotonic translations (more common among classical encoder-decoder NMT models that constitute most of the translations that the model has seen during training) than paraphrastic or non-literal ones (more prevalent among the more novel LLM-based translation approaches (Raunak et al., 2023)).

Gender subset In most instances, both systems score the hypothesis with the correct gender inflection higher. However, we noticed that some cases have ties, which we consider as errors: the model does not capture the difference in gender forms and wrongly assigns equal scores to the hypothesis and the contrast. Expectedly, this phenomenon is more present in Pister Lab's scores, as Llama 3.1 tends to assign more coarse-grained assessments. In analyzing sources with non-overlapping content, Llama 3.1 exhibits a higher frequency of errors for male sources in en-de translation while demonstrating increased error rates for female sources in en-es. Conversely, CometKiwi maintains a comparable error rate across genders in both language pairs, with an elevated error rate in en-es translation overall. When examining sources with identical content differentiated only by gender (categorized as "overlapping"), we observed higher errors for female sources across all configurations, except for CometKiwi's performance in en-es.

Closing remarks Our analysis of Llama 3.1 and CometKiwi on various challenge sets reveals distinct behaviours and potential areas for improvement. Both models excel at identifying critical errors like detached translations and omissions.

However, they differ in their handling of formatting, idioms, and word order, with Llama 3.1—perhaps for the more discrete nature of its quality assessments—often showing neutrality (manifested through a large number of ties) and CometKiwi demonstrating more varied preferences, some of which are problematic (e.g., preference towards literalness in the translation of idiomatic expressions). Gender-related evaluations suggest potential biases in both systems, mainly due to scoring masculine and feminine gender inflections equally despite only one being correct. When controlling for the source content, we notice more errors for the instances mentioning a feminine referent in specific contexts. These findings indicate that both models display gender-dependent behaviour in source processing, warranting further investigation into potential model biases.

8 Discussion

In the following, we discuss the main findings of this year's shared task based on the goals we had previously identified for it.

Large language models in Quality Estimation In this edition, we observed an increased use of LLMs, not only in order to generate pseudo-data for training or as a complementary system –which was the trend in the previous year– but rather as the primary model to address a task. Indeed, across tasks, it was possible to observe the performance of encoder-based models that follow the predictor-estimator architecture (Kim et al., 2017), as well as models that relied on large decoder-based approaches, where the emphasis was more on prompt engineering or instruction tuning. This is in line with recent works (Huang et al., 2023; Fernandes et al., 2023a; Kocmi and Federmann, 2023; Vu et al., 2024; Hada et al., 2024) that suggest that multilingual LLMs can be prompted to predict the quality of a translation, given some tuning or in-context learning.

Looking at the results for Tasks 1 and 2, however, we can see that the methods that rely on LLMs are still outperformed by predictor-estimator-based systems, especially when it comes to predicting sentence-level scores. One key disparity, in this case, relates to the fact that methods relying on scores generated by such models lack the granularity of predictor-estimator architectures that treat the QE task as a regression and, hence, can differentiate better between different translations and quality levels. Instead, LLMs tend to default to a smaller range of values (as we can also see in the ties detected in the analysis of Section 7 and Figures 10a and 10b. However, we can see that the LLM-based methods are closing the gap in terms of performance when compared to the predictor-estimator-based model for Task 2, which involves error detection. More importantly, LLM-based approaches perform on par and even outperform other methods for Task 3, which focuses on translation correction (APE). Thus, it seems that in the MT evaluation and correction family of tasks, there is potential for both LLMs and "traditional" neural systems. Potentially, more hybrid methods, i.e. methods that employ sentence-level quality scores predicted from encoder-based models to inform LLM decisions on error detection and correction, would lead to improved performance and could take the lead in future editions for the shared task.

Role of QE signals in APE Both participants in Task 3 used QE information to perform APE in alignment with the task objectives. Their approaches share similarities, as they both involve a final QE-driven selection step to choose between the original MT output and the generated APE hypothesis. One participant (HW-TSC) exploited QE information only for this final selection step, while the other (IT-Unbabel) integrated the two technologies more tightly by generating APE outputs with an LLM informed by free-text explanations for translation errors, which can be considered as proxies for QE predictions. Overall, despite being obtained with different degrees of QE integration, the evaluation results reinforce previous findings regarding the effectiveness of combined QEAPE and approaches for enhancing MT output (Chatterjee et al., 2017; Deoghare et al., 2023).

9 Conclusions

This year's edition of the QE Shared Task introduced two key new elements besides fresh test sets: (1) A new task on QE-informed APE, motivating participants to consider the QE scores to improve the generated MT corrections and (2) an updated challenge set for En-De and En-Es language pairs to help analyse the behaviour and robustness of submitted models for different phenomena such as gender bias, idiomatic expressions, handling of numerical entities, hallucinations, and word order changes.

We found that overall QE performance is consistently high across languages on the sentence level. Still, there is ample room for improvement regarding fine-grained error span detection. The addition of quality informed APE sub-task made it easier for participants to leverage their QE system for the APE task, achieving significant gains for *en-hi* and marginal (non-significant) gains on *en-ta* language pairs. In addition, we found that approaches that employ LLMs still have some way to go in competing on correlations with human scores at the sentence level but can provide competitive solutions for error span detection and QE-informed APE tasks.

In future iterations, we aim to redefine meaningful fine-grained QE tasks, targeting attainable error detection that can help detect critical errors, explain predicted quality, and better inform APE systems. Additionally, we intend to expand further the provided resources to aid the finer grained analysis of model behaviour, as it was discussed in Section 7.

10 Ethical Considerations

Post-editing, MQM, and DA annotations in this paper are carried out by professional translators. They are all paid at professional rates. In creating the gender subset, we drew examples from MT-GenEval (Currey et al., 2022), a corpus where gender is treated as a binary variable. We recognize that gender identities exist on a spectrum, going beyond just the masculine-feminine dichotomy. Our intention is to expand the evaluation of gender-related aspects to include more inclusive forms of machine translation.

Organisers from Unbabel and IT have submitted to this task without using prior access to test sets or any insider information.

A Hyper-parameters of pre-trained baseline models for Task 1 and Task 2 Quality Estimation

Hyper-parameter	T1 Sentence-level COMETKIWI-DA-22	T2 Fine-grained COMETKIWI-MULTITASK-22
Encoder Model	XLM-RoBERTa (large)	XLM-RoBERTa (large)
Optimizer	Adam (default parameters)	Adam (default parameters)
n frozen epochs	0.3	0.3
Keep embeddings frozen	True	True
Learning rate	3e-05 and 1e-05	3e-06 and 1e-05
Batch size	4	4
Loss function	MSE and CE	MSE and CE
Dropout	0.15	0.1
FP precision	32	32
Feed-Forward hidden units	[2048, 1024]	[3072, 1024]
Word weights	[0.3, 0.7]	[0.1, 0.9]
Feed-Forward activation	Tanh	–
Language prefix	False	False

Table 7: Hyper-parameters of both the CometKiwi models used as baselines for Task 1 Quality Estimation.

B Official Results of the WMT24 Quality Estimation Task 1 Sentence-level

Tables 8, 9, 10, 11, 12, 13, 14 and 15 show the results for all language pairs and the multilingual variants, ranking participating systems best to worst using Spearman correlation as primary key for each of these cases.

Model	**Spearman**	Pearson	Kendall
Unbabel	0.553	0.438	0.410
BASELINE	0.520	0.474	0.382
Pister Labs	0.452	0.378	0.354

Table 8: Official results of the WMT24 Quality Estimation Task 1 Sentence-level **Multilingual** (average over all language pairs). Teams marked with "•" are the winners, as they are not significantly outperformed by any other system according to the Williams Significance Test (Williams, 1959). Baseline systems are highlighted in grey.

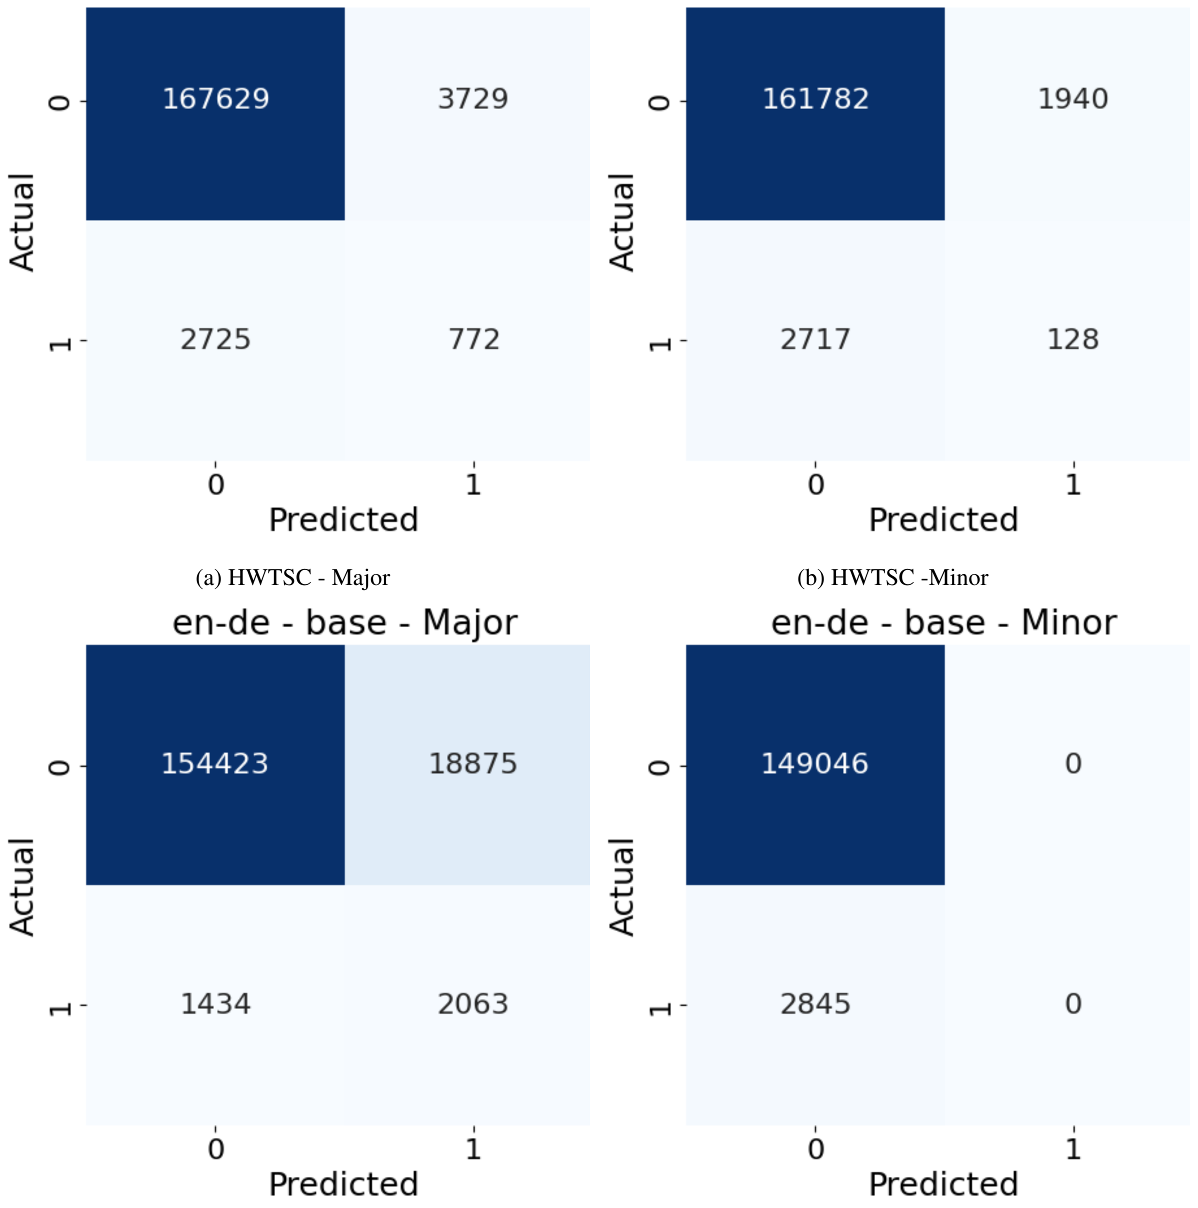
E Confusion Matrices for Task 2

We present below the confusion matrices for Major and Minor error span prediction between HW-TSC and the Baseline, for each language pair. We can see that overall HW-TSC targets precision, being more conservative in error span prediction, while the Baseline model greedily predicts major errors.



(a) HWTSC - Major

(b) HWTSC -Minor

(c) Baseline - Major

(d) Baseline - Minor

Figure 11: Confusion matrices for Task 2 English-German, comparing Minor and Major predictions between the Baseline system and the HWTSC one.

Abstract

We present the results of the WMT 2024 shared task of the Open Language Data Initiative. Participants were invited to contribute to the FLORES+ and MT Seed multilingual datasets, two foundational open resources that facilitate the organic expansion of language technology's reach. We accepted ten submissions covering 16 languages, which extended the range of languages included in the datasets and improved the quality of existing data.

1 Introduction

Machine translation research has advanced at breakneck speed in recent years (Kocmi et al., 2023). That said, progress made in translation quality has largely been directed at high-resource languages, leaving many languages behind. More recently, the focus has shifted towards under-served languages (also called low-resource) (Haddow et al., 2022). Foundational, high-coverage datasets have made it easier to develop and evaluate language technologies for a growing number of languages. Given the high impact of these components, extending such datasets becomes imperative.

The aim of the WMT 2024 shared task of the Open Language Data Initiative (OLDI) is to empower language communities to contribute such key datasets. In particular, we solicited contributions to the MT evaluation dataset FLORES+ and the MT Seed dataset. Additionally, we also solicited other high-quality, human-verified monolingual text datasets in under-resource languages. This builds on previous work to create these datasets and extend machine translation (MT) models and evaluation tools to more languages (Guzmán et al., 2019; Goyal et al., 2022; NLLB Team et al., 2024; Maillard et al., 2023).

We accepted ten submissions to the task, and the data contributed covered 16 languages. We required all contributions to be released under open licenses so that they can be useful to as many community members as possible. We make the data available online and encourage future work to build on these foundational datasets even further.[1]

2 Related Work

In recent years, there has been a growing recognition of the need for high-quality, representative datasets to broaden access to language technologies across a more diverse range of languages. Several initiatives have emerged to address this need.

In machine translation, the FLORES family of datasets (Guzmán et al., 2019; Goyal et al., 2022; NLLB Team et al., 2024) and NTREX-128 (Federmann et al., 2022) have provided the research community with massively multilingual, professionally translated benchmark data that is open source; while NLLB-Seed (Maillard et al., 2023; NLLB Team et al., 2024) played a similar role but focused on training data. Since the release of these resources, several authors have provided coverage for new languages (Gala et al., 2023; Doumbouya et al., 2023; Aepli et al., 2023) or even extended the datasets to the speech modality (Conneau et al., 2022).

Thanks to the availability of higher-quality data for an increasingly larger number of languages, recent language identification models have been able to expand coverage. Projects such as AfroLID (Adebara et al., 2022) and OpenLID (Burchell et al., 2023) improved upon pre-existing models by a careful curation and auditing of existing data sources; while LIMIT (Agarwal et al., 2023) further expanded data coverage and performance by creating and releasing a new high-quality corpus.

Several crowdsourced projects have proven invaluable as a source of knowledge for under-served

languages. The Tatoeba project,[2] not designed explicitly for language technologies but as a language learning aid, provides a large database of aligned multilingual sentences. Mozilla Common Voice (Ardila et al., 2020) has enabled communities to build open-source ASR corpora for their own language and counts over 160 languages to date. The Aya initiative (Singh et al., 2024) has created the largest instruction finetuning dataset for large language models.

3 Datasets: FLORES+ and MT Seed

3.1 FLORES+

One of the biggest challenges in extending effective natural language processing (NLP) to underserved languages is a lack of high-quality, high-coverage evaluation benchmarks. In particular, few benchmarks are suitable for evaluating multilingual translation, since this requires many-to-many alignment between different languages in the evaluation dataset.

The FLORES family of datasets was released to address this problem. While the first iteration of this dataset covered only three languages (Guzmán et al., 2019), following iterations increased coverage to 101 languages (FLORES-101, Goyal et al., 2022) and finally to over 200 languages as part of the "No Language Left Behind" project (FLORES-200, NLLB Team et al., 2024). The current iteration of this dataset set is managed by OLDI, and we refer to it as FLORES+ to disambiguate between the original datasets and this new actively developed version.

FLORES+ consists of sentences extracted from English Wikinews, Wikijunior, and Wikivoyage: 997 for the dev split and 1012 for the devtest split.[3] These were then professionally translated into each language (almost universally from English) and underwent quality assessment and adjustment as necessary. The fact that all sentences in all languages are translations of each other means that they can be used for any-way multilingual evaluation.

3.2 MT Seed

The MT Seed dataset (previously NLLB Seed) was created as a source of "starter data" for languages without publicly-available high-quality bitext in sufficient quantity for training NLP models (NLLB Team et al., 2024, p.23). Previous work showed that employing the relatively small amount of high-quality data in MT Seed for training models had a significant impact on performance even when larger but lower quality corpora are used (Maillard et al., 2023). By extending MT Seed, OLDI aims to improve the quality of NLP applications for under-served languages by providing an initial source of reliable training data.

MT Seed consists of around 6000 sentences sampled from the Wikipedia articles listed in English Wikimedia's "List of articles every Wikipedia should have". These were professionally translated into each of the 38 languages covered by the first iteration of this dataset (39 if including English). Since this dataset is intended as a source of training data rather than evaluation, it did not undergo the quality assurance as the FLORES family of datasets.

4 Shared Task Definition

The goal of this shared task was to expand the open datasets managed by OLDI. Primarily, we solicited contributions to FLORES+ and MT Seed (described in Section 3), which could be either fixes to existing data or entirely new translations. It also accepted other high-quality, human-verified monolingual text datasets in under-resource languages.

4.1 Contributing to FLORES+ and MT Seed

To contribute to FLORES+ and MT Seed, we encouraged participants to translate from English into the target language so as to follow the original standard FLORES-200 workflow (NLLB Team et al., 2024, p.21). We required that translations were performed by qualified, native speakers of the target language and that translators acknowledged our translation guidelines (Appendix A). We strongly encouraged the verification of the data by at least one additional native speaker.

The acceptability of machine-translated content varied between the two datasets. Since the FLORES+ dataset is used to evaluate MT systems, new contributions must be entirely human-translated. Using or even referencing MT output was not allowed, including post-editing. However, post-edited MT content was allowed for contributions to MT Seed, provided all content was verified manually. This was done because MT Seed is intended for training rather than evaluation and, therefore, has less stringent translation requirements.

[2] https://www.tatoeba.org

[3] The separate blind test set, originally developed by Meta, is not managed by OLDI and is not part of FLORES+.

Participants were encouraged to provide experimental validation to demonstrate the quality of their submitted datasets. Due to the heterogeneous nature of submissions, we left the exact nature of the experimental validation up to the participants, though we gave some suggestions. For example, MT Seed data contributions could train a simple MT model and evaluate it on FLORES+.

All submissions were labeled with the same standardized language codes used throughout OLDI. These are made up of three parts, separated by underscores:

- An ISO 639-3 language code. Macrolanguage codes must not be used if a more specific code is possible: e.g., cmn, yue, wuu, etc., rather than zho.
- An ISO 15924 script code
- A Glottocode identifying the specific language variety.

For example, `apc_Arab_sout3123` indicates South Levantine Arabic written in the Arabic script.

All submissions were accompanied by a dataset card summarizing key facts about the data and how it was created. This is critical to foster informed and responsible use of the submitted data (Pushkarna et al., 2022). Submitted datasets were required to be released under the open CC BY-SA 4.0 license to match FLORES+ and MT Seed.

4.2 Contributing other monolingual data

Contributions of monolingual data had similar requirements to those for FLORES+ or MT Seed. The aim was to collect high-quality, human-verified monolingual text in multiple under-served languages for training NLP tools and systems. Synthetic data of any kind was not allowed. Parallel datasets were excluded from the scope of the shared task to not conflict with existing corpus-building efforts like Opus (Tiedemann, 2009).

For FLORES+ and MT Seed, submissions were encouraged to be manually verified by native speakers of the target language. All submissions needed to be accompanied by a data card and released under an open license (allowing free research use as a minimum).

5 Submissions

There were 24 expressions of interest in the shared task, and we ultimately accepted 10 papers. Table 1 summarizes the data submitted. We describe each submission in the following section.

Abdulmumin et al. (2024) contributed an improved version of the FLORES+ datasets for Hausa, Northern Sotho (Sepedi), Xitsonga, and isiZulu. They carried out error analysis of the datasets for the four languages and found problems such as poor translation of named entities, incorrect handling of morphological changes, a lack of consistency in vocabulary, and poor handling of borrowed terms. The Hausa dataset was particularly weak, with evidence that it was built upon Google Translate outputs. The participants corrected the translations following the guidelines in the shared task description and evaluated the alterations to the dataset using a range of metrics.

Ahmed et al. (2024) contributed a translation of MT Seed into the Bangla variety of Bangla/Bengali, an Indo-Aryan language that is the official language of Bangladesh and the state of West Bengal in India (as well as others). The dataset was translated by a native speaker with translation experience, per the OLDI translation guidelines. They validated the quality of their dataset by fine-tuning a range of pre-trained multilingual models on their generated translations and compared performance with the same pre-trained models fine-tuned on different but comparable datasets. They found that the models pre-trained on their translation of MT Seed showed the best performance after controlling for dataset size.

Ali et al. (2024) produced a translation of the FLORES+ dataset into the Central variety of Emakhuwa, a Bantu language spoken primarily in Mozambique. They verified their translation by using a second translator to revise the work of the first, followed by quality assessment involving three raters using a Direct Assessment pipeline. The participants conducted several experiments to benchmark current progress in Emakhuwa–Portuguese MT. They found that a lack of standardized orthography remains a challenge for Emakhuwa MT, though multiple reference translations can help with this issue.

Cols (2024) released Seed-CAT, an open-source web application specifically designed to assist human translators in translating MT Seed dataset files.[4] Using Seed-CAT, they produced a trans-

Perez-Ortiz et al. (2024)	FLORES+ (new and corrected)	Aragonese, Aranese, Asturian, Valencian
Yu et al. (2024)	FLORES+ (new)	Wu Chinese

Table 1: A summary of all accepted contributions to the WMT 2024 Shared Task of the Open Language Data Initiative.

lation of MT Seed into Latin American Spanish. To validate their dataset's quality, they trained an English–Spanish MT model using the MT Seed data and compared its performance to models trained to translate between English and three Italic languages using existing MT Seed data. They found similar performance, suggesting that quality was similar to existing data in MT Seed.

Ferrante (2024) contributed a translation of MT Seed into Italian, building on a previous translation by Haberland et al. (2024). For this submission, the existing post-edited machine translation was reviewed and amended by two native speakers. The dataset was verified by training an Italian–Ligurian MT system and finding comparable results to those of Haberland et al. (2024).

Gordeev et al. (2024) contributed a translation of FLORES+ into Erzya, a Finno-Ugric language spoken primarily in Russia. As part of their work, they created a set of neologisms to aid future translators working in the digital space. They used their FLORES+ translation to evaluate the quality of existing English–Erzya and Russian–Erzya MT systems and train new competitive models for translating these language pairs.

Kuzhuget et al. (2024) translated the FLORES+ dataset from Russian into the Central dialect of Tuvan, a Turkic language primarily spoken in the Republic of Tuva in South Central Siberia, Russia. The team of translators worked from guidelines prepared in Russian to ensure consistent and high-quality translation.

Mamasaidov and Shopulatov (2024) contributed a translation of FLORES+ devtest split into Karakalpak, a Turkic language primarily spoken in the Republic of Karakalpakstan, which is an autonomous region within Uzbekistan. In addition, they also released a training dataset containing 100,000 sentence pairs for each of the language pairs: Uzbek–Karakalpak, Russian–Karakalpak, and English–Karakalpak. They carried out MT experiments using their datasets, releasing the trained models for further research.

Perez-Ortiz et al. (2024) contributed translations of FLORES+ into four Romance languages spoken in Spain: specifically new datasets for Aragonese, Aranese, and Valencian, and a corrected dataset for Asturian. The datasets were used as part of the evaluation of a shared task on MT from Spanish to low-resource languages of Spain (Sánchez-Martínez et al., 2024). Even though post-edited MT was used in the creation of these datasets, they were exceptionally accepted due to their use in a major shared task with the use of post-editing flagged in the metadata.

Yu et al. (2024) contributed a translation of FLORES+ into the Chongming dialect of Wu Chinese. The translation was done by two native speakers and checked by a third. Since Wu Chinese is typically colloquial while FLORES+ contains relatively formal text, the translators examined online written content and asked for community guidance about translations on fora to arrive at the best translations. To validate their dataset, the participants ran a three-way language identification task between Wu Chinese, Mandarin Chinese, and Yue Chinese. Their language identification model could distinguish between the three language varieties with high accuracy, though there was some confusion between Mandarin and Wu Chinese.

6 Discussion

Despite recent releases of state-of-the-art large-scale models (NLLB Team et al., 2024) and the growing attention directed at speech and sign language translations (Seamless Communication et al., 2023a,b; Rust et al., 2024), the work on text-based MT remains ongoing. This is particularly true for many of the world's under-served languages, which compete with their higher-resource counterparts for research attention. Without sustained interest and contributions to key evaluation and seed data sets, the delta between high and low-resource languages will continue to expand, exacerbating already prominent technical divides.

Covering 16 languages spanning five continents, the papers in this shared task present a rigorous effort to improve the quality and scope of such data sets. Taken collectively, the authors developed protocols and tools to both refine and introduce new languages to existing FLORES+ and MT Seed data sets. Beyond their technical attributes, the work presented here also aligns with one of OLDI's core commitments: to be community-centric. Every paper in this shared task involves engaging with speakers of the languages of interest, with many authors being native speakers themselves. The linguistics expertise and cultural nuances these researchers brought, alongside the personal convictions many may have, culminated in a body of work that is both scientifically and socially meaningful. It is our hope that the papers showcased in this shared task are the first of a long series designed to consolidate the building blocks needed to advance language technologies for under-served linguistics communities across the world.

7 Conclusion

We presented the results of the WMT 2024 OLDI shared task. We accepted ten submissions covering 16 languages, which extend the range of languages included in the foundational datasets FLORES+ and MT Seed. We thank all participants for their contributions and hope that this shared task encourages further efforts towards improved language technologies for more language varieties.

A Translation Guidelines

These translation guidelines must be acknowledged by all translators who will be contributing data.

Important note

Your translations will be used to help train or evaluate machine translation engines. For this reason, this project requires **human translation**.

- If you are translating data for evaluation purposes, such as for FLORES+, using or even referencing machine translation output is not allowed (this includes post-editing).
- **Note** that some machine translation services – including DeepL, Google Translate, and ChatGPT – prohibit the use of their output for training other translation or AI models, so their use is not permitted.

General Guidelines

1. You will be translating sentences coming from different sources. Please refer to the source document if available.
2. Do not convert any units of measurement. Translate them exactly as noted in the source content.
3. When translating, please maintain the same tone used in the source document. For example, encyclopedic content coming from sources like Wikipedia should be translated using a formal tone.
4. Provide fluent translations without deviating too much from the source structure. Only allow necessary changes.
5. Do not expand or replace information compared to what is present in the source documents. Do not add any explanatory or parenthetical information, definitions, etc.
6. Do not ignore any meaningful text present in the source.
7. In case of multiple possible translations, please pick the one that makes the most sense (e.g., for gender concordance, cultural fit in the target language, level of formality, etc.).
8. Translations must be faithful to the source in terms of pragmatics such as (if applicable) level of hedging/modality, sentiment and its intensity, negation, speech effects (disfluencies), etc.
9. For proper nouns and common abbreviations, please see the guidelines on Named Entities below.
10. Idiomatic expressions should not be translated word for word. Use an equivalent idiom if one exists. If no equivalent idiom exists, use an idiom of similar meaning. If no similar expressions exist in the target language, paraphrase the idiom such that the meaning is retained in the target language.
11. When a pronoun to be translated is ambiguous (for instance, when it could be interpreted as either him/her or he/she), opt for gender-neutral pronouns (such as them/they) if those exist in the target language. However, when a pronoun to be translated is clearly marked for gender, you should follow the source material and continue to mark for gender.
12. Foreign words and phrases used in the text should be kept in their original language when necessary to preserve the meaning of the sentence (e.g., if given as an example of a foreign word).

Named entities

Named entities are people, places, organizations, etc., commonly referred to using a proper noun. This section provides guidance on how to handle named entities. Please review the following guidelines carefully:

1. If there is a commonly used term in the target language for the Named Entity:
   (a) If the most commonly used term is the same as in the source language, keep it as it is.
   (b) If the most commonly used term is a translation or a transliteration, use that.
2. If there is no commonly used term:
   (a) If possible, a transliteration of the original term should be used.
   (b) If a transliteration would not be commonly understood in the context, and the source term would be more acceptable, you may retain the original term.

Results of the WAT/WMT 2024 Shared Task on Patent Translation

Shohei Higashiyama
National Institute of Information and Communications Technology, Japan
shohei.higashiyama@nict.go.jp

Abstract

This paper presents the results of the patent translation shared task at the 11th Workshop on Asian Translation and 9th Conference on Machine Translation. Two teams participated in this task, and their submitted translation results for one or more of the six language directions were automatically and manually evaluated. The evaluation results demonstrate the strong performance of large language model-based systems from both participants.

1 Introduction

The patent translation task using the JPO Patent Corpus has been held under the Workshop on Asian Translation (WAT) in 2015–2023 (Nakazawa et al., 2023) and under the Conference on Machine Translation (WMT) this year.[1] Due to the high demand for patent translation, this task has attracted many participants particularly in the early WAT workshops: a total of 30 teams over the past 10 years as in Table 1.

Year	# of teams
2015	8
2016	6
2017	4
2018	2
2019	3
2020	2
2021	3
2022	0
2023	0
2024	2
Total	30

Table 1: The number of participant teams for the patent task over the years.

This year, two teams participated in this task; one participant submitted translation results for two language directions, and the other for six out of six language directions, that is, Chinese↔Japanese, Korean↔Japanese, and English↔Japanese. Both teams employed large language model (LLM)-based systems, and the submitted translation results were evaluated by both automatic and human evaluation metrics. In this paper, we describe the evaluation dataset and procedure, and report the evaluation results for the submitted outputs.

2 Dataset

The JPO Patent Corpus (JPC)[2] was constructed by the Japan Patent Office (JPO) in collaboration with National Institute of Information and Communications Technology (NICT). The corpus consists of Chinese-Japanese (zh-ja), Korean-Japanese (ko-ja), and English-Japanese (en-ja) parallel sentences of patent descriptions. Most sentences were extracted from documents with one of four International Patent Classification sections: chemistry, electricity, mechanical engineering, and physics. As shown in Table 2, the dataset for each language pair consists of training, development, development-test, and multiple test sets. These datasets were constructed from patent families using automatic sentence alignment (Utiyama and Isahara, 2007), except for the test-N4 set where target sentences were manual translated from the source sentences.

A characteristic of the corpus is the use of fixed training and test datasets over the years, which allows for the comparison of new systems with past systems. The possible issue of data leakage is minimized: the data is provided only to applicants who have committed to participating in each annual workshop, and participants are required to delete the data after the workshop concludes.

[1] Similarly to other WAT shared tasks, this task is organized by WAT organizers but is held under WMT this year due to the collaboration between the workshop and conference.

Table 2: Statistics of the JPO Corpus. The published years column represents the years for the source sentences. The introduced event column indicates the events for which each dataset was first introduced.

3 Evaluation Procedure

3.1 Automatic Evaluation

Task participants were required to submit translation results via the WAT Submission site.[3] For the results submitted with the “publish” checkbox selected, automatic evaluation scores were calculated and displayed in the WAT Evaluation site.[4] As the automatic evaluation metrics, we used BLEU (Papineni et al., 2002) with `multi-bleu.perl` in the Moses toolkit (Koehn et al., 2007) version 2.1.1[5] and RIBES (Isozaki et al., 2010) with `RIBES.py` version 1.02.4.[6]

Prior to calculating scores, reference sentences and output translation sentences were tokenized with the tokenization tools for each language: Juman 7.0 (Kurohashi et al., 1994), KyTea 0.4.6 (Neubig et al., 2011) with the full SVM model[7] and MeCab 0.996 (Kudo et al., 2004) with IPA dictionary 2.7.0[8] for Japanese, KyTea 0.4.6 with the full SVM Model (MSR model) and Stanford Word Segmenter (Tseng, 2005) version 2014-06-16 with the CTB and PKU models[9] for Chinese, mecab-ko[10] for Korean, and `tokenizer.perl`[11] in the Moses toolkit for English. The detailed procedures are shown on the WAT Evaluation site.[12]

5	All important information is transmitted correctly. (100%)
4	Almost all important information is transmitted correctly. (80%–)
3	More than half of important information is transmitted correctly. (50%–)
2	Some of important information is transmitted correctly. (20%–)
1	Almost all important information is NOT transmitted correctly. (–20%)

Table 3: Ratings and their descriptions in the JPO adequacy criterion.

3.2 Human Evaluation

We conducted human evaluation for selected translation results based on the JPO adequacy evaluation criterion, which is originally defined by JPO to assess the quality of translated patent documents. For this evaluation, we used the test-N3 set for each language direction for the following reasons: (1) parallel sentences have been manually aligned (translations were manually created from the original sentences), and (2) both participants submitted results for this test set.

The evaluation was performed by two annotators (translation experts) for each system as follows. First, 200 sentences for evaluation were randomly selected from the test-N3 set in advance (the same 200 sentences were used for all systems). (2) The 200 pairs of the source sentences and translated sentences by the system were shown to each annotator, and the ratings between 1 and 5 were assigned to each sentence by the annotator as shown in Table 3.

Table 4: The configuration used for the baseline model. For other parameters, tge default values were used.

4 Baseline System

The organizers built a baseline system, a recurrent neural network (RNN) encoder-decoder model with attention (Bahdanau et al., 2014) using OpenNMT (Klein et al., 2017) with the configuration shown in Table 4 and the same tokenizers for automatic evaluation explained in §3.1. This baseline system uses the old neural machine translation (NMT) model built for WAT 2018 and serves as a weak baseline for comparison. However, as shown in §6, many past participants have adopted Transformer-based systems, allowing for the performance comparison with Transformer models (Vaswani et al., 2017) for recent participants.

5 Participant Systems

Two teams participated in the patent translation task: GenAI (Yonsei University) and sakura (Rakuten Institute of Technology). The details on the submitted systems are as follows.

sakura used an LLM-based system fine-tuned with simple translation prompt on the JPC training set for the corresponding language pair. As their backbone model, they adopted RakutenAI-7B-chat,[13] which had been pretrained on English and Japanese texts.

GenAI used an LLM-based system fine-tuned on only 1,000 sentences from the JPC training set. Their backbone model is Mistral-Nemo-Instruct-2407 (12B),[14] which had been pretrained on multilingual texts. During both fine-tuning and testing, their system identified domain-specific terms in each input source sentence by matching them with their bilingual terminology dictionary, and then generated the translation based on prompt that required the use of the specified term pairs.

6 Evaluation Results

6.1 Main Results

For the same reasons mentioned in §3.2, we only present the results for the test-N3 set; results for other test sets can be found at the WAT Evaluation site.[15] Table 5, 6, 7, 8, 9, and 10 show the performance of evaluated system for each language direction (systems with “∗r” indicate they used external resources). The tables present the automatic and human evaluation scores of the two participants' systems (one system per participant, selected based on the BLEU score), as well as the organizer's baseline and the best participant systems from previous years. The model type columns indicate whether the system employed statistical machine translation (SMT), RNN-based NMT, or Transformer (TF)-based NMT, and whether it corresponds to a decoder-only model (Dec) or an encoder-decoder model (EncDec). The BLEU/RIBES scores for the translation tasks into Japanese and Chinese represent the average BLEU/RIBES scores based on three different tokenizers.[16] The JPO adequacy scores (Adeq) represent the average of the scores assigned by two annotators.

We observed the following findings. (1) Unsurprisingly, both participants' systems as well as all previous best systems outperformed the baseline for all language directions in terms of automatic metrics. (2) The LLM-based systems by the two participants achieved strong results in terms of automatic metrics; GenAI's system outperformed the previous systems for ko→ja and ja→ko and sakura's system outperformed the previous systems for ja→ko and ja→en. However, the previous systems maintained the highest scores for zh→ja, ja→zh, and en→ja. (3) Both participants' systems achieved high adequacy scores of over 4. However, importantly, a system with a higher automatic evaluation score did not necessarily achieved a higher human evaluation score. Specifically, sakura's system yielded lower automatic evaluation scores than GenAI's system (e.g., BLEU of 52.77 vs. 67.10 for ja→ko and 68.00 vs. 70.60 for ja→ko), but

achieved similar or better adequacy scores (4.67 vs. 4.66 for ja→ko and 4.76 vs. 4.39 for ja→ko). This result highlights the need for using a variety of evaluation metrics, such as neural-based metrics, which have been demonstrated to correlate well with human judgement (Freitag et al., 2023).

6.2 Detailed Human Evaluation Results

Table 11 shows the detailed results of the JPO adequacy evaluation for a total of eight participant systems, which were selected from among the same participant's systems based on the BLEU score. The "Adequacy Score" column represents the average of ratings assigned to 200 sentences by each annotator for the Annotator="A"/"B" rows and the average and standard deviation of the average score by the two annotators (A and B) for the Annotator="Both" row, which is shown as the adequacy score (Adeq) in Table 5–10.

We observed the following findings. First, most sentences were assigned scores over 4 (75% or more sentences for each translation result, except for sakura's ja-en result evaluated by Annotator B). This indicates that there were many high-quality translation overall, but more accurate systems have room for development, considering that the translations with a score lower than 5 account for more than 20–50% in most cases of annotator-level evaluation results.

Second, the difference of sentence-level scores between two annotators ("Diff Score") was 0 or 1 in most cases, and there were only nine sentences with the difference score of 2 over all translation results. As a result, the adequacy scores between two annotators were close in many cases, but relatively large standard deviation (close to or greater than 0.2) was observed in three cases, i.e., sakura ja-zh, GenAI ja-ko, and sakura ja-en results. In the latter cases, there were somewhat many mismatches; each translation result included over 100 sentences with a score difference of 1 from the two annotators and/or a few sentences with a score difference of 2.

For the nine sentences with a score difference of 2, we conducted a meta-review by a third evaluator, distinct from the two annotators. We found that which annotator provided the more appropriate rating varied depending on the example. In some examples, one annotator overlooked a mistranslation and assigned a higher rating. In other examples, there were no mistranslations, but one annotator still assigned a lower rating. Additionally, in cases

Lang	Team	Data ID	Annotator	Adequacy Score	Distribution of Ratings					Diff Score		
				(Avg. ± SD)	1	2	3	4	5	0	1	2
zh-ja	sakura	7302	A	4.24	4	4	24	76	92			
			B	4.24	2	6	26	74	92			
			Both	4.24 ± 0						130	70	0

			Both	4.66 ± 0.15						124	76	0
ja-ko	sakura	7224	A	4.64	0	4	4	52	140			
			B	4.87	0	1	4	15	180			
			Both	4.76 ± 0.12						148	52	0
ja-ko	GenAI	7267	A	4.16	0	7	38	71	84			
			B	4.61	0	0	9	60	131			
			Both	4.39 ± 0.23						98	102	0
en-ja	sakura	7278	A	4.49	0	4	15	61	120			
			B	4.40	0	3	35	41	121			
			Both	4.44 ± 0.04						123	73	0
ja-en	sakura	7309	A	3.83	2	22	59	43	74			
			B	4.33	1	5	26	64	104			
			Both	4.08 ± 0.25						79	144	7

Table 11: Detailed results of the JPO adequacy evaluation for the test-N3 set. The "Distribution of Ratings" column shows the number of sentences with each rating of 1–5. The "Diff Score" represents the number of sentences with each difference score, which means the difference of ratings between two annotators.

where the translation contained garbled characters, one annotator assigned a lower rating.

7 Conclusion

This paper summarizes the results of the WAT/WMT 2024 shared task on patent translation. The patent translation task using the JPO Patent Corpus has been held for ten years, and this will be the last time.[17] We believe that extensive development efforts by task participants over the past 10 years have contributed to advance machine translation technologies for the patent domain.

Abstract

We present the results of the ninth edition of the Biomedical Translation Task at WMT'24. We released test sets for six language pairs, namely, French, German, Italian, Portuguese, Russian, and Spanish, from and into English. Each test set consists of 50 abstracts from PubMed. Differently from previous years, we did not split abstracts into sentences. We received submissions from five teams, and for almost all language directions. We used a baseline/comparison system based on Llama 3.1 and share the source code at https://github.com/cgrozea/wmt24biomed-ref.

1 Introduction

In this paper, we present a description and the findings of the ninth edition of the Biomedical Translation Task,[1] which took place at the ninth edition of the Conference for Machine Translation (WMT'24). The shared task aims to support advances in Machine Translation (MT) in the biomedical domain, especially for scientific literature. Previous editions of the shared task addressed up to seven language pairs and included the release of training and test sets (Bojar et al., 2016; Jimeno Yepes et al., 2017; Neves et al., 2018; Bawden et al., 2019, 2020; Yeganova et al., 2021; Neves et al., 2022, 2023). All previous data is available in the shared task repository.[2]

Similar to previous years, our test sets consist of biomedical abstracts, which have been included to PubMed[3] just before publishing the test set, to decrease the likelihood of data contamination. We prepared test sets for six languages from and into English, namely, French (fr2en, en2fr), German (de2en, en2de), Italian (it2en, en2it), Portuguese (pt2en, en2pt), Russian (ru2en, en2ru), and Spanish (es2en, en2es). The test sets consist of 50 abstract pairs for each of the 12 language directions above. Some of the test sets were also released as test suites in the General Task of WMT (Kocmi et al., 2024). After the release of the test sets, the participants had around two weeks to submit their automatic translations. For this year's shared task, the following features were introduced:

- The selection of the articles for the test sets was based on topics of interest to the task organizers (Section 2);

[*] The contributions of the authors are the following: MN prepared the MEDLINE test sets, performed manual validation, and organized the shared task; CG developed the baseline system; PT, RR, RB, AN, SC, VB, GMN, FV, MVN, LY performed manual validation; AJY performed manual validation and the automatic evaluation, as well as co-organized the shared task; All authors approved the final version of the manuscript. - The test sets consist of paragraphs comprising the papers' title and the abstract, i.e. no sentence splitting and alignment were carried out (Section 2);
- Consequently, we only performed a manual evaluation on the abstract level (cf. Section 6);
- We used as a baseline/comparison a local large language model, Llama 3.1 (cf. Section 3);
- We performed the automatic evaluation also based on COMET (Rei et al., 2020), besides BLEU (Papineni et al., 2002).

2 Test sets

We downloaded the daily update files from PubMed[4] around mid-April for the preparation of the test sets. As usual, we first identify all articles that are available in English as well as one of the non-English languages that we address in the shared task. Subsequently, we selected 100 pairs of articles for each language pair, which were later split into two sets, i.e., from and into English.

This year, we aimed to prioritize three topics[5] in our test sets. While selecting the articles, we restricted each topic to around a third of the total. Still, this limit was frequently not reached because too few articles included any of the three selected topics. The three topics are listed below:

- Animals: D000818
- SARS-CoV-2: D000086402
- Pancreatic Neoplasms: D010190

Subsequently, the 100 selected articles for each language pair were split between the two test set directions. Test set statistics are shown in Table 1. No further processing was performed on the test sets, and these were released as a plain text file, one for each language pair, each with 50 lines, and one for each article. Each line is composed of the title and abstract of the article.

3 Baseline/Comparison system

While we used GPT 3.5 as a comparative model last year, we decided to use a self-hosted open-weight large language model this year. Several such models are available of various sizes, licenses, and performance levels in the MT task. Based on the previously accumulated hands-on experience in informally evaluating several open-weight models in multiple tasks, including translation, we selected one of the best performing models, namely Llama 3.1 (Dubey et al., 2024).[6]

The Llama models are open in the sense that their weights and supporting code are freely available, but the usage is limited by a relatively liberal license. In the case of the model used here, the precise licenses are "LLAMA 3.1 COMMUNITY LICENSE AGREEMENT" and "Llama 3.1 Acceptable Use Policy". The last one prohibits using the model to violate the law or the rights of others, to activities related to bodily harm, including military, to generate false information, and includes a clause making it compulsory to report "risky content generated by the model". This risky content can arise when used for medical texts in the form of mistranslated medical procedures.

To interact with the model, we used ollama,[7] through which the model can be queried (i.e. we can programmatically perform tasks with the selected LLM and retrieve the response to those tasks, e.g. from a program written in the Python programming language). In addition, ollama provides a command line interface that can be used to pull further models or to interact with a model in a text-based chat interface.

Implementation decisions We used "Meta Llama 3.1 70B Instruct"[8] (known in ollama as llama3.1:70b), which means the approximate number of parameters is $70 * 10^9$. Such an LLM is run fully accelerated by a GPU only when the parameters fit into the video RAM of the GPU. Since we used a Nvidia A6000 ADA, a 48 GB RAM GPU card, we used the quantization Q4_0 (4 bits per parameter). This makes the actual size of such a model 37.22 GiB and fits in the 48 GB VRAM of the GPU. With the other temporary data needed in the same memory during processing, the occupation of the VRAM went up to 41.2 GB (85%). To evaluate the impact of using the same model with a smaller card, we also tested a 24 GB VRAM card, Nvidia A5000. This raised the CPU usage to 28 cores (from 2) and processing was slower.

[8] "Instruct" indicates that the model was further trained to follow instructions and not just to predict the next text tokens that could follow after a given text prefix.

topics	fr2en	de2en	it2en	pt2en	ru2en	es2en	en2fr	en2de	en2it	en2pt	en2ru	en2es
SARS-CoV-2	15	18	-	5	11	17	9	15	-	-	13	16
Pancr. Neopl.	2	15	1	-	3	2	-	15	2	1	4	1
Animals	15	17	5	17	14	22	20	17	5	18	20	13
other	19	-	44	28	22	9	21	4	43	31	14	20

Table 1: Statistics of the topics in the test sets. The topic "other" refers to articles that do not contain any of the three selected topics. The sum of the values for one language pair might be higher than 50 because some articles contain more than one topic.

Prompt used Choosing the right prompt is important for instruction-tuned LLMs and is still rather an art than a science. We started with the prompt "*You are a helpful assistant specialised in biomedical translation. You will be provided with a text in {src}, and your task is to translate it into {dest}.*" where *src* is the name of the source language and *dest* is the name of the target language.

Visual examination of one text entry (out of the 50 in the test set) per language pair showed the following undesirable behaviour in the MT output generated by the LLM, which we tried to fix by changes to the prompt:

- in one case some additional text, with the meaning "this is the translation into German", which was fixed by adding "*You will add nothing and comment nothing, just produce the accurate translation of the text in specialist language.*" to the prompt;
- additional formatting of the output text through the insertion of newlines, which was almost entirely fixed by adding "*Keep the formatting as close as possible to the source and especially do not insert any newline.*" to the prompt.
- the occasional replacement of digits by their names. We decided not to try to fix this.

After a complete run, we noticed that the LLM still failed to respect the original format of the source texts (it still sometimes produced multiple lines per source text). Visual inspection showed that in a few cases it still attempted to format the subsections of the translated test despite being asked to refrain from doing that. Therefore, explicit postprocessing was carried out to eliminate the line breaks from the LLM's outputs.

Some good features of the translated texts were also noticed, such as localized acronyms e.g. translating English *Real-time functional magnetic resonance imaging (fMRI)* to French *L'imagerie fonctionnelle par résonance magnétique (IRMf)*. Quite impressive was how well the translation retained the quantitative results in the fairly long source texts, while simultaneously applying number localization transformations, such as swapping the decimal point with the decimal comma.

Run-time Statistics Measured duration in seconds with an A6000 in each case for 50 texts:

en2de	1232	en2es	1065	en2fr	1202
de2en	728	es2en	902	fr2en	859
en2it	1413	en2pt	1098	en2ru	1110
it2en	810	pt2en	748	ru2en	641

With an A5000, the speed was about 10 times slower. A GPU-free execution is also possible, but it can be too slow to be practical.

Energy consumption, CO_2 emissions For the A6000 card, a total of $11,607$ seconds at about 1 kW (300W the GPU itself) equals an amount of 3.22 kWh and an equivalent CO_2 emission of 1.16 kg – at the average 360 g CO_2/kWh in Germany, equivalent to the emission of an ICE (internal combustion engine) car driven for about 9.5km. For the slower card, which totalled $131,898$ execution seconds, the figures are 36.64 kWh and therefore 13.2 kg CO_2.

4 Teams and systems

We followed similar dates to the WMT General Translation Shared Task, releasing the test sets on June 27th, 2024 and allowing submission until July 12th, 2024 (after an extension). We released all test sets both in our submission system (Google Form) and the OCELoT tool.[9] We also included our test sets for en2de, en2es, and en2ru as test suites in the General Task[10] in OCELoT. These were the only language pairs that overlapped with the ones from the General Task.

Team ID	Institution	Publication
ADAPT	Dublin City University, Ireland	(Castaldo et al., 2024)
AIST	National Institute of Advanced Industrial Science and Technology, Japan	
DCU	Dublin City University, Ireland	
HW-TSC	Huawei Translation Service Center, China	
Unbabel	Unbabel, Portugal	

Table 2: List of the participating teams and systems.

We received submissions from five teams that directly registered to our task. We list them in Table 2 and present details about their systems below.

ADAPT (Castaldo et al., 2024). For the submissions identified as "run1" for de2en, en2de, fr2en, and en2fr, the participants relied on NLLB-200's distilled 600M variant (NLLB Team et al., 2022), which was fine-tuned on around 10k parallel segments from in-domain training data in the respective language pair. Run2 for en2de, in addition to the above approach, included post-edition by LLM agents powered by GPT-4o.[11] Finally, for run3 for de2en, they relied on LLama-3-8B[12] fine-tuned on around 10k parallel sentences and few-shot prompting using fuzzy matches retrieved by similarity search from the training dataset.

AIST. For run1 of de2en, the team relied on a Mega model (Ma et al., 2023) trained from scratch and fine-tuned on parallel biomedical data from MEDLINE. For run2 for both en2de and de2en, they used a Mega model, an ensemble of four checkpoints trained from scratch and fine-tuned on the same data. For all submissions, they estimate the following sizes of training data used: 3M from in-domain, 5M from open domain, and 3M monolingual.

DCU. We do not have much information about the system behind the submissions for this team, except for a short description citing the Mistra-7B language model[13] for ru2en and fr2en.

HW-TSC. For all submissions to en2de and de2en, the team relied on a system based on Transformers that was trained from scratch on in-domain and open-domain parallel and monolingual data (Wu et al., 2023). It is not clear which changes were carried out for the distinct runs.

Unbabel The submissions for all language pairs consisted of a new version of the Tower LLM (Alves et al., 2024), either with Greedy (run1) or MBR (run2) decoding. The LLM has 70B parameters, was built on top of Llama3, and its continued pre-training phase used 25B tokens for 15 languages, followed by fine-tuning with instructions for all the languages in a variety of tasks, including MT.

5 Automatic evaluation

We ran automatic evaluation based on BLEU (Papineni et al., 2002) and COMET (Rei et al., 2020). We present the results for the submissions to the biomedical translation task using our form in Tables 3 (from English) and 4 (into English), as well as the ones from OCELoT for our task in Table 5 and for our test suites submitted to the General Task in Table 6. All scores were multiplied by 100.

5.1 Biomedical Task submission system

Among all submissions, including our baseline system, the highest BLEU score was 55.63 for pt2en (Unbabel run1) and the highest COMET score was of 89.71 for en2ru (Unbabel run2). The submissions that scored better were the ones from Unbabel and our baseline system, e.g., for en2de, en2fr, en2it, en2pt, and en2ru, with some few exceptions where another system also obtained a high score, e.g., AIST for en2de and DCU for en2ru. The submissions from Unbabel usually scored slightly higher than our baseline, with a few exceptions, e.g., en2pt, fr2en, and es2en.

We observed that the two types of metric score were rather equivalent and that submissions that scored high for BLEU also did so for COMET. However, some submissions had very different BLEU scores for similar COMET scores. For instance, the baseline system obtained the BLEU scores of 31.67 and 51.65 for en2de and en2pt, respectively, but around 87.00 for the COMET score in both cases. Overall, the scores from this year's

For the submissions from Unbabel, runs "1" are the ones identified as "Greedy", and runs "2" are the ones for "MBR".

submissions are not directly comparable to the ones from the previous year since, for the first time, we ran an evaluation on the abstract level.

5.2 OCELoT Biomedical Translation task

Only one team (AIST) submitted to the biomedical task in OCELoT, but also for the same language pairs in our submission system and for our test

Team	Run	Metric	en2de	de2en
AIST	517	BLEU	28.30	
		COMET	83.75	
	542	BLEU		39.68
		COMET		82.55
	544	BLEU		39.68
		COMET		82.55
	545	BLEU	28.30	
		COMET	83.75	

Table 5: BLEU scores for submissions to OCELoT for the Biomedical Translation Task.

suites in the general task. While their results as shown in Table 5 were similar to the ones in Table 6, they were slightly inferior to the ones that the same team obtained for the runs to our submission system, e.g., for en2de, a BLEU score of 28.30 versus 33.80, and a COMET score of 85.59 versus 83.75.

5.3 OCELoT General Machine Translation task

We included test suites only for the language pairs in our task that overlap with the ones considered in the general task, namely, en2de, en2es, and en2ru. The scores for the submissions to the general task (cf. Table 6) varied much more than the ones submitted directly to the biomedical task (cf. Table 3), from very low to high, e.g., BLEU scores of 1.63 (certainly due to mistakes in the system) to 52.56. It is safe to assume that most systems were not trained especially for the biomedical domain. In spite of this, we observed some submissions with scores even higher than the ones for the biomedical task. Amongst the submissions to the general task, the highest scores for en2de were 38.07 BLEU (ONLINE-W) and 88.25 COMET (TransionMT), as opposed to a BLEU score of 34.22 (Unbabel run1) and a COMET score 88.09 (Unbabel run2) in the biomedical task. For en2ru, the highest scores in the general task were 41.25 BLEU (Claude-3.5) and 89.88 COMET (Claude-3.5 and Unbabel-Tower70B), as opposed to 35.76 BLEU (Unbabel run1) and 89.71 COMET (Unbabel run2). Therefore, submissions from the same team (Unbabel) scored slightly higher in the general task than in the biomedical task.

6 Manual evaluation

Similar to previous years, we performed manual validation of a sample of the submissions for most of the language pairs. The number of abstracts that we considered for each language was of either 10 or 20 depending on the availability of the human evaluators. We used the three-way function of the Appraise tool (Federmann, 2018), which includes the following elements:

- the abstract in the original language (e.g., English for en2fr);
- translation A: first translation in the target language (e.g. French for en2fr);
- translation B: second translation in the target language (e.g. French for en2fr).

The task consists of validating whether a translation is better than the other (i.e., A>B or A<B), or whether they are of similar quality (A=B). In cases where the evaluators notice that an error might have occurred, e.g., translation from another text or a translation shorter than it should be, it is possible to skip the validation of this particular pair.

For all language pairs, we considered the best run from each of the team that submitted directly to the biomedical task. The best run was the one identified by the participants during the submission process. Otherwise, we selected the best performing one. We evaluated pairs of either two translations from the teams, or one translation from a team and the reference translation. We present the results for submissions from English in Table 7 and for submission into English in Table 8.

We present below a summary of the mistakes that we observed during manual evaluation.

en2fr Translation quality was uneven, as suggested by the 20 point difference in BLEU scores obtained by the systems. While some translations were of very high quality, others exhibited serious issues including conveying meaning drastically different from the original sentence. In example 1, numerical values are erroneous and inconsistent with the corresponding percentages. In Example 2 the resulting translation is medically unacceptable.

(1) **en:** Of the 273 patients, 164 (60.1%) required invasive mechanical ventilation. One hundred and forty-two patients (52.0%) survived their hospital stay.

Table 8: Pairwise manual evaluation results for the test set (into English).

Cent quarante-deux personnes (52,0 %) ont survécu à leur séjour à l'hôpital.

(2) **en:** Deaths by mechanical asphyxiation constitute a social drama
fr*: La prévention constitue un drame social
fr: Les morts par asphyxies mécaniques constituent un drame social

In both cases, the translation errors likely result from mixing information contained in different parts of the original texts. Arguably, this is very concerning because users of such a translation system could conclude that the erroneous translations are correct by checking that the information is present in the original text. Other issues are more easily detected, such as the interruption of the translation by a loop repetition of a set of tokens (e.g., *une mobilité allant de 5,6% à 5,6% à 5,6% à 1211% à 1211% à 1211% à 1211% à 1211% à 1211% à 1211% à 1211% à 1211% à 1211%...*).

The choice of having full abstract translation instead of sentence-by-sentence translation this year seems to have both a positive impact on the overall consistency of translations (e.g., overall consistent use of terms and acronyms throughout a document) and a negative impact on the end of translation for some systems, where translation quality was decreasing as the text unfolded and sometimes just interrupted (with or without loop repetitions).

Specialized term translation was sometimes erroneous, in particular with terms referring to animal species (for example, translating *waterfowl* by *oiseaux d'eau* instead of *sauvagine*), which were more frequent this year due to the selection method for the test documents. Polysemous terms were also a source of erroneous translations (e.g., *hood* translated as *capot* – car context instead of *capuche*, which is correct in a clothing context).

In addition to the manual evaluation through appraise, a complementary assessment of the best system submission outputs was conducted, with a focus on *Acronyms* and *Lab Values*, consistently with the evaluations conducted in the two previous years. Overall, 31 out of 50 test documents contained acronyms and none contained lab values. Acronym translations were considered correct when the system translation was identical to the reference translation or consisted of an attested acronym use in a similar context. Correct acronym translations (79%) included frequent acronyms such as USI (*Unité de Soins Intensifs* – Itensive Care Unit) or IC (*Intervalle de Confiance* – confidence interval). In other cases, acronyms were either untranslated (16%) or erroneous (5%). Some of the acronym translation strategies used by human translators and not by machine translation consist of explicitly stating that an English acronym is used, for example: *la santé mentale du nourrisson (IMH en anglais)*. This is sometimes combined with a strategy of using the long form of a term in French, when an acronym was used in English. These strategies are often used with acronyms that stand for infrequent terms.

It is also interesting to notice that reference translations contain idiomatic linguistic traits not used in machine-translated text, such as inclusive writing (as seen in Example 1).

en2pt All translations into Portuguese were of very good quality, except for some empty translations from one submission and the remains of the prompt used, which were included in the translations of the same submission. Therefore, the decision of whether one translation was better than the other was generally based on small details, often one single mistake.

Small mistakes that we found were the following: (a) lack of capitalization at the start of the sentence (e.g., "...profunda (TVP). o sangue ..."); (b) nominal concordance (e.g., "o febre pós-anestésica"); (c) missing words (e.g., "com uma [força] média de 526N"); (d) words that remained in English (e.g., "odds ratio") (e) typos ("registe" instead of "registre"); (f) and grammatical mistakes (e.g., "acompanhou [por] mais de 18 meses").

As in previous years, we found mistakes related to the non-translation of acronyms. For easier or more common terms, e.g., Artificial intelligence (AI), the translations were all correct, i.e., "inteligência artificial (IA)". However, mistakes were often found for other terms, as in Example 3 below in which only the translation pt$_3$ is correct and has the right acronym:

(3) **en:** Computer vision (CV)
pt$_1$: visão por computador (CV)
pt$_2$: visão computacional (CV)
pt$_3$: visão computacional (VC)

Often we observed a copy of the English acronym for much more complex terms, as in Example 4:

(4) **en:** hydrogenated castor oil (HCO ethoxylates)
pt$_1$: Óleo de castor hidrogenado polioxietileno (etoxilações de HCO)
pt$_2$: óleo de rícino hidrogenado de polioxietileno (HCO-etoxilados)
pt$_3$: hydrogenated castor oil (HCO ethoxylates)

However, we had some difficult examples in which the translation and acronym were correct, e.g. pt$_2$: in Example 5:

(5) **en:** hospital standardized mortality ratio (HSMR)
pt$_1$: taxa de mortalidade hospitalar padronizada (HSMR, na sigla em inglês)
pt$_2$: razão de mortalidade hospitalar padronizada (RMHP)

Finally, we observed many examples in which we favored some translation over others because they either sounded better or more correct, namely, translations pt$_2$: in Examples 6, 7, 8, and 9:

(6) **en:** was highly expressed in CTCs
pt$_1$: foi altamente expresso em CTCs
pt$_2$: tinha uma expressão elevada nas CTCs

(7) **en:** A quasi-experimental study, which compared
pt$_1$: Estudo quase-experimental, que comparou
pt$_2$: Um estudo quase experimental, que comparou

(8) **en:** Case signalment
pt$_1$: Fatores de identificação do caso
pt$_2$: O sinalamento do caso

(9) **en:** axis of the femoral neck
pt$_1$: eixo do colo do fêmur
pt$_2$: eixo do colo femoral

fr2en With the change in protocol this year (from sentence-level to paragraph-level translation and evaluation), there were several differences in the observed quality of translations.

Translation issues brought up in previous years remained present, namely the copying or wrong translation of acronyms and specialised terms (Example 10), the wrong translation of personal pronouns (e.g. *son* 'his/her/their' in Example 11) and errors linked to the ambiguity of source terms (e.g. *taille* 'height or waist' in Example 12).

(10) **fr:** la thérapie de substitution de la nicotine (TSN)
en: nicotine replacement companies (NTS)
en*: nicotine replacement therapy (NRT)

(11) **fr:** . . . la capacité d'un individu à rechercher des soins . . . pour son animal de compagnie
en: an individual's ability to seek . . . care for their companion animal
en*: an individual's ability to seek . . . care for his companion animal

(12) **fr:** la circonférence de la taille (CT)
en: waist circumference (WC)
en*: circumference of height (CT)

However, the overall quality of the translations was visibly lower than in previous years, due to the use of LLMs and the translation of whole paragraphs rather than individual sentences. LLMs tended to exhibit more volatile behaviour, often copying the source document instead of translating, and also including the initial prompt in the output. The consequence of the longer documents to translate was mostly seen in skipping sentences within the documents or (more commonly) at the end of documents (i.e. translation finishing too early or repeating the final sentence multiple times). We also observed the merging of multiple sentences/clauses into a single one and the negative influence of previous sentences on later translations, resulting in the repetition of terms in inappropriate places and errors in the translation of numbers (both problems illustrated in Example 13).

(13) **fr:** Cent six médecins ont répondu au sondage et 12 ont participé à un entretien
en: One hundred and six physicians responded to the survey and 12 participated in an interview
en*: One hundred and twelve respondents participated in the survey

The consequence of the appearance of these more serious errors (i.e. non-translation, missing parts of the translation etc.) meant that they often formed the basis of the evaluation rather than distinctions being based on errors more traditionally resulting from the translation of scientific texts (terminology, acronyms, etc.). Not evaluating on the sentence level meant that an improved translation on the sentence level was easily overridden by a more technical problem, such as a missing sentence at the end of the document. It could be useful in the following years to consider evaluation via error analysis to get more detailed insights into the strengths and weaknesses of different systems on a more granular level.

es2en Contrary to past years, the Spanish to English language pair had very few contributions, totalling 30 examples from two different MT models both compared between each other and against a reference human translation.

In the past, sentence-to-sentence translation has provided good results in terms of translation quality at sentence level. However, the trade-off was inconsistency in the usage of medical terminology and medical specific acronyms. This year however, the use of full abstracts for translation led to greater consistency in the translation of terminology and acronyms specific to medicine.

When working well, the MT output has a good quality, sometimes producing a result that was comparable to human translation in terms of quality, as shown in Table 8, where the MT system Unbabel had very good results compared against DCU and the reference translation.

However, the MT output still lacks the fluency of a human translation, as the systems had a tendency to replicate the structure of the original Spanish source text, resulting in translations that can be considered "literal translations". In many instances, the MT output would require copy editing and rewriting by a native English speaker to render the text more fluent and increase the overall quality of the output.

Despite the good quality level of some translations, the overall quality of the outputs for this year's challenge is very uneven, with some very good abstracts in English and some abstracts that were not translated or still contained Spanish words in them.

At least one of the system used LLMs to produce the output in English, with this prompt: “1. While being factual, accurate and not missing out any detail, translate the given Spanish text into the specified English language. Spanish Text:”. The use of the prompt ensured the output did not miss information from the original source text, as has sometimes been the case in past years. Nevertheless, the LLM system was not very robust.

As shown in the example below, the LLM system sometimes did not translate the text in English as requested. The text remained in Spanish. That is considered a missing translation and is considered a major error.

(14) **en:** While being factual, accurate and not missing out any detail, translate the given Spanish text into the specified English language. La prevalencia de alergia alimentaria ha aumentado en algunas regiones del mundo, y con ello la incidencia, según la variabilidad geográfica, en el fenotipo y manifestaciones clínicas...

Another error the LLM system made was the inclusion of the prompt used to generate the translated output as part of the response. This add superfluous information to the English translation and breaks the readability and fluency of the text (see previous example).

As mentioned before, fluent translation was still an issue for the machine translation system, in particular for the DCU system. This system sometimes generated sentences that were clunky or ungrammatical in English.

(15) **es:** Se registraron 4 casos de morbilidad post punción (2 dolores epigástricos y 2 hematomas de pared abdominal

en: Were registered 4 cases of morbidity post puncture (2 pain epigastric and 2 hematomas of abdominal wall).

In conclusion, LLMs systems still seem to have an unreliable performance when it comes to machine translation, producing very good quality translations, missing translations or ungrammatical translations at the same time. A better out-of-box LLM or refine the prompting techniques might obtain better results with these systems.

It must be noted, however, that there were very few examples for the Spanish to English translation to reach an indisputable conclusion.

en2de Similar to previous years, a generally high level of translation quality was seen for English to German translation. The strongest models produced translations that not only conveyed the content well but also maintained consistency in terms of style and structure. However, certain systems exhibited notable flaws. In particular, one model consistently omitted portions of the text, often truncating the translation towards the end of the document or, at times, even mid-sentence. Another system struggled with basic capitalization, failing to begin sentences with an uppercase letter, which detracted from the overall readability of the output.

Numerical translations were also an issue, with *Eighty-nine* frequently mistranslated as either *Achtundachtzig* “eighty-eight” or *Achtundneunzig* “ninety-eight”, revealing inaccuracies in number handling. The translation of abbreviations varied across systems, with some attempting to expand or translate them, occasionally resulting in errors. For example, the *European Commission (EC)* was incorrectly translated as *EG (Europäische Gemeinschaft)* instead of EU. Furthermore, specialized terminology presented additional challenges, with terms like *compulsory elective* rendered awkwardly as *obligatorische elektive Veranstaltung* rather than the more appropriate *Wahlpflichtkurs*.

Grammatical errors also persisted in some translations, indicating that while overall quality was high, there is still room for improvement in handling both sentence structure and more nuanced linguistic elements.

de2en Overall, results varied for the German-to-English translation task. While at least one system was able to provide a human-level translation for each source sample, there was generally also at least one translation that was either incomplete or difficult to understand.

The most serious mistakes included omission of whole sentences, or synthesis of text that was not present in the original. This was especially evident in cases where the sample text ended in an incomplete sentence, which caused some systems to generate a completion to the sentence. In the most egregious example of this phenomenon, an incomplete sentence at the end of a description of an animal’s skin condition after an insect bite led to more than one translation mentioning euthanasia, when no such language was present in the source. In some instances, text would be translated to nonexistent words, e.g. translation of *porös* to the nonexistent word *sporeous*. Other mistranslations included rendering *mittleren Werte* as *median* instead of *mean* values as was intended in the text.

The most frequently occurring mistakes were related to the capitalization of words at the beginning of sentences. Other formatting mistakes failed to take into account the structure of the text, omitting paragraph headings. These mistakes did not affect the overall intelligibility of the text.

All in all, the majority of the systems were able to provide a translation that, while not perfect, was understandable and correctly conveyed important information.

en2it The quality of the translation was higher than in previous years, even more so than last year, which set a new threshold in the accuracy of the translation from English to Italian and vice versa. The quality of most of the abstract was almost identical and fluent in terms of the quality of language. The terminology and the syntax was of very high quality in both translation directions. There were rarely major issues with the choice of terms or the construction of the sentences.

One mistake was the addition of parts of the text that were not present in the original version. For example, the original version is “Among those diagnosed with COVID-19 during follow-ups between March 2020 and March 2021 [...]”

While the Italian translation: “MATERIALE E METODO: TRA marzo 2020 e maggio 2021, sono stati analizzati [...]”

Where there is the addition of “MATERIALE E METODO”. There is also some minor issue with the punctuation (the semicolon between “rene” and “o dobbiamo farlo” should not be there) as well as uppercase letters (“TRA” instead of “tra”).

There were two problems concerning the cause effect or correlation among pathologies. For example, in the original English version: "Chronic rhinosinusitis with nasal polyps is a common disease with still unclear pathophysiologic mechanisms." The "Chronic rhinosinusitis with nasal polyps" are one thing all together that is documented to be a common disease.

On the other hand, the Italian version: "La rinosinusite cronica e la poliposi nasale sono patologie frequenti" the "Rinusite cronica" ("Chronic rhinosinusitis) and "poliposi nasale" ("nasal polyps") are considered as two distinct pathologies.

The other example happens with the following sentence: "The airway epithelial barrier has been shown to be involved in different chronic disorders, including rhinitis, nasal polyposis and asthma" and its Italian translation: "La barriera epiteliale delle vie respiratorie sembra essere coinvolta in diverse patologie croniche come la rinite, la poliposi nasale e l’asma"

In this case, the translation gives a slightly different interpretation of the fact that, in the original version, "airway epithelial barrier has been shown to be [...]" as in "it has been demonstrated that", while the Italian "sembra essere coinvolta" ("seems to be involved") shoes a less strong connection between the entities (airway epithelial barrier and chronic disorders).

it2en For the Italian to English translation direction, we observe an opposite problem compared to the English one that is removing a part of the text.

For example, in the original "Conclusione: sebbene non abbiamo riscontrato differenze significative tra i pazienti sottoposti a gastrectomia standard e quelli sottoposti a NACT prima della gastrectomia, [...]" we have "Conlusione:" as the initial part of this sentence.

In the English version, we have "Although we found no significant difference between the patients undergoing standard gastrectomy and those undergoing NACT before gastrectomy," Where "Conclusions" ("conclusione") is missing.

From Italian to English, there was a missing agreement in gender for the translation of the following sentence: "A total of 192 female feral cats were investigated for a large-scale trap-neuter-release program." One of the Italian translations overlooked the female gender with: "Un totale di 192 gatti selvatici sono stati studiati per un ampio programma di trappola, sterilizzazione e rilascio." Where "gatti" is the masculine plural of a cat which, in this case, is wrong.

Another type of wrong accordance was found in the translation of the following sentence: "La gangrena di Fournier è una fascite necrotizzante a rapida progressione che coinvolge il perineo, le regioni perianale e genitali e costituisce una vera emergenza chirurgica con un tasso di mortalità potenzialmente elevato" where the English version: "Fournier’s gangrene is a rapidly progressing necrotizing fasciitis involving the perineal, perianal, or genital regions and constitutes a true surgical emergency with a potentially high mortality rate." considers the "perineal [...] region" instead of the "perineum" alone.

en2ru and ru2en This year, two systems, Unbabel and DCU, participated in the Biomedical Machine Translation task. Generally, the translations to and from English were of high quality. We did not encounter examples that were completely unacceptable, aside from a few cases where text boundaries were mapped incorrectly. Compared to previous years, we observed a general improvement in how the systems handled abbreviations, which is a notable challenge in biomedical translation.

This year translations were evaluated at the abstract level, and at times determining which translation was superior often came down to small details. In some instances, we preferred one translation over another purely due to stylistic differences. There were only a handful of cases where the systems diverged significantly in quality. Overall, Unbabel outperformed DCU, as reflected by manual evaluation (Table 7 and 8) and better BLEU and COMET scores (Tables 3 and 4).

7 Conclusions

We presented the results for this year's edition of the Biomedical Translation Task at WMT, in which we considered 12 language pairs. In this paper, we described the development of the test sets, the submissions we received, our baseline system, and the details about the automatic and manual evaluation. Different from previous years, we did not split and align the sentences, instead we had the test sets simply composed of the title and abstracts of the articles.

Limitations

Concerning the quality of the extracted test sets, the passage from sentence to paragraph level is likely to require additional post-processing in future years. Whereas in previous years, sentence alignment resulted in additional validation of the extraction process, a number of errors were present in the test sets this year, resulting in more skipped evaluations. These included (i) missing or additional sentences in the reference translations with respect to the source texts, (ii) the truncation of certain sentences after special characters and subscript text, the inconsistent inclusion of headers (e.g. *Methods*, *Results*) in the abstracts and the non-capitalised of accented characters in the headers (e.g. French *RéSUMé* 'Abstract' instead of *RÉSUMÉ*), a consequence of the original source text, but which could be corrected in a post-processing step.

Ethics Statement

Our test sets were derived from PubMed, a database of biomedical citations. These publications are used in many areas of medicine, including decisions about the diagnosis and treatment of patients. Machine translation in this domain should be used as part of a larger framework that should include human experts for the interpretation of translations and, if necessary, the correction and adaptation of the generated text.

Abstract

The MSLC (Metric Score Landscape Challenge) submissions for English–German, English–Spanish, and Japanese–Chinese are constrained systems built using Transformer models for the purpose of better evaluating metric performance in the WMT24 Metrics Task. They are intended to be representative of the performance of systems that can be built relatively simply using constrained data and with minimal modifications to the translation training pipeline.

1 Introduction

Lo et al. (2023) introduced the Metric Score Landscape Challenge (MSLC) dataset for the WMT23 Metrics Task, with the goal of examining automatic MT evaluation metric performance across a wider range of quality. That work found unexpected behaviours in several MT metrics, by examining performance across a wide range of quality and by analyzing metric characteristics other than correlation. A major limitation of that work was that there was no human evaluation of the medium- to low-quality MT outputs that were included in the MSLC dataset. To resolve this disconnect between the high-quality WMT systems and the core MSLC systems, we submit the higher performing end of the MSLC systems to the WMT General MT task for human evaluation. The systems described here are not highly-competitive systems, and are useful primarily for their purpose in evaluating metrics.

We build MSLC models for three language pairs: English→German (eng→deu), English→Spanish (eng→spa), and Japanese→Chinese (jpn→zho). All models are sentence-level models that handle paragraph- or document-level translation by performing sentence splitting, translation, and then concatenating the translated sentences. They are built without any additional modifications to the Transformer architecture and without additional components like backtranslation, tagging, factors, or domain-specific features (with one exception for preprocessing input in the Japanese→Chinese speech domain). The English→German model is the same model described in Lo et al. (2023). The English→Spanish model uses language identification for training data filtering. The Japanese→Chinese model incorporates additional postprocessing.

In the remainder of this system description paper, we describe the data used (Section 2), the preprocessing and postprocessing performed (Section 3), and the models trained (Section 4) for our submissions for the three language pairs. Using the human evaluations produced by the Metrics task, we use the MSLC systems as a case study of some risks of the new automatic metric-based pre-selection of systems for human annotation at the General MT task (Section 5).

2 Data

We retrieved the corpora using the provided tool `mtdata==0.4.1` (Gowda, 2024) for eng→spa and jpn→zho and reused what we had downloaded (without the use of the tool) from the 2023 data download table for eng→deu.

2.1 English→German

We re-used the English→German model from Lo et al. (2023), and refer the reader to that paper for full details of the training data used. The *newstest2020* data was used for validation, and the training corpora were downloaded from the WMT 2023 General Machine Translation download table.[1]

[1] https://www2.statmt.org/wmt23/translation-task.html#download. Note that this includes `News Commentary v18.1` rather than `v16`, which the download tool delivered. By email communication with the organizers, we confirmed that both versions were permitted for the constrained track.

2.2 English→Spanish

We used some of the available corpora for the General Machine Translation constrained track[2] and filtered based on language ID (due to large amounts of target-side English in some training corpora). We opted not to use *OPUS-multiccaligned-v1*, *ParaCrawl-paracrawl-9*, *Statmt-ccaligned-1* and *Statmt-commoncrawl_wmt13-1*, due to known issues of noise in web-crawled corpora; for more discussion see, i.a., Khayrallah and Koehn (2018); Lo et al. (2018); Kreutzer et al. (2022). The full set of corpora used is shown in Table 1.

As a first filtering step, we kept sentence pairs where sentences have less than or equal to 4000 characters and less or equal to 200 words. We then proceeded with a second filtering step. For each corpora, we used `lingua-language-detector==2.0.2` (M. Stahl, 2023) in two ways. First, we ran `lingua` in a constrained bilingual mode, limiting the available languages to only English and Spanish. Second, we ran it again but this time in an unconstrained mode where it had to guess the language using all of its supported languages. We then did the final filtering by dropping sentence pairs if any of the following were true:

1. the source English sentence wasn't detected as English by both modes of `lingua`
2. the target Spanish sentence wasn't detected as Spanish by both modes of `lingua`
3. both sentences were identical

While we did not perform ablation experiments to compare these steps for filtering by language ID, we note that this process of filtering was introduced due to the observation of English output observed (by manual inspection) in our preliminary systems. Introducing this filtering resulted in output that was qualitatively observed to contain much less English text.

Finally, with a restricted subset of the initially chosen corpora, we sampled 20,000,000 sentence pairs from the corpora listed in Table 1 using the implementation of reservoir sampling in Larkin (2024) with 2024 as the seed.

We used *Statmt-newstest-2012-eng-spa* as our *validation* set, as suggested by `mtdata.recipes.wmt24-constrained.yml`.

2.3 Japanese→Chinese

We fetched all `jpn`→`zho` corpora available for WMT24's General Machine Translation.[3] We sampled 2000 sentence pairs for *validation* and 2000 sentence pairs for *test* (unused) from *Facebook-wikimatrix-1*, *Neulab-tedtalks_train-1*, *OPUS-wikimedia-v20210402*, *Statmt-news_commentary-18.1*. The remaining sentence pairs and all sentence pairs listed in the corpora of the second part of Table 2 were included in *train*.

3 Preprocessing and Postprocessing

There are two main types of preprocessing performed: subword segmentation (Section 3.1), which is perfomed on both the training data and the test data, and sentence splitting (Section 3.2) which is performed only on the WMT test data (as our models are trained primarily as sentence-level systems and should thus be applied to sentences rather than the full paragraphs and documents supplied at test time). We also describe the postprocessing that we performed (Section 3.3).

3.1 Subword Segmentation (Train and Test)

For details on our subword segmentation approach for `eng`→`deu`, see Lo et al. (2023). Our subword segmentation approach for `eng`→`spa` and `jpn`→`zho` is described here. To segment the corpora, a separate bilingual tokenizer (`SentencePieceUnigramTokenizer`) for each language pair was trained using HuggingFace's tokenizers (Moi and Patry, 2022), library version `0.14.1`. For each language pair, the vocabulary size was set to 32k tokens. Each tokenizer performs:

- control character and white space normalizations through HuggingFace's `Nmt`[4]
- NFKC normalization using HuggingFace's `NFKC`[5]
- and also applies a few normalizations done by Portage (Larkin et al., 2022). Some of these may overlap with the other normalization steps; see Appendix A.

Table 2: Number of sentence pairs in each `jpn`→`zho` corpus. Corpora in the first part (*Facebook-wikimatrix-1* to *Statmt-news_commentary-18.1*) were used to sample *validation* and *test*. All corpora, except for the sentence pairs in *validation* and *test* were use for *train*.

The Neural Machine Translation (NMT) vocabulary is also augmented with 25 generic tokens (unused in these experiments); this yields a final vocabulary of 32029 tokens.

To train the `eng`→`spa` tokenizer, we used all training corpora provided except for *Facebook-wikimatrix-1*, *LinguaTools-wikititles-2014*, *OPUS-multiccaligned-v1*, *OPUS-wikimatrix-v1*, *OPUS-wikimedia-v20210402*, *OPUS-wikipedia-v1.0*, *OPUS-xlent-v1.1*, *ParaCrawl-paracrawl-9*, *Statmt-ccaligned-1*.

We used all 40 corpora available to train the `jpn`→`zho` subtokenizer model.

3.2 Sentence Splitting (Test-Only)

This year's General News Task test segments consist of paragraphs. To match our system's training configuration, we first split the paragraphs and documents into sentences before performing subword segmentation and translation for all language pairs. We do this for both the official test set and the test suites. We used `utokenize.pl` from Larkin et al. (2022) to sentence split the English segments of `eng`→`deu` and `eng`→`spa`. Since `utokenize.pl` doesn't support Japanese, we used `ersatz` (Wicks and Post, 2021) for `jpn`→`zho`. The speech documents in `jpn`→`zho` contain some punctuation but, in some cases, utterances appear to be separated only by spaces. For this domain only, we first split sentences using `ersatz` then followed this with a heuristic of splitting on spaces. We kept track of each sentence's segment and document ID to later enable us to reconstruct the translations into their corresponding segment.

After sentence splitting is complete, we apply the subword segmenters described in Section 3.1 and perform translation at the level of the sentence. Since we perform sentence splitting of the source, the original source segments (paragraphs and documents) have to be reconstructed. We take this sentence-level output and concatenate the sentences belonging to a given input segment back together; for English→German and English→Spanish, we insert a space between sentences, while for Japanese→Chinese we concatenate without spaces.

3.3 Postprocessing (Test-Only)

In two cases, we performed additional postprocessing to handle issues specific to a language pair and/or a domain (as our training and validation data is more news-focused).

3.3.1 English→Spanish

Our eng→spa translations contained some <unk> that clearly aligned to an emoji in the source (likely due to our training data not having strong coverage of social media domains). As a custom postprocessing step for eng→spa, we replaced the first <unk> with the first emoji in the source, the second <unk> with the second emoji and so on. For <unk> that did not have an emoji, they were considered spurious and were simply removed. Any extra emojis that couldn't be matched to a <unk> were simply added at the end of that translation. This was done because we noticed that our system would produce a single <unk> for multiple consecutive emojis.

3.3.2 Japanese→Chinese

We noted some recurrent deficiencies in our Chinese translations. To fix those, we applied the following postprocessing steps:

- remove spaces between two Chinese characters
- remove spaces surrounding Chinese punctuation ：；，。？！
- when a Chinese character is repeated three or more times in a row, replace this with a single instance of that character
- fold repeating quotation marks onto a single quotation mark

4 MT System

We train all NMT models using Sockeye version `3.1.31` (Hieber et al., 2022), commit `13c63be5`, with PyTorch `1.13.1` (Paszke et al., 2019). Training was performed on 4 `Tesla V100-SXM2-32GB` GPUs. Table 3 lists the parameter settings in our experiments that differ from the Sockeye defaults.

We train the models until convergence which is defined as no improvement in BLEU (Papineni et al., 2002; Post, 2018) for 32 checkpoints (when a model reaches this definition of convergence, training stops). The jpn→zho model trained for 390 checkpoints yielding its best checkpoint at update 358 and a BLEU score of 34.3 as reported on OCELoT over the WMT General Test Set. The eng→spa model trained for 832 checkpoints yielding its best checkpoint at update 800 and a BLEU score of 17.6 as reported on OCELoT over the WMT General Test Set. The eng→deu model had a score of 20.1 as reported on OCELoT over the WMT General Test Set.

5 Risks of Automatic System Selection for Human Evaluation

We submitted these systems with the intent of having them evaluated by human annotators, based on the understanding that "All submitted systems will be scored and ranked by human judgement."[6] Unfortunately, the task included a larger number of submissions than anticipated (Kocmi et al., 2024), resulting in the decision to remove some systems from human evaluation, as per the note in the evaluation section of the task page: "In the unlikely event of an unprecedented number of system submissions that we couldn't evaluate, we may decide to preselect the best performing systems for human evaluation with automatic metrics (such as COMET), we will primarily remove closed systems from the evaluation. However, we believe this won't be applied and all primary systems will be evaluated by humans." Among these, our submitted eng→deu and jpn→zho systems were removed from human evaluation, leaving only the eng→spa system to receive human evaluation by the General Task evaluation process.

However, all three of our submitted systems were evaluated using MQM (Multidimensional Quality Metrics; Lommel et al., 2013) by the Met-

(c) English→German

Figure 1: MQM scores on the News portion of the General MT test data, produced by the Metrics Task over a subset of the submitted WMT systems. Error bars represent bootstrap resampling, 1000 times, for $p < 0.05$. In all cases, our MSLC system appears at the far left of the plots, which are ordered by mean segment-level MQM score.

rics Shared Task. This offers a rare opportunity to examine the risks of selecting a subset of systems for human evaluation by using automatic metrics. In Fig. 1, we observe that the human rankings produced by MQM differ enough from the predicted rankings that they arguably demonstrate exactly the two types of errors one might be concerned about making: including a poorer quality system in human evaluation and, worse, failing to include a system with substantial confidence interval overlap with a system that was included for evaluation. In the first case, our `eng`→`spa` system, which was included for evaluation, appears substantially worse than other systems evaluated by MQM (Fig. 1a); however, we do note that IKUN-C, which could conceivably bridge the gap, was not included for evaluation by the Metrics Task, so it is possible that this does not represent an error. Unfortunately, without either human evaluation containing both, it is unlikely we can reach a definitive answer. In the second case, our `jpn`→`zho` system was excluded from human evaluation by the General MT task but IKUN-C was included for General MT task evaluation. In Fig. 1b, we can see that there is substantial confidence interval overlap between the MQM scores for the MSLC `jpn`→`zho` system and the IKUN-C system. We note that there are stronger ways to more definitively make this comparison (e.g., to do pairwise significance tests), but we primarily provide these examples for discussion and consideration. Finally, the `eng`→`deu` appears to represent the successful intended result of this approach to filtering sytems (Fig. 1c).

This highlights the risks of the mismatches between automatic evaluation and human evaluation; it may be better to perform some sort of smaller-scale initial human evaluation to separate systems rather than doing so based on automatic metrics.

6 Conclusion

We have built simple Transformer NMT models, primarily for the purpose of the MSLC dataset at the Metrics Task. We submit them to the WMT General Task to enable human evaluation, which will be useful to better understand how metrics perform and compare to human evaluation on a wider range of MT output quality. Of the three submitted systems, only one was included for human evaluation in the shared task.

Limitations

As described, we submit extremely simple models, with minimal additional modifications. As our focus for MSLC is on news data, we expend only minimal effort on additional domains. We submit only three language pairs. We would not recommend the use of these MT systems outside of their intended uses for metric evaluation in MSLC.

Ethics Statement

We build constrained MT systems, using the permitted training data from WMT24. Since our goal in this work is to build systems to be used to evaluate metrics across a wider range of translation quality, we expect that these systems may have a number of problems, including but not limited to: producing errors in translation, producing output in dialects (or languages) other than the desired ones, or otherwise produced biased output. We do not recommend their use for purposes other than the intended purpose of MSLC; their limitations for that purpose are discussed in more depth in the corresponding Metrics Task submission.

Acknowledgements

We thank the WMT General Task organizers for their clarifications regarding data for the constrained task. We thank the WMT Metrics Task organizers for including our systems in their MQM human evaluation, to enable us to use those results to better understand the performance of automatic metrics across a range of MT quality.

IOL Research Machine Translation Systems for WMT24 General Machine Translation Shared Task

Wenbo Zhang, Qiaobo Deng, Zeyu Yan, and **Hongbao Mao**
Transn IOL Research, Wuhan, China

Abstract

This paper illustrates the submission system of the IOL Research team for the WMT24 General Machine Translation shared task. We submitted translations for all translation directions in the general machine translation task. According to the official track categorization, our system qualifies as an open system due to the utilization of open-source resources in developing our machine translation model. With the growing prevalence of large language models (LLMs) as a conventional approach for managing diverse NLP tasks, we have developed our machine translation system by leveraging the capabilities of LLMs. Overall, we first performed continued pretraining using the open-source LLMs with tens of billions of parameters to enhance the model's multilingual capabilities. Subsequently, we employed open-source Large Language Models, equipped with hundreds of billions of parameters, to generate synthetic data. This data was then blended with a modest quantity of additional open-source data for precise supervised fine-tuning. In the final stage, we also used ensemble learning to improve translation quality. Based on the official automated evaluation metrics, our system excelled by securing the top position in 8 out of the total 11 translation directions, spanning both open and constrained system categories.

1 Introduction

In the current year's WMT General Machine Translation shared task, our team, IOL Research, took part in all 11 translation tasks, which involved translating text between various language pairs such as Czech to Ukrainian (cs->uk), Japanese to Chinese (ja->zh), English to Chinese (en->zh), English to Czech (en->cs), English to German (en->de), English to Hindi (en->hi), English to Icelandic (en->is), English to Japanese (en->ja), English to Russian (en->ru), English to Spanish (en->es), and English to Ukrainian (en->uk). One notable difference in this year's task compared to previous years is that participants were required to translate paragraph-level texts, with one paragraph equating to one line. This change has significantly increased the length of the text to be translated. While traditional neural machine translation systems (Vaswani et al., 2017) based on encoder-decoder structures may struggle with processing long texts due to the lack of enough document parallel data. However, the large language models (LLMs) do not necessitate a large amount of lengthy text data for fine-tuning, making them more effective in handling long texts. As a result, we meticulously trained an LLM with 20 billion parameters to successfully address all translation tasks in the competition.

Our main strategy is to explore using LLMs to build machine translation systems. This includes fine-tuning the translation task on foundational LLMs and leveraging advanced open-source instruction-tuned LLMs to generate high-quality translation data for further enhancement. Before supervised fine-tuning, we also performed continued pretraining, which has been proven to be very beneficial for translation tasks (Xu et al., 2023), because many open-source LLMs such as LLaMA (Touvron et al., 2023) are usually pretrained on English monolingual data, lacking the necessary knowledge of other languages required for translation tasks. Moreover, we experimented with ensemble learning, a technique known to be effective for neural machine translation models. We discovered that it provided some degree of assistance for machine translation tasks based on LLMs. In the end, our billion-parameter machine translation system achieved comparable performance to hundred billion parameter LLMs in high-resource languages and even outperformed them in certain low-resource languages.

The subsequent paper is designed as follows. We introduce the data source and processing strategy in Section 2; Section 3 describes the details of our training procedure; Section 4 presents the experi-

mental settings and results.

2 System Overview

2.1 Model Architecture

We selected the Qwen1.5 model (Bai et al., 2023) as our foundational model because of its outstanding performance and considerable multilingual capabilities. Specifically, we utilized the Qwen1.5-14B[1] as our starting point, which has 40 layers and 14 billion parameters. To enhance the model's capacity within our hardware constraints, we concatenated the first 32 layers with the last 32 layers, resulting in duplication of the middle 24 layers, following the approach used in SOLAR (Kim et al., 2023). This fusion led to a scaled-up model with 64 layers and 21 billion parameters. Since this approach alters the structure of the pretrained model, continual pretraining becomes a necessary step to recover its performance.

2.2 Continual Pretraining

Continual pretraining is an effective method to enhance the knowledge embedded within LLMs. This method has been extensively utilized to adapt LLMs from English to various other languages, as well as to augment the domain-specific knowledge inherent in these models. In the context of using LLMs for translation tasks, it has been substantiated that the continuous pretraining of LLMs with multilingual monolingual data, encompassing languages involved in all the translation directions, is crucial (Xu et al., 2023). This year's WMT24 general machine translation task includes 11 translation directions, involving 10 distinct languages. Therefore, our continued pretraining is carried out on monolingual data in these 10 languages.

We sampled the required multilingual monolingual data from the mC4 (Raffel et al., 2019) and OSCAR (Jansen et al., 2022) datasets, then proceeded to refine the chosen data. For refinement processes, we employed fastText (Joulin et al., 2017) for language identification, the minLSH algorithm for document deduplication, and KenLM (Heafield, 2011) tool for filtering the documents with high perplexity. Many studies (Lin et al., 2020; Yang et al., 2021) have shown that integrating bilingual data with monolingual data in the pretraining stage can help the model achieve better cross-lingual proficiency. Therefore, we also incorporated a portion of the CC-Aligned parallel data (El-Kishky et al., 2019) into our continuous pretraining stage. This data includes language pairs such as English-Czech, English-Ukrainian, English-Japanese, English-Chinese, English-German, English-Hindi, English-Icelandic, English-Russian, and English-Spanish. Specifically, we randomly swapped the order of the two articles in the bilingual document, and then merged them into a new document as the pretraining document. The distribution of the number of documents in all languages in the pretraining dataset is shown in Table 1.

Language	Rate(%)
en	21.99
ja	15.02
de	12.48
cs	11.60
es	10.35
zh	9.32
uk	7.98
ru	7.2
hi	3.53
is	0.47

Table 1: The distribution of the number of documents in all languages in the pretraining dataset.

2.3 Supervised Fine-tuning

Through supervised Fine-tuning, we can unlock the capabilities of LLMs using only a minimal amount of aligned data. Many fine-tuning LLMs experiences (Zhou et al., 2024; Xia et al., 2024) have demonstrated that the quality and diversity of fine-tuning data are far more important than its quantity. In the context of translation tasks, high-quality parallel data is the ideal fine-tuning data for LLMs. However, obtaining such high-quality parallel data is challenging. Usually, we need to invest significant effort and undergo numerous steps to clean publicly available parallel data, aiming to achieve high-quality data. However, this process does not always guarantee the quality of filtered data due to its inherent complexity. On the other hand, start-of-the-art machine translation systems have shown competitive performance comparable to human translators. Consequently, we opted to employ LLMs to generate parallel data as the supervised fine-tuning data.

We used the c4ai-command-r-plus[2] and

[1] https://huggingface.co/Qwen/Qwen1.5-14B

[2] https://huggingface.co/CohereForAI/c4ai-command-r-

Qwen1.5-110B-Chat[3], these two instruction fine-tuned models, to generate synthetic parallel data for all languages, with the exception of Icelandic. Specifically, when the task requires generating Chinese content, our go-to model is the Qwen1.5-110B-Chat. However, for English content generation, we make a random selection between the Qwen1.5-110B-Chat and c4ai-command-r-plus models. For all other scenarios, we consistently utilize the c4ai-command-r-plus model. The selection of models in different languages is based on our evaluation of these two models in translation tasks. Please refer to Table 3 for specific comparison. Considering the lack of proficiency of both c4ai-command-r-plus and Qwen1.5-110B-Chat in generating Icelandic content, we adopted an alternative strategy. We leveraged our supervised fine-tuning model, which has been fine-tuned on synthetic data of all other languages, to produce the synthetic data for Icelandic. Therefore, our model only utilized Icelandic monolingual data for pre-training, and the Icelandic bilingual synthesis data was generated by unsupervised method.

We have tried two synthetic data generation methods commonly used in traditional neural machine translation systems, forward translation (Kim and Rush, 2016) and back translation (Sennrich et al., 2016). Forward translation refers to using the established translation model to translate real source language sentences into target language sentences, and then combining the translated target language sentences with the real source language sentences to form synthetic parallel sentence pairs. Back translation refers to translating real target language sentences back into the source language using another established reverse translation model, and then combining the real target language sentences with the translated source language sentences to form synthetic parallel sentence pairs. In the process of generating back translation data based on real target language data, we found that the real target language data has many problems such as incoherence, fluency deficits, and even grammatical errors. To address these problems, we utilized automatic post-editing technology. This approach involves taking the translated source language sentences and the real target language sentences as inputs, and subsequently producing superior quality target language sentences. These improved sentences are then used to replace the real target language sentences in the back translation synthetic data. Lastly, we also utilized LLMs to filter all the generated synthetic data, including both forward and back translation data, to ensure higher quality fine-tuning data. All the prompts we use to generate synthetic data are shown in the table 2. For each language pair, after filtering, we retained around 100,000 FT and BT sentence pairs respectively.

In addition to synthetic data, we also incorporated document parallel data from News Commentary v18.1[4], which assists the model in translating long text, and instruction fine-tuning data TowerBlocks-v0.2 (Alves et al., 2024) to help the model follow more diverse instructions. The News Commentary v18.1 data we used includes sections ja-zh, en-zh, en-de, en-hi, en-ja, en-ru, en-es, en-cs, cs-ru, cs-de, cs-es, cs-hi, cs-ja, cs-zh, and ja-ru. We also excluded the data from TowerBlocks-v0.2 that includes FLoRes (Goyal et al., 2021), and the NTREX-128 (Federmann et al., 2022) sections, as we used these two datasets as our test sets to verify the performance of the model.

2.4 Ensemble Learning

The ensemble learning approach has demonstrated significant efficacy in a wide range of machine learning tasks. In machine translation tasks, ensemble learning completes the generation of the entire translation by using multiple different machine translation models to autoregressively vote for the probability distribution of the next word. However, for LLMs, this method implies a huge memory occupancy and computational resource consumption, so we use transductive ensemble learning (Wang et al., 2020) to replace this way of generating with multiple models simultaneously. Transductive ensemble learning first utilizes multiple different translation models to generate translations for the same test set separately, then aggregates all translations as fine-tuning data. The final translation is generated by one translation model after fine-tuning on this data. Ensemble learning conventionally entails training diverse models via different random initializations. However, this approach proves inefficient in our context, as we are mandated to employ the identical pre-trained model for supervised fine-tuning. Therefore, we used dif-

ferent fine-tuning data to train multiple models for ensemble learning. Different fine-tuning data is obtained by randomly sampling synthesized data from different parts.

3 Experiments

3.1 Experiment Settings

For continual pretraining phase, we trained the scaled-up model with 21 billion parameters on 8 NVIDIA H800 GPUs. For the optimization process, we employed the Adam optimizer (Kingma and Ba, 2014), with $\beta 1 = 0.9, \beta 2 = 0.99$. We adopted a learning rate scheduling strategy that remained constant after warmup phase, setting the number of warmup steps to 200, the maximum learning rate at 0.00001 and weight decay to 0.1. The batch size was set to 3.14 million tokens, the length of each sequence was set to 4096, and a total of 56 billion tokens have been trained.

For supervised fine-tuning phase, we fine-tuned the continual pretrained model on 16 NVIDIA H800 GPUs. We leveraged the Adam optimizer for the optimization process, setting $\beta 1 = 0.9, \beta 2 = 0.99$. We employed a cosine learning rate scheduling strategy, with a warmup ratio of 0.01, a peak learning rate at 0.000007, and a weight decay of 0.1. Configuring the batch size to 480 sentences, we trained the model for a single epoch encompassing approximately 1.5 million sentences.

When conducting transductive ensemble learning, we increased the batch size to 800 sentences, adopted a fixed learning rate, and reduced the learning rate to 0.000001. Similarly, we only fine-tune for one epoch on the ensemble data.

3.2 Results

The FLoRes (Goyal et al., 2021) and NTREX-128 (Federmann et al., 2022) test sets were utilized as our evaluation benchmarks. The performance of the machine translation system was assessed using SacreBLEUpost-2018-call and COMET (Rei et al., 2022)[5] metrics. We uesed vLLM (Kwon et al., 2023) to infer all LLMs. We chose c4ai-command-r-plus and Qwen1.5-110B-Chat as our baselines for comparison, and all results were obtained through zero-shot evaluation.

Test results on the FLoRes test set for all translation directions are shown in Table 3. We used greedy decoding and beam search with beam size = 5 to generate translations for our model, and provided the ensemble effect on this test set. It is clear that, just like traditional neural machine translation models, beam search performs better than greedy decoding in terms of BLUE and COMET scores across all translation directions. Ensemble learning has a steady improvement on BLEU scores, but the overall change in COMET scores is not significant. Compared with the two baseline systems CMD-R-P and Qwen1.5-L, our model achieved equivalent or better performance in the seven directions of cs→uk, en→zh, en→de, en→hi, en→is, en→uk, and en→cs. The performance outcomes presented in Table 4 are based on evaluations conducted using the NTREX-128 test set. These results mirror those observed in the FLoRes test set, indicating a consistent performance trend across both datasets.

3.3 Forward Translation vs Back Translation

To determine the effectiveness of forward translation versus back translation, we separately finetuned the continual pretrained model using forward translation data, back translation data, and a combination of both. For each approach, we randomly chose 80,000 data samples per language translation direction. For the combined dataset, we selected 40,000 samples from both the forward translation and back translation pools. The results are presented in Table 5, all of which were generated using beam search. We can see that the back translation yields better performance, whereas mixed data does not result in significant improvement. Due to time constraints, we used mixed data in the WMT24 competition, this conclusion will guide us to further improve our model in the future.

4 Conclusion

In this paper, we present IOL Research's contributions to the WMT24 General Translation shared task, covering all translation aspects. Our approach utilizes LLMs to develop an effective translation system. Experimental results demonstrate that our model, which contains 21 billion parameters, achieves competitive results comparable to models with 100 billion parameters. According to the official automatic evaluation metrics (Kocmi et al., 2024), our system achieved 8 first places in 11 translation directions spanning both open and constrained system categories, including Czech to Ukrainian, English to German, English to Spanish, English to Hindi, English to Russian, English to Ukrainian, English to Chinese, and Japanese to Chinese.

Abstract

This paper presents the submission of Huawei Translate Services Center (HW-TSC) to the WMT24 general machine translation (MT) shared task, where we participate in the English to Chinese (en→zh) language pair. Similar to previous years' work, we use training strategies such as regularized dropout, bidirectional training, data diversification, forward translation, back translation, alternated training, curriculum learning, and transductive ensemble learning to train the neural machine translation (NMT) model based on the deep Transformer-big architecture. The difference is that we also use continue pre-training, supervised fine-tuning, and contrastive preference optimization to train the large language model (LLM) based MT model. By using Minimum Bayesian risk (MBR) decoding to select the final translation from multiple hypotheses for NMT and LLM-based MT models, our submission receives competitive results in the final evaluation.

1 Introduction

Machine translation (MT) (Brown et al., 1990) predominantly utilizes transformer encoder-decoder architectures (Vaswani et al., 2017), which is evident in prominent models such as NLLB-200 (Costa-jussà et al., 2022), M2M100 (Fan et al., 2021), and MT5 (Xue et al., 2021). Significant research effort has been devoted to task-specific neural machine translation (NMT) models (Wei et al., 2022; Wu et al., 2023b) trained in a fully supervised manner with large volumes of parallel data. Their performance has been enhanced through techniques such as regularized dropout (Wu et al., 2021), bidirectional training (Ding et al., 2021), data diversification (Nguyen et al., 2020), forward translation (Abdulmumin, 2021), back translation (Sennrich et al., 2016), alternated training (Jiao et al., 2021), curriculum learning (Zhang et al., 2019), and transductive ensemble learning (Wang et al., 2020b).

The emergence of decoder-only large language models (LLMs) such as the GPT series (Wu et al., 2023a; Achiam et al., 2023), Mistral (Jiang et al., 2023), and LLaMA (Touvron et al., 2023a,b) shows remarkable efficacy in various NLP tasks, providing a fresh perspective on the MT task. Recent studies (Hendy et al., 2023; Jiao et al., 2023) indicate that larger LLMs such as GPT-3.5 (175B) and GPT-4 exhibit strong translation abilities. However, the performance of smaller-sized LLMs (7B or 13B) still falls short when compared to conventional NMT models (Zhu et al., 2024). Therefore, there are studies (Yang et al., 2023; Zeng et al., 2024) intend to enhance the translation performance for these smaller LLMs, but their improvements are relatively modest, primarily due to the predominant pre-training of LLMs on English-centric datasets, resulting in limited linguistic diversity. Addressing this limitation, Xu et al. (Xu et al., 2023) initially continue pre-training (CPT) LLaMA-2 (Touvron et al., 2023b) with extensive non-English monolingual data to enhance their multilingual abilities, and then perform supervised fine-tuning (SFT) with high-quality parallel data to instruct the model to generate translations. Nonetheless, the performance still lags behind leading translation models such as GPT-4 and WMT competition winners. Subsequently, Xu et al. (Xu et al., 2024) bridged this gap by further fine-tuning the LLM-based MT model using contrast preference optimization (CPO).

Ensembling (Zhou et al., 2002) has a long history in machine learning, being well known for leveraging multiple complementary systems to improve performance on a given task and provide good/robust generalization. Minimum Bayesian risk (MBR) (Finkelstein and Freitag, 2023; Farinhas et al., 2023) decoding has successfully improved translation quality using task-specific NMT models, and subsequently it has also been shown to be suitable for LLM-based MT models.

For the WMT24 general MT shared task, we participate in the en→zh language pair. Similar to previous years' work (Wei et al., 2021, 2022; Wu et al., 2023b), we use training strategies such as regularized dropout (Wu et al., 2021), bidirectional training (Ding et al., 2021), data diversification (Nguyen et al., 2020), forward translation (Abdulmumin, 2021), back translation (Sennrich et al., 2016), alternated training (Jiao et al., 2021), curriculum learning (Zhang et al., 2019), and transductive ensemble learning (Wang et al., 2020b) to train NMT models based on the deep transformer-big architecture. In addition, we use CPT, SFT and CPO methods to train LLM-based MT models. Finally, we use MBR decoding to select the final translation from multiple hypotheses of NMT and LLM-based MT models.

2 Data

2.1 Data Source

We obtain bilingual and monolingual data from ParaCrawl v9, News Commentary v18.1, Wiki Titles v3, UN Parallel Corpus V1.0, CCMT Corpus, WikiMatrix, News Crawl and Common Crawl data sources. The amount of data we used for training NMT and LLM-based MT models is shown in Table 1. It should be noted that in order to obtain better translation performance in the general domain, we mix the monolingual data from Common Crawl and News Crawl.

2.2 NMT Data Pre-processing

Our data pre-processing methods for NMT include:

- Remove duplicate sentences or sentence pairs.
- Convert full-width symbols to half-width.
- Use fasttext[1] (Joulin et al., 2016) to filter other language sentences.
- Use jieba[2] to pre-segment Chinese sentences.
- Use mosesdecoder[3] (Koehn et al., 2007) to normalize English punctuation.
- Filter out sentences with more than 150 words.
- Use fast-align (Dyer et al., 2013) to filter sentence pairs with poor alignment.
- Sentencepiece[4] (SPM) (Kudo and Richardson, 2018) is used to perform subword segmentation, and the vocabulary size is set to 32K.

Since there may be some semantically dissimilar sentence pairs in bilingual data, we use LaBSE[5]

[1] https://github.com/facebookresearch/fastText
[2] https://github.com/fxsjy/jieba
[3] https://github.com/moses-smt/mosesdecoder
[4] https://github.com/google/sentencepiece
[5] https://huggingface.co/sentence-transformers/LaBSE

(Feng et al., 2022) to calculate the semantic similarity of each bilingual sentence pair, and exclude bilingual sentence pairs with a similarity score lower than 0.7 from our training corpus.

2.3 LLM-based MT Data Pre-processing

The training of the LLM-based MT model requires three stages: CPT, SFT and CPO. As shown in Figure 1, the training data templates of the LLM-based MT model in these three stages are different.

In the CPT stage, considering that most LLMs are trained on English-dominated data, we using Chinese and English monolinguals for CPT to improve LLM's proficiency in Chinese. To preserve the long-context modeling capability of LLM, we concatenate multiple sentences into a long text with no more than 4096 words, and preferentially concatenate sentences from the same document.

In the SFT stage, drawing inspiration from the recognized significance of data quality in other applications (Zhou et al., 2024; Maillard et al., 2023), we fine-tune the model with high-quality parallel data. In order to obtain high-quality parallel data, we use cometkiwi model [6] (Rei et al., 2022) to calculate the score of bilingual data on the en→zh language pair, and then retain bilingual data with a cometkiwi score greater than 0.8.

In the CPO stage, to learn an objective that fosters superior translations and rejects inferior ones, access to labeled preference data is essential, yet such data is scarce in machine translation. The following describes our process of constructing the triplet preference data required for CPO training. First, we randomly sample 50,000 data from high-quality bilingual data. Then, we use the NMT model to obtain N-best (N=10) hypotheses based on beam search decoding, and then use the comet-da model[7] (Rei et al., 2020) to calculate the score of each hypothesis, select the hypothesis with the highest score as the preferred translation, and select the hypothesis with the lowest score as the dis-preferred translation.

3 NMT System

3.1 System Overview

Transformer is the state-of-the-art model structure in recent NMT evaluations. There are two parts of research to improve this kind: the first part uses wide networks (eg: Transformer-Big (Vaswani et al., 2017)), and the other part uses deeper language representations (eg: Deep Transformer (Wang et al., 2019)). For the WMT24 general MT shared task, we combine these two improvements, adopting the Deep Transformer-Big (Wei et al., 2022; Wu et al., 2023b) model structure to train the NMT system. Deep Transformer-Big uses pre-layer normalization, features 25-layer encoder, 6-layer decoder, 16-heads self-attention, 1024-dimensional word embedding and 4096-dimensional FFN embedding.

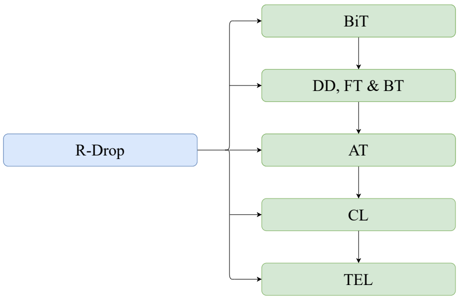

Figure 2: The overall training flow of NMT system.

Fig. 2 shows the overall training flow of NMT system. We use training strategies such as regularized dropout (R-Drop) (Wu et al., 2021), bidirectional training (BiT) (Ding et al., 2021), data diversification (DD) (Nguyen et al., 2020), forward translation FT) (Abdulmumin, 2021), back translation (BT) (Sennrich et al., 2016), alternated training (AT) (Jiao et al., 2021), curriculum learning (CL) (Zhang et al., 2019), and transductive ensemble learning (TEL) (Wang et al., 2020b) for training.

3.2 Regularized Dropout

Regularized Dropout (R-Drop)[8] (Wu et al., 2021) is a simple yet more effective alternative to regularize the training inconsistency induced by dropout (Srivastava et al., 2014). Concretely, in each mini-batch training, each data sample goes through the forward pass twice, and each pass is processed by a different sub model by randomly dropping out some hidden units. R-Drop forces the two distributions for the same data sample outputted by the two sub models to be consistent with each other, through minimizing the bidirectional Kullback-Leibler (KL) divergence (Van Erven and Harremos, 2014) between the two distributions. That is, R-Drop regularizes the outputs of two sub models ran-

[6] https://huggingface.co/Unbabel/wmt22-cometkiwi-da

[7] https://huggingface.co/Unbabel/wmt20-comet-da

[8] https://github.com/dropreg/R-Drop

domly sampled from dropout for each data sample in training. In this way, the inconsistency between the training and inference stage can be alleviated.

3.3 Bidirectional Training

Many studies have shown that pre-training can transfer the knowledge and data distribution, hence improving the model generalization. Bidirectional training (BiT) (Ding et al., 2021) is a simple and effective pre-training method for NMT. Bidirectional training is divided into two stages: (1) bidirectionally updates model parameters, and (2) tune the model. To achieve bidirectional updating, we only need to reconstruct the training samples from "src→tgt" to "src→tgt & tgt→src" without any complicated model modifications. Notably, BiT does not require additional parameters or training steps and only uses parallel data.

3.4 Data Diversification

Data Diversification (DD) (Nguyen et al., 2020) is a data augmentation method to boost NMT performance. It diversifies the training data by using the predictions of multiple forward and backward models and then merging them with the original dataset which the final NMT model is trained on. DD is applicable to all NMT models. It does not require extra monolingual data, nor does it add more parameters. To conserve training resources, we only use one forward model and one backward model to diversify the training data.

3.5 Forward Translation

Forward translation (FT) (Abdulmumin, 2021), also known as self-training, is one of the most commonly used data augmentation methods. FT has proven effective for improving NMT performance by augmenting model training with synthetic parallel data. Generally, FT is performed in three steps: (1) randomly sample a subset from the large-scale source monolingual data; (2) use a "teacher" NMT model to translate the subset data into the target language to construct the synthetic parallel data; (3) combine the synthetic and authentic parallel data to train a "student" NMT model.

3.6 Back Translation

An effective method to improve NMT with target monolingual data is to augment the parallel training data with back translation (BT) (Sennrich et al., 2016; Wei et al., 2023). There are many works expand the understanding of BT and investigates a number of methods to generate synthetic source sentences. Edunov et al. (2018) find that back translations obtained via sampling or noised beam outputs are more effective than back translations generated by beam or greedy search in most scenarios. Caswell et al. (2019) show that the main role of such noised beam outputs is not to diversify the source side, but simply to tell the model that the given source is synthetic. Therefore, they propose a simpler alternative strategy: Tagged BT. This method uses an extra token to mark back translated source sentences, which generally outperforms noised BT (Edunov et al., 2018). For better joint use with FT, we use sampling back translation (ST) (Edunov et al., 2018).

3.7 Alternated Training

While synthetic bilingual data have demonstrated their effectiveness in NMT, adding more synthetic data often deteriorates translation performance since the synthetic data inevitably contains noise and erroneous translations. Alternated training (AT) (Jiao et al., 2021) introduce authentic data as guidance to prevent the training of NMT models from being disturbed by noisy synthetic data. AT describes the synthetic and authentic data as two types of different approximations for the distribution of infinite authentic data, and its basic idea is to alternate synthetic and authentic data iteratively during training until the model converges.

3.8 Curriculum Learning

A practical curriculum learning (CL) (Zhang et al., 2019) method should address two main questions: how to rank the training examples, and how to modify the sampling procedure based on this ranking. For ranking, we choose to estimate the difficulty of training samples according to their domain feature (Wang et al., 2020a). The calculation formula of domain feature is as follows, where θ_{in} represents an in-domain NMT model, and θ_{out} represents a out-of-domain NMT model. One thing to note is that we treat domains including news, user-generated (social), conversational, and e-commerce domains as in-domain, and others as out-of-domain. Specifically, we use the WMT22 test set to fine-tune a baseline model, and then use the baseline model and the fine-tuned model as the out-of-domain model and the in-domain model respectively.

$$q(x,y) = \frac{\log P(y|x;\theta_{in}) - \log P(y|x;\theta_{out})}{|y|} \quad (1)$$

For sampling, we adopt a probabilistic CL strategy that leverages the concept of CL in a nondeterministic fashion without discarding the original standard training practice, such as bucketing and mini-batching.

3.9 Transductive Ensemble Learning

Ensemble learning (Garmash and Monz, 2016), which aggregates multiple diverse models for inference, is a common practice to improve the performance of machine learning models. However, it has been observed that the conventional ensemble methods only bring marginal improvement for NMT when individual models are strong or there are a large number of individual models. Transductive Ensemble Learning (TEL) (Zhang et al., 2019) studies how to effectively aggregate multiple NMT models under the transductive setting where the source sentences of the test set are known. TEL uses all individual models to translate the source test set into the target language space and then finetune a strong model on the translated synthetic data, which significantly boosts strong individual models and benefits a lot from more individual models.

4 LLM-based MT System

4.1 System Overview

There is recently a surge in research interests in Transformer-based LLMs, such as ChatGPT (Wu et al., 2023a), GPT-4 (Achiam et al., 2023), and LLaMA (Touvron et al., 2023a,b). Benefiting from the giant model size and oceans of training data, LLMs can understand better the language structures and semantic meanings behind raw text, thereby showing excellent performance in a wide range of natural language processing (NLP) tasks. Although the training methodology of LLMs is simple, high computational requirements have limited the development of LLMs to a few players. In order to avoid training LLM from scratch, we chose to conduct research work on the open source Llama2-13b[9] (Touvron et al., 2023b) model. Llama2-13b is an autoregressive language model using an optimized transformer architecture that is pre-trained on 2 trillion tokens of data from publicly available sources. As shown in Figure 3, we train Llama2-13b into a powerful LLM-based MT model through three-stage training of CPT, SFT and CPO.

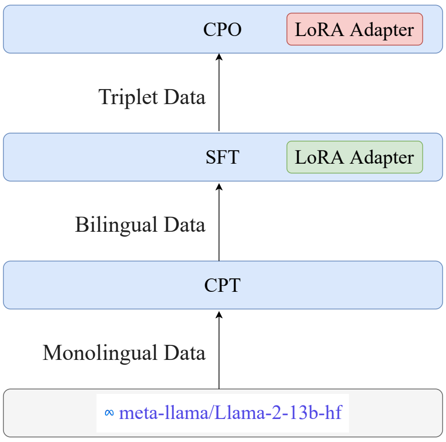

Figure 3: The training flow of LLM-based MT system.

4.2 Continue Pre-training

LLMs like LLaMA are pre-trained on English-dominated corpora. This potentially explains their inadequate translation performance which necessitates cross-lingual capabilities. To ameliorate this, our first stage is to perform continue pre-training (CPT) on LLM with Chinese and English monolingual data to improve proficiency in Chinese and prevent forgetting of English knowledge. Previous studies also offer some clues that monolingual data help in translation. For instance, guo et al. (Guo et al., 2024) proposed a three-stage training method, which proved that using CPT can improve the performance of MT task in the SFT stage. Note that we use full fine-tuning at this stage.

4.3 Supervised Fine-tuning

LLMs have shown remarkable performance on a wide range of NLP tasks by leveraging in-context learning (Brown et al., 2020). However, this approach exhibits several drawbacks: performance is highly dependent on the quality of examples (Vilar et al., 2023), outputs are plagued by overgeneration (Bawden and Yvon, 2023), and inference cost are greatly increased by processing all input pairs. When parallel data is available, LLMs can perform supervised fine-tuning (SFT) on translation instructions (Li et al., 2024). Drawing inspiration from the recognized significance of data quality in other applications (Zhou et al., 2024),we use the cometkiwi model (Rei et al., 2022) to filter out large amounts of high-quality parallel data. Here, we use efficient lightweight low-rank adaptation (LoRA) fine-

[9] https://huggingface.co/meta-llama/Llama-2-13b-hf

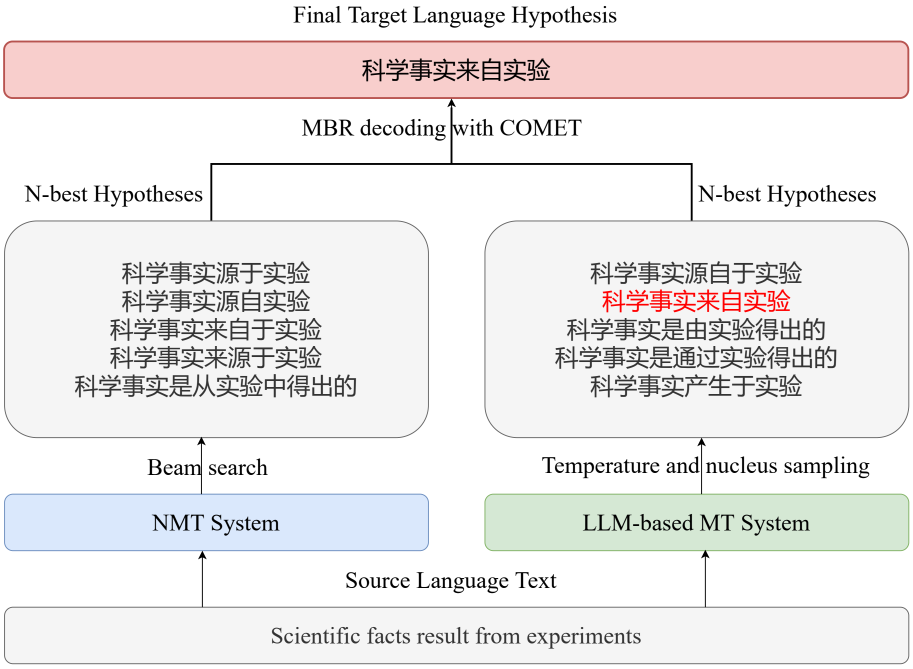

Figure 4: Choose the Final Translation from NMT and LLM hypotheses Using MBR Decoding.

tuning, where we apply LoRA to all modules of feed-forward network.

4.4 Contrastive Preference Optimization

Contrastive Preference Optimization (CPO) (Xu et al., 2024) aims to mitigate two fundamental shortcomings of SFT. First, SFT's methodology of minimizing the discrepancy between predicted outputs and gold-standard references inherently caps model performance at the quality level of the training data. This limitation is significant, as even human-written data, traditionally considered high-quality, is not immune to quality issues. Secondly, SFT lacks a mechanism to prevent the model from rejecting mistakes in translations. While strong translation models can produce high-quality translations, they occasionally exhibit minor errors, such as omitting parts of the translation. Preventing the production of these near-perfect but ultimately flawed translation is essential. To overcome these issues, we introduce CPO to train the LLM-based MT model using specially curated triplet preference data. Here, we construct a high-quality preference data for the WMT24 general MT task, and like the SFT stage, only update the weights of the added LoRA parameters.

4.5 Minimum Bayes Risk Decoding

Minimum Bayesian Risk (MBR) (Kumar and Byrne, 2004; Eikema and Aziz, 2020) decoding aims to find the output that maximizes the expected utility function, which measures the similarity between the hypothesis and the reference. For MT, this could be an automated evaluation metric such as COMET (Rei et al., 2020). Garcia et al. (Garcia et al., 2023) train their own language models, sample multiple hypotheses and choose a final translation using MBR decoding, which has been shown to improve the translation capabilities of task-specific models (Fernandes et al., 2022). Subsequently, Farinhas et al. (Farinhas et al., 2023) find that MBR is also suitable for LLM-based MT. They provide a comprehensive study on ensembling translation hypotheses, proving that MBR decoding is a very effective method and can improve translation quality using a small number of samples. As shown in Figure 4, we simultaneously collect the N-best translations generated by the NMT system based on beam search and the N-best translations generated by the LLM-based MT system based on temperature and nucleus sampling (with t=0.8 and p=0.95), and then use MBR Decoding selects the final translation.

5 Experiment

5.1 Setup

We use the open-source fairseq (Ott et al., 2019) to train NMT models, and then use SacreBLEU

(Post, 2018)[10] and wmt20-comet-da model (Rei et al., 2020) to measure system performance. The main parameters are as follows: each model is trained using 8 GPUs, batch size is 6144, parameter update frequency is 2, and learning rate is 5e-4. The number of warmup steps is 4000, and model is saved every 1000 steps. The architecture we used is described in section 3.1. We adopt dropout, and the rate varies across different training phases. R-Drop is used in model training, and we set λ to 5.

We use Llama2-13B as the backbone model of our LLM-based MT system. In our three-stage training process, the first stage uses full fine-tuning, and the last two stages use LoRA fine-tuning. If LoRA is used, lora_rank is 32, lora_alpha is 64, lora_dropout is 0.05, and lora_modules are "q_proj", "v_proj", "k_proj", "o_proj", "gate_proj", "down_proj", "up_proj". Furthermore, in the first and third stages, we use open-source ALMA [11] for training, while in the second stage, we use open-source llama-recipes [12] for training. The parameters during training are the default configurations of the corresponding codes.

5.2 Results

Tables 2 shows the evaluation results of en→zh NMT systems and LLM-based MT systems on WMT23 general test sets. On NMT systems, we use BiT and R-Drop to build a strong baseline, then use DD, FT and ST for data enhancement, and use AT and CL for more efficient training, and finally use TEL to ensemble multiple models ability. On LLM-based MT systems, we use CPT and SFT to build a strong baseline, and use CPO for further optimization. To ensemble two different types of translation systems, we use MBR decoding to select the final translation, which has been shown to be better than MBR decoding of a single translation system in terms of COMET scores.

5.3 Pre-processing and Post-processing

On the WMT24 general test set, we observe that there are some emoticons and URLs in the source text. To prevent the model from translating them incorrectly, we replace the emoticons and URLs with ”Do Not Translate“ (DNT) labels in pre-processing, and then restore the DNT labels back in post-processing. By doing so, we can reduce some translation errors for emoticons and URLs.

WMT23 general test set	BLEU	COMET
NMT baseline (BiT & R-Drop)	54.24	0.6289
+ DD, FT & ST	56.33	0.6580
+ AT	57.03	0.6648
+ CL	58.58	0.6830
+ TEL	**59.34**	0.6928
+ NMT MBR	58.88	0.7178
LLM-based MT baseline (CPT & SFT)	52.18	0.6553
+ CPO	53.09	0.6907
+ LLM-based MT MBR	52.16	0.7102
+ NMT & LLM-based MT MBR	56.41	**0.7234**

Table 2: BLEU and COMET scores of en→zh NMT systems and LLM-based MT systems.

6 Conclusion

This paper presents the submission of HW-TSC to the WMT24 general MT Task. On the one hand, we use training strategies such as R-Drop, BiT, DD, FT, BT, AT, CL, and TEL to train the NMT system based on the deep Transformer-big architecture. On the other hand, we use CPT, SFT, and CPO to train the LLM-based MT system. Finally, we use MBR decoding to select the final translation result from the hypotheses generated by these two systems. By using these enhancement strategies, our submission achieved a competitive result in the final evaluation. Relevant experimental results also demonstrate the effectiveness of our strategies.

Abstract

CycleGN is a Neural Machine Translation framework relying on the Transformer architecture. Its approach is similar to a Discriminator-less CycleGAN, specifically tailored for non-parallel text datasets.

The foundational concept of our research posits that in an ideal scenario, retro-translations of generated translations should revert to the original source sentences. Consequently, a pair of models can be trained using a Cycle Consistency Loss only, with one model translating in one direction and the second model in the opposite direction.

As a contribution to the WMT24 challenge, this study explores the efficacy of the CycleGN architectural framework in learning translation tasks across two language pairs, English-Chinese and German-English, under two distinct non-parallel dataset conditions: permuted and non-intersecting. Our findings demonstrate the robust adaptability of CycleGN in learning translation tasks, irrespective of the language pair.

1 Introduction

The introduction of the Transformer architecture (Vaswani et al., 2017) marked a significant advancement in the field of Machine Translation, witnessing widespread adoption since its inception. Although self-attention mechanisms were not novel and had been investigated in prior studies (Bahdanau et al., 2016), the Transformer model demonstrated its formidable capabilities within Natural Language Processing (NLP). Characterized by its parallelized structure, the Transformer architecture facilitated computational efficiency, enabling the incorporation of a larger number of parameters. This enhancement has been exemplified in NLP systems like Charles University Block-Backtranslation-Improved Transformer Translation (cubbitt) (Popel et al., 2020), which have surpassed the performance levels of human professionals in certain contexts.

Neural Machine Translation (NMT) datasets necessitate substantial text corpora, structured as aligned pairs. This alignment implies the requirement for sentences with equivalent meaning to be present in a minimum of two distinct languages, enabling the initiation of model training to forge linguistic linkages. Ongoing initiatives, including OPUS (Tiedemann and Thottingal, 2020) and Tatoeba (Tiedemann, 2012), are committed to facilitating public access to these datasets. Parallel datasets comprise a small subset of the volume of data in monolingual datasets.

Despite the widespread availability of large parallel corpora for numerous language pairs, the capacity to employ solely monolingual datasets would substantially expand the pool of training data. This approach is particularly beneficial for languages with scarce parallel text corpora.

Regardless of the remarkable efficacy exhibited by Large Language Models (LLM) in NMT without the necessity of exclusive training on parallel data (Zhu et al., 2023), their considerable magnitude renders them costly in terms of both training and operation. This economic burden consequently restricts their widespread availability.

Back-translation (Sennrich et al., 2016) is a technique leveraging a trained MT (Machine Translation) model to translate sentences from a monolingual dataset to produce corresponding pairs, thereby synthetically augmenting the training data. Our research is founded on the premise that the process of translating a sentence from a source language to a target language, followed by its retro-translation from the target language back to the source language, allows for the measurement of the disparity between the original and the machine-retro-translated sentences. This disparity serves as a metric to assess the efficacy of the models and facilitates the backpropagation of gradients within

Proceedings of the Ninth Conference on Machine Translation, pages 165–175
November 15-16, 2024 ©2024 Association for Computational Linguistics

the networks. Notably, this methodology has been previously implemented in the realm of Image-to-Image Translation, as evidenced in the renowned CycleGAN framework from Zhu et al. (2017).

2 Previous work

The TextCycleGAN model (Lorandi et al., 2023), while not utilizing the Transformer architecture nor operating within the MT field, introduced an innovative strategy for text style transfer. This approach employed a CycleGAN on the Yelp dataset to facilitate the learning of mappings between positive and negative textual styles, notably in the absence of paired examples.

Shen et al. (2017) exemplified the feasibility of training two encoder-decoder networks in an unsupervised manner that enables the sharing of a latent space, thereby permitting style transfer. Lample et al. (2018), adopting a similar technique within the MT context, substantiated that the use of parallel datasets is not a prerequisite for effective translation.

3 Definitions

Machine Translation models are most commonly trained using "parallel" datasets, which are structured collections of text pairs. Each pair comprises a segment of text in a source language and its translation in the target language. By providing direct translations, models learn correspondences between text units to map the source language to the target language.

A non-parallel dataset on the other hand does not consist in pairs of text segments, consequently the source and target sentences do not share any explicit correspondence. Such a dataset can be creating by combining any two monolingual datasets of two distinct languages and adjusting for the number of samples. In the context of this research, two sub-categories of non-parallel datasets are introduced.

3.1 Permuted dataset

A "permuted" dataset is defined as a parallel dataset wherein the sentences of one language have been systematically rearranged. Consequently, this results in a non-parallel corpus where it is guaranteed that each sentence has a corresponding translation located at an unspecified index within the dataset. The authors postulate that when employing sufficiently large monolingual datasets, which are not derived from permuted parallel corpora, it is likely that most sentences will possess an accurate translation "somewhere" within the dataset.

3.2 Non-intersecting dataset

A "non-intersecting" dataset is a non-parallel dataset for which it is guaranteed that no sentence has an exact translation. A non-intersecting dataset is derived from a meticulously curated parallel dataset devoid of duplicate entries. Two unique sets of natural integers are produced, each functioning as an index list of phrases to retain for each respective language.

4 Datasets

The datasets employed in this study are the English-German and Chinese-English language pairs from the WMT23 challenge (Kocmi et al., 2023). The data released for the WMT23 General MT task can be freely used for research purposes. Due to the current implementation's high computational demands, the models were not trained for the entirety of an epoch. Specifically, only 10% of the English-German dataset was used, while about half of the Chinese-English dataset in the non-intersecting condition.

Type	English-German	Chinese-English
Permuted	27,801,496	27,801,496
Non-intersecting	27,801,496	17,676,442
Original dataset	295,805,439	35,452,884

Table 1: Number of sentences used during training depending on the dataset type

5 Training

For greater clarity, the mathematical notations from the original CycleGAN work will be employed in the present study. Given two languages $\mathcal{X}$ and $\mathcal{Y}$ with appropriate datasets, the objective is to obtain two NMT models $\mathcal{G} : \mathcal{X} \mapsto \mathcal{Y}$ and $\mathcal{F} : \mathcal{Y} \mapsto \mathcal{X}$ such that if the translations are perfect, $\mathcal{G}(\mathcal{F}(y)) = y$ and $\mathcal{F}(\mathcal{G}(x)) = x$, with $x \in \mathcal{X}$ and for $y \in \mathcal{Y}$.

By using the Cross-Entropy Loss (CEL) (Zhang and Sabuncu, 2018) in the role of the Cycle Consistency Loss (CCL), we can determine the distance between the original sentence and its double translation in order to compute the gradients.

As in the original CycleGAN work, our current study also implements an Identity Loss (IL), which also relies on the CEL, to help with the training stability. As $\mathcal{G}$ consists in a mapping $\mathcal{X} \mapsto \mathcal{Y}$, if given an input $y \in \mathcal{Y}$, the input should remain unchanged such that $\mathcal{G}(y) = y$. The same loss is applied to $\mathcal{F}$ between $\mathcal{F}(x)$ and x, as displayed in Figure 1.

5.1 Model architecture

The architecture used for both models, $\mathcal{G}$ and $\mathcal{F}$, is the Marian framework (Junczys-Dowmunt et al., 2018) implemented by Huggingface's Transformers library (Wolf et al., 2020), which is licensed under the Apache Licence. While most parameters follow the default configuration, Table 2 references the changes that were made in order to reduce the computational cost of the architecture.

Parameter	Huggingface	Current work
Vocabulary size	58,101	32,000
Encoder layers	12	6
Decoder layers	12	6
Encoder attention heads	16	8
Decoder attention heads	16	8
Encoder feed-forward	4096	2048
Decoder feed-forward	4096	2048
Position embeddings	1024	128
Activation function	GELU	ReLU

Table 2: Non-default parameters in the configuration of Marian Transformer models

5.2 Vocabulary organization

NMT models usually employ either a unified tokenizer or two distinct tokenizers. In the case of a single tokenizer, it is trained using sentences from both the source and target distributions, avoiding any duplicates. This approach facilitates the sharing of the encoder and decoder embedding layers, thereby diminishing computational demands and enhancing model accuracy (Press and Wolf, 2017).

Conversely, the alternative approach entails training one tokenizer on the source distribution and another one on the target distribution. While this method restricts the possibility of tying embeddings, it can potentially double the vocabulary size without increasing the dimensions of the embeddings. The overall vocabulary size of the model in this scenario, is the cumulative total of the two individual vocabularies, barring shared tokens like punctuation symbols.

While contemporary Transformer models like Bidirectional Encoder Representations from Transformers (BERT) (Devlin et al., 2019) and Generative Pre-trained Transformers (GPT) (Radford et al., 2018) typically utilize a single tokenizer, this study introduces a novel vocabulary methodology that amalgamates the aforementioned approaches. This method involves training two tokenizers, each for a respective language and with half the vocabulary size. Subsequently, the identifiers of one tokenizer are adjusted to prevent overlap, yielding a result analogous to a single tokenizer that includes duplicates across languages. It is important to note that special tokens such as $< eos >$ (End of Sentence) and $< pad >$ (Padding) are shared and not duplicated. This strategy is designed to simplify model analysis during development, albeit at the expense of a reduced vocabulary.

5.3 Obtaining labels

In the training process of a Transformer model, it is imperative to have prior knowledge of the labels, as the decoder predicts tokens sequentially. Each token prediction, barring the initial one, is contingent upon all preceding predictions. By possessing prior knowledge of the reference translation, it becomes feasible to contrast each predicted token against the ground truth, enabling the calculation of the loss at every step.

Nevertheless, in the case of non-parallels datasets, the labels are by definition not known in advance. It is therefore not possible to calculate the loss after each predicted token. Furthermore, the act of selecting the most probable token for each prediction constitutes a non-differentiable operation, thus precluding the possibility of backpropagation once the sentence is fully generated.

Naturally, in inference mode, Transformers are able to generate sentences without labels. Thus, the first step is to generate the pseudo-labels $\hat{x}$ and $\hat{y}$, where $\hat{x}$ is used as the label of y and $\hat{y}$ as the label of x. Even though this step cannot be used to compute the gradients, it is crucial for the entire process.

$\hat{\hat{x}}$ is computed from from $\mathcal{F}(\hat{y})$ with x as the label, and $\hat{\hat{y}}$ is computed from $\mathcal{G}(\hat{x})$ with y as the label. The CCL is applied between $\hat{\hat{x}}$ and x, and between $\hat{\hat{y}}$ and y to compute the gradients and update the weights of $\mathcal{G}$ and $\mathcal{F}$.

5.4 A Discriminator-less GAN

The CycleGAN methodology, as indicated by its nomenclature, is predicated on the Generative Adversarial Network (GAN) framework, initially introduced in Goodfellow et al. (2014). This paradigm involves the training of a Generator model in conjunction with another model, termed

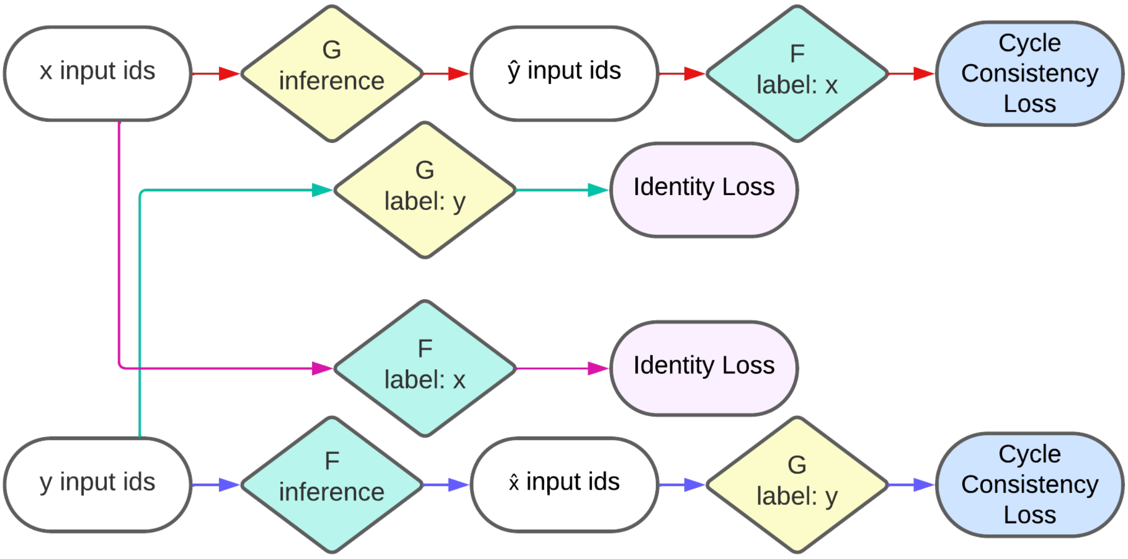

Figure 1: CycleGN training process

the Discriminator. The Discriminator is specifically trained to distinguish between authentic samples drawn from the dataset and synthetic samples produced by the Generator. In the CycleGAN training process, the Discriminators intervene after the generation of $\hat{x}$ and $\hat{y}$, helping the training of the Generators. However, as mentioned in Section 5.3, there can be no gradient computation during the generation of $\hat{x}$ and $\hat{y}$ in a Transformer and as such, Discriminators cannot be used in the present work. This is why CycleGN is not an "Adversarial" approach, hence the name.

6 Pre-training

During the development of CycleGN, a critical issue became clear, which prevented the model's ability to converge and learn effectively. As described in Section 5.3, the first step of the CycleGN framework is to generate $\hat{x}$ and $\hat{y}$. During the first initialisations, these pseudo-labels will be generated randomly and will depend only on the initialization of the weights of $\mathcal{G}$ and $\mathcal{F}$. However, the models consistently converge towards a trivial solution wherein by merely reproducing the input, they satistisfy the loss function criteria without achieving any meaningful learning or transformation of the data.

6.1 Absence of intermediate evaluation

As there is no Discriminator to ensure that $\hat{x}$ belongs to $\mathcal{X}$ and $\hat{y}$ belongs to $\mathcal{Y}$, $\mathcal{G}$ and $\mathcal{F}$ converge towards $x = \hat{y} = \hat{\hat{x}}$ and $y = \hat{x} = \hat{\hat{y}}$, as this approach achieves an optimal outcome on the CCL function, registering a value of zero, as schematised in Figure 2.

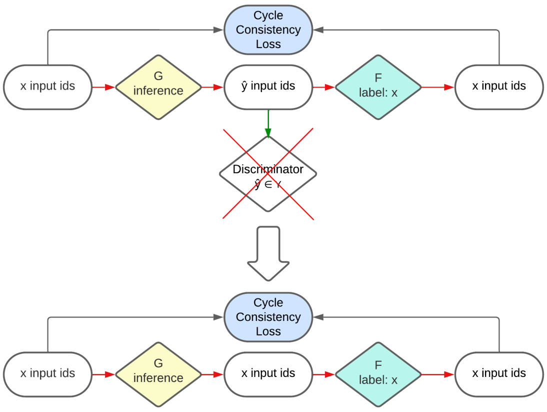

Figure 2: In the absence of a Discriminator $y \in \mathcal{Y}$ and pre-training is not employed, the CycleGN architecture will converge towards a state where no translation happens and still perfectly satisfy the CCL function

6.2 Moving away from the easiest path

Masked Language Modeling (MLM) is a pre-training strategy implemented in BERT, where a specified proportion of the input tokens are substituted with a unique $< mask >$ token. The objective of the neural network under this paradigm is to accurately reconstruct the original sentence from this degraded input. This process enables the model to discern intricate relationships between words and to develop a profound representation of the language. This pre-training has revealed excellent performances in diverse NLP application such as sentiment analysis (Alaparthi and Mishra, 2021), text classification (Sun et al., 2020), Named Entity Recognition (NER) (Souza et al., 2020) (Chang et al., 2021) (Akhtyamova, 2020) and paraphrase detection (Khairova et al., 2022).

As MLM does not require any labels, as the labels are generated from the dataset, it is perfectly adapted to the CycleGN approach. A single model $\mathcal{H}$ is trained on the non-parallel dataset to reconstruct both languages, with 15% of the input tokens masked. This model $\mathcal{H}$ has the exact same architecture as $\mathcal{G}$ and $\mathcal{F}$. When training the CycleGN, rather than randomly initializing $\mathcal{G}$ and $\mathcal{F}$, the parameters from $\mathcal{H}$ are directly transferred to both $\mathcal{G}$ and $\mathcal{F}$. Indeed, as $\mathcal{H}$ learns to reconstruct both language $\mathcal{X}$ and $\mathcal{Y}$, it can be used to initialize both networks. Figure 3 shows the training process of $\mathcal{H}$.

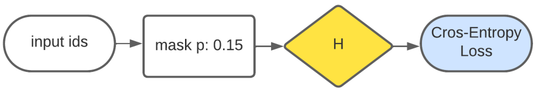

Figure 3: Masked Language Modeling training process

7 Training stability

It is crucial for the CycleGN framework that the two models exhibit approximately equivalent levels of performance. Given the interdependent nature of these models, where the output of one serves as the input for the other, maintaining consistency between them during training is imperative. Without a strategy in place to prevent the performance of the models from diverging, it is possible for one model to gain the "upper hand" over the other.

7.1 Divergence between the Generators

Figure 4 presents the evolution of the CCL of an early prototype of CycleGN and it can clearly be seen that one of the two generators, $\mathcal{F}$, ends up performing much better than its counterpart $\mathcal{G}$, which blocks any future training.

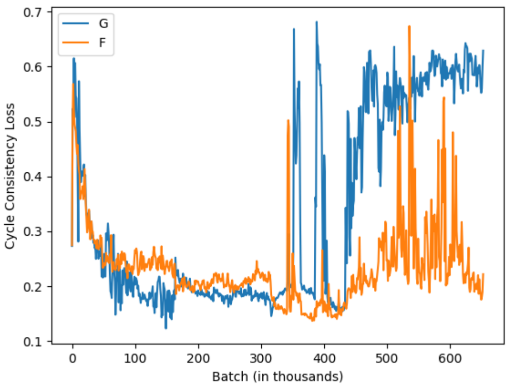

Figure 4: Evolution of the Cross-Entropy Loss during the training of an early prototype on the permuted German-English dataset

7.2 Gradient Clipping

Gradient clipping is a technique utilized in the training of Deep Learning (DL) models, to address the problem of "exploding" gradients. This issue occurs when gradients escalate to excessively high values during training, leading to numerical instability and impeding the model's convergence to an optimal solution.

Gradient clipping can be implemented through two primary methods: norm clipping and value clipping. Norm clipping involves establishing a threshold on the overall magnitude of the gradient vector. On the other hand, value clipping involves individually adjusting elements of the gradient vector that exceed the specified threshold.

By clipping the gradients by norm, with a threshold of 1.0, as advised by the Huggingface library, the training stabilizes and the divergence between $\mathcal{G}$ and $\mathcal{F}$ disappears.

Figure 5 demonstrates how the addition of gradient clipping helps with training stability during the training of the permuted German-English model.

7.3 Batch size

The original CycleGAN research mentions using a batch size of 1, and while they did not state the reason in the research paper, one of the authors explained it in a GitHub issue (Junyanz, 2017) as a lack of GPU memory.

Rajput et al. (2021) examined the impact of batch size within the CycleGAN architecture, observing a significant decline in performance the more the batch size is increased. This deterioration was evident both through the example images presented in

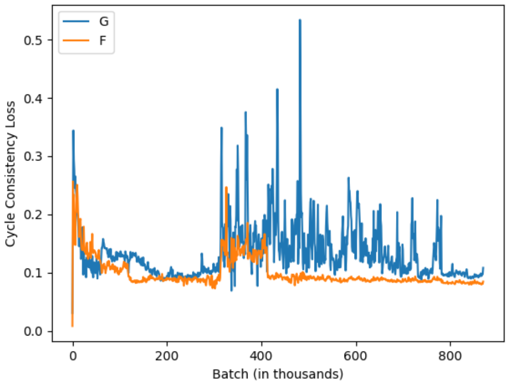

Figure 5: Evolution of the Cross-Entropy Loss during the training of the permuted German-English models

that study and through the calculated cosine dissimilarity, indicating inferior model performance with larger batch sizes. However, quality was achieved at the expense of computational efficiency, as the training duration to achieve 200 epochs was 8 hours with a batch size of 1, but this was reduced to just 2 hours with a batch size of 64.

In the context of this research, however, the tradeoff between quality improvement and computing resource, as observed in the aforementioned study, does not hold true. Utilizing a batch size of 1 in the CycleGN experiments hindered any form of convergence. Consequently, a batch size of 32 was selected, as it represents the maximum capacity that could be accommodated within the available 24GB of GPU memory of the NVidia 4090 used for this work.

7.4 One large epoch or multiple smaller ones?

The CycleGAN framework is recognized for its computational expense due to several inherent factors. Primarily, as CycleGAN operates on the principle of cycle consistency, it necessitates the training of two GANs simultaneously – one for each direction of the transformation. This structure requires substantial computational resources, as each GAN consists of both a Generator and a Discriminator.

The resource-intensiveness of the CycleGAN process, thus limits the size of the dataset that can be used in a reasonable time. This necessitated a decision between training for a single epoch on a large dataset, or training for multiple epochs on a smaller corpus arose.

The CycleGN framework was compared on the permuted German-English dataset under four different conditions:

1. One epoch containing 1% of the dataset
2. Five epochs containing 0.2% of the dataset
3. One epoch containing 2% of the dataset
4. Five epochs containing 0.4% of the dataset

The Crosslingual Optimised Metric for Evaluation of Translation (COMET) score (Rei et al., 2020) was selected as our comparison criterion, as this metric has proven to be one of the most effective in recent WMT competitions, according to Kocmi et al. (2022), due to its strong correlation with human judgment, aligning well with our goal of mirroring human evaluative standards. Multiple COMET models have been made available and the default "wmt22-comet-da" model was chosen. The average scores obtained on 10,000 test sentences that were not part of the model training set are presented in Table 3.

Condition	English->German	German->English
1	0.2727	0.2715
2	0.2411	0.2635
3	0.2741	0.2665
4	0.2258	0.2658

Table 3: COMET scores of CycleGN models depending on the permuted German-English dataset condition

Models exposed to a larger portion of the total dataset demonstrate superior performance compared to those limited to a smaller, repetitive subset, especially when the dataset encompasses over half a million to a million sentences. The authors extrapolate this result to larger datasets and thus chose to train the CycleGN models for a single epoch on the largest dataset possible.

8 Results

Even if tracking the CCL is an inexpensive manner to estimate the progress of the training of the CycleGN architecture, a low loss value can also hide an absence of translation, as mentioned in Section 6.1. This is why an evaluation metric such as COMET is crucial to assess the progression of the CycleGN framework.

8.1 Evolution of COMET score during training

To measure the performances of CycleGN, every 1,000$^{\text{th}}$ batch the CCL was averaged and 1,000 sentences from the test set were translated to compute the COMET score.

Figures 6, 7, 8 and 9 demonstrate that the actual quality of translation, as measured by the COMET metric, increases with time. Figures 6 through 9 illustrate a progressive enhancement in the translation quality over time, as quantified by the COMET metric. This enhancement is observed respectively in the permuted and non-intersecting German-English models (Figures 6 and 7), as well as in the permuted and non-intersecting English-Chinese models (Figures 8 and 9). Figures 6 and 7 exhibit a sudden drop in the increase of accuracy, which is acknowledged by the authors. This anomaly will be thoroughly examined and discussed in a subsequent academic study.

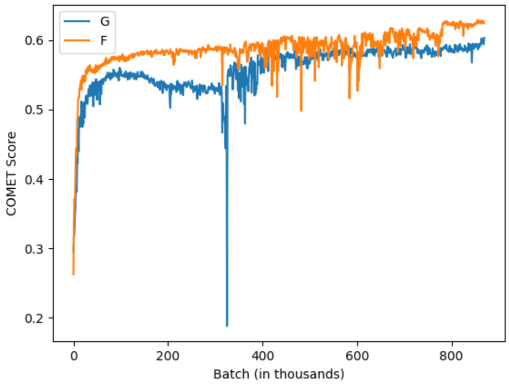

Figure 6: Evolution of the COMET score during the training of the permuted German-English models

8.2 COMET Scores post-training completion

After the end of the training, a test set of 10,000 sentences per language were translated and the COMET scores are displayed in Table 4. In order to give a point of comparison, architecture-matched models using the original parallel datasets were trained. As in the case of the CycleGN training, these parallel models were only trained for a single epoch on the exact same number of sentences as the permuted models were.

The authors expected the COMET score of the CycleGN to be inferior to architecture-matched models trained using parallel corpora, as information is by definition lost during the permutation of the parallel datasets. However, the authors argue that the differences between the scores is likely smaller with larger datasets.

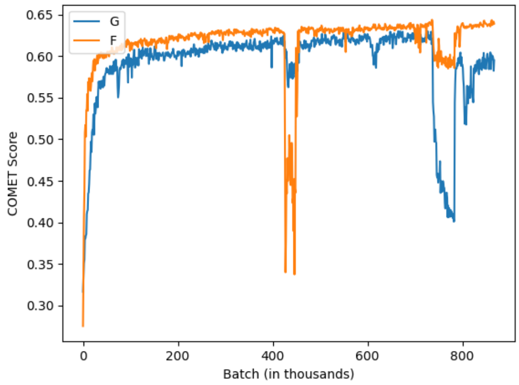

Figure 7: Evolution of the COMET score during the training of the non-intersecting German-English models

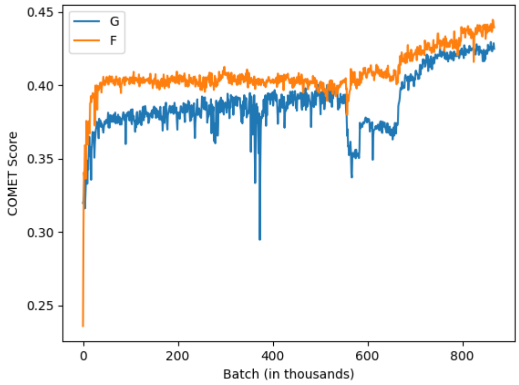

Figure 8: Evolution of the COMET score during the training of the permuted Chinese-English models

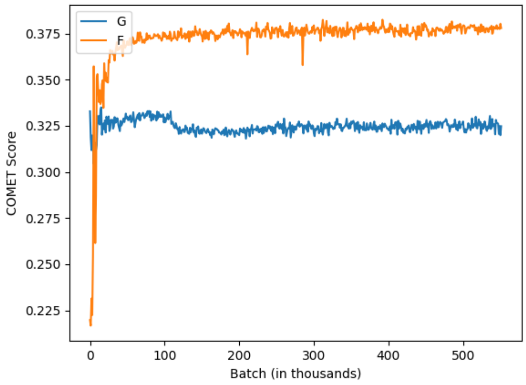

Figure 9: Evolution of the COMET score during the training of the non-intersecting Chinese-English models

	English → German	German → English
Permuted	0.505	0.537
Non-intersecting	0.556	0.579
Parallel	0.780	0.775

Table 4: COMET score of the German-English models

	English → Chinese	Chinese → English
Permuted	0.425	0.537
Non-intersecting	0.382	0.448
Parallel	0.000	0.749

Table 5: COMET score of the Chinese-English models

9 Future Work

Further investigations will benefit from the incorporation of a more extensive dataset and an exploration of larger model architectures.

9.1 Largert dataset

The current work has been trained on a small dataset compared to MT standards. Future work should try to see how convergence progresses with more iterations. Further computational optimizations are probably necessary to shorten the training time required.

9.2 Larger models

The current architecture relies on a total of 158,769,152 parameters, which is only about a third of the size of the default in the Huggingface library. Although Tables 4 and 5 demonstrate that the current number of parameters, when trained using a parallel dataset, is capable of producing better translations than when exposed to permuted and non-intersecting datasets, an increase in both the number of epochs and the size of the dataset should be prioritized, larger models being common in NMT.

10 Source Code

The source code of CycleGN is available at https://github.com/SorenDreano/CycleGN.

Limitations

The investigation acknowledges certain inherent limitations which may impact the generalizability and applicability of the findings.

Language diversity

Another issue that arises from the computing cost of CycleGN is the lack in language diversity. Indeed, our current work only used the English-German and Chinese-English language pairs. Consequently, it cannot be certain that the approach presented can be applied to other languages and all alphabets. This is why CycleGN is taking part in WMT24, to explore the framework's performance on a wide range of language pairs.

Training limitations

Since training a CycleGN model is particularly costly, there is a trade-off between training models on all language pairs, or choosing a subset of these pairs to train fewer models with more iterations and on a greater number of examples. In order to demonstrate the effectiveness of CycleGN on a wide range of language pairs, the first choice was made, i.e. to train models on all pairs, even if this means obtaining inferior results.

Unused models

Unlike the previous edition (Kocmi, 2023), where most language pairs were bidirectional, i.e. the evaluations were to and from, the 2024 General Translation task is unidirectional. This means that for each language pair, it is sufficient to train a model that translates from the source to the target.

This is not a change that is favourable to CycleGN, since it is a bidirectional training architecture. Indeed, its cyclical nature means that one model must be trained from one language to another, and another model must complete the cycle, i.e. from this second language to the first. In other words, half the time spent training CycleGN is spent training a model which only serves to train the first, but which will never be evaluated in the contest.

This change has been accompanied by an increase in the number of language pairs, from 6 bidirectional and 2 unidirectional in 2023 to 11 unidirectional in 2024.

Monolingual datasets

During the WMT challenge, teams are provided with monolingual datasets. Although this dataset format is perfectly suited to CycleGN training, they have been discarded for two reasons. The first is that for the majority of language pairs, the parallel datasets supplied have been truncated in order to reduce training time. The second is related to the construction of permuted and non-intersecting datasets, since it is preferable to build them from non-parallel datasets, as detailed in Section 3.

Reduced dataset sizes

The datasets were truncated to obtain a maximum of 27,801,496 sentences for training and 100,000 sentences for the development set. The final size of the datasets used and the number of epochs is shown in Table 6 for permuted models and Table 7 for non-intersecting models. While the permuted models have all been trained, this was not the case for the non-intersecting models, due to lack of time.

Training time

To make it possible to train so many models, several machines were used, with different technical characteristics, in particular different GPUs. However, by estimating the training time according to the number of sentences in the dataset and the GPU used, the total training time for all the models trained on the WMT24 datasets represents approximately 3,700 hours on an NVidia 4090.

Ethics Statement

This study, focusing on the training of NMT models using non-parallel datasets, adheres to the highest ethical standards in research. We recognize the critical importance of ethical considerations in computational linguistics and machine learning, especially as they pertain to data sourcing, model development, and potential impacts on various linguistic communities.

Our research utilizes publicly available, non-parallel linguistic datasets. We ensure that all data is sourced following legal and ethical guidelines, respecting intellectual property rights and privacy concerns.

In our commitment to scientific integrity, we maintain transparency in our research methodologies, model development, and findings. We aim to make our results reproducible and accessible to the scientific community, contributing positively to the field of machine translation.

Abstract

Fine-tuning Large Language Models (FT-LLMs) with parallel data has emerged as a promising paradigm in recent machine translation research. In this paper, we explore the effectiveness of FT-LLMs and compare them to traditional encoder-decoder Neural Machine Translation (NMT) systems under the WMT24 general MT shared task for English to Chinese direction. We implement several techniques, including Quality Estimation (QE) data filtering, supervised fine-tuning, and post-editing that integrate NMT systems with LLMs.

We demonstrate that fine-tuning LLaMA2 on a high-quality but relatively small bitext dataset (100K) yields COMET results comparable to much smaller encoder-decoder NMT systems trained on over 22 million bitexts. However, this approach largely underperforms on surface-level metrics like BLEU and ChrF. We further control the data quality using the COMET-based quality estimation method. Our experiments show that 1) filtering low COMET scores largely improves encoder-decoder systems, but 2) no clear gains are observed for LLMs when further refining the fine-tuning set. Finally, we show that combining NMT systems with LLMs via post-editing generally yields the best performance for the WMT24 official test set.

1 Introduction

Generative Large Language Models (LLMs) have demonstrated significant capabilities across various English-centric NLP tasks (Zhang et al., 2022; Touvron et al., 2023a,b). However, they often underperform in multilingual contexts, particularly with low-resource languages (Hendy et al., 2023; Stap and Araabi, 2023; Wang et al., 2023). To enhance the multilingual proficiency of LLMs, recent studies have explored several strategies, including vocabulary expansion (Lin et al., 2022; Liang et al., 2023; Yang et al., 2023), continual training on multilingual data (Le Scao et al., 2023; Dubey et al., 2024; Xu et al., 2024a), and instruction tuning (Zhu et al., 2023; Alves et al., 2024; Stap et al., 2024). These approaches have collectively improved LLM performance on a variety of multilingual tasks, such as understanding (Lai et al., 2023), reasoning (Ponti et al., 2020; Shi et al., 2022), summarization (Hasan et al., 2021; Bhattacharjee et al., 2023), and machine translation (Kocmi et al., 2023).

Fine-tuning Large Language Models (FT-LLMs) with parallel data largely enhances translation capabilities, but such approach relies heavily on high-quality parallel data. For instance, prior research often uses development and test datasets like WMT and Flores (Alves et al., 2023; Xu et al., 2024a; Li et al., 2024) for the training, limiting the scalability to a broader range of languages. In this paper, we explore the feasibility of mining high-quality bi-texts from open-source corpora like OPUS. We utilize COMET (Rei et al., 2020), an automated Quality Estimation (QE) tool, to score sentences in the WMT-24 Constraint track. Unlike Peter et al. (2023), who found that selecting the highest quality sentences using COMET improves translation quality, our findings show that while this QE-based data filtering does not provide clear benefits for LLMs when refining fine-tuning datasets, it significantly enhances the performance of NMT systems when applied to filter training samples with low COMET scores.

Recent studies show that LLMs fine-tuned with MT data can rival state-of-the-art NMT models like NLLB (Costa-jussà et al., 2022). However, such comparisons may be unfair, as NMT models like NLLB typically support a broader range of languages. For example, ALMA-13b (Xu et al., 2024a) outperforms NLLB-54b (Costa-jussà et al., 2022) despite targeting only eight language pairs versus 200. Additionally, expanding languages in multilingual models often causes interference that degrades performance (Tan et al., 2024; Shaham et al., 2023). In this paper, we focus exclusively on the English-to-Chinese translation direction[1], investigating how FT-LLMs compare to NMT models trained from scratch using the same parallel data source. Specifically, we use the full WMT-24 constraint track data to train an encoder-decoder NMT model, and we fine-tune LLaMA2-7B on a selected high-quality subset of up to 300K sentences. we found that, despite fine-tuned LLama2-7B being 17 times larger, it yields comparable COMET scores and worse scores for BLEU and ChrF.

While small NMT systems are resource-efficient in production, LLMs in practice, generate less literal translations (Vilar et al., 2023). In this paper, we integrate NMT and LLM systems by prompting LLMs to post-edit (PED) NMT outputs. Additionally, we implement a QE-guided PED system that selects the final outputs based on the higher QE score, as determined by COMET, between NMT and post-edited outputs. Our experiments show that the QE-guided PED system delivers the best performance on the WMT24 en-zh official test set, improving ChrF up to +3.7 over pure NMT outputs and +2.1 than direct translations by LLMs. Surprisingly, this approach brings negative performance gains on the Flores-devtest and Ntrex.

2 Data Preprocessing

In this section, we provide an overview of the data sources and the cleaning strategy. We use all the available data from the constrained track of the WMT-24 shared task for all three directions in which we participate, including English→Chinese, English→Japanese, and Japanese→Chinese. Following Wu et al. (2023), we perform a thorough preprocessing phase involving three key steps to enhance the data quality, as outlined below.

- Character-level Cleaning
    - Deescaping special characters in XML.
    - Removing non-printable characters.
    - Segmenting Chinese sentences with Jieba[2] and tokenizing Japanese data using KyTea (Neubig et al., 2011).
- Sentence-level Cleaning
    - Filtering out sentences longer than 256 tokens.
    - Eliminating sentences where over 75% of the words on both the source and target sides are identical.
    - Removing sentences with a source-to-target token ratio exceeding 3.0.
    - Eliminating duplicated sentences.
- Language-level Cleaning
    - Removing off-target sentences using the FastText language identification tool (Joulin et al., 2016).
    - Excluding sentences exhibiting one-to-many or many-to-one mappings, for example, a single source sentence having multiple different target sentences.

In specific, we use the Moses toolkit[3](Koehn et al., 2007) for all procedures in cleaning step 1 and use FastText (Joulin et al., 2016) for the language identification step. As shown in Table 1 (Cleaned), we removed 29%, 22%, and 45% of the data for en→zh, en→ja, and ja→zh directions.

Directions	Raw	Cleaned	QE-filtered
en→zh	55,346,004	39,354,051	22,606,804
en→ja	33,875,162	26,415,631	14,507,351
ja→zh	22,642,553	12,560,471	6,679,265

Table 1: Number of parallel sentences for three datasets.

3 Systems

3.1 NMT Systems

MMT baseline In this section, we describe the backbone architecture and adjustments made to our baseline systems. We train a multilingual-Transformer-large (mT-large) model for all three en→zh, en→ja, ja→zh directions. The mT-large is a 12-layer Transformer (Vaswani et al., 2017) architecture with specific modifications, including prenorm for both the encoder and decoder, and layernorm for embedding. To enhance stability and performance, we tie the parameters of encoder embedding, decoder embedding, and decoder output. We also introduce dropout and attention dropout with a probability of 0.1, along with label smoothing at a rate of 0.1. In addition, to specify the translation directions, we prepend the source language tags in the source, and target language tags in the target side, e.g.: en2zh.

[1] We investigate FT-LLM for en-zh, and explore the data filtering for en-zh, en-ja, and ja-zh diretcions.

[2] https://github.com/fxsjy/jieba

[3] https://github.com/moses-smt/mosesdecoder/

Similar to the approach described by Vaswani et al. (2017), we employ the Adam optimizer with a learning rate of 5e-4, implementing an inverse square root learning rate schedule with 4,000 warmup steps. We set the maximum number of tokens to 10,240, with gradient accumulation every 21 steps to facilitate large-batch training in Tang et al. (2021). We train all of our systems with 4 NVIDIA A6000 Gpus, and to expedite the training process, we conducted all experiments using half-precision training (FP16). Additionally, we save checkpoints every 2000 steps and implement early stopping based on perplexity, with a patience of 5 epochs.

Quality-Estimation Filtering. Due to data scarcity in the machine translation community, a large amount of Machine Translation data is mined from web-crawled data such as CCAligned (El-Kishky et al., 2020). Nonetheless, recent research found that there are many misaligned data exist in such web-crawled datasets, which impair performance when training models on it (Khayrallah and Koehn, 2018; Ranathunga et al., 2024). In addition, incorrect language and non-linguistic contents could affect the model in generating off-target or hallucinated outputs (Kreutzer et al., 2022). Similarly, recent studies on instruction fine-tuning of LLMs have shown that increasing data quality is more effective than data quantity (Du et al., 2023; Pan et al., 2024; Zhou et al., 2024), especially in inducing instruction-related capabilities (Xia et al., 2024). Additionally, Peter et al. (2023) shows that using QE metrics is not as effective at detecting translation noises like untranslated sentences, but is much better at identifying more fine-grained problems in the data, like small translation or grammatical errors.

Motivated by that, we investigate the feasibility of extracting high-quality parallel data using an automated Quality Estimation (QE) tool. We utilize the COMETKiwi model and apply this data-filtering phase to the cleaned data that we discussed in Section 2. Figure 1 presents the COMET score distributions for three directions. We found that for both English→Chinese and English→Japanese, the distributions are quite similar, that is, nearly half of the data falls into the poor quality range (0-80% Comet scores). For Japanese→Chinese, approximately half dataset ranges from 0% to 65% of COMET score. According to this observation, we filtered out parallel data that has smaller than 80% Comet scores for both English→Chinese and English→Japanese, and set the threshold at 65% for Japanese→Chinese. As a result, we show the number of parallel sentences after Quality Estimation filtering in Table 1.

Directional Fine-tuning. Lastly, to encourage the MMT model to gradually narrow down the data distribution to focus on task-specific data, we further fine-tune the MMT model on direction-specific data. Note that the direction-specific data, i.e., En → Zh, En → Ja, and Ja → Zh are the same data that included in the MMT baseline training data.

3.2 LLM Systems

We use LLaMA2-7B as the backbone because it is permitted for the constraint track of WMT24. We reuse the framework of ALMA (Xu et al., 2023) to conduct fine-tuning, however, we discard their first stage of monolingual continue training.

We set the training batch as 32 and accumulated 4-step gradients. The learning rate is set as 2e-5. The model was trained for one epoch using bf16 precision. The beam size is set as 5 for inference.

For the fine-tuning dataset, we further apply the quality estimation method described in Section 3.1 to filter out data with a QE score below a certain threshold. Then, we sample a certain number of bitext from the filter dataset. For example, in Table 4, the number of samples with a score above 89 is 53k, all of which are used for fine-tuning. Additionally, we sample data with scores higher than 87 at various levels, such as 53k, 100k, and 300k. We fine-tune LLaMA2 with different kinds of data to show the impact of data qualities.

3.3 NMT+LLM Systems

Previous studies have shown that leveraging Large Language Models (LLMs) to post-edit the outputs of supervised Neural Machine Translation (NMT) models can reduce translationese and enhance translation quality (Chen et al., 2023). This strategy has proven effective with LLMs such as ChatGPT (Chen et al., 2023), GPT-4 (Raunak et al., 2023), PaLM (Xu et al., 2024b), and LLaMA-2 (Ki and Carpuat, 2024). Specifically, post-editing utilizes LLMs either to refine the outputs of supervised NMT models or to perform "Self-Refinement" on their own outputs. Furthermore, Ki and Carpuat (2024) demonstrate that tuning LLMs with error-annotated translations can further enhance performance.

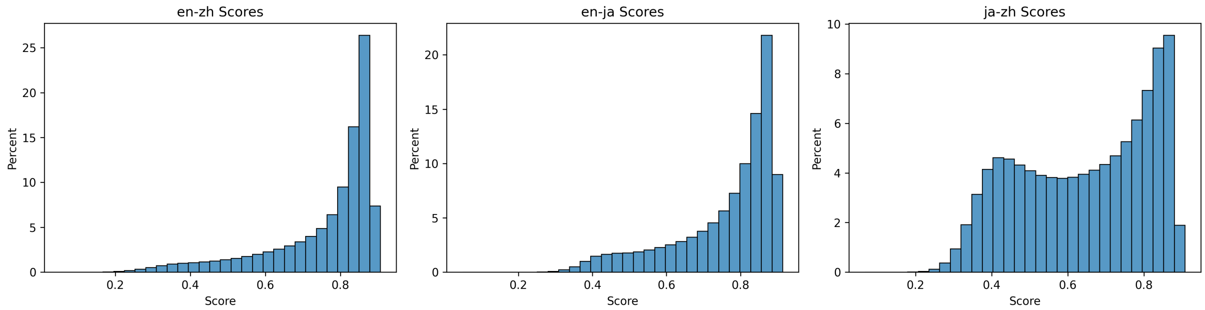

Figure 1: Comet score distributions for WMT-24 constraint training data on en→zh, en→ja, and ja→zh directions.

In this paper, we explore the effectiveness of Post-Editing (PED) in improving translation quality for the English-to-Chinese direction. We focus on a training-free PED approach due to computational constraints, utilizing pre-trained open LLMs to edit the outputs of our supervised NMT models. Given the limited Chinese capability of LLaMA2, we employ Tower-LLMs (Alves et al., 2024) (Tower-Instruct 7B and 13B), which have been continuously pre-trained on monolingual corpora including Chinese. Additionally, we implement a Quality Estimation-guided Post-Editing (QE-based PED) approach, where the NMT outputs and post-edited outputs are selected based on the higher QE score using COMETKiwi (wmt22-cometkiwi-da).

4 Experimental Setups

4.1 Systems

In this section, we briefly describe the systems we implemented. It is important to note that some of our implementations were focused only on the English-to-Chinese direction, specifically for FT-LLaMA2, Tower-Instruct, the PED system, and the QE-based PED system.

mT-large. A multilingual Transformer-large model trained in many-to-many directions using the "Cleaned" data (see Table 1 and Section 3.1 for details). It consists of 12 layers with 16 attention heads, d = 1,024, and d_{ff} = 4,096.

mT-large + QE. This model shares the same architecture and hyper-parameter settings as the *mT-large* model but is trained using the "QE-filtered" data outlined in Table 1.

mT-large + QE + FT. The *mT-large + QE* model was further fine-tuned on direction-specific data.

FT-LLaMA2. We use supervised fine-tuning to fine-tune LLaMA2. Detailed settings can be found in Section 3.2.

Tower-Instruct. We directly evaluate the performance of the Tower-Instruct models for comparison with our systems.

Self-Refined PED. We prompt the Tower-Instruct model to post-edit the translations they originally generated.

PED system. We prompt Tower-Instruct models to post-edit the outputs generated by our supervised NMT system (*mT-large + QE + FT*).

QE-guided PED system. We determined the final outputs by selecting between the NMT outputs and the post-edited outputs, based on the higher QE score as determined by COMETKiwi.

4.2 Data

For training, we utilize both the "Cleaned" and "QE-filtered" datasets, see details in section 2. For evaluation, we employ previous WMT validation and test sets as our validation set, and Flores, Ntrex as our test set.

4.3 Implementation and Evaluation

For our Neural Machine Translation (NMT) systems, we utilize the Fairseq toolkit (Ott et al., 2019) for both training and inference. For Large Language Model systems, we employ the Transformers toolkit for training and inference. To evaluate our models, we report detokenized SacreBLEU[4], ChrF++(Popović, 2017), and COMET (Rei et al., 2020) (wmt22-comet-da) scores.

5 Results and Analyses

In this section, we present the final results of our experiments and discuss the findings. Table 3 and 2 show the results of English→Chinese and the other two directions (en→ja and ja→zh) on Flores-devtest, Ntrex, and WMT24 official test sets.

5.1 Quality-Estimation Filtering improves NMT systems

Our key finding is that implementing Quality-Estimation (QE) Filtering effectively reduces low-quality data samples, leading to improved NMT system performance. Specifically, we observed BLEU score improvements of +4.4 and +0.2 for the English→Japanese and Japanese→Chinese directions, respectively, on the WMT24 official test sets. For the English→Chinese direction, we observed BLEU gains of +1.6 on the Flores-devtest and +1.4 on the Ntrex test sets. Similar positive performance improvements were also noted across other metrics, such as ChrF and COMET. These results indicate that filtering training samples with low COMET scores enables our supervised NMT system to generate higher-quality translations.

5.2 Fine-tuned LLaMA2 and Data Quality

We conduct experiments on LLaMA2-7B in English to Chinese translation direction, where we collect 300K parallel samples from the training set, controlling the QE scores are all higher than 87. In Table 3, ④ shows the results. It is easy to see that the fine-tuned LLaMA2 results in the best COMET performance (86.60) on the Flores benchmark. However, the results on surface-level metrics, such as BLEU and ChrF, significantly lag

Language	Data	BLEU	COMET
LLama2-7B	10k (Cleaned)	28.0	82.7
LLama2-7B	100k (Cleaned)	35.7	85.6
LLama2-7B	53k (COMET > 87)	**36.1**	86.1
LLama2-7B	53k (COMET > 89)	33.5	84.3
LLama2-7B	100k (COMET > 87)	35.5	85.7
LLama2-7B	300k (COMET > 87)	34.6	**86.6**

Table 4: Evaluation results of fine-tuned LLama2-7B models for the English→Chinese direction on the Flores-devtest set. 'Cleaned' indicates random sampling from the 'Cleaned' training dataset, while 'COMET>x' refers to the sampling of data with COMET scores greater than x.

behind encoder-decoder-based NMT systems by 7.6 and 3.8 points, respectively.

We further control the fine-tuning data quality to show the impact. We select 10K and 100K samples from the cleaned dataset (See Table 1). To further improve the quality of parallel semantic alignment, we score all of the 39M cleaned training samples using COMET, and then we construct fine-tuning sets under the following settings:

- We selected all 53k samples with very high COMET scores, using a threshold of 89.
- We then lowered the score threshold to 87 and selected another 53k samples.
- We extend the number of samples with scores higher than 87 to 100k and 300k.

Table 4 shows the corresponding results after fine-tuning using datasets with different qualities. We observe that: 1) Simply extending the fine-tuning set from 10k to 100k largely improves the resulting performance. 2) However, no clear improvements can be observed when further raising the fine-tuning data QE quality. E.g., using 100k trivial samples (after data cleaning, QE score lower than 80) achieves comparable performance to that of using 100k samples with a QE score higher than 87. Additionally, fine-tuning with samples that have extremely high QE scores (COMET > 89) even resulted in a decline in translation quality compared to using 53k samples with relatively lower QE scores (COMET > 87). 3) Further extending the fine-tuning size from 100k to 300k yields no clear improvements.

Our experiments suggest that simply enhancing the quality of fine-tuning data for LLMs, at least when using COMET as the central measure of quality, is not a promising approach.

5.3 Post-Editing Enhances Translation Quality

As shown in Table 3, using the Tower-Instruct 7B LLM to post-edit the outputs of our strongest supervised NMT model (PED (③ + ⑤)) resulted in large improvements, with BLEU and ChrF gains of +4.6 and +3.3, respectively, over the NMT model alone on the WMT24 official test set. Notably, this post-editing approach also outperformed direct translation with Tower-Instruct 7B, achieving additional gains of +1.9 BLEU and +1.7 ChrF. In contrast, applying the Tower-Instruct model to post-edit its own generated translations (self-refined PED) resulted in negative improvements across all test sets. These findings suggest that integrating supervised NMT models with LLMs is a promising strategy for enhancing translation quality by leveraging the strengths of both systems.

Furthermore, Table 3 demonstrates that the QE-guided PED system (QE-based PED (③ + ⑤)) can further improve translation quality, as evidenced by the positive performance gains across the Flores-devtest, Ntrex, and WMT24 official test sets. In particular, the QE-guided PED system, utilizing Tower-Instruct 7B as the LLM backbone, achieved performance on par with Tower-Instruct 13B in the ChrF metric on the WMT24 official test set.

Despite the promising results on the WMT-24 Official test set, we found this Post-Editing approach delivered negative performance improvements on Flores and Ntrex sets (Table 3).

6 Conclusions

In this paper, we investigate three aspects of using LLMs for translation: 1) Comparison with Encoder-Decoder NMT Systems: directly fine-tuning LLaMA2 on a relatively small bitext dataset (100K) yields COMET results comparable to those of strong encoder-decoder NMT systems trained on over 50 million parallel sentence pairs. However, this approach significantly underperforms in surface-level metrics such as BLEU and ChrF. 2) Impact of Data Quality: properly filtering samples with low COMET scores largely improves encoder-decoder systems, however, no clear improvements can be observed for LLMs when further controlling the fine-tuning set with higher COMET scores. 3) Combining NMT Systems with LLMs: lastly, we show that combining NMT systems with LLMs via post-editing generally yields the best performance in our experiments.

Abstract

In this work, we present TOWER-V2, an improved iteration of the state-of-the-art open-weight TOWER models, and the backbone of our submission to the WMT24 General Translation shared task. TOWER-V2 introduces key improvements including expanded language coverage, enhanced data quality, and increased model capacity up to 70B parameters. Our final submission combines these advancements with quality-aware decoding strategies, selecting translations based on multiple translation quality signals. The resulting system demonstrates significant improvement over previous versions, outperforming closed commercial systems like GPT-4O, CLAUDE-SONNET-3.5, and DEEPL even at a smaller 7B scale.

1 Introduction

Large Language Models (LLMs) are making strides towards becoming the *de facto* solution for multilingual machine translation (MMT). Many works have shown that it is possible to adapt LLMs for translation and achieve state-of-the-art results (Zhang et al., 2023; Wei et al., 2023; Alves et al., 2023; Reinauer et al., 2023; Zhu et al., 2024).

One such example is our recent work on TOWER (Alves et al., 2024), which demonstrates that open NMT models like NLLB200 can be outperformed by adapting an LLM to translation. Specifically, we continue the pre-training of LLaMA-2 (Touvron et al., 2023) on both monolingual and parallel data, and fine-tune the resulting model on high-quality instructions covering several MT-related tasks. This approach requires much less parallel training data than traditional NMT and preserves the general capabilities of the LLM to respond to various prompts.

For the WMT24 General Translation task (Kocmi et al., 2024a), we enhance TOWER by significantly improving its training data, by extending its language support from 10 to 15 languages — including low-resource ones like Icelandic —, and by scaling the underlying model to 70 billion parameters. Furthermore, because the WMT24 General Translation task focuses on paragraph-level translation instead of sentence-level, we also experiment with full-document translation and longer contexts, where TOWER originally struggled. These key improvements result in TOWER-V2 7B and 70B.

For our primary submission, we combine TOWER-V2 70B with Quality-Aware Decoding (QAD) strategies (Fernandes et al., 2022), such as Minimum Bayes Risk decoding (MBR) and Tuned Reranking (TRR). These techniques use reward models during inference to select the best candidate from a set of generated samples, enhancing the overall output quality.

We report our results, including the human evaluation and final submission, in Section 5. By outperforming strong commercial systems like GPT-4, CLAUDE-SONNET-3.5, and DEEPL across the board, TOWER-V2 — even at 7B parameters — challenges the belief that in MMT there must be a trade-off in performance between high- and low-resource language pairs (Fernandes et al., 2023).

Our contributions are:

- We show that expanding from 10 to 15 languages maintains the quality of translations for the initial 10 and significantly improves the newly added languages.
- We significantly improve the paragraph- and document-level translation capabilities of the previous TOWER.
- We demonstrate that scaling the model from 7 to 70B parameters yields improvements, indicating that increased capacity benefits not only general LLM abilities but also task-specific performance.

- We analyze the impact of QAD on larger models than those studied by Fernandes et al. (2022), showing that MBR decoding outperforms TRR according to both automatic metrics and human evaluation.

2 Overview of the Shared Task

The primary aim of the general machine translation shared task is to evaluate the ability of various models to translate across different domains, genres, and possibly modalities (e.g., speech). This year's shared task, compared to previous editions, emphasizes English→X (en→xx) and Non-English→Non-English (xx→yy) language pairs.[1]

The WMT24 test sets include source sentences from four domains: news articles, social media posts, speech (machine-generated transcripts), and literary texts. Additionally, all test sets from this year are focusing on the paragraph level rather than sentence-level.

Throughout this paper we will evaluate several of our models using both automatic and human evaluation; yet, for the shared task only primary submissions are evaluated, and final results are based solely on human evaluation using the ESA protocol (Kocmi et al., 2024c).

3 TOWER-V2: A New Translation LLM

We create TOWER-V2 by improving upon the original TOWER recipe: continued pre-training of a base model on a multilingual dataset with billions of tokens and subsequent supervised fine-tuning for translation-related tasks.

We focus on three key areas: 1) careful refinement of the training data; 2) expansion of language coverage to support all of the shared task's languages; 3) scaling up model capacity.

Improving the training data. To enhance the general translation capabilities of TOWER, we mainly focus on improving the quality of its training data, be it for translation, post-translation, or general instructions.

For continued pre-training (CPT), we train on monolingual data from sources of superior quality, and apply more aggressive quality and length filters on the parallel data.

Regarding the supervised fine-tuning (SFT) phase, we use data created by humans — similarly to the previous version of TOWER— and introduce high-quality synthetic data. Human translations are sourced from well-known translation benchmarks. We go beyond simple sentence-level translation by transforming sentence-level to document-level data or into multi-parallel translation data (translating a single source sentence into multiple languages). When language variants are available, we include them in the training prompt (e.g. Chinese (simplified) vs Chinese (Taiwan)). All datasets were carefully filtered[2] and converted to instructions using a diverse set of templates.

Improving post-translation data and general instructions. Data from tasks like APE, MQM evaluation, and translation ranking are carefully filtered using several quality signals. Similarly to XTOWER (Treviso et al., 2024), APE and MQM evaluation always expect the model to return a "translation correction," so we always ensure that the post-edition (PE) is deemed better than the original translation according to several metrics. For translation ranking, we choose only samples where there is significant alignment between human annotations and automatic metrics.

Like in the previous TOWER version, we aim to build a model that adheres to different prompts and can work as a general multilingual LLM. Thus, we include filtered and adapted multilingual general-purpose instruction data from publicly available high quality datasets such as AYA (Singh et al., 2024).

Going from 10 to 15 Languages. We extend the language support of TOWER-V2 to Czech, Icelandic, Hindi, Ukrainian, and Japanese by adding training data of these languages to both CPT and SFT stages. For CPT, we add monolingual and parallel training data, increasing the total number of training tokens considerably. Aside from to-/from-English language pairs, we also include Czech-Ukrainian and Japanese-Chinese (and vice-versa) parallel data. In the SFT stage, we mostly add translation data for the new language pairs.

More Paragraphs/Documents. In addition to the sentence-level parallel data we also add parallel documents to the CPT stage. For SFT, we sample high quality monolingual documents and per-

[1] The complete list of language pairs for this year's task includes: Czech→Ukrainian, Japanese→Chinese, and English→Chinese, Czech, German, Hindi, Icelandic, Japanese, Russian, Spanish (Latin America), Ukrainian

[2] We found low-quality translations even on datasets built by professionals.

Table 1: Translation quality (via METRICX-QE-XXL) on the WMT24 test set. TOWER-V2 with MBR/TRR ranks first across all language pairs. Even with Greedy decoding TOWER-V2-70B still ranks above other strong systems like CLAUDE-SONNET-3.5, GPT-4O and DEEPL except in en→hi and ja→zh where CLAUDE-SONNET-3.5 has similar scores.

formed full document translations using previous TOWER models while controlling for translation quality using COMETKIWI (Rei et al., 2022). At the end, we are left with more data for document-level than segment-level, further contributing to improved performance on paragraph- and document-level translation.

Model suite. TOWER-V2 now comes in two sizes: a 7B parameter model based on MISTRAL-7B (Jiang et al., 2023) and a larger 70B model based on LLAMA-3-70B (AI@Meta, 2024).

4 Quality-aware decoding with TOWER-V2

On LLM-based MT, translations are typically generated through lightweight decoding strategies such as greedy or nucleus sampling. Nevertheless, strategies informed by quality metrics such as Minimum Bayes Risk Decoding (MBR) and Tuned Reranking (TRR) consistently perform better compared to other methods (Fernandes et al., 2022; Freitag et al., 2022; Nowakowski et al., 2022; Farinhas et al., 2023). As such for our submission, we experiment with MBR and TRR. For both methods, we use a candidate pool of 100 samples and ϵ-sampling (Freitag et al., 2023a) with $\epsilon = 0.02$, and COMET22 as the target objective. For TRR, we use the WMT23 test set for tuning the weights[3]. The translation quality features used include: model log probabilities, COMET-QE-20, COMETKIWI22, COMETKIWI-XL, and XCOMET-QE-XL.

To leverage the strengths of both approaches, we also experiment with a second step of refinement. After obtaining translations from both MBR and TRR, we select the TRR translation only if all quality features (except the model log probabilities) agree that the TRR translation is better than the MBR translation; otherwise, we retain the MBR translation[4].

5 Experimental Setup

5.1 Evaluation Setup

During the development of TOWER-V2, we used WMT23 as our validation set. For our final analysis, we use WMT24 test set source sentences and report only QE metrics: COMETKIWI-XXL (Rei et al., 2023), METRICX-QE-XXL (Juraska et al., 2023), and XCOMET-QE-XXL (Guerreiro et al., 2023). Additionally, we add the official preliminary results to the Appendix which include METRICX (reference-based) (Kocmi et al., 2024b).

We use evaluation metrics to develop and op-

[3] We sample 5000 sentences from the WMT23 test set to train the weights more efficiently.

[4] According to both automatic and human evaluation (Table 2 and Table 3 respectively) results of MBR translations are generally better.

Table 2: Translation quality aggregated by language pairs on the WMT24 test set (without testsuites). We omit DeepL from the en→xx averages because it does not support two language pairs. All metrics are their XXL variant.

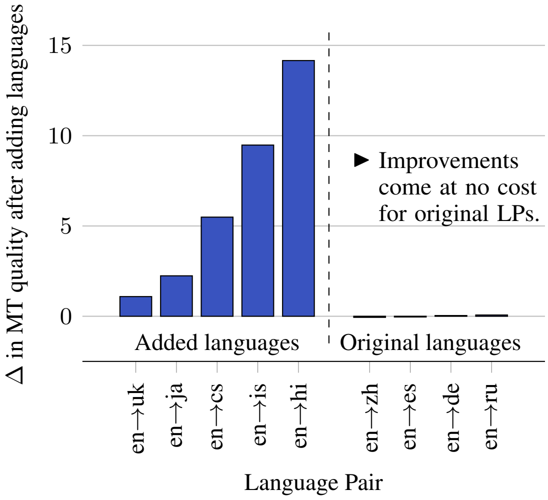

Figure 1: Improvement in MT quality after adding new languages to Tower-v2; measured in negative MetricX-XXL-QE so taller bars equate to better quality.

timize our models (e.g., using MBR and/or TRR during inference), with the exception of metrics of the MetricX family. Thus, to mitigate potential biases, we report MetricX-QE-XXL as our main evaluation metric and conduct human evaluation for English→German and English→Chinese. For the human evaluation, we use SQM quality levels with full document context. The annotators are in-house expert linguists familiar with evaluating MT outputs.

On Table 1, we report performance clusters based on statistically significant performance gaps at a 95% confidence threshold. On Table 2, we create per-language groups for systems with similar performance, following Freitag et al. (2023b), and obtain system-level rankings using a normalized Borda count (Colombo et al., 2022), which is defined as an average of the obtained clusters.

Regarding baselines, we report three commercial systems, GPT-4o, Claude-Sonnet-3.5, and DeepL, along with an open-source NMT model, NLLB 54B. While little is known about the commercial systems, they show top performance on the WMT23. All models are evaluated in a 0-shot setting, unless stated otherwise.

5.2 Main Results

Table 1 shows our main results on English→X language pairs according to MetricX-QE-XXL (↓). Table 2 shows aggregated scores for English→X and X→Y according to different metrics. From Table 1, we observe that even the 7B model with greedy decoding outperforms, or is on par, with the best baseline, Claude-Sonnet-3.5, for English→X. Scaling to 70B brings consistent improvements across all language pairs, and both TRR and MBR decoding bring MetricX-QE-XXL further down. Our final submission (2-step) ranks first for all language pairs with statistical significance.

5.3 Impact of Adding 5 Languages

To evaluate the impact of adding 5 languages, we train two 7B models: one with the initial 10 languages of Tower; another with the 10 languages

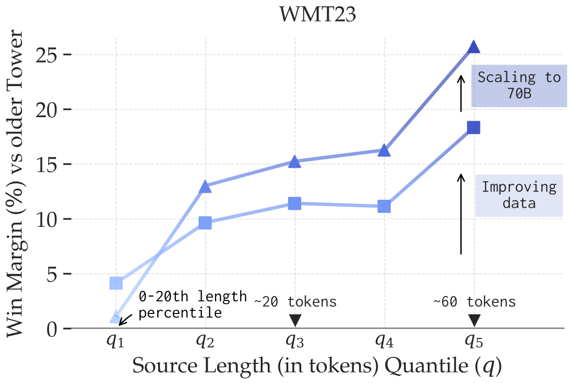

Figure 2: Win rates margin by length of the tokenized source of TOWER-V2-7B (squares) and TOWER-V2-70B (triangles) against an older iteration that was not trained on long-context translation training data. All language pairs of the WMT23 dataset that intersect with WMT24 are considered. We define a (sentence-level) win if the delta between two systems is superior to 1×10^{-3} METRICX-XXL points

Decoding	en→de	en→zh
Batch 1		
Greedy	85.43	84.11
TRR	87.16	85.55*
MBR	88.50*	85.47*
Batch 2		
TRR	—	68.55
MBR	—	72.76*

Table 3: SQM quality evaluation for three different decoding methods using TOWER-V2 70B. Numbers marked with an asterisk (*) are statistically significant. For English→Chinese, since the results of the first batch were not significant, we conducted a second batch comparison between TRR and MBR.

plus Hindi, Japanese, Ukrainian, Czech, and Icelandic. The data distribution for CPT remains unchanged, but we increase the number of training tokens of the second model to accommodate the additional languages. For SFT, we extend the dataset by incorporating human-translated data from several sources.

Figure 1 illustrates the absolute difference in 0-shot translation quality between the two models. As expected, the model with additional support performs considerably better on the new languages[5]. Perhaps more interestingly, its performance on the initially supported languages — which is already state-of-the-art (Table 1) — remains largely unchanged.

5.4 Beyond sentence by sentence translation

Figure 2 compares the new versions of TOWER-V2 (7B and 70B) with an older TOWER version that had yet to be trained on data specifically tailored to improve long-context translation. Not only do TOWER-V2 models vastly outperform the older version, but the quality gap widens as source length increases.

Further to this point, we created a paragraph-level version of the WMT23 dataset, by joining segments of the same document into paragraphs with at most 4 sentences. Results in Table 4 show that our final models are considerably better at translating paragraphs than their older counterpart.

5.5 Putting all together into 70B parameters

The gains from scaling up the number of parameters are clear from Tables 1 and 2, where we show that TOWER-V2-70B consistently outperforms all baselines in all language pairs, except ja→zh. Coupling TOWER-V2-70B with QAD methods yields state-of-the-art results for all languages and metrics considered. Remarkably, Figure 2 shows that the 70B model considerably improves upon its 7B counterpart suggesting that the benefits of scaling up are particularly noticeable when translating longer sources.

5.6 Human Evaluation: Greedy vs TRR vs MBR

To validate our findings with automatic metrics, we conducted a small-scale human evaluation for English→German and English→Chinese (Table 3). In a first phase, linguists annotated 100 samples from TOWER-V2-70B with different decoding strategies on the WMT24 test. For both language pairs, annotators scored greedy decoding lower than the other two methods. While there was a noticeable quality difference between MBR and TRR for English→German, this distinction was not evident for English→Chinese, with both decoding strategies achieving similar results. Therefore, we conducted a second round of annotations for English→Chinese, comparing only TRR with MBR. This provided more concrete results that favored MBR outputs.

[5] We note that the initial version of TOWER has ability to translate to other languages outside the supported ones, especially when given few-shot examples (Richburg and Carpuat, 2024) Still, their zero-shot performance is weak for languages like Hindi or Icelandic, which are less represented in the pre-training of the base models like LLaMA-2.

	WMT23-Paragraphs					
	en→xx			xx→yy		
Models	MetricX ↓	Comet ↑	chrF ↑	MetricX ↓	Comet ↑	chrF ↑
Tower (older)	5.14	79.11	50.93	6.99	75.45	53.29
Tower-v2-7B	2.72	84.45	54.35	1.87	87.57	61.36
Tower-v2-70B	**2.40**	**84.87**	**55.06**	**1.72**	**87.75**	**62.29**

Table 4: Performance of different Tower versions on our paragraph-level version of WMT23 (measured by MetricX-XXL, Comet-22, and chrF). Tower (older) is a version prior to the interventions we ultimately made on the training data of Tower-v2 to make it better at translating longer sources. These changes led to major improvements in paragraph-level translation for Tower-v2-7B, which are further realized with Tower-v2-70B.

5.7 Context-aware translation

	en→xx	
Models	MetricX ↓	xComet↑
Tower-v2-70B 0-shot	0.510	96.96
Tower-v2-70B 5-shot	0.495	96.89
	xx→en	
Tower-v2-70B 0-shot	1.051	94.84
Tower-v2-70B 5-shot	0.766	95.54

Table 5: Translation quality of Tower-v2-70B on the development set of the WMT24 Chat Shared Task. Using a prompt that incorporates conversational context (see Appendix A), the model provides high-quality translations, especially with examples (5-shot).

To evaluate Tower-v2 in a different domain, we tested it on chat translation data. In this domain, the model translates a segment based on the context of previous conversation turns. Ignoring this context can result in subpar translations with pronoun mistakes and lexical inconsistencies (Läubli et al., 2018; Toral et al., 2018). Table 5 shows that Tower-v2-70B excels at chat translation, even without specific training for this task. Using the prompt in Appendix A, which includes the conversation context, the model provides high-quality translations, especially when given domain-specific examples.

6 Conclusion

In this paper, we describe the joint submission from Unbabel and IST to the WMT24 General MT shared task. Our new model, Tower-v2, significantly improves upon previous versions by expanding language coverage from 10 to 15 languages and enhancing translation quality for longer paragraphs. Our largest model, with 70 billion parameters, combined with QAD strategies, achieved first place on the WMT24 test set according to both reference-free automatic evaluation, which we employed, and reference-based evaluation, as reported in the preliminary results from the WMT24 organizers (Kocmi et al., 2024b).

Limitations

This paper highlights the key improvements in Tower-v2 compared to previous versions and benchmarks it against other commercial state-of-the-art systems like GPT-4o, Claude-Sonnet-3.5, and DeepL. However, our submission is "unconstrained and closed," meaning the information provided is not sufficient for full system replication. Furthermore, our comparisons primarily focus on translation quality and do not consider factors like inference speed, training budget, or model efficiency.

We also disclose the number of parameters in our models, from the 7B version to the final 70B version, to facilitate a clearer understanding of their scale. However, these comparisons with other systems do not account for differences in model parameters and other operational metrics.

A Appendix

A.1 Metrics for QAD

The translation quality features used include: model log probabilities, COMET-QE-20[6], COMETKIWI22[7], COMETKIWI-XL[8], and XCOMET-QE-XL[9].

A.2 Chat Translation Prompt

Given a source (SRC) to be translated from SRC_LANG to TGT_LANG, and previous turns

[6] Unbabel/wmt20-comet-qe-da

[7] Unbabel/wmt22-cometkiwi-da

[8] Unbabel/wmt23-cometkiwi-da-xl

[9] Unbabel/XCOMET-XL

in a conversation between two agents (TURN_i), the 0-shot prompt used was:

Context: <TURN_1>\n <TURN_2>. . . \n <TURN_k>.\n\nTranslate the <SRC_LANG>source text to <TGT_LANG>, given the context.\n<SRC_LANG>: <SRC>\n<TGT_LANG>:

When using five in-context examples, the prompt is repeated six times separated by two new lines; five times with a reference translation at the end, and one times exactly as written above.

A.3 Further analysis on long-context translation

Compared to the first version of TOWER, the ability of TOWER-V2 to translate long sources has greatly improved. Whereas the translation quality of latter fell behind GPT-4 for longer sources, TOWER-V2-70B is superior across the board compared to the current best closed model for translation, CLAUDE-SONNET-3.5. In fact, the performance gap tends to widen as source length increases. TOWER-V2-7B is also competitive for the first 4 quantiles of length, but falls slightly behind on the last one.

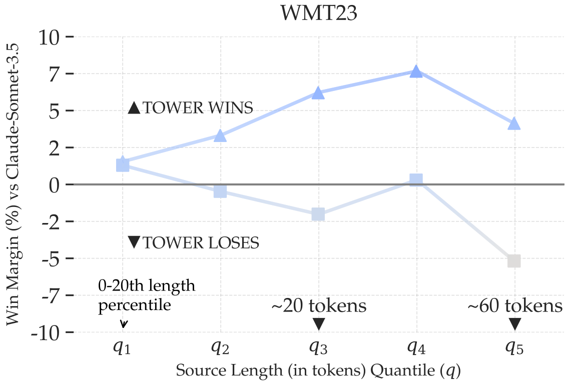

Figure 3: Win rates margin by length of the tokenized source of TOWER-V2-7B (squares) and TOWER-V2-70B (triangles) against CLAUDE-SONNET-3.5. All language pairs of the WMT23 dataset that intersect with WMT24 are considered. We define a (sentence-level) win if the delta between two systems is superior to 1×10^{-3} METRICX-XXL points

A.4 Preliminary Results from Kocmi et al. (2024b)

See Tables 6 to 16 for the official automatic evaluation conducted by WMT 24 organizers. Our submission, Unbabel-Tower70B, ranks first on all language pairs and metrics.

Abstract

This paper describes the TSU HITS team's submission system for the WMT'24 general translation task. We focused on exploring the capabilities of discrete diffusion models for the English-to-{Russian, German, Czech, Spanish} translation tasks in the constrained track. Our submission system consists of a set of discrete diffusion models for each language pair. The main advance is using a separate length regression model to determine the length of the output sequence more precisely.

1 Introduction

This report gives an overview of TSU HITS submissions in the WMT 2024 general machine translation tasks. We focused on exploring the capabilities of discrete diffusion models for the English-to-{Russian, German, Czech, Spanish} translation tasks in the constrained track. Our main contributions are

1. the use of regression-based output length prediction model
2. the use of the input length as a key feature for the output length prediction

The report is organized as follows. In the Section 2, we provide a general description of the discrete diffusion approach to machine translation, as it is not yet very widespread. In the Section 3, we describe the experimental setting and training processes. Section 4 discusses the results.

2 Discrete Diffusion Approach to Machine Translation

2.1 Diffusion: Preliminaries

Diffusion approaches (Sohl-Dickstein et al., 2015 , Ho et al, 2020) to generating objects (for example images) include forward (data to noise) and reverse (noise to data) diffusion processes. In the forward process, a small amount of noise is gradually added to the data. In the classical direct diffusion process, the original object x_0 is repeatedly and additively perturbed by a small Gaussian random noise, and in a fixed number of steps T goes into state x_T with a normal distribution (and thus is converted to noise):

$$q(x_t|x_{t-1}) = \mathcal{N}\left(x_t;\ x_{t-1}\sqrt{1-\beta_t}, \beta_t\right), \quad (1)$$

where $\forall\, t = \overline{1..T}\ \beta_t \in (0; 1]$ are the hyperparameters that regulate the diffusion rate.

During the reverse diffusion process, the machine learning model step by step reconstructs the object's states from x_T to x_0, and this denoising restores an object from the original distribution:

$$p_\theta(x_{t-1}|x_t) \sim \mathcal{N}\left(x_{t-1};\ \mu_\theta(x_t,t), \sigma_\theta(x_t,t)\right), \quad (2)$$

where θ are the model's trainable weights.

Texts in typical representations do not have the property of continuity and are a sequence of tokens with discrete values that do not have an order relation and correspond to the categorical data type. Thus, we follow the path of adapting the diffusion processes to categorical data - such approaches are called discrete diffusion.

2.2 Discrete Diffusion for Text Generation

Diffusion models with discrete state spaces were first introduced by Sohl-Dickstein et al. (2015), who considered a diffusion process over binary

Proceedings of the Ninth Conference on Machine Translation, pages 205–209
November 15-16, 2024 ©2024 Association for Computational Linguistics

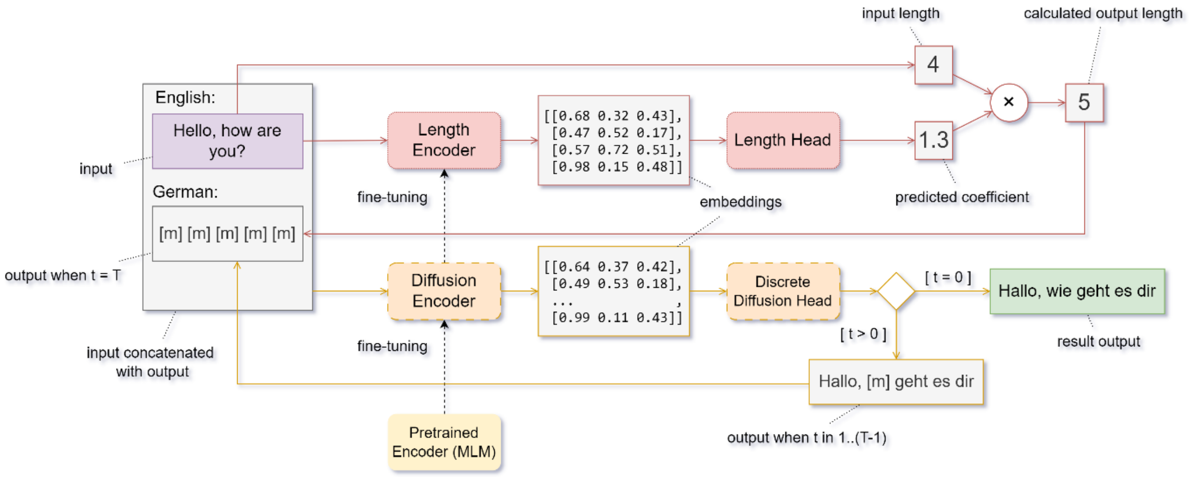

Figure 1: Overview of the system

random variables. Hoogeboom et al. (2021) extended the model class to categorical random variables with transition matrices characterized by uniform transition probabilities. We follow Austin et al. (2021) to define a discrete diffusion model for texts.

Namely, we consider each text token x_t to be a discrete random variable with K categories. For text data, $K = |V|$ is the size of the vocabulary. (He et al., 2023). The forward transition probabilities can be represented by matrices: $[Q_t]_{ij} = q(x_t = j|x_{t-1} = i)$. The process of adding noise can then be written as

$$q(x_t|x_{t-1}) = Cat(x_t;\, p = x_{t-1}Q_t) \qquad (3)$$

where $Cat(\cdot)$ is a category distribution (Austin et al., 2021).

2.3 Masked Language Models and Discrete Diffusion

He et al. (2023) noted the relationship between the discrete diffusion process and the task of pretraining of masked language modeling (MLM) encoder models. Namely, they suggested incorporating an absorbing state, e.g., [MASK] for BERT, into the Markov process of diffusion. In particular, each token in the sequence either stays the same or transitions to [MASK] with some probability. Formally, each entry of the transition matrix at step t is as follows,

$$[Q_t]_{ij} = \begin{cases} 1 & if\ i = j = [\mathrm{M}] \\ \beta_t & if\ j = [\mathrm{M}], i \neq [\mathrm{M}] \\ 1 - \beta_t & \text{if i = j} \neq [\mathrm{M}] \end{cases} \qquad (4)$$

where [M] is short for [MASK].

Such a Markov process converges to a stationary distribution $q(x_T)$ that places all the probability mass on the sequence with all [MASK] tokens.

The most common transformer (Vasvani et al., 2017) models pre-trained for the MLM task are models from the BERT family (Devlin et al, 2019). He et al. (2023) suggested DiffusionBERT that uses a pretrained BERT model as an encoder due to the similarity of the tasks. The length of the output sequence of the DiffusionBERT model is fixed and is set to different values depending on the problem solved.

2.4 Discrete Diffusion for Translation

Reid et al. (2023) suggested a diffusion model using Leventstein operations for machine translation. They have tested the model on WMT14 EN-DE dataset. It is unclear from the paper how do the authors determine the target length of the output sequence.

Zheng et al. (2023) suggest a reparameterized discrete diffusion (RDM) approach to text generation, and report results for the machine translation task on the IWSLT14 DE-EN, WMT14 EN-DE and WMT16 EN-RO datasets. To determine the translation length, the authors of RDM trained a separate model similar to the one of Ghazvininejad et al. (2020). They pose the problem of determining the length of the output sequence as a classification problem, selecting k best options out of N possible, where N is the maximum text length that the model used can process. Similarly to Gao et al. (2024), several options are selected and the best one is chosen based on the metrics of the overall text quality.

Ye et al. (2023) explore the possibilities of increasing applicability domain of discrete diffusion approaches, while considering an approach similar to DiffusionBERT, except that instead of the BERT encoder, the authors use the RoBERTa model (Liu et al., 2019). The quality of machine translation is assessed on the IWSLT14 DE-EN and WMT14 EN-DE data sets, using the same quality metrics and the same idea for determining the length as in the RDM approach.

3 System Overview

3.1 General Translation Process

The general translation process is presented on Figure 1. Our system consists of a discrete diffusion model and an output length prediction model.

On each diffusion step, a concatenation of the source text and output is used as the input to the generative model, but the absorbing tokens are distributed only within the output part. We do not use any special separation tokens, but just use the prompt "{Source Language}: {Source Text} \n {Target Language}: {x_t}".

Since we use XLM-RoBERTa's (Conneau et al, 2020) positional embedding model as an encoder and are forced to fit the input sequence of the model into 512 tokens, we apply punctuation splitting of the source texts, limiting the maximum size of the source text to 200 tokens, and then glue the results back. We also do not use the extended context to improve translation; this is left for the future work.

We take a fixed number of the diffusion steps T equal to 50. Tokens that were unmasked in the previous steps are likely to be replaced with subsequent ones, just like in DiffusionBERT (He et al., 2023). The standard argmax approach is used as a sampling method. We do not use temperature and do not limit the number of tokens to choose from.

3.2 Generative Model

We largely follow Ye et al. (2023) and use XLM-RoBERTa (Conneau et al, 2020) family pre-trained model that includes a multilayer transformer encoder and a single-layer MLM head.

We fine-tune both the encoder and the head for discrete diffusion text generation that differs from MLM mainly by the percentage of the masked tokens. We use the cross-entropy weighted relative to the diffusion step t loss proposed by Zheng et al. (2023):

$$L_t = -\lambda_{t-1} \sum_{i}^{N} y_i \log p_i \tag{5}$$

where y_i is the true probability (0 or 1) of token with index i in model dictionary, p_i is the predicted probability, N is the size of the dictionary, λ_{t-1} is the parameter that depends on the percentage of the masked tokens at the steps t and $t-1$.

Generative Model	
Architecture	XLM-RoBERTa-Large
Optimizer	AdamW($\beta_1 = 0.9, \beta_2 = 0.98$)
Weights decay	0.01
Learning Rate Schedule	Cosine
Max learning rate	5E-05
Batch size	16
Accumulation step	8
Steps	30000
Warmup ratio	0.01
Loss	(Section 3.2)
Number format	FP16
Length Model	
Hidden size	1024
Optimizer	AdamW($\beta_1 = 0.9, \beta_2 = 0.999$)
Learning Rate Schedule	OneCycleLR (Smith et al, 2017), two phases
Max learning rate	7E-07
Batch size	8 / 16
Steps	30000
Embedding calculation	Mean pooling
Activation	ELU
Loss function	MSE
Number format	FP16

Table 1: Hyperparameters of the models

Following Chang et al. (2022), we use the cosine noise schedule:

$$\beta_t = \cos(\frac{\pi t}{2T}) \tag{6}$$

3.3 Length Predictor

Our length predictor also consists of an encoder and a task-specific head. Although our length prediction model is based on the same XLM-RoBERTa, physically these two models are completely separate. We tried not to fine-tune the encoder for the length problem and to use the standard XLM-RoBERTa, but we got worse metrics on the test data.

We use a regression predictor of the output length, unlike other works that use classifiers with the number of categories equal to the length of the context, for example, 512 tokens. Our regression head is a two-layer perceptron with ELU-activation. Standard MSE loss is used when the length predictor is trained.

	#tokens	#model parameters
EN-DE	68,333	444,158,849
EN-RU	91,932	492,511,151
EN-ES	31,380	368,444,201
EN-CS	65,514	438,382,718

Table 2: Numbers of tokens and model parameters after pruning the tokenizer

The main improvement in length prediction is because of the use of the input length. There is a fairly strong relationship between the length of the text in the source language and the length of its translation, which, in general, is almost linear. We suggest taking this into account when the target is defined. Our model predicts the ratio of the input and output lengths, normalized by the average ratio for the training set. We employ standard mean pooling to convert the matrix of token embeddings obtained from the encoder into a common embedding of text, which will be used as features for the length head.

3.4 Training Data

The WikiMatrix dataset (Schwenk et al., 2021) was used as a train dataset for EN-DE, EN-RU, EN-CS language pairs; Neulab-TedTalks (Tiedemann, 2012) was used for EN-ES. The training sets were trimmed to 480 thousand examples when training the generation model and to 240 thousand when training a length prediction model.

3.5 Pruning the tokenizer

Due to the computational limitations we reduce the token set of our models for each pair of languages to the minimum required (all the other tokens are replaced with [UNK]). The effect of reduction on the number of model parameters is demonstrated in Table 2. According to our observations, it increases the quality of models when tested on validation datasets for the selected language pair, but may degrade the quality of general translation when tested on complex examples.

Pruning the tokenizer was made before trimming the training sets to keep as much tokens as possible.

4 Results

The official automatic scores of our system on the test data are presented in the Table 3. The gap between our results and the leading system is significant.

	AutoRank	MetricX	CometKiwi
EN-DE	13.3	5.6	0.395
EN-RU	10.8	9.8	0.421
EN-ES	16.3	14.2	0.289
EN-CS	19.5	16.6	0.235

Table 3: System official scores

4.1 Model size

We used XLM-Roberta-Large with 561 million parameters as the main model for generating translation, while other systems participating in the competition this and last years had tens of billions of parameters. This makes our model largely uncompetitive. Unfortunately, today there are no pretrained open-weight encoder models comparable to leading open-weight decoder models in terms of parameters number and pretrain token count.

4.2 Quantity and quality of training data

Due to technical limitations, we used only a small part of the translation datasets provided, no more than 480 thousand examples for each language pair. Increasing the training set and better cleaning should significantly improve the quality, especially when using a larger pretrained model.

Acknowledgments

We are grateful to Prof. O. Zmeyev for the support of this research and Dr. V. Goiko for the computing resources provided.

Abstract

We participated in the constrained track for English-Japanese and Japanese-Chinese translations at the WMT 2024 General Machine Translation Task. Our approach was to generate a large number of sentence-level translation candidates and select the most probable translation using minimum Bayes risk (MBR) decoding and document-level large language model (LLM) re-ranking. We first generated hundreds of translation candidates from multiple translation models and retained the top 30 candidates using MBR decoding. In addition, we continually pre-trained LLMs on the target language corpora to leverage document-level information. We utilized LLMs to select the most probable sentence sequentially in context from the beginning of the document.

1 Introduction

This paper details Team-J's system submission for the WMT 2024 Shared Task: General Machine Translation. We participated in the English-Japanese (En→Ja) and Japanese-Chinese (Ja→Zh) translation tasks under the constrained track.

As with last year's competition, the use of publicly available pre-trained models and metrics evaluated in the WMT Metrics shared tasks, such as COMET (Rei et al., 2020), was permitted. Following the Kudo et al.'s (2023) system, we employed multiple machine translation (MT) models to generate numerous candidate sentences for each source text. We then applied minimum Bayes risk (MBR) decoding (Fernandes et al., 2022) using the COMET metric to select the optimal translations.

Additionally, contrary to the previous years, the use of large language models (LLMs) was also permitted this year. Our primary objective was to use these LLMs to achieve consistent document-level machine translation. Specifically, we aimed to develop models based on LLMs and also implemented a reranking system. Figure 1 provides an overview of our system. The following sections describe its components in detail.

2 Dataset Construction

In this section, we describe the training data, the process of synthetic data generation, and the data cleaning methodologies.

2.1 Provided Data

Since we participated in the constrained track, we solely used the data officially provided by the organizer.

Bitext data. We used all the provided bitext data. For English to Japanese translation, we used JParaCrawl v3.0 (Morishita et al., 2022a), News Commentary v18, Wiki Titles v3, WikiMatrix (Schwenk et al., 2021), Japanese-English Subtitle Corpus (JESC) (Pryzant et al., 2018), The Kyoto Free Translation Task (KFTT) Corpus (Neubig, 2011), and TED Talks (Cettolo et al., 2012). For Japanese to Chinese translation, we used JParaCrawl Chinese (Nagata et al., 2024), News Commentary v18, Linguatools Wiki Titles, WikiMatrix, OPUS, and Neulab TED Talks (Tiedemann, 2012).

Monolingual data. We also used the following provided monolingual data for Japanese and Chinese: News Crawl, News Commentary, Leipzig Corpora (Goldhahn et al., 2012), Common Crawl (Buck et al., 2014), and Extended Common Crawl (Conneau et al., 2020; Wenzek et al., 2020). For the continual pre-training of the language models, we only used the Common Crawl and Extended Common Crawl due to the limited availability of document-level data beyond these two datasets.

Development data. We used NTREX-128 (Federmann et al., 2022), Flores-200 (Team et al., 2022;

*: Equal contributions.

Proceedings of the Ninth Conference on Machine Translation, pages 210–226

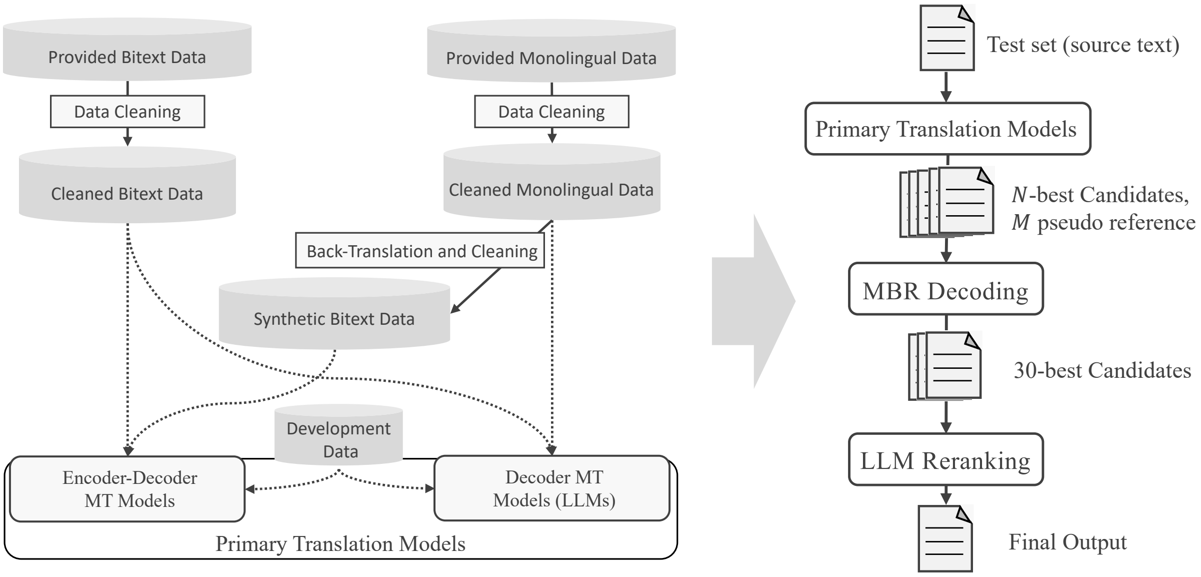

Figure 1: System overview

Goyal et al., 2022; Guzmán et al., 2019) and the past WMT test sets as development data. These datasets were also employed to fine-tune the models.

2.2 Synthetic Data

We constructed synthetic data to augment the training dataset. We used the synthetic data created by Kudo et al. (2023) for the En→Ja task, and newly created data for the Ja→Zh task as follows. For preprocessing, we tokenized the bitext (Section 2.1) into truecased[1] subwords using a unigram language model with Sentencepiece (Kudo and Richardson, 2018), with "byte_fallback", and "split_digits" options enabled following Touvron et al. (2023); Dubey et al. (2024); Kudo et al. (2023). After that, we created a back translation model (Sennrich et al., 2016), which we call an initial translation model using the training configurations in Table 7 (Appendix C) and trained it on the bitext. Then, we translated the Chinese monolingual data (Section 2.1) with a beam size of 10 and a length penalty of 1.0.

2.3 Data Cleaning

We conducted data cleaning on the corpus. Specifically, we applied several rules to clean and filter out noisy sequences using HojiChar (Shinzato, 2023). HojiChar is a text preprocessing tool that mainly supports monolingual corpus in Japanese and English, with typical filters preinstalled. We first extended HojiChar to make it work with parallel corpus and implemented a variety of rules with careful investigation of the provided data. Table 1 shows the list of data cleaning methods we applied on the bitext and monolingual data. Table 2 shows the amount of data after filtering.

The following provides a detailed explanation of the cleaning rules that were mainly implemented using tools other than HojiChar.

Character count-based filtering. We qualitatively examined the Common Crawl and Extended Common Crawl datasets. Our analysis revealed that shorter sequences tend to be noisy. Therefore, we discarded sequences that were less than or equal to 200 characters for Japanese and 100 characters for Chinese, respectively (see `(26)` in Table 1). This threshold also helps us retain document-level data that is suitable for the continual pre-training of LLMs. To efficiently filter out shorter sequences, we used the `awk` command.

Toxic content cleaning. Qualitative analysis of the Common Crawl data revealed a significant amount of low-quality toxic contents, such as adult material, are included in the corpus. To address this, we applied a toxic content filter to exclude such samples from our training data (`(9)` in Table 1). For the Japanese data, we used filters originally implemented in HojiChar.[2] For the Chinese corpus, we defined a list of toxic words based on

Table 1: List of data cleaning rules.

those used for the ChineseWebText (Chen et al., 2023) dataset.

Compression rate-based cleaning. We used a cleaning method based on the compression rate to remove non-textual data ((19) in Table 1).[3] Samples with a high compression rate typically contain excessive repetitions, while those with a low compression rate often consist of random strings. Specifically, we calculated the compression rate for each sample and removed those that did not fall within a specified range.

Language detection. To ensure the collection of data in the target language, we used language detection (20) in Table 1. Simple heuristic language detection methods are implemented in Hojichar, such as a method that checks for the presence of *hiragana* or *katakana*. Alongside these simple methods, we also used FastText-based language detection (Joulin et al., 2017b,a).

Conversion of traditional Chinese to simplified Chinese. We converted Chinese data written in traditional characters to simplified characters to augment the bitext data ((27) in Table 1). We used OpenCC[4] for these conversions.

Deduplication. Duplicate data in training sets can negatively impact the performance of language models (Lee et al., 2022). To mitigate this, we performed exact deduplication using the sort command ((28) in Table 1) and fuzzy deduplication using MinHash (Broder, 1997) ((29) in Table 1). We used the text-dedup tool (Mou et al., 2023) for implementation.

Bitext similarity cleaning. We performed cleaning based on bitext similarity using LaBSE (Feng et al., 2022) to filter out semantically irrelevant pairs ((33) in Table 1). We set the lenient threshold of 0.5 for bitext and more strict threshold of 0.7 to synthetic data.

Table 2: The amount of training data used for LLMs and Encoder-Decoder MT models. The token count for LLMs is based on the tokenizer of Mistral-7B, and the count for Encoder-Decoder MT models is based on the subwords on the target side.

3 Primary Translation Models

We developed translation models using two architectures: Encoder-Decoder and Decoder-only (LLMs).

3.1 Encoder-Decoder MT Models

For En→Ja, we used the existing translation models created by Morishita et al. (2022b); Kudo et al. (2023). For Ja→Zh, we newly constructed translation models through pre-training and fine-tuning.

Pre-training. We trained the pre-training model using the pre-training configuration in Table 7 (Appendix C). For the training data, we used the bitext (Section 2.1) and the synthetic data (Section 2.2) after applying data cleaning (Section 2.3). We performed upsampling to achieve a $1:4.7$ ratio between the bitext and the synthetic data. Moreover, we applied the tagged back-translation technique (Caswell et al., 2019), adding a special token `<BT>` at the beginning of the source sentences in the synthetic data and storing this tag in the vocabulary dictionary.

Fine-tuning. After pre-training, we conducted fine-tuning using the development data (Section 2.1) with the fine-tuning configuration in Table 7 (Appendix C).

3.2 LLM-based MT Models

We used the Llama2-13B (Touvron et al., 2023) and Mistral-7B (Jiang et al., 2023), which are permitted for use in the constrained track. These LLMs were used only for the En→Ja direction and not for the Ja→Zh direction. For Mistral-7B, we also prepared a variant with an expanded vocabulary to improve its Japanese generation capability. For more details on vocabulary expansion, please refer to Section B.

Continual pre-training. Although the datasets used for training Llama2 and Mistral are not publicly disclosed, it is generally believed that they are predominantly in English. Consequently, continual pre-training has been conducted to enhance performance on Japanese tasks (Fujii et al., 2024a; Okazaki et al., 2024). This approach has been reported to improve English-Japanese translation performance. To further boost Japanese language capability, we also performed continual pre-training using the cleaned monolingual corpus detailed in Section 2.3. The training configurations are shown in Table 8, 9, and 10.

Supervised fine-tuning After continual pre-training, we conducted supervised fine-tuning for the translation task. In this phase, we used the cleaned bitext corpus and development data described in Section 2. Initially, we fine-tuned the model using the bitext corpus, followed by additional fine-tuning with the development data which is relatively clean. To prepare for the Stepwise MBR-Enhanced LLM decoding detailed in Section 4.2, we used all combinations of the first n sentences from each document as training samples for the development data fine-tuning. Figure 2 shows the prompt template, and Table 8, 9, and 10 shows hyperparameters used in the training process.

Preference learning. To align the translation results with human preferences, we conducted preference learning for Mistral-7B.[5] We used Contrastive Preference Optimization (CPO) (Xu et al., 2024) as the preference learning algorithm. In preliminary experiments, we also tried Direct Preference Optimization (DPO) (Rafailov et al., 2023) as an alternative to CPO. However, despite the decrease in loss during training, we observed that the DPO often resulted in output collapse (complete loss of input-output correspondence) during decoding. Therefore, we selected CPO as our preference learning.

Let $L_{\mathrm{NLL}}(\pi_\theta)$ and $L_{\mathrm{pref}}(\pi_\theta)$ be the negative log-likelihood of π_θ and preference of output given by

[5] Due to computational resource limitations, we applied LoRA fine-tuning (Hu et al., 2022).

次の英語を日本人のネイティブのように日本語に翻訳してください。 原文：{src} 訳文：{tgt}

Figure 2: The general prompt for supervised fine-tuning. {src} denotes the source sentence. {tgt} denotes the target sentence.

π_θ, respectively, that is:

$$\begin{aligned} L_{\text{NLL}}(\pi_\theta) &= -\mathbb{E}_{(s,r)\sim\mathcal{D}}\left[\log \pi_\theta(r \mid s)\right] \\ L_{\text{pref}}(\pi_\theta) &= -\mathbb{E}_{(s,r,y_r)\sim\mathcal{D}}\left[\log \sigma(\beta d)\right] \quad , \\ d &= \log \pi_\theta(r \mid s) - \log \pi_\theta(\hat{y} \mid s) \end{aligned} \tag{1}$$

where σ is the Sigmoid function. Then, CPO minimizes the following objective function during training:

$$\min_\theta \left[L_{\text{pref}}(\pi_\theta) + \alpha L_{\text{NLL}}(\pi_\theta)\right] \quad . \tag{2}$$

Here, $\mathcal{D} = \left\{\left(s^{(i)}, r^{(i)}, \hat{y}^{(i)}\right)\right\}_{i=1}^{N}$ represents the dataset. π_θ denotes a parameterized policy, and α and β are hyperparameters. We used the development data for training in preference learning. In this context, s corresponds to the source text from the development data, r to the reference text from the development data, and $\hat{y}$ to the output of the model before preference learning.

To prevent the model output from collapsing, we introduced a minor modification to the CPO objective function. Specifically, we implemented a warm-up phase to reduce the impact of the preference learning loss at the beginning of training. This approach is formulated as follows:

$$\min_\theta \left[\min\left(1, \frac{i}{i_{\text{w}}}\right) L_{\text{pref}}(\pi_\theta) + \alpha L_{\text{NLL}}(\pi_\theta)\right] . \tag{3}$$

Here, i represents the number of training steps, and i_{w} denotes the number of warm-up steps for the preference learning loss.

4 Decoding

This year's test set consists of segments with multiple sentences in context. Since most bitext corpora are at the sentence level, translating larger segments in one shot is not preferable. Thus, we initially divided each segment in the test set into individual sentences using spaCy (Honnibal et al., 2020).[6] In case the resulting split was overly short, we combined texts from its adjacent splits.

	hypotheses	pseudo-references	
		top-p sampling	epsilon sampling
En→Ja	1272.15	3288.5	3421.99
Ja→Zh	261.84	884.11	3108

Table 3: The average number of hypotheses and pseudo references for each source sentence generated by the Encoder-Decoder MT models. Note that due to errors during decoding, the number of hypotheses and pseudo-references generated for a single source sentence varies.

4.1 MBR Decoding

We apply minimum Bayes risk (MBR) decoding (Eikema and Aziz, 2020) to select high-quality translations from the set of hypotheses generated by the multiple translation models using MBRS (Deguchi et al., 2024). Let $\mathcal{Y}$ be the output space of translation models. We use the Monte Carlo method to estimate the expected utility (Eikema and Aziz, 2022), as follows:

$$\begin{aligned} y^{\text{MBR}} &= \operatorname*{argmax}_{h\in H} \mathop{\mathbb{E}}_{\hat{r}\in\hat{R}}\left[u(h,\hat{r})\right], \\ &= \operatorname*{argmax}_{h\in H} \frac{1}{|\hat{R}|}\sum_{\hat{r}\in\hat{R}} u(h,\hat{r}), \end{aligned} \tag{4}$$

where y^{MBR} is the selected translation by MBR decoding, $H \subseteq \mathcal{Y}$ is the hypotheses set, and $\hat{R}$ is the multiset (a.k.a bag) of translation samples[7], called "pseudo-references". $u\colon \mathcal{Y}\times\mathcal{Y} \to \mathbb{R}$ is the utility function that returns scores of the translation quality of the hypothesis under the given pseudo-references, which is formally defined as $h \succeq h' \iff u(h,\hat{r}) \geq u(h',\hat{r})$ where $\succeq$ denotes the preference relation. We employ COMET-22[8] (Rei et al., 2020, 2022) for the utility function u. Therefore, the MBR decoding using COMET-22 is formulated as follows:

$$y^{\text{MBR}} = \operatorname*{argmax}_{h\in\mathcal{H}} \frac{1}{|\hat{R}|}\sum_{\hat{r}\in\hat{R}} \texttt{COMET-22}(s,h,\hat{r}). \tag{5}$$

Note that COMET-22 also takes the source sentence s as input.

[6] We used "en_core_web_lg" model for English and "ja_core_news_lg" model for Japanese.

[7] The support set is a subset of the output space, i.e., $\text{Supp}(\hat{R}) \subseteq \mathcal{Y}$

[8] https://huggingface.co/Unbabel/wmt22-comet-da

In our system, we select the 30-best translations using MBR decoding instead of selecting the 1-best translation as shown in Equation 4 to determine the final decision using another algorithm than MBR decoding. In other words, MBR decoding is used to prune translation hypotheses. We generate hypotheses for each source sentence using an ensemble of Encoder-Decoder MT models with beam search decoding. In addition, we prepare two types of pseudo-references by decoding with top-p sampling ($p = 0.9$) and epsilon sampling (Freitag et al., 2023) ($\epsilon = 0.02$). The number of hypotheses and pseudo-references used in MBR decoding is presented in Table 3.

4.2 Stepwise MBR-Enhanced LLM Decoding

Algorithm 1: Stepwise MBR-Enhanced LLM decoding

```
  Input: $D_{\text{src}} = \{s_0, s_1, \dots, s_n\}$
  Output: $D_{\text{hyp}} = \{h_0, h_1, \dots, h_n\}$
1 $D_{tgt} \leftarrow \{\}$;
2 $S_{hist} \leftarrow \{\}$;
3 for $i \leftarrow 0$ to $n$ do
      // Generate candidates for $s_i$
4     $H \leftarrow \text{LLMs}_{\text{MT}}(s_i, S_{hist}, D_{tgt})$;
5     $h_i \leftarrow \text{MBR}(H, H)$;
6     $D_{tgt} \leftarrow D_{\text{hyp}} \cup \{h_i\}$;
7     $S_{hist} \leftarrow S_{\text{hist}} \cup \{s_i\}$;
8 return $D_{\text{hyp}}$
```

During our preliminary experiments with fine-tuned LLMs, we observed frequent issues where some sentences were skipped during decoding. This led to discrepancies in the number of sentences between the source and the translated output. Additionally, we observed samples where the same token was generated repeatedly. To address these issues, we propose a decoding method called `Stepwise MBR-Enhanced LLM Decoding` (Algorithm 4.2). This method translates documents sentence by sentence, considering the overall document context (see Figure 3). This approach resolves the issue of mismatched sentence counts between the source and hypothesis. Furthermore, we applied MBR decoding to achieve high-quality sentence-level translation without repeated tokens or other errors (line 5 of Algorithm 4.2). We used the outputs of four LLMs for this method. Specifically, we used four LLMs with different settings: Mistral-7B with and without vocab expansion and with and without preference learning.

5 LLM Reranking

As mentioned in Section 3 and Section 4, primary translation models decode at the sentence level. To improve the overall document-level consistency of the translation results, we performed reranking using LLMs. We used the top 30 highest-scoring hypotheses from MBR decoding as the candidate pool and reranked them based on context-aware scoring. Specifically, we used the LLMs fine-tuned for the translation task described in Section 3.2 to calculate the likelihood of each hypothesis with context information. We repeated this process to select hypotheses with the highest likelihood scores, resulting in the final translation output. The details are described in Algorithm 2. In our system, we use supervised fine-tuned Mistral-7B as the reranker, and we set the beam size to $b = 2$.

Algorithm 2: LLM Reranking Algorithm

```
Input: $D_{\text{src}} = \{s_0, s_1, \dots, s_n\}$
Input: $D_{\text{hyps}} = \{H_0, H_1, \dots, H_m\}$
Input: $b$: Beam size
Output: $D_{\text{hyp}} = \{h_0, h_1, \dots, h_n\}$
$\mathcal{C}_{\text{beam}} \leftarrow \{(\emptyset, -\infty)\}$;
$P \leftarrow \emptyset$;
for $H \in D_{\text{hyps}}$ do
    for $(\mathbf{c}, \_) \in \mathcal{C}_{beam}$ do
        for $h \in H$ do
            $p_h \leftarrow \text{LLM}_{\text{MT}}(D_{\text{src}},\ \mathbf{c} \cup \{h\})$;
            $P \leftarrow P \cup \{(\mathbf{c}, h,\ p_h)\}$;
    $\mathcal{T}_b \leftarrow \text{Top}_b\,(P,\ \text{with respect to } p_h)$;
    $\mathcal{C}_{\text{beam}} \leftarrow$
        $\{(\mathbf{c} \cup \{h\},\ p_h) \mid (\mathbf{c}, h,\ p_h) \in \mathcal{T}_b\}$;
$(\mathbf{c}^*, p_c^*) \leftarrow \arg\max_{(\mathbf{c},\ p_c) \in \mathcal{C}_{\text{beam}}} p_c$;
$D_{\text{hyp}} \leftarrow \mathbf{c}^*$;
return $D_{\text{hyp}}$
```

6 Post processing

Finally, we applied the following postprocessing rules to the selected translations. The rules are designed based on alignment errors commonly seen in the model translations of the development sets.

- Apply NFKC normalization

```
次の英語を日本人のネイティブのように日本語に翻訳してください。
原文: {src0} {src1} {src2} 訳文: {hyp0} {hyp1}
```

Figure 3: The prompt for stepwise MBR-enhanced LLM decoding from English to Japanese. This is an example for translating {src2}. {src0} and {src1} correspond to S_{hist} in Algorithm 1, and {src2} corresponds to s_i in Algorithm 1. Line breaks are added for readability; there are no them in the actual prompt.

- Append an emoji to the end of the hypotheses if it's present at the end of the source sentence
- Replace Japanese brackets (「」) to its Chinese counterparts (“”) (Ja→Zh only)
- Replace Japanese commas (、) to its Chinese counterparts (,) (Ja→Zh only)
- Remove whitespaces before and after parentheses
- Remove whitespaces before and after commas, periods, exclamations, and question marks
- Fix letter case of alphabets in the hypotheses to match its counterparts in the source sentence
- Fix punctuations in the hypotheses to match their counterparts in the source sentence

7 Post Evaluation

We evaluated the performance of our system using automatic evaluation metrics. Specifically, using this year's test set as the evaluation data, we conducted the evaluation using COMET-22[9] (Rei et al., 2022), MetricX-XL[10] (Juraska et al., 2023), and CometKiwi-XL[11] (Rei et al., 2023) as the evaluation metrics. Note that, since several segments in this year's WMT test set contain multiple sentences, the scores could not be computed at the sentence level.

The results of the post-evaluation from En→Ja are presented in Table 4, while those for the Ja→Zh direction are shown in Table 5. In these tables, "VE" refers to the vocabulary-expanded model, and "CPO" refers to the model where Contrastive Preference Optimization was performed. Additionally, "EncDec" represents outputs from Encoder-Decoder MT models, "MBR (top-p)" refers to the case where MBR decoding was performed using pseudo references generated by top-p sampling, and "MBR (epsilon)" refers to the case where epsilon sampling was used.

Performance of the LLM-based MT models. Table 4 shows that the translation performance of Llama2-13B is lower than that of Mistral-7B. One potential reason for this is the limited amount of data used for continual pre-training of Llama2-13B due to constraints in computational resources.

Efficiency of vocabulary expansion. Comparing the models with and without vocabulary expansion (`(b)` vs. `(d)`), there is no significant difference in performance. However, as shown in Table 13, the model with vocabulary expansion requires fewer training tokens than the model without it in our settings. The generation speed is also faster for the model with vocabulary expansion compared to the one without it. Thus, we believe vocabulary expansion could be a good option for improved inference efficiency.

CPO is effective but challenging. Comparing the performance before and after preference learning, the model with vocabulary expansion shows improvement across all evaluation metrics (`(d)` vs. `(e)`). On the other hand, the model without vocabulary expansion exhibits a significant decrease in performance for COMET-22 and CometKiwi-XL (`(b)` vs. `(c)`), leading to inconsistent results.

Qualitative analysis of outputs from the model without vocabulary expansion (i.e., `(c)`) revealed instances where decoding of byte-fallbacked text failed, resulting in text being replaced with replacement characters. This may be due to insufficient adjustment of the hyperparameters during CPO training.

Difference in pseudo references for MBR decoding. Comparing settings `(A)` vs. `(B)` and `(C)`, we observe that the performance improves when using MBR decoding compared to the 1-best output from the ensemble of models[12]. The difference in performance with regard to the pseudo-reference generation algorithms (`(i)` vs. `(j)` and `(B)` vs. `(C)`) was not significant.

[9] https://huggingface.co/Unbabel/wmt22-comet-da

[10] https://huggingface.co/google/metricx-23-xl-v2p0

[11] https://huggingface.co/Unbabel/wmt23-cometkiwi-da-xl

[12] In the En→Ja, we use results from multiple models with different vocabularies for MBR decoding; hence we cannot compare the performance with the 1-best output from the ensemble of all transformers.

	COMET-22↑	MetricX-XL↓	CometKiwi-XL↑
(a) Llama2-13B	0.820	3.050	0.677
(b) Mistral-7B	0.841	2.806	0.711
(c) Mistral-CPO-7B	0.651	2.254	0.557
(d) Mistral-VE-7B	0.836	2.881	0.695
(e) Mistral-VE-CPO-7B	0.866	2.254	0.732
(f) NT5 (Morishita et al., 2022b)	0.847	2.697	0.718
(g) Stepwise MBR-Enhanced LLM Decoding	0.882	**2.052**	0.729
(i) EncDec → MBR (top-p)	**0.885**	2.263	0.737
(j) EncDec → MBR (epsilon)	0.884	2.264	**0.743**
(k) EncDec → MBR (top-p) → LLM Reranking	0.881	2.269	0.740

Table 4: Results of post evaluation in En→Ja.

	COMET-22↑	MetricX-XL↓	CometKiwi-XL↑
(A) EncDec ensemble	0.818	3.550	0.548
(B) EncDec → MBR (top-p)	**0.841**	**3.168**	**0.570**
(C) EncDec → MBR (epsilon)	**0.841**	3.230	0.566

Table 5: Results of post evaluation in Ja→Zh.

Performance of stepwise MBR-enhanced LLM decoding. `Stepwise MBR-Enhanced LLM Decoding` achieves the highest score on MetricX-XL. Additionally, compared to using a single LLM, the scores of COMET-22 and MetricX-XL improved. This improvement is likely because generating hypotheses at each step with MBR decoding helps eliminate obvious errors, such as repeated tokens.

Effectiveness of LLM reranking. LLM Reranking did not result in any significant improvements according to automatic evaluation metrics. However, we noted improved consistency within segments qualitatively. We intend to evaluate performance through human evaluation as part of future work.

8 Submission System

For the final submission system, we adopted system `(k)` for the En→Ja direction and system `(B)` for the Ja→Zh direction. However, particularly in the En→Ja direction, different systems ranked highest across various automatic evaluation metrics, leaving us uncertain about which system to select even after post-evaluation. Thus, further refinement of automatic evaluation metrics is essential to develop a superior system.

9 Negative Results and Discarded Trials

Poor performance of LLMs for Japanese-to-Chinese translation. We conducted continual pre-training and supervised fine-tuning of LLMs for Ja→Zh translation. However, the translation performance did not meet our expectations, leading us to exclude it from the submission system (see Table 5 for post evaluation results). This shortfall likely resulted from our computational resource constraints, which limited continual pre-training to Chinese datasets only. For further details, please refer to Section A.

Use of LLM outputs as candidates for MBR decoding. We also explored the inclusion of LLM outputs in the candidate pool for MBR Decoding. However, we observed a decrease in translation quality when these outputs were included, leading us to exclude this approach from the final system. This decline in quality can be attributed to two main factors: i). a substantial difference in the distribution between the outputs generated by LLMs and the pseudo references produced by Encoder-Decoder MT models, and ii). inadequate tuning of hyperparameters during decoding with LLMs.

10 Conclusion

This paper described our systems for the constrained track of the WMT 2024 Shared Task: General Machine Translation. We developed translation systems for En→Ja and Ja→Zh. To achieve consistent document-level machine translation, we concentrated on investigating the application of LLMs, which have become available for use this year, employing methods such as LLM Reranking and Stepwise MBR-Enhanced LLM Decoding.

Our submitted system consists of the following steps: i) First, we generate translations using multiple Encoder-Decoder MT models. ii) Next, we narrow down the generated candidates by selecting the optimal translation through MBR decoding. iii) Finally, we apply LLM reranking to incorporate contextual information in order to determine the final output (only for En→Ja). The results from the post-evaluation did not provide quantitative confirmation of the final submission system's effectiveness. However, we did observe a qualitative improvement in consistency within the documents. We hope for future research on better automatic evaluation metrics that can assess these document-level translation performances.

Acknowledgments

We would like to thank the member of the Tohoku NLP Group and NAIST NLP Laboratory for their cooperation in conducting this research. We would like to especially thank Mengyu Ye, Yunmeng Li, Qin Dai, Zhang Ying, and Suchun Xie for their advice on constructing clean Chinese datasets.

This work was supported by Moonshot R&D Grant Number JPMJMS2011 (fundamental research) and JST BOOST, Japan Grant Number JPMJBS2421 and JPMJBS2423.

Contributions

Keito Kudo conducted the cleaning of the monolingual data, trained and decoded LLM-based MT models, developed the Ja→Zh Encoder-Decoder MT models, and performed post-evaluations.

Hiroyuki Deguchi conducted MBR decoding.

Makoto Morishita cleaned the monolingual and bitext data, pre-trained and fine-tuned the Ja→Zh translation model.

Ryo Fujii designed and implemented rules for filtering and post-processing, and performed qualitative evaluation of the resulting translations.

Takumi Ito designed and customized Hojichar for data cleaning, and designed and implemented Section 4.2.

Shintaro Ozaki, **Koki Natsumi** conducted pre-training and fine-tuning of the Ja→Zh Encoder-Decoder MT models, along with back-translation.

Kai Sato, **Kazuki Yano** implemented filters for data cleaning.

Ryosuke Takahashi implemented filters for data cleaning, conducted preference learning, and prepared scripts for decoding.

Subaru Kimura conducted the cleaning of the monolingual data, implemented checkpoint averaging, fine-tuned the LLM-based MT models, and implemented post-processing.

Tomomasa Hara implemented filters for the cleaning of the monolingual data and performed hyperparameter tuning for LLM-based MT models.

Yusuke Sakai managed the training process for the Ja→Zh Encoder-Decoder MT models.

Jun Suzuki provided the primary computational budget and overall project advice and carried out the decoding of NT5.

Table 6: Post evaluation results of the LLM trained for Ja→Zh translation. Compared to the ensemble of Encoder-Decoder MT models, the performance of the LLM for Ja→Zh translation was not sufficient.

A Japanese-Chinese LLM

Training configurations. We trained LLMs for Ja→Zh translation, although these were not included in the final system. Due to time and computational resource constraints, we only conducted continual pre-training and supervised fine-tuning on Chinese monolingual corpora. During supervised fine-tuning, we used the template shown in Figure 4. Table 12, 13 lists the hyperparameters used for training in the Ja→Zh direction.

Post evaluation. We conducted evaluations for the LLMs trained for the Ja→Zh translation. Table 6 presents the results. The performance of the LLMs in the Ja→Zh translation was insufficient compared to the ensemble of Encoder-Decoder MT models. This is likely because we were limited to continual pre-training using only Chinese corpora due to computational resource constraints.

B Vocabulary Expansion for LLM

As described in Section 3.2, we aimed to improve the Japanese language generation capability of Mistral-7B by expanding the model’ s vocabulary. Here, we provide details on the vocabulary expansion.

Construction of additional vocabulary. We first constructed a Japanese vocabulary using the unigram algorithm of the `Sentencepiece` tool (Kudo and Richardson, 2018). This vocabulary was trained on a subset of 30,000,000 samples from the Japanese Monolingual Corpus. We set the vocabulary size to 27,000. During vocabulary training, we enabled the options "byte_fallback" and "split_digits".

Vocabulary initialization. We initialized the embeddings for the additional vocabulary using the weighted average of the original Mistral embeddings. The weights were determined based on the similarity scores between the new and original Mistral vocabularies, computed by LaBSE (Feng et al., 2022). The process is described by the following equation:

$$\begin{aligned}\mathbf{v}_{\text{new}} &= \sum_{i=1}^{N}\left(\frac{\exp(w_i)}{\sum_{j=1}^{N}\exp(w_j)}\right)v_i \\ &= \sum_{i=1}^{N}\text{softmax}(w_i)v_i\end{aligned} \tag{6}$$

Here, $\mathbf{v}_{\text{new}}$ represents the embedding for the additional vocabulary, w_i is the similarity score between the additional vocabulary and vocabulary entry i as calculated by LaBSE, $\mathbf{v}_i$ is the vector of the existing vocabulary entry i, and n is the size of the original vocabulary. This method was also used to initialize the language modeling head.

Given our focus on the English-to-Japanese translation task, vocabularies other than English and Japanese are considered less critical. Therefore, we replaced any vocabulary not identified as Japanese, English, or special tokens with the new additional vocabulary. The determination of the language for each token followed these rules:

Japanese: Tokens consisting of *hiragana*, *katakana*, common-use *kanji*, symbols, JIS level 1 *kanji*, and ASCII characters

English: Tokens consisting solely of ASCII characters

Special tokens: Tokens split by byte fallback, as well as bos, eos tokens, etc.

Consequently, we expanded the vocabulary to 51,200.

Vocabulary warmup training. To address inconsistencies introduced by adding new vocabulary, prior research has proposed gradually training the model while fixing specific parameters after adding the vocabulary (Kim et al., 2024). We adopted a similar method to resolve these inconsistencies. Initially, we fixed the parameters of all transformer layers except for the embedding layer and the language modeling head and conducted the training. The hyperparameters used during this initial training phase are detailed in Table 11.

C Training Hyperparameters

The hyperparameters during the training of each model are shown in Table 7- 13.

Initial Translation Model	
Subword Size	32,000
Architecture	Transformer (big) with 6 layers, Encoder and Decoder FFN size of 8,192
Optimizer	Adam $\beta_1 = 0.9$, $\beta_2 = 0.98$, $\epsilon = 1 \times 10^{-8}$, $\mathrm{weight\_decay} = 0.0$
Learning Rate Schedule	Inverse square root decay, Cosine
Warmup Steps	4,000
Max Learning Rate	0.001
Dropout	0.1
Gradient Clip	1.0
Batch Size	1,048,576 tokens
Max Number of Updates	50,000 steps
Averaging	Save a checkpoint every 500 steps and average the last ten
Implementation	`fairseq` (Ott et al., 2019)
Pre-training Configuration	
Subword Size	16,000
Architecture 1	Transformer (big) with 9 layers, Encoder FFN size of 16,384, and Decoder FFN size of 4,096
Architecture 2	Transformer (big) with 9 layers, Encoder and Decoder FFN size of 8,192
Optimizer	Adam $\beta_1 = 0.9$, $\beta_2 = 0.98$, $\epsilon = 1 \times 10^{-8}$, $\mathrm{weight\_decay} = 0.0$
Learning Rate Schedule	Inverse square root decay, Cosine
Warmup Steps	4,000
Max Learning Rate	0.001
Dropout	0.1
Gradient Clip	0.1
Batch Size	1,048,576 tokens
Max Number of Updates	50,000 steps
Averaging	Save a checkpoint every 500 steps and average the last ten
Implementation	`fairseq` (Ott et al., 2019)
Fine-tuning Configuration	
Learning Rate Schedule	Fixed
Warmup Steps	N/A
Max Learning Rate	1×10^{-5}
Dropout	0.2
Gradient Clip	1.0
Batch Size	14,400 tokens
Max Number of Updates	1,000 steps
Averaging	Save a checkpoint every ten steps and average the last ten

Table 7: List of hyper-parameters. We used the initial translation model to generate synthetic data, the pre-training configuration to build the models described in Section 3.1, and the fine-tuning configuration to develop the models for submission. We created two models for pre-training and fine-tuning, labeled as "Architecture 1" or "Architecture 2," and used them for ensembling. The hyperparameters listed in the fine-tuning configuration represent only the differences from the pre-training configuration.

Llama2-13B Pretraining

Abstract

This paper presents the submission from Global Tone Communication Co., Ltd. and Dalian University of Technology for the WMT24 shared general Machine Translation (MT) task at the Conference on Empirical Methods in Natural Language Processing (EMNLP). Our participation encompasses two language pairs: English to Japanese and Japanese to Chinese. The systems are developed without particular constraints or requirements, facilitating extensive research in machine translation. We emphasize back-translation, utilize multilingual translation models, and apply fine-tuning strategies to improve performance. Additionally, we integrate both human-generated and machine-generated data to fine-tune our models, leading to enhanced translation accuracy. The automatic evaluation results indicate that our system ranks first in terms of BLEU score for the Japanese to Chinese translation.

1 Introduction

In this study, we employ fairseq (Ott et al., 2019) as our development framework and adopt the transformer (Vaswani et al., 2017) as the main architecture. The primary ranking index for the submitted systems is BLEU (Papineni et al., 2002), which also serves as the evaluation metric for our translation system via sacreBLEU[1], consistent with our methodology from the previous year.

For data preprocessing, we conduct punctuation normalization, tokenization, and Byte Pair Encoding (BPE) (Sennrich et al., 2015) across all languages involved. Furthermore, we applied a truecase model for English, tailored to the specific linguistic features of each language. Regarding tokenization, we utilize Jieba[2] for Chinese, Mecab[3] for Japanese, and the Moses tokenizer.perl (Koehn et al., 2007) for English. Additionally, we incorporate knowledge-based rules along with a language model to cleanse parallel data, monolingual data, and synthetic data.

For the multilingual translation model, we consolidate all languages into a single model and enhance it with an English to Chinese parallel corpus to enrich the language information.

The remainder of this paper is structured as follows: Section 2 discusses the translation task and provides dataset statistics. Section 3 describes our baseline systems and introduces the proposed multilingual translation model. The data selection methodology is elaborated in Section 4. Section 5 presents experiments conducted on all translation directions, addressing data filtering, model architectures, back-translation, joint training strategies, adaptations of the multilingual model, fine-tuning, data selection, and ensemble decoding. Section 6 analyzes the results, offering insights into the efficacy of various techniques. Finally, Section 7 concludes the paper.

2 Task Description

This task focuses on bilingual text translation, with the provided data elaborated in Table 1, which includes both parallel and monolingual data. For the English-Japanese directions, the primary sources of parallel data include WikiMatrix (Schwenk et al., 2019), CCAligned (Rozis and Skadiņš, 2017), JESC (Pryzant et al., 2017), JParaCrawl v3.0 (Morishita et al., 2022), LinguaTools-WikiTitles (Tiedemann, 2012), News Commentary v16, and XLEnt (Tiedemann, 2012). For the Japanese-Chinese direction, the main parallel data is sourced from CCAligned, JParaCrawl, LinguaTools-WikiTitles, News Commentary v16, WikiMatrix, and XLEnt. Monolingual data comprises News Crawl (Kocmi et al., 2022) in English, Japanese, and Chinese; News Commentary in English, Japanese, and Chinese; and Europarl v10 in English. We uti-

lized the provided development set from newstest2020 for English-Japanese and the FLoRes101 (NLLB Team, 2022) dataset for Japanese-Chinese.

3 Bilingual Baseline Model and Multilingual Translation Model

To establish a robust baseline for comparison with the multilingual model, we utilize the transformer_wmt_en_de as our bilingual baseline model, consisting of 24 encoder layers and 24 decoder layers. The multilingual translation model is designed to closely resemble the GTCOM2023 (Zong, 2023) model, referred to as the X to X model. To achieve superior translation quality, we include the English-Chinese parallel corpus as the primary auxiliary language pair to enhance linguistic information. We train a single multilingual model that encompasses all translation directions while applying joint Byte Pair Encoding (BPE) separately for all languages.

4 Data Selection

Similar to the last year, we use source test sets to train a text classification model based on RoBERTa (Liu et al., 2019). Specifically, we treat the in-domain test set as positive examples and select an equivalent amount of sentence pairs from the out-of-domain test set as negative examples. We fine-tune RoBERTa on this labeled dataset to develop a binary classifier capable of effectively distinguishing between in-domain and out-of-domain data. This classifier aids in selecting domain-specific training data from the general training corpus, with the chosen in-domain training data subsequently used to fine-tune the multilingual neural machine translation model.

Additionally, we also use prompt learning to explore an alternative data selection method. We develop a prompt template and leverage the generative capabilities of Meta-Llama-3-8B-Instruct [4] to create a domain classifier using loRA (Hu et al., 2021). The prompt template mirrors that used in GTCOM2023 from the last year, shows in Table 2. Specifically, we extract 800 sentences from the development set which belong to the news, social, e-commerce, or conversation domains. We manually select 200 sentences from the training set that do not match these domains or are of inferior quality, categorizing them as "other." We then utilize these 1,000 labeled examples to fine-tune the Meta-Llama-3-8B-Instruct model in loRA. The resulting prompt-based classifier effectively differentiates between domains in the training data. Sentences predicted as "News," "Social," "E-commerce," and "Conversation" are classified as in-domain data, while those labeled as "Other" are considered out-of-domain data.

5 Experiment

This section outlines the step-by-step experiments we conducted, with the entire workflow depicted in Figure 1.

- **Data Filtering:** The data filtering techniques largely replicate those utilized last year, incorporating human rules, language models, and repetition cleaning.
- **Baseline:** Our baseline is constructed using the transformer big architecture, which comprises 24 encoder layers and 24 decoder layers.
- **Back-translation:** We employ the best translation model to translate target sentences back to the source side, cleaning synthetic data using a language model. This process includes translating each language pair featured in the multilingual translation model. We combine the cleaned back-translation data with parallel sentences and train the multilingual translation model accordingly.
- **Joint Training:** We repeat the back-translation step using the optimal model until no further improvements are observed.
- **Multilingual Translation Model:** A single model is trained for all translation directions, with each direction utilizing joint BPE and a

[4] https://huggingface.co/meta-llama/Meta-Llama-3-8B-Instruct

Instructions	Please determine the domain to which the given sentence belongs based on the following criteria. 1. Sentence Correctness: If the sentence is incomplete, incoherent, or grammatically incorrect, label it as "Other" domain. If the sentence is complete, fluent, and grammatically correct, proceed to the next step. 2. Domain Identification: Analyze the content of the sentence to identify the possible domain it belongs to. Consider the following domains: News, Social, E-commerce, Conversation, and Other. If the sentence shows clear indications of being from a specific domain, label it accordingly, otherwise label it as "Other" domain. Please label the sentence with the appropriate domain: - If the sentence is from the News domain, label it as "News". - If the sentence is from the Social domain, label it as "Social". - If the sentence is from the E-commerce domain, label it as "E-commerce". - If the sentence is from the Conversation domain, label it as "Conversation". - If the sentence does not fit any specific domain or is incorrect, label it as "Other".

shared vocabulary. The multilingual translation model consists of 24 encoder layers and 24 decoder layers, employing the transformer big architecture.

- **Fine-tuning:** The multilingual translation model is fine-tuned for each direction and bi-direction separately. For instance, we fine-tuned en2ja and ja2en on the multilingual translation model and fine-tuned en2ja on the multilingual translation model for English to Japanese separately.
- **Data Selection:** The model described in the Data Selection section is employed to choose a domain-specific training dataset, which is then fine-tuned on the multilingual translation model.
- **Ensemble Decoding:** We utilize the GMSE Algorithm (Deng et al., 2018) to select models, aiming for optimal performance.

6 Results and Analysis

Table 3 displays the BLEU scores evaluated on the development set for English to Japanese and Japanese to Chinese. As indicated in the table, back-translation remains the most effective data augmentation technique for enhancing translation quality from a data perspective. The multilingual translation model also demonstrates significant improvements across all translation directions. As shown in Table 4, our prompt learning strategy is

Model	en2ja	ja2zh
Baseline	26.36	15.07
+ Back-translation	27.26	20.75
Multilingual Translation Model	26.50	15.20
+ Back-translation	27.40	21.24
+ Bilingual Fine-tuning	27.51	21.34
+ Single Fine-tuning	27.22	20.98
Ensemble Decoding	27.95	22.21

Table 3: BLEU scores for English to Japanese and Japanese to Chinese. Values are calculated based on word counts.

Direction	BLEU	BLEU with DS
en-ja	39.2	39.7
ja-zh	32.9	32.3

Table 4: The final online automatic evaluation BLEU with/without prompt learning in data selection.

still able to improve the BLEU score on the direction of English to Japanese, but there was some decline in the Japanese-to-Chinese direction.

7 Conclusion

This paper introduces the neural machine translation systems developed by GTCOM and DLUT for the WMT24 shared general MT task. We apply three primary techniques to enhance translation quality: back-translation, a multilingual translation model, and fine-tuning accompanied by data selection. Through these methods, we achieve notable improvements in automatic evaluation metrics, as illustrated in Table 5.

Direction	BLEU	CometKiwi
en-ja	39.7	0.697
ja-zh	32.9	0.586

Abstract

This paper presents the contributions of Charles University teams to the WMT24 General Translation task (English to Czech, German and Russian, and Czech to Ukrainian) and the WMT24 Translation into Low-Resource Languages of Spain task. Our most elaborate submission, CUNI-MH for en2cs, is the result of fine-tuning Mistral 7B v0.1 for translation using a three-stage process: Supervised fine-tuning using QLoRA, Contrastive Preference Optimization, and merging of model checkpoints. We also describe the CUNI-GA, CUNI-Transformer and CUNI-DocTransformer submissions, which are based on our systems from the previous year.

Our en2ru system CUNI-DS uses a similar first stage as CUNI-MH (QLoRA for en2cs) and follows with transfer learning for en2ru.

For en2de (CUNI-NL), we experimented with an LLM-based speech translation system, to translate without the speech input.

For the Translation into Low-Resource Languages of Spain task, we performed QLoRA fine-tuning of a large LLM on a small amount of synthetic (backtranslated) data.

1 Introduction

This paper describes the CUNI submissions to the WMT24 General Translation task (from English to Czech, German and Russian, and from Czech to Ukrainian) and the Translation into Low-Resource Languages of Spain task.

Our underlying goal for this year was to test the applicability of primarily small open-source LLMs to the languages of interest, and we also provide our English-to-Czech systems from the previous years for comparison.

The setups for the various target languages differ considerably in the methods used. Table 1 provides an overview of the individual system highlights. In Section 2, we detail the basic building steps and methods across our systems (not all setups use all of them). Section 3 describes the training and development data used across the target languages. In Section 4, we evaluate the systems and compare their results with various available baselines and benchmarks. Section 5 summarizes our future plans, and we conclude in Section 6.

2 Methods

For the CUNI-MH submission, we fine-tuned Mistral 7B v0.1 (Jiang et al., 2023) using three stages:

1. Supervised fine-tuning on CzEng 2.0 training dataset (Kocmi et al., 2020)[1], see Section 2.3.
2. Contrastive Preference Optimization (Xu et al., 2024b), see Section 2.4.
3. Averaging model checkpoints (Utans, 1996; Wortsman et al., 2022; Gueta et al., 2023), see Section 2.5.

CUNI-Transformer and CUNI-DocTransformer are the same systems as submitted last year (Jon et al., 2023), relying on standard NMT training with Block backtranslation (Section 2.1) and optionally document-level training (Section 2.2).

For CUNI-GA, in English-to-Czech, we used outputs from CUNI-Transformer and a genetic algorithm to combine and modify them, again in the same way as previous year (Section 2.8; Jon et al., 2023; Jon and Bojar, 2023). For coincidentally identically called CUNI-GA submission in Translation into Low-Resource Languages of Spain task, we fine-tune larger LLMs (Command-R and Aya-23), without applying the genetic algorithm.

For the CUNI-NL system, we fine-tuned Llama 2 7B (Touvron et al., 2023) for the speech translation task, while also adapting it for text-only translation at the same time; see Section 2.6.

Finally CUNI-DS starts as step 1 of CUNI-MH but continues with transfer learning to target Russian instead of Czech, see Section 2.7.

Table 1: Overview of CUNI systems in WMT24 General Translation task and Translation into Low-Resource Languages of Spain task (spa). Systems in the upper part of the table are our last year's baselines. §· refer to the methods in Section 2.

2.1 BlockBT

For training CUNI-Transformer and CUNI-DocTransformer, we used iterated Block backtranslation (BlockBT) (Popel, 2018; Popel et al., 2020; Gebauer et al., 2021; Jon et al., 2022) in a standard Transformer (Vaswani et al., 2017) NMT training from scratch. The BlockBT method organizes the training data, so that the model can optimize the balance between authentic English-to-Czech parallel texts (exhibiting more translationese artifacts) and synthetic data created by back-translating Czech-only texts) by averaging eight checkpoints reflecting more of the former or the latter domain. The use of eight checkpoints for averaging is derived from the original paper (Popel, 2018) and a study on hyperparametrs for training Transformers (Popel and Bojar, 2018).

2.2 Document-level training

The approach for training CUNI-DocTransformer is described in Popel et al. (2019). Starting with the initial sentence-level model (CUNI-Transformer), we continued training on sequences of consecutive sentences coming from a coherent text with at most 3000 characters, where both sides (en and cs) have the same number of sentences. The sentences are separated by a special token in each of the languages.

2.3 Supervised fine-tuning (SFT)

For the CUNI-MH submission, we used 4-bit QLoRA (Dettmers et al., 2023) with a large LoRA rank of $r = 512$. We used a batch size of 32, a learning rate of $2e-5$, 20 warm-up steps, 8-bit AdamW (Loshchilov and Hutter, 2019) optimizer and weight decay of 0.01. We also used a scheduler with linear learning rate decay. Starting from the freely available Mistral 7B v0.1 model, we trained in a language modeling fashion on individual sentences, calculating the loss on each token. To reduce the number of padding tokens, we also used packing: examples are concatenated with the EOS token as a separator to achieve a total sequence length of 1000. In Appendix A, we present our translation prompt template and example of its processed form with packing as used during training.

We trained for a single epoch on the authentic part of CzEng 2.0. In Figure 1, we show how the performance of the model develops during the first stage, starting from 100 steps. A notable observation is that the COMET22 and COMETKIWI22 scores seem to plateau relatively early, despite the evaluation loss steadily decreasing, while BLEU seems to be steadily increasing. This appears to be consistent with the results presented by Xu et al. (2024a), although we suspect it could also be the result of insufficient regularization.

For training, we used the HuggingFace Transformers and TRL libraries by Wolf et al. (2020) and von Werra et al. (2020). We also used the Unsloth library,[2] which provides speed and VRAM optimizations to Transformers and TRL libraries.

Another of our submissions that made use of a pre-trained LLM and SFT was CUNI-GA in the Translation into Low-Resource Languages of Spain task. We used 4-bit QLoRA with the rank of $r = 16$ and the learning rate of $4e-4$ for fine-tuning the pretrained *Command-R* model, and $1e-3$ for fine-tuning the *Aya* model, with an effective batch size

[2] https://github.com/unslothai/unsloth/

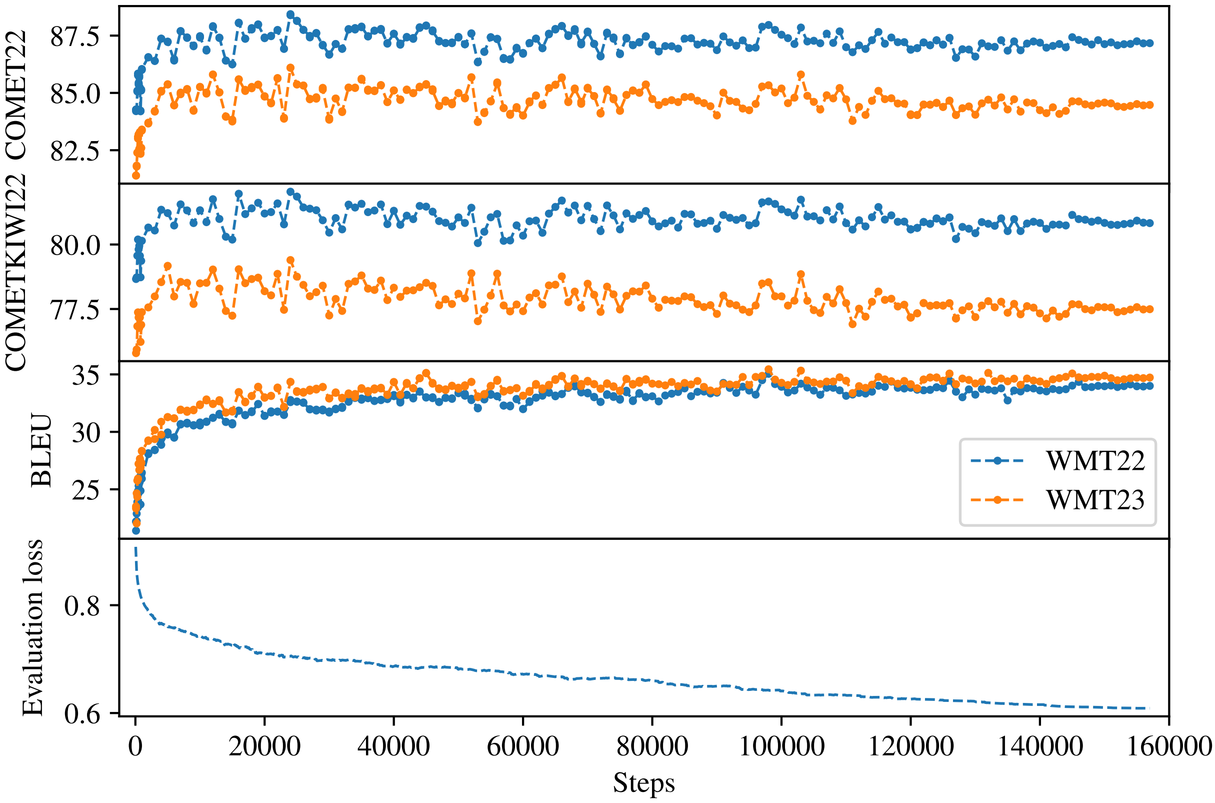

Figure 1: CUNI-MH Stage 1 – metrics during training.

of 32 and an AdamW optimizer with the weight decay value of 0.001.

2.4 Contrastive Preference Optimization (CPO)

CPO is a fine-tuning method introduced by Xu et al. (2024b) as an approximation of Direct Preference Optimization (Rafailov et al., 2024).

The goal of CPO is to fine-tune the model to directly optimize for preferences between translation candidates, rather than just optimizing the likelihood of the reference translations.

From a high-level point of view, the main difference between using SFT and CPO for translation is that for a given source text, we need two translations: *preferred* and *dis-preferred*. This means that the training dataset consists of triplets, rather than pairs as is typical for supervised training of NMT. For a more detailed description of the dataset we used and how it was created, see Section 3.2.

To apply CPO during the second stage of CUNI-MH training, we started two separate training runs from models we created during the first stage. One of the runs starts from model ③ and the other from model ④ in Table 2.

We selected these models because they had the best COMET22 and COMETKIWI22 scores among the models we had available at the time, when evaluated on the sentence-level WMT22 validation set.

Because we wanted to use a smaller LoRA rank size comparable to those used in the original paper (Xu et al., 2024b), we merged LoRA adapters with the quantized model into a 16-bit model and added new, smaller adapters.

We trained for two epochs with the following parameters: LoRA rank $r = 32$, LoRA $\alpha = 64$, CPO $\beta = 0.1$. We trained two separate runs, starting from the checkpoints mentioned earlier. Similarly to the SFT stage, we used 8-bit AdamW, this time without learning rate decay. Our GPU memory capacity was limiting us to the batch size of 4, so to compensate, we used 64 gradient accumulation steps to simulate a larger effective batch size of 256.

Stage	ID	Model	Checkpoint	COMET22	COMETKIWI22	BLEU
	⓪	Mistral 7B v0.1 5-shot		67.16	59.79	17.35

Table 2: CUNI-MH's training stages, models and their sentence-level scores on WMT23 (test set). The final CUNI-MH submission ⑧ is in bold.

Checkpoints were saved every 50 steps[3] and evaluated on the validation test set using COMETKIWI22. The performance peaked around checkpoint 150 for the first run, leading us to conclude that further training beyond 2 epochs was unnecessary. However, we acknowledge that the training parameters may not be optimal and could potentially be tweaked further for better results.

2.5 Checkpoint merging

To further improve the performance of the CUNI-MH model, we experimented with two methods for merging model weights: linear interpolation (Utans, 1996) and spherical linear interpolation (SLERP, Shoemake, 1985) in different training stages.

In particular, after the SFT stage, we merged two promising checkpoints from the same training run using SLERP, which led to a small improvement in all metrics, as can be seen by looking at model ④ in Table 2.

After the CPO stage, we once again experimented with model merging, this time we merged the best performing checkpoints from two different CPO training runs. This led to a further modest improvement in all COMET22, COMETKIWI22 and BLEU metrics, as shown by model ⑧ in Table 2.

For model merging using both SLERP and linear interpolation, we used the `mergekit` library by Goddard et al. (2024).

2.6 SFT from Speech Translation System (SFTSpeech)

The CUNI-NL system was adapted from a speech translation system, which features a frozen HuBERT component (Hsu et al., 2021) and the Llama 2 7B (Touvron et al., 2023) LLM.

The original speech translation system applied the CTC collapsing strategy to extract the speech hidden features; these features would subsequently be given as the prompt to a LLM to generate the ASR transcription and its corresponding translation simultaneously.

For the purposes of the General Translation Task, we avoid any audio features during inference and directly prompt the LLM with the source language text. We expect the LLM to translate using that only information. The motivation for this experiment was to check if a LLM-based speech translation system remains versatile enough to support text-only translation.

The original speech translation system was a fine-tuned LLM using 4-bit QLoRA (Dettmers et al., 2023) adapters, with the rank of $r = 8$ and alpha of $\alpha = 8$. Other training hyperparameters included the batch size of 1, the learning rate of $1e-4$ with 10 warmup steps, and an AdamW optimizer (Loshchilov and Hutter, 2019) with a cosine scheduler (Loshchilov and Hutter, 2017).

2.7 SFT for Transfer Learning

We used transfer learning across languages in the CUNI-DS system for English-to-Russian, transferring from English-to-Czech system.

2.7.1 Phase 1: en2cs Training

In the first phrase, we proceeded very similarly as described in Section 2.3. We started with the 4-bit quantized Mistral 7B v0.1 model (Jiang et al., 2023) and trained it using QLoRA (Dettmers et al., 2023) with a rank of 64 and an alpha of 128. The training followed Alpaca-like (Taori et al., 2023)

[3] Resulting in total of 7 checkpoints for each of the two runs.

instructions, with 20 warmup steps, a learning rate of $2e-5$, weight decay of $1e-2$, and a cumulative batch size of 32.

The model was trained on CzEng 2.0 for 24 hours, with segments packed into chunks of 2048 tokens. The final checkpoint was selected for the next phase.

2.7.2 Phase 2: en2ru Fine-Tuning

The model was then fine-tuned for en2ru translation using the Yandex Corpus for sentence-level data and the News Commentary v18.1 dataset for paragraph-level data. The datasets were shuffled and concatenated, and fine-tuning was conducted under the same conditions as the first stage, lasting 24 hours.

2.8 Genetic algorithm

For the CUNI-GA submission in English-to-Czech, we used a genetic algorithm to combine and modify n-best lists (Jon and Bojar, 2023) produced by CUNI-Transformer (at the sentence level), in the same manner as in Jon et al. (2023). We combined 5 metrics for the fitness function by a weighted average: BLEU (Papineni et al., 2002), chrF (Popović, 2015), wmt22-comet-da (Rei et al., 2022a), wmt22-cometkiwi-da (Rei et al., 2022b) and wmt23-cometkiwi-da-xl (Rei et al., 2023). The reference-based metrics use MBR decoding (Freitag et al., 2022) in place of the unknown reference.

3 Data

This section details the dataset used across the various training steps and language pairs.

3.1 SFT dataset

3.1.1 English-Czech

For the first stage of the CUNI-MH training, we used the authentic part CzEng 2.0. We did not use any preprocessing, except for applying the prompt template and packing described in Appendix A.

3.1.2 English-German

The CUNI-NL system was trained using the MuST-C dataset (Cattoni et al., 2021), a large multilingual corpus built from English TED Talks, containing the audio data, the English transcription of such audio, with its translation in multiple languages. Specifically, we used the en2de subset, consisting of approximately 400 hours of speech data.

During training, we randomly took 25% of the dataset, in which the input was the source transcript itself, instead of the audio features, so that the system could know how to translate from text-only data.

We trained the system for two epochs, both checkpoints of which were then used for evaluating against the WMT23 test set.

3.1.3 English-Russian

The initial phase of CUNI-DS system training (en2cs) utilized the first million segments from the CzEng 2.0 (Kocmi et al., 2020) dataset. In the second phase (en2ru), a combination of the Yandex Corpus[4] and the News Commentary v18.1[5] dataset was used, with the latter segmented into chunks of 10 sentences each.

3.1.4 Translation into Low-Resource Languages of Spain

For the Translation into Low-Resource Languages of Spain task, we backtranslated the literary part (`literary.txt`) of the PILAR dataset (Galiano-Jiménez et al., 2024) into Spanish using Apertium (Forcada and Tyers, 2016), resulting in 230k, 25k and 24k sentence pairs for Aranese, Aragonese and Asturian, respectively. For Aranese, we also backtranslated the Aranese side of the parallel part of the corpus, while keeping the paragraphs whole up to the length of 30 sentences, resulting in 726k sentences in 4329 documents. To make use of the paragraph-level context, we employed a context-aware prompt shown in Appendix B.

3.2 CPO dataset

To create a dataset for CPO (Section 2.4), we need triplets: source segment, preferred output and dis-preferred output. We construct these triplets at the *paragraph level* (i.e. several sentences concatenated into a single segment) but sentence-level processing, inspired by the approach of (Xu et al., 2024b), is used in the preparation as described below.

Given a source segment, we select both preferred and dis-preferred translation from three candidates: our stage 1 output, our last year's constrained system and human reference. Our approach ensures that we still satisfy the requirements for a constrained submission.

Our CPO source segments (and their corresponding manual reference translations) are ran-

Table 3: Short examples from the CPO dataset. Errors (underlined) are, resp.: Kirkenes located *in* Barents Sea; missed the adverb *seriously*; and grammatically inacceptable form of passivization mentioning the subject Ghana. The third example's dis-preferred translation does not mention the detail that we are referring to a poem ("báseň"), although this fact is not explicit in the source either; other lexical variations are minor.

domly sampled documents from CzEng 2.0, a total of 47257 documents containing 200k sentences. We then used the best checkpoint from stage 1 (see model ④ in Table 2) together with our constrained model from the previous year, CUNI-DocTransformer, to generate translations for the samples.[6]

Because we want to consider the manual translation as one of the candidates for the (dis-)preferred translation, we cannot use it as the reference to select the better candidate. Therefore, we use the reference-free wmt20-comet-qe-da[7] model to rank the translations, selecting the one with the highest score as the preferred one and the one with the lowest score as the dis-preferred one.

Note that wmt20-comet-qe-da scores individual sentences, not complete paragraphs, so we do this for each sentence in the sampled dataset, while giving all preceding sentences in the corresponding document (as translated by the given system) as a context (DocCOMET, Vernikos et al., 2022).

Since this DocCOMET approach is currently not supported by the COMET project[8] for newer model architectures, such as those used by COMETKIWI22 and XCOMET, we have not tried to build the data set using these newer models.

To arrive back at paragraph-level segments for CPO, we concatenate all the sentences in each original document. The result is a dataset consisting of 47k paragraph-level triplets for CPO. Each triplet consists of the paragraph in source language and two translations: preferred[9] and dis-preferred.[10] Due to the sentence-level selection, both preferred and dis-preferred translations may actually mix sentences from each of the three seed translations: human, our CUNI-DocTransformer and CUNI-MH Stage 1. We leave the analysis of document-level errors that arise in this process for future.

In Figure 2, we show which sentences were selected as preferred and dis-preferred. Note that this comparison is done on sentence-level, because the resulting paragraph-level examples can be composed of sentences from different sources. Interestingly, reference sentences were scored lowest by wmt20-comet-qe-da most frequently. We also show a few short examples from our dataset in Table 3. During training, the source sentences are formatted with the prompt template shown in Appendix A, similarly to how they are handled in the SFT stage Section 2.3.

We are aware that there are several potential issues with our method of preparing the dataset. First, there is a reason to be concerned about potential overfitting to a given metric (wmt20-comet-qe-da in our case) used to select the sentences. Second, our stage 1 CUNI-MH model did the translation in sentence-level fashion, potentially disregarding the relevant context. Third, we select sentences for preferred vs. dis-preferred class considering their preceding source-side context and their preceding target-side context as translated by the candidate system, not as selected so far within the document. This leaves document-level properties both in the positive and negative cases unhandled. Ideally, the preferred paragraph would avoid also any contextual errors, and for the dis-preferred paragraph, we

[6] For clarity, we note that we create only one CPO dataset, using translations by ④, and we apply the CPO method using this dataset three times, starting from three different models, see Table 2.

CUNI-MH $k = 1$	87.35	73.30	37.47
CUNI-MH $k = 8$	**87.73**	**74.82**	**35.42**

Table 5: CUNI-MH's document-level scores on the en2cs WMT23-para test set. k denotes how many sentences at most are translated together in one chunk. The CUNI-MH final submission is in bold.

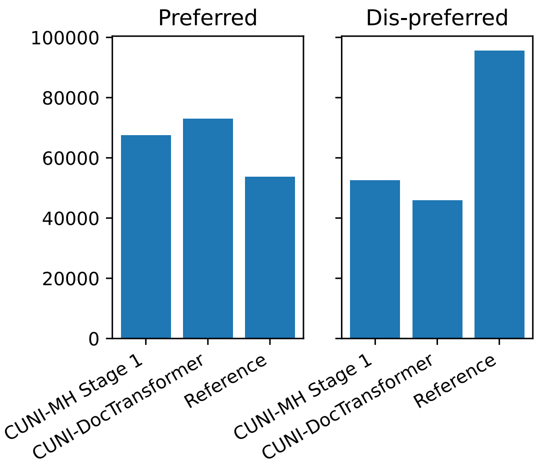

Figure 2: CPO dataset - sources of preferred and dis-preferred translations.

could construct worse translations in two ways: (1) using worse individual segments, as we do, and (2) combining better or worse individual segments in a way that purposefully damages paragraph context. Fourth, because we sampled uniformly from the CzEng 2.0 documents, our final dataset actually has a large number of documents, namely 24744 out of 41835, that only consist of a single sentence. We opted for a trivial sampling because we were concerned that naive solutions aiming at having more longer documents could potentially have a negative impact on the diversity of the dataset, however this is something we would like to address in the future.

All in all, we believe that there is potential to make subsequent iterations of the dataset higher quality by alleviating some of these concerns.

3.3 Validation and test datasets

During training of CUNI-MH, we used the WMT22 test set as the validation data set and the WMT23 test set as the test data set. In particular, we used WMT22 when selecting the best checkpoints and hyperparameters and only used WMT23 to estimate the final performance compared to baselines.

To prepare for paragraph-level evaluation, we also concatenated all the sentences in each document to a long paragraph, creating what we call WMT22-para and WMT23-para data sets. For CUNI-GA in English-to-Czech, we did not use validation sets, we did not compare the possible configurations on validation set, we chose the parameters based on our experience. For CUNI-GA in Translation into Low-Resource Languages of Spain, we use FLORES+ validation set (NLLB Team et al., 2022).

4 Evaluation

4.1 English-Czech

We show the sentence-level metrics on the WMT23 test set for the CUNI-MH system in Table 4 and the document-level metrics on the WMT23 test set in Table 5. We used greedy decoding for this system.

Since our preliminary experiments on WMT22-

Submission	W_{BLEU}	W_{CHRF}	W_{CMT22}	W_{QE22}	$W_{QE23-XL}$	CHRF	BLEU	QE22	QE23-XL	MetricX
CUNI-Transformer	-	-	-	-	-	57.3	29.3	X	0.614	4.3
CUNI-GA	0.1	0.1	0.4	0.4	0	56.4	29.5	0.819	0.658	-
CUNI-GA	0	0	0.5	0.5	0	55.5	26.5	0.827	0.650	-
CUNI-GA	**0**	**0**	**0.5**	**0**	**0.5**	**54.8**	**25.6**	**0.797**	**0.726**	**3.7**

Table 6: Paragraph-level scores on WMT24 test set for the CUNI-GA submission, primary submission in bold. CUNI-Transfomer was used to produce the n-best lists which are combined and modified for the CUNI-GA submission.

Model	COMET22	COMETKIWI22	BLEU
Baseline	24.04	28.55	0.20
CUNI-NL (epoch=1)	81.07	77.23	29.61
CUNI-NL (epoch=2)	80.90	77.51	30.75

Table 7: CUNI-NL's sentence-level scores on the en2de WMT23 test set.

para showed that our model did not handle longer paragraphs or documents well, we used sentence-splitter from Moses[11] to split segments into sentences. We then concatenate these sentences into chunks of up k, which we translate together as a whole. We then concatenate all the chunks to the original segments.

By testing our model on the WMT22-para validation dataset, we chose to use $k = 8$ for our final submission to optimize for the highest COMET22 and COMETKIWI22 scores. This can also be seen in Table 5, where the model with $k = 8$ has better COMET22 and COMETKIWI22 scores than the one with $k = 1$, at the cost of worse BLEU score.

The submitted CUNI-MH system also seems to perform well according to the preliminary automatic rankings, where it surpasses most of our systems from previous years and closely matching the performance of another of our systems, CUNI-GA. These results are shown in Table 8.

However, since both systems use COMET or COMETKIWI metrics during either training or inference, raising potential concerns about overfitting, we are also awaiting the results of human evaluation (Kocmi et al., 2024).

We also tried to use CPO with our new dataset to train the base Mistral model directly, skipping the supervised fine-tuning stage. The results are shown in Table 2, see ⑦, which is the best performing checkpoint of the training run, according to its COMETKIWI22 score on the validation dataset. It can be seen that the performance of this model is significantly worse in all metrics, so the SFT stage seems necessary in our setting.

We have also submitted CUNI-Transformer and CUNI-DocTransformer systems from previous year to provide reasonable constrained baselines for our newer models.

The CUNI-GA in this task submission combines hypotheses from CUNI-Transformer n-best lists created with beam sizes 4, 10 and 25 for each sentence. The resulting 39 translation candidates were processed by the genetic algorithm. The fitness (objective) function was a weighted combination of 5 metrics: BLEU, chrF, wmt22-comet-da (CMT22 in Table 6), wmt22-cometkiwi-da (QE22) and wmt23-cometkiwi-da-xl (QE23-XL). The weights and the obtained scores (chrF, BLEU, QE22, QE23-XL and MetricX (Juraska et al., 2023)) on the WMT24 test set are shown in Table 6. We did not use a development set due to high computational requirements of this approach, the weights are chosen based on our previous experience. An expected conclusion is that our approach allows us to easily optimize for the fitness metrics, which can be seen by comparing the QE23-XL scores of baseline translations (first row) and the score of the translations directly optimized for this metric (last row).

4.2 Czech-Ukrainian

We will add results for the Czech-Ukrainian submission in the camera-ready version.

4.3 English-German

For the CUNI-NL submission, we performed inference using the beam search algorithm, with the beam size of 2 for both checkpoints. We evaluated the performance of the two checkpoints of this system (as trained for speech translation), after epoch

1 and after epoch 2 of en2de MuST-C corpus, with the latter performing better, so we chose it for the final evaluation against the test set this year. The results of the evaluation on the WMT23 test set are shown in Table 7.

4.4 English-Russian

For the CUNI-DS submission, we ran the evaluation on the paragraph level, i.e. the model needed to output the translation of the whole input at once. We used greedy decoding due to frequent emission of repeated tokens (sometimes called "spasm" by NMT practitioners) we observed with beam search. The outcomes of the CUNI-DS system's two-stage training are presented in Tables 9 and 10.

4.5 Translation into Low-Resource Languages of Spain

We compare Apertium and two open-source LLMs – Aya-23-8B and Command-R (35B version, quantized to 4 bits) – in translation from Spanish into the other languages of the task. We show the scores in Table 11. We fine-tuned both LLMs as a single joint model for all the languages on the back-translated literary data described in Section 3. We present BLEU, chrF and COMET-22 scores of the best-performing checkpoints after fine-tuning in Table 12. We submitted the translations produced using the Aya-23 model fine-tuned for 5000 steps. While the results are at best comparable to Apertium scores, we note that we only did a very lightweight fine-tuning on synthetic (backtranslated) data, which shows the potential of LLMs for translation into previously unsupported low-resource languages related to a language present in the training data. For instance, we obtained improvement from 46.7 to 70.2 ChrF (12.4 to 39.0 BLEU) in Aragonese by fine-tuning on 24k backtranslated sentence pairs from a different (literary) domain.

5 Future work

We have several ideas to improve the performance of the future iterations of our CUNI-MH model:

- Longer sequences: During our SFT stage, we trained on short sequences, mostly single sentences. In the future, we would like to experiment with training on larger sequences, so that the model is able to handle longer inputs in end-to-end fashion.

- Better CPO dataset: Our current dataset for CPO (Section 3.2) was created without including any filtering steps. The Stage 1 model we used to create one kind of translation candidates also translated in sentence-level fashion only. We think there is potential to create a higher quality dataset by using our final model, ensuring all translations are done with paragraph or document level context and possibly investigating means of filtering out lower quality examples.

- Better QLoRA initialization: During our SFT stage, we used the default initialization from the original LoRA paper (Hu et al., 2021). There are other initialization methods specifically for the combination of LoRA adapters and quantization, such as LoftQ (Li et al., 2023) which seems to consistently perform better for QLoRA. In the future, we would like to evaluate using this initialization method.

- Monolingual pretraining stage: Xu et al. (2024a) have shown promising results by including a stage where they continue pretraining Llama 2 7B and Llama 2 13B models on monolingual data covering their target languages. We think including such a stage before our SFT stage is worth considering in our future models.

- Optimization of model merging: Our experiments with checkpoint merging (Section 2.5) were extremely sparse. In the future, we would also like to evaluate SLERP and linear interpolation in comparable settings and a broader range of possible combined models (checkpoints from a single run vs. checkpoints across different run branches).

6 Conclusion

In this paper, we presented the CUNI submissions for the WMT24 General Translation task and the Translation into Low-Resource Languages of Spain task. Our primary focus was on using small open-source language models for various language pairs and providing comparisons with our systems from previous years.

The CUNI-MH system for English-to-Czech translation, based on Mistral 7B, showed promising results, possibly because of its CPO stage which led to a significant improvement of COMET and

A CUNI-MH Model Prompt Template and Packing

We used the following prompt template for the model, inspired by the one used in Alpaca (Taori et al., 2023):

```
### Instruction:
Translate Input from English to Czech
### Glossary:

### Previous text:

### Input:
{source_text}
### Response:
{target_text}
```

The *Glossary* and *Previous text* sections were not used for the current task, so we left them empty. Since we trained only a single translation direction this time, the instruction remains constant.

Below is a shortened example of the packed[13] and tokenized training data, where <s> stands for the beginning of sequence token, </s> stands for the end of sequence token and \n stands for newline, the tokens are separated by spaces:

```
<s> ▁### ▁Inst ruction : \n Trans late
▁Input ▁from ▁English ▁to ▁Czech
\n ### ▁Gl oss ary : \n \n ### ▁Pre
vious ▁text : \n \n ### ▁Input : \n It
▁had ▁been ▁bad ▁enough , ▁calling
▁Brother ▁when ▁she ▁was ▁with
▁him . \n ### ▁Response : \n By lo
▁d ost ▁z lé ▁př iv ol at ▁Br atra
, ▁k dy ž ▁byla ▁s ▁n ím . </s>
<s> ▁### ▁Inst ruction : \n Trans late
▁Input ▁from ▁English ▁to ▁Czech
\n ### ▁Gl oss ary : \n \n ### ▁Pre
vious ▁text : \n \n ### ▁Input : \n To
▁do ▁it ▁now ? \n ### ▁Response :
\n A le ▁te ď ? </s> <s> ▁### ▁Inst
ruction : \n Trans late ▁Input ▁from
▁English ▁to ▁Czech \n ### ▁Gl oss
ary : \n \n ### ▁Pre vious ▁text :
\n \n ### ▁Input : \n Here ? \n ###
▁Response : \n T ady ? </s>
```

[13] The packing itself is implemented by TRL's ConstantLengthDataset, see `https://github.com/huggingface/trl/blob/e3fe28ee1a8bfab9739f849759c93d56776376e2/trl/trainer/utils.py#L431`

B CUNI-GA Model Prompt Template

We used the following prompt for context-aware translation in the Translation into Low-Resource Languages of Spain task, in order to make use of document-level context, while still keeping alignment on the sentence level, necessary for the evaluation:

```
We need to translate a single line from
conversation in Spanish into
{target_language}.  This is the
conversation: {src_context}

The start of the conversation is already
translated into English: {prev_context}
Translate the following line from
{src_lang} to {tgt_lang}.

Be very literal, and only translate the
content of the line, do not add any
explanations: {src_line}
```

From General LLM to Translation: How we dramatically improve translation quality using human evaluation data for LLM finetuning

Abstract

This paper describes Yandex submission to the WMT2024 General Translation Task. More specifically, we present a novel pipeline designed to build a strong paragraph-level translation engine with an emphasis on video subtitles domain. In particular, we apply a multi-stage adaptaion pipeline on top of LLM pretraining to align the model for translation task and subsequently to the video subtitles format. Our submission ranks 3rd on the preliminary general translation leaderboard.

1 Introduction

In this paper, we present unconstrained system submitted by the Yandex LLC NLP team to the WMT 2024 General MT Translation track, focusing on English-to-Russian translation. Our approach involves training a YandexGPT[1] LLM-based model for translation tasks using a multi-stage process to ensure high-quality and contextually accurate translations.

We are not capable of revealing all the details of the model due to NDA reasons, however, we can say that it is a Yandex GPT-like model, specifically trained for the translation task.

Our multi-stage approach, which combines extensive pre-training, targeted fine-tuning, advanced prompt-tuning, and structure-preserving techniques, ensures that our model delivers high-quality, fluent, and structurally consistent translations and performs well both in competitive benchmarks and real-world applications.

2 System Overview

2.1 Pretraining

The foundation of our approach is a robust pretraining phase involving a Large Language Model (LLM) trained on a vast corpus of clean texts in multiple languages, with a predominant focus on Russian and English. The quality of this pretrained model is evaluated using a comprehensive suite of benchmarks, including both automated metrics and human evaluation.

This initial phase ensures that the model captures a wide range of linguistic features and nuances across different languages, thereby establishing a strong base for subsequent fine-tuning.

2.2 Incorporating Parallel Data

Following the pretraining phase, we enhance the model by incorporating parallel data, where English and Russian texts are concatenated using a delimiter. This step is crucial for aligning the model's understanding of both languages in a translation context. We use a proprietary CommonCrawl-like parallel corpus of pages crawled from the Web. The data is meticulously curated to ensure high quality using Bicleaner-likeRamírez-Sánchez et al. (2020)

[1] https://yandex.cloud/en/services/yandexgpt

pipeline:

- Texts are selected using automated parallelism filters.

- Duplicates are removed to maintain a clean dataset.

This concatenation strategy enables the model to establish connections between two languages and to learn direct mappings from English to Russian and vice versa.

2.3 Sentence-level vs. Paragraph-level Translation

Our initial translation model primarily focuses on sentence-level translation. However, through extensive experimentation, we have observed that paragraph-level translation benefits significantly more from clean, coherent paragraph-level data. Unlike isolated sentences, paragraphs provide a broader context, which is essential for maintaining the flow and coherence in translations.

To leverage this, we gather texts that are inherently structured in paragraphs. These texts are preprocessed to ensure they meet our quality standards:

- Automated filters are employed to assess text parallelism and quality.

- Rigorous deduplication processes are applied to eliminate any repeated content, ensuring that the data fed into the model is both diverse and representative.

2.4 Structured content translation

Although the document-level translation system we have obtained using the pipeline above has high translation quality on generic textual data, it is incapable of consistently translating data in structured format, e.g. data in HTML format. Particularly, when presented texts with tags or other strict markup, model is prone to dropping or altering the markup and thus generating an invalid HTML page.

To handle this problem, we have designed a data augmentation strategy aimed at guiding the model towards HTML domain and such an augmentation have been incorporated into our document-level alignment stage.

2.5 Fine-Tuning LLM for Subtitle Translation

Building on a pre-trained LLM proficient in translating tagged web pages, we developed a method to train the model for subtitle translation. The key idea of this approach involves enclosing each speaker and dialogue in brackets, ensuring accurate parsing into individual dialogues.

This adaptation enhances the LLM's ability to meet the specific challenges of subtitle translation, ensuring contextually accurate outputs with proper segmentation by speaker and timing.

In the subsequent sections we further describe the main stages of our pipeline.

3 Supervised Fune-Tuning (SFT)

Firstly, we align the pretrained language model to the machine translation task. We conduct supervised fine-tuning (SFT) on an in-house dataset of parallel books fragments of up to 1000 tokens length.

We use multilayer prompt-tuning as in Liu et al. (2021) with each p-tuning block size of 100.

Overall LLM input consists of an English source text surrounded by two p-tuning blocks:

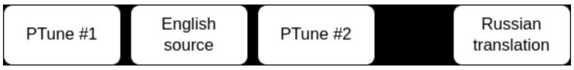

Figure 1: PTune blocks layout.

4 Human Feedback Alignment

Following the Supervised Fine-Tuning stage, we further improve core translation capabilities of the model using our internal Human Preferences dataset.

4.1 Data

We collect the training data using Side-By-Side human evaluation of paragraph-level translations, where an expert has to choose which of the two translations is better. The annotated data is presented in triplets (source, winner, loser), where 'winner' and 'loser' correspond to the compared translations. The source segments are sampled from various domains including books of different genres, web pages etc.

Our training dataset consists of the following parts:

Sentence-level data

Sentence part of the corpus consists of side-by-side comparisons between different model generations, in total 100.000 sentence triplets.

Document-level data
Document part of the corpus contains two primary sources of human feedback annotations.

Firstly, similarly to the sentence-level alignment data, we collect several thousands of document-level side-by-side comparisons between different versions of our model.

Secondly, we collect an additional contrastive triplet corpus aimed specifically at improving translation fluency.

Total document-level corpora size is several tens of thousands triplets.

4.2 Modeling

We fine-tune the model obtained at SFT stage using contrastive learning objective.
The model is trained using Contrastive Preference Optimization (CPO) loss function as in Xu et al. (2024).

$$\mathcal{L}(\pi_\theta; U) = \min_\theta \underbrace{\mathcal{L}(\pi_\theta, U)}_{\mathcal{L}_{\text{prefer}}} \underbrace{- E_{(x,y_w)\sim\mathcal{D}}[\log \pi_\theta(y_w|x)]}_{\mathcal{L}_{\text{NLL}}} . \tag{1}$$

where

$$\begin{aligned}\mathcal{L}_{\text{prefer}}(\pi_\theta, U) = &- E_{(x,y_w,y_l)\sim\mathcal{D}}\Big[\log\sigma\Big(\beta\log\pi_\theta(y_w|x)\\ &- \beta\log\pi_\theta(y_l|x)\Big)\Big].\end{aligned} \tag{2}$$

We train with batch size of 64, 1 epoch and triangular learning rate schedule (warmup length of 0.1 epochs, peak learning rate 1e-6).
It is worth mentioning that, due to the dataset imbalance between sentences and documents, training on a uniform mixture yields results almost equal to only sentence-wise training. To handle this discrepancy between sources, we employ a variation of curriculum learning (Bengio et al. (2009)).
In particular, we implement an easy-to-hard schedule, where we start with training only on sentence-level data and shift towards longer documents to the end of the training. This enables more effective leveraging of low-resource document-level corpora.

5 Structured content translation

In this section, we explore the methodology developed to improve the translation of pages with structured data (e.g. web page or video subtitles data) by Large Language Models (LLMs). Traditional LLMs, when tasked with translating structured content, often exhibit significant hallucination level. This manifests as omission of tags, partial tag loss, or incorrect translation of tags. Our goal is to achieve a more robust and accurate translation of such content by ensuring the correct transfer of tags.

5.1 Current Challenge: Tag Hallucination

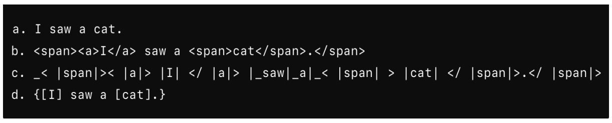
During free-form translation, LLMs struggle to maintain the integrity of HTML tags. This issue is critical as tags are essential for preserving the structure and formatting of HTML documents. A common problem observed is the complete omission of tags or their partial loss, which leads to a significant decrease in the quality of the translated document. An initial assessment showed a low percentage of correctly transferred tags. Tags are preserved only in 36% for CPO model that proves the need of a more reliable approach to tag preservation.

Test data: To test the accuracy of tag preservation we used a corpus of HTML-fragments. We collected innerHTML of block HTML tags from 10 Wikipedia pages.

Proposed Solution: Bracket Substitution and Model Adaptation
To address the issue of hallucination and improve tag preservation, we propose the following approach:

5.1.1 Tag Substitution with Brackets

Paired HTML tags are replaced with paired brackets (e.g., <div> becomes {, and </div> becomes }) to simplify the text structure for the model. Unpaired tags are also converted to a bracket format: every unpaired tag becomes a pair {}. This increases the proportion of sentences with retained tags to 76%.



```
a. I saw a cat.
b. <span><a>I</a> saw a <span>cat</span>.</span>
c. _< |span|>< |a|> |I| </ |a|> |_saw|_a|_< |span| > |cat| </ |span|>.</ |span|>
d. {[I] saw a [cat].}
```

Figure 2: a. Plain sentence. b. Sentence with html tags. c. Sentence with tags displayed as subword tokens processed by LLM. d. Sentence with tags replaced with braces.

5.1.2 Adaptation Using Parallel Corpus

We utilize a parallel corpus of HTML texts sourced from open repositories. This corpus serves as a foundation for generating synthetic data necessary for model fine-tuning.

5.1.3 Training Dual-Network System

Train data: We used the same parallel corpus as for SFT training but with tags aligned from original HTML documents. Sentence pairs with non-matching HTML tags were filtered out.

First Network: This network is trained to insert brackets and line breaks correctly into the text in the original language. This step helps to maintain the structural consistency of the text.

Second Network: Given a source text with tags and its translation without tags, this network learns to accurately re-insert the tags into the translated text. This network ensures that the translated content preserves the necessary HTML tags.

5.2 Synthetic Data Generation

By leveraging the dual-network system, we generate a substantial amount of synthetic data. This data includes the original text with brackets and line breaks, and the corresponding translated text with correctly inserted tags. Specifically, for the Contrastive Preference Optimization (CPO), we use:

1. The output of the first network as the source sentence in English.

2. The output of the second network on a good translation as the positive example.

3. The output of the second network on a poor translation as the negative example.

The good/poor translation pairs were obtained using human annotation as described above.

5.3 Results

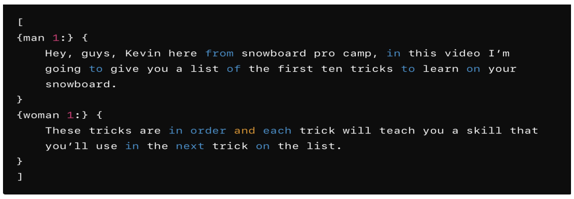
Our experimental results demonstrate that the proposed methodology effectively increases the percentage of sentences with correctly transferred tags to 99%.

This substantial improvement underscores the effectiveness of our approach in reducing tag hallucination and ensuring a more stable and accurate translation of HTML content.

By substituting HTML tags with brackets, adapting the model using a parallel HTML corpus, and incorporating a dual-network system for synthetic data generation, we have developed a robust method to enhance HTML translation. This approach not only mitigates the problem of tag hallucination but also ensures the structural integrity of translated HTML documents. The success of this methodology paves the way for more reliable and efficient translation of structured data formats, significantly benefiting applications in web content translation and beyond.

6 Fine-Tuning LLM for Subtitle Translation

Building upon a pre-trained model that has demonstrated proficiency in translating tagged web pages, we have adapted the following approach to train a subtitles translation system. Its core idea is straightforward: we enclose each speaker and their corresponding dialogue in brackets, as shown in figure below.



```
[
{man 1:} {
    Hey, guys, Kevin here from snowboard pro camp, in this video I’m
    going to give you a list of the first ten tricks to learn on your
    snowboard.
}
{woman 1:} {
    These tricks are in order and each trick will teach you a skill that
    you’ll use in the next trick on the list.
}
]
```

Figure 3: Subtitles input format.

This ensures that the translation preserves these brackets, allowing the entire text to be parsed into individual speaker dialogues.

The production version of the algorithm is somewhat more sophisticated, as it must align the translations of longer dialogues with their corresponding timestamps. However, for the purposes of this discussion, a more detailed description is unnecessary and is therefore omitted from this paper.

We fine-tune the model using publicly available subtitle corpora, which we preprocess to fit the above mentioned format. This additional training step has led to noticeable improvements in our human evaluation scores, particularly within the domain of movies and YouTube video subtitle translation. The reason for employing this model is that part of the competition data is presented in audio format, making effective subtitle translation a critical component of our approach.

By adapting the LLM in this manner, we enhance its ability to handle the unique challenges posed by subtitle translation, ensuring that the final outputs are both contextually accurate and properly segmented according to speaker and timing, which is crucial for maintaining the integrity of the original content in the translated version.

7 Evaluation Metrics and Results

Ablation

In order to estimate the effect of each stage of the pipeline, we compare our models using BLEURT-20 (Sellam et al. (2020)) and COMET (Rei et al. (2020)) automatic metrics, as well as BLEU. We rely primarily on neural metrics results as suggested in Freitag et al. (2022). Table 1 shows the scores on WMT-22 English to Russian testset.

Model Ablation (wmt-22 fwd)			
Model Stage	BLEURT	COMET	BLEU
PTune	0.76	0.836	31.3
cpo-sents	**0.789**	**0.860**	**31.52**
cpo-curriculum-base	0.787	0.855	24.8
cpo-curriculum-tags	0.784	0.855	27.1

Table 1: Metrics by stage (sentence-level).

Model Ablation (wmt-22 fwd news)			
Model Stage	BLEURT	COMET	BLEU
PTune	0.728	0.835	**27.78**
cpo-sents	0.733	0.847	25.55
cpo-curriculum-base	**0.743**	**0.850**	19.61

Table 2: Metrics by stage (document-level).

Firstly, the model trained only on parallel data (PTune) is already capable of generating decent quality translations. However, it exhibits bias towards literal translations and poor fluency.

During the alignment stage (cpo-curriculum-base) the model is exposed to a variety of high-quality translations (including contrastive triplets aimed specifically at improving fluency) and, hence, the model after initial CPO training is much more fluent, but prone to tags omission and format inconsistency.

Augmented CPO training solves the problem with format and tags without sacrificing the model's target language fluency capabilities.

Overall, the metrics ablation highlights the following:

1) BLEU correlates poorly with model quality, especially on document-level benchmarks due to high preference for literal translations.

2) On sentence-level evaluation contrastive learning model trained only on sentence data yields superior results both on neural and n-gram based metrics.

3) Tag-focused augmentation does not lead to quality degeneration on primary benchmarks whilist increasing model stability (see tag accuracy evaluations).

4) Contrastive learning phase with curriculum learning training improves the quality on document-level inputs, but only on neural metrics. We hypothesize that curriculum learning model increases fluency of the translations and introduces more complicated paraphrases that BLEU fails to score adequately.

WMT'24 Results

The quality of our system is assessed by the organizers using the following metrics:

MetricX-23-XL (Juraska et al. (2023)) – a reference-based metric built on top of the mT5 model. CometKiwi-DA-XL (Rei et al. (2023)) – a quality estimation metric built on the XLM-R XL model. Both metrics are among the top-performing metrics in the field (Freitag et al. (2023)). According to these metrics, our system currently ranks third on the leaderboard, with a MetricX score of 2.9 and a CometKiwi-DA-XL score of 0.705. The final leaderboard will be determined based on human evaluation results.

Ethics Statement

Our system was trained on the publicly available data. This unrestricted access to data allowed us to leverage a vast and diverse set of examples, enabling the model to learn from a wide array of linguistic patterns, contexts, and domains.

The absence of data limitations contributed to the development of a robust and versatile model, capable of generalizing well across various tasks and applications. By incorporating extensive datasets from different sources, our system gained the ability to handle complex and varied scenarios, enhancing its overall performance and adaptability. This approach ensured that the model could effectively capture and respond to the nuances of different data types, ultimately leading to more accurate and reliable outputs in real-world applications.

Acknowledgements

We are grateful to the organizers for providing a challenging dataset that allowed us to apply and evaluate our subtitle model.

Abstract

This paper presents the submission of the Árni Magnusson Institute's team to the WMT24 General translation task. We work on the English→Icelandic translation direction. Our system comprises four translation models and a grammar correction model. For training our models we carefully curate our datasets, aggressively filtering out sentence pairs that may detrimentally affect the quality of our system's output. Some of our data are collected from human translations and some are synthetically generated. A part of the synthetic data is generated using an LLM, and we find that it increases the translation capability of our system significantly.

1 Introduction

We describe our submission to the 2024 WMT general translation task. Large Language Models (LLMs) have become near-ubiquitous in the field of Natural Language Processing (NLP) in the last couple of years. They have shown remarkable translation capabilities (see e.g. Xu et al., 2024a), but require significantly larger computational resources than previous neural MT (NMT) models, both for training and inference. Most openly available LLMs are primarily trained on English texts and may therefore need further training in order to be able to translate from or into less-resourced languages, such as Icelandic.

The ALMA models (Xu et al., 2024a) are LLM-based translation models, built on LLaMA-2. They have been trained to translate ten directions, including English↔Icelandic. We explore the capabilities of some of these models, the 7B and 13B parameter versions of ALMA-R (Xu et al., 2024b), and find that they generate very competitive translations as measured against the English–Icelandic WMT21 test sets (Akhbardeh et al., 2021), especially from Icelandic into English. Unfortunately, using our settings the translation speed was quite slow (approximately one sentence per second) on an NVIDIA A100 GPU card.

We are interested in building faster models so we use the more traditional encoder-decoder Transformer architecture described in Vaswani et al. (2017). We collect all parallel data available to us for our language pair, generate additional synthetic pairs using the ALMA-R 13B parameter model and apply iterative back-translation using our own models. We apply filters to remove sentence pairs that may have detrimental effects on the models output.

We train four Transformer models[1] of varying sizes and let each model generate five translation candidates. A spelling and grammar checking model is then applied to the translations to generate "corrected" versions of the sentences. Finally the best candidate is selected from the pool of translations, corrected or not, using a reranking model.

We evaluate our models and approaches on the WMT21 test set for English→Icelandic.

2 Related Work

We only submit a system for the English→Icelandic translation direction. This language pair was previously one of the pairs for the WMT General Translation shared task in 2021 but prior to that, limited work had been published on MT for Icelandic. Brandt et al. (2011) describe a rule-based system for translating Icelandic→English, based on Apertium (Forcada et al., 2011). Jónsson et al. (2020) was the first published work describing SMT and NMT for Icelandic. Since 2021 the WMT21 evaluation data, as well as various parallel corpora projects, have made it more accessible to train and evaluate MT systems translating to or from Icelandic, and with that the language has been included in various research projects. We believe this is an indicator of the importance of evaluation campaigns, such

[1] Models available at https://huggingface.co/arnastofnun.

Proceedings of the Ninth Conference on Machine Translation, pages 253–262
November 15-16, 2024 ©2024 Association for Computational Linguistics

as the ones run in association with the WMT conferences, for less prominent languages.

Our approach uses an ensemble of four different translation models and a reranking model to select the best candidate. This is a common approach, motivated by the intuition that different systems may have different strengths. In recent work, Toral et al. (2023) use this approach in their experiments with literary translations. In their work on bidirectional reranking, Imamura and Sumita (2017) discuss reranking and ensembling for MT in some detail. Examples from the period of statistical MT include the work of Olteanu et al. (2006) and Wang et al. (2007), describing language model-based reranking on hypotheses generated by phrase-based SMT systems.

3 Data Selection and Filtering

Various parallel data are available for the English–Icelandic language pair. ParIce (Barkarson and Steingrímsson, 2019) is partly a collection of parallel corpora available elsewhere, which has been realigned and refiltered, and partly data compiled for that project, the largest source being regulatory texts published in relation with the European Economic Area (EEA) agreement. Data for the English–Icelandic language pair were collected within the Paracrawl project (Bañón et al., 2020), CCMatrix (Schwenk et al., 2021), MaCoCu (Bañón et al., 2022) and HPLT (Aulamo et al., 2023). Data for the language pair are also available from multiple smaller datasets distributed on OPUS (Tiedemann and Thottingal, 2020). We utilize all these datasets in training our models.

We also use synthetic data: Backtranslations made available by Jónsson et al. (2022), translations generated using the ALMA-R 13B parameter model and backtranslations generated by our trained models. We describe these in more detail in Section 3.3.

Khayrallah and Koehn (2018) show that incorrect translations, untranslated target text, misalignments, and other noisy segments in training data can have a detrimental effect on the quality of translations generated by NMT systems trained on that data. By filtering our training data rather aggressively, we try to minimize such noise.

3.1 ParIce

Even though care has been taken to realign and refilter data for the ParIce corpus, Steingrímsson et al. (2023) show that it still contains noise, such as misalignments and mistranslations, that may be detrimental when training NMT systems. They refilter the data using a combination of approaches: Shallow filters based on simple heuristics, by using Bicleaner (Sánchez-Cartagena et al., 2018; Ramírez-Sánchez et al., 2020) and by employing classifiers (support vector machine-based ones (Cortes and Vapnik, 1995) had the best outcome) with a combination of scoring mechanisms, including LASER (Artetxe and Schwenk, 2019), LaBSE (Feng et al., 2022), NMTScore (Vamvas and Sennrich, 2022) using the M2M100 multilingual translation model (Fan et al., 2021), and WAScore, a word alignment-based score devised to measure word-level parallelism, introduced in Steingrímsson et al. (2021). In Steingrímsson (2023) these data are processed further by realigning the EEA texts in the ParIce corpus using SentAlign (Steingrímsson et al., 2023).

As the basis for our training we use the ParIce dataset, processed as described above, as well as parallel data extracted from Wikipedia using the comparable corpora mining approach described in (Steingrímsson et al., 2021) and sentence pairs extracted from version 9 of Paracrawl using the filtering approaches described above and in Steingrímsson et al. (2023).

3.2 Filtering the OPUS Datasets

An overview of the data for Icelandic-English parallel texts sourced from the OPUS catalog is provided in Appendix A. This data, accounting for redundant sentence pairs, amounts to 21.167.708[2] sentence pairs. At face value, this is a substantial amount of available data. However, the quality of these parallel texts is not reliable, with noisy and incorrect pairs being prevalent throughout most individual datasets in the catalog. To remedy this, and thus ensure that the data sourced via OPUS can be used effectively in our project, we applied an aggressive, sequential filtering process, with the goal of whittling away the majority of the low-quality sentence pairs.

Our sequential filtering process consists of ten individual steps, most of which only remove sentences from the data without modifying the content of other sentences. The process is *sequential*, in that the input of a filtering step is the output of the previous filtering step. Furthermore, the order of

[2] This applies to the state of the OPUS catalog at the time of development, i.e., April 2024.

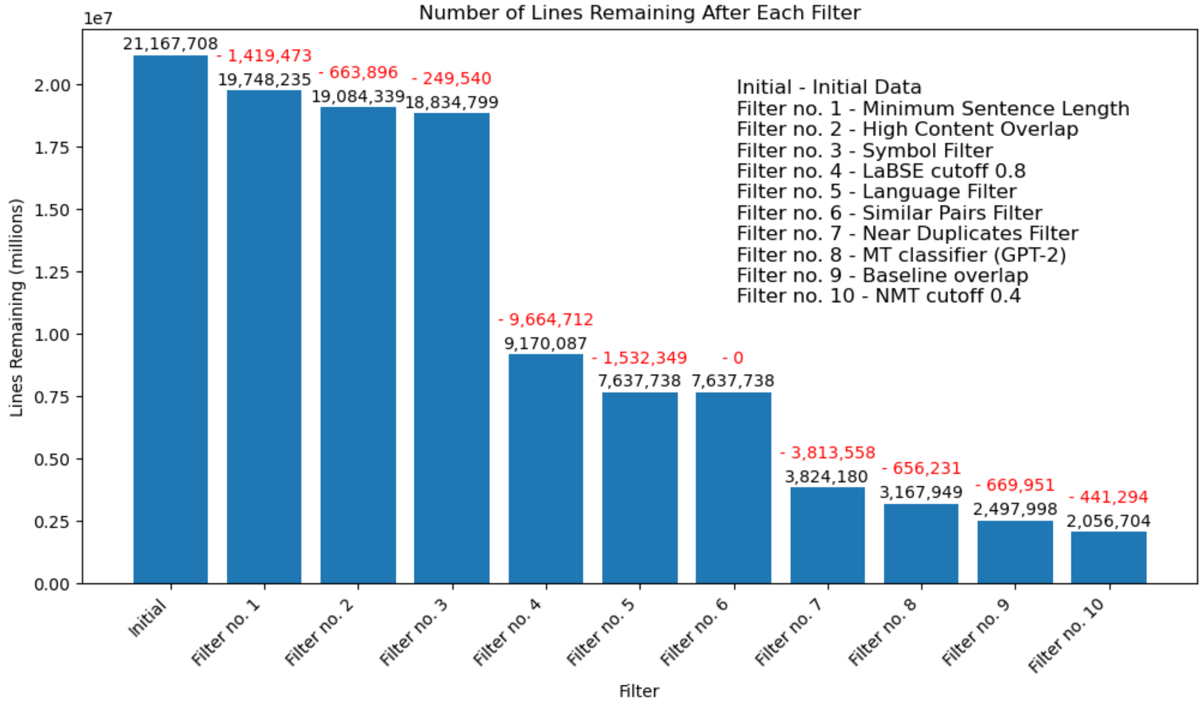

Figure 1: Each filtering step's effect on OPUS dataset size

these steps is decided to ensure optimal processing time of the filters so that computationally heavy filtering steps process the least amount of data, which minimizes run time. For a detailed overview of each filtering step, see Appendix B.

The effects of each filtering step on the data amount is shown in Fig. 1. To ensure that our filtering methods affected our implementation positively, we intermittently added the output of the filtering process to our training pipeline and evaluated the performance. In particular, we used this approach to dial in the optimal LaBSE and NMT score cutoffs in our filters.

The final output of our filtering process produces a relatively high-quality data set of 2.056.704 English-Icelandic sentence pairs (roughly 9.71% of the original 21.167.708 raw sentence pairs sourced from the OPUS catalog), which we then add to our training data.

3.3 Synthetic Data

The dataset made available by Jónsson et al. (2022) contains translations from Europarl, Newscrawl, Wikipedia and the IGC. We perform a filtering step similar to the one used applied on the OPUS data, consisting of a length filter, removing all sentences that have fewer than four word tokens and more than 150, an overlap filter, removing all sentence pairs that share 40% or more of word tokens, and a symbol filter removing all sentence pairs where more than 20% of characters in one of the sentences is non-alphabetical. Furthermore we use two scoring mechanisms for filtering, LaBSE, using a score threshold of 0.8, and NMTScore with a threshold of 0.4. These scores are selected based on the evaluation in (Steingrímsson et al., 2023). After filtering, we are left with 4.4M sentence pairs from this dataset.

We use the 13B parameter ALMA-R model to translate English sentences from Newscrawl to Icelandic and Icelandic texts from the Icelandic Gigaword Corpus (IGC) (Steingrímsson et al., 2018) to English. The Icelandic texts are sampled from three different subcorpora of the IGC, comprising news, scholarly journals, and literary texts. For each source sentence we generate five translations and use LaBSE to select the two best ones, granted that they exceed a threshold of a LaBSE score of 0.8 and pass through the three shallow filters described above: length, overlap and symbol filters. Our final set contains 8.9M sentence pairs translated from Icelandic to English and 700K sentence pairs translated from English to Icelandic.

Finally, we do iterative back-translation. We use the same training data as described above to train models to translate texts from the IGC to English. For the back-translations we use Transformer$_{\text{BIG}}$

model	d_{model}	d_{ff}	h	N_{enc}	N_{dec}
$Base$	512	2048	8	6	6
$Base_{deep}$	512	2048	8	36	12
Big	1024	4096	16	6	6
Big_{deep}	1024	4096	16	36	12

Table 1: Model dimensions, heads and number of layers.

models (Vaswani et al., 2017), as described in Table 1. We use the same approach as before, generate five translations for each sentence and use LaBSE to select the two best ones, as long as they exceed the threshold of 0.8 and are not filtered out by the other filters. We do two iterations of translating and training models in both translation directions using backtranslated data. This results in a total of approximately 60M sentence pairs.

3.4 Other Data

To decide which datasets to use, we trained Transformer$_{\text{BASE}}$ models as described in Vaswani et al. (2017) and evaluated the models using the test set from WMT21. We started by training a baseline system using the dataset described in Section 3.1. We then added different datasets to the baseline data, trained new systems and evaluated them. If the new dataset seemed to improve the output we used that for our final system. In addition to previously described datasets we tried generating backtranslations using SMT and to add data from a bilingual lexicon using token-pair training as described by Jones et al. (2023). Table 2 shows chrF scores (Popović, 2015) for our different experiments.

Dataset	chrF
Baseline	50.4
Baseline+lexicon	50.4
Baseline+OPUS	53.7
Baseline+Jónsson	53.5
Baseline+Jónsson+SMT	53.2
Baseline+Jónsson+ALMA	54.7
Baseline+Jónsson+ALMA+OPUS	55.1
Baseline+Jónsson+ALMA+OPUS+BT1	56.4
Baseline+Jónsson+ALMA+OPUS+BT2	56.8

Table 2: The table shows that when most of the datasets in our experiments are added to the training data the quality, as measured by chrF, increases. Exceptions to that are the experiments with adding token-pairs from an English-Icelandic lexicon and with using backtranslations generated by an SMT system. These two datasets are therefore not used in our final systems.

Dataset	Sentence Pairs
Base	2,277,023
OPUS-filtered	2,056,704
Miðeind-BT	2,559,806
Miðeind-FT	1,837,945
ALMA-BT	8,927,720
ALMA-FT	700,253
IGC-BT-1	27,794,398
IGC-BT-2	33,465,175

Table 3: Datasets used for training and number of sentence pairs in each dataset.

The total number of sentence pairs used for training is shown in Table 3

4 System Description

Our motivation for using multiple models is twofold: First, we want to use models that are computationally inexpensive to run and so we train models that can run on one consumer grade GPU. Second, systems of different sizes may have complementary strengths and so training multiple systems and reranking the results may give us better results than any one model.

We train four encoder-decoder Transformer models, all of which play a part in the translation pipeline. Two of the models follow the exact architecture described in Vaswani et al. (2017), i.e. the 'base' and 'big' versions of the original Transformer model, while the other two are deeper, using 36 encoder layers and 12 decoder layers instead of six. The difference between the four models is shown in Table 1.

The outputs from the translation models undergo two post-processing steps. First, they are run through a grammatical error correction model, a version of the byte-level sequence-to-sequence model ByT5 (Xue et al., 2022) that has been finetuned by Ingólfsdóttir et al. (2023) to correct spelling errors in Icelandic as well as handling more complex grammatical, semantic and stylistic issues. Second, we fix punctuation errors which translation models are prone to making when translating into Icelandic (mostly to do with quotation marks, which are different in Icelandic and English) as well as some that might be unique to our system, such as their incapability to translate emojis. As the grammatical error correction model proved too aggressive for our purposes, merging and splitting

model	chrF
$Base$	56.8
$Base_{deep}$	57.1
Big	57.7
Big_{deep}	57.7
Ensemble+COMETKIWI	58.3
Ensemble+error correction +COMETKIWI	**58.4**
ALMA-R 7B	52.2
ALMA-R 13B	53.4

Table 4: chrF scores for each of our models, compared with scores for the model ensembles and for the ALMA-R models. The scores are calculated on the WMT21 evaluation set.

model	Selected	Unique
$Base$	293	158
$Base_{deep}$	347	186
Big	287	163
Big_{deep}	419	246

Table 5: The number of sentences generated by each model selected for the final output when translating the WMT21 test set.

some sentences, normalizing informal language usage and hashtags, etc., we also revert some of the changes it introduced.

Using the WMT21 test set we experiment with an ensemble approach, using COMETKIWI-DA-22 (Rei et al., 2022) to select the best sentence out of 20 hypotheses made by the four models (each model generates five hypotheses using beam search with beam size 12). This raises the chrF score to 58.3 for our evaluation set. On top of this we add the spelling and grammar error correction, which gives us a very modest increase in quality as measured by chrF, shown in Table 4.

We investigate whether the COMETKIWI-DA-22 model prefers the output from some of the translation models over the others. Table 5 shows which translation models generated the translations ultimately chosen by the scoring model when experimenting on the WMT21 evaluation set of 1000 sentences. While translations by the deeper model are more likely to be selected, it is evident that all models are contributing, with the final selection containing 753 translation generated by only one model, and of these all models contribute over 150 translations each. 247 of the selected translations were generated by more than one model (non-unique translations). An ensemble approach thus seems to be likely to improve overall translation quality.

4.1 The pipeline

Basing our system on the most succesful approach in our experiments, our translation pipeline consists of three steps: First, using each of our four models, we generate five translation hypotheses using beam search for all source paragraphs, resulting in a total of 20 candidates.

Furthermore, each paragraph is segmented into sentences, $s_1, \ldots, s_n$. For each sentence, every model produces five hypotheses. These hypotheses are evaluated using COMETKIWI-DA-22, and the highest-scoring hypothesis is selected for each sentence. The selected hypotheses are concatenated to form a new paragraph. Finally, a single paragraph is created by combining the best translation of each sentence, leaving us with 25 translation candidates.

Each of these candidates is then corrected with regard to grammar, spelling and style using the ByT5 model described above.

These two steps, translating the source text and correcting the translations, result in a total of 50 translation candidates. In order to find the best candidate we use COMETKIWI-DA-22 to score all candidates. The highest scoring one is the selected translation of our system.

5 Results

We evaluate our system on the test data from WMT21. As expected, the bigger models perform better, but the best results are achieved by selecting translations from an ensemble of differently trained Transformer models. We use COMETKIWI-DA-22 to select the best translation out of 20 hypotheses made by the four models, five hypotheses by each using beam search with beam size 12. This raises the chrF score to 58.3 and when we add error correction on top, the score is slightly higher, 58.4, as shown in Table 4.

In the WMT24 general translation task, systems were evaluated using two automatic metrics, MetricX-23-XL (Juraska et al., 2023) and COMETKIWI-DA-XL (Rei et al., 2023), as well as by human evaluation. According to the automatic metrics, reported in Kocmi et al. (2024), our model is competitive among the open systems, although four closed systems achieve better scores. Results

6 Conclusions and Future Work

We show that while Large Language Models have become nearly ubiquitous in Natural Language Processing, traditional encoder-decoder Transformer models remain a viable approach to machine translation, particularly when computational efficiency is a priority.

Nevertheless, our findings also reveal that integrating LLMs can be advantageous during the training process. Specifically, ALMA-R 13B proved to be an important part of our training pipeline, as the synthetic data it generated increased the quality of our translation systems.

Furthermore, our results indicate that while more training data usually result in a better translation system, low-quality data, such as the backtranslations generated with an SMT system, can have a detrimental impact on performance. Similarly, our experiments with a bilingual lexicon using token-pair training negatively affected the system's output. This may be due to a variety of reasons. Our SMT system could probably be improved as well as our approach to include data from a bilingual lexicon in the training data. This warrants further investigation.

Our filtering method, as described in Sections 3.2, 3.3 and Appendix B, has proven effective, even though it may be argued that it is still somewhat crude and more work into minimizing the loss of useful sentence pairs and more effectively remove detrimental sentence pairs would very likely improve the training data and in turn the translation models. For example, while we use LaBSE, LASER and NMT to evaluate sentence pairs, we apply individual cutoff values for each score. A better approach could entail using a classifier to combine all metrics for an optimal result.

Although currently impractical at production-scale, genetic algorithms, as shown by Jon and Bojar (2023) and Jon et al. (2023), show promising results in generating translation candidates. Given larger computational resources, similar approaches might prove useful and await future study.

B Filtering steps

Filter 1. Sentence length

Sentences should contain at minimum four characters and at maximum 150 characters.

Filter 2. High inter-pair content overlap

Sentence pairs where the content of the source and target sentences are highly similar should be removed from the dataset.

Filter 3. Character symbol filtering

All characters in the English and Icelandic alphabets (along with punctuation and numbers) designated as a set of allowed characters. Sentences containing less than 60% of these characters removed from the data and all characters outside the allowed set removed from the remaining sentences.[3]

Filter 4. LaBSE scoring

We use score each sentence pair using LaBSE (Feng et al., 2022) and remove all sentences with a score lower than 0.8[4].

Filter 5. Language detection

We use various language detection software to gauge whether both the source and target sentences are in the correct language. The software we used was *fasttext* (Joulin et al., 2016), *franc* (Wormer, 2024), *lingua* (Stahl, 2024) and *langdetect* (Nakatani, 2010).

Filter 6. Similar dataset pairs

As a safeguard, we remove any duplicate entries of our dataset if, for any reason, there remain duplicate instances after the previous filters. In our final experiment, this was rendered redundant, but was required in previous iterations and may prove useful in future iterations.

Filter 7. Near-duplicate dataset pairs

Sentences are compared by removing content-specific words that are likely proper names and dates, etc., and comparing the remainder.

Filter 8. Likely machine-translated target sentences

A GPT-2 (Radford et al., 2019) classifier is used to evaluate whether a given target sentence is machine-translated, based on a 10.000 sentence hand-evaluated reference set. If this is true for the target sentence, that pair is removed from the dataset.

Filter 9. Existing datasets

As a final safeguard check, we remove any sentence pair that we already have on file in other datasets, as touched on in section 3.2.

Filter 10. NMTScore cross-likelyhood 0.4

Finally, we use a translation cross-likelyhood NMTScore (Vamvas and Sennrich, 2022) to determine the translation quality of a given sentence pair. This step is computationally heavy and was therefore saved for last. Our experiments suggest that 0.4 is a suitable cutoff for our dataset.

[3] This is the last filtering step that inherently modifies the content inside individual sentences.

[4] This is a higher cutoff than the original LaBSE authors suggest to use, but our experiments suggets it better suits our data.

IKUN for WMT24 General MT Task: LLMs Are here for Multilingual Machine Translation

Baohao Liao[1,2] **Christian Herold**[2] **Shahram Khadivi**[2] **Christof Monz**[1]
[1]Language Technology Lab, University of Amsterdam
[2]eBay Inc., Aachen, Germany
b.liao@uva.nl

Abstract

This paper introduces two multilingual systems, *IKUN* and *IKUN-C*, developed for the general machine translation task in WMT24. IKUN and IKUN-C represent an *open system* and a *constrained system*, respectively, built on Llama-3-8b and Mistral-7B-v0.3. Both systems are designed to handle all 11 language directions using a single model. According to automatic evaluation metrics, **IKUN-C achieved 6 first-place and 3 second-place finishes among all constrained systems, while IKUN secured 1 first-place and 2 second-place finishes across both open and constrained systems**. These encouraging results suggest that large language models (LLMs) are nearing the level of proficiency required for effective multilingual machine translation. The systems are based on a two-stage approach: first, continuous pre-training on monolingual data in 10 languages, followed by fine-tuning on high-quality parallel data for 11 language directions. The primary difference between IKUN and IKUN-C lies in their monolingual pre-training strategy. IKUN-C is pre-trained using constrained monolingual data, whereas IKUN leverages monolingual data from the OSCAR dataset. In the second phase, both systems are fine-tuned on parallel data sourced from NTREX, Flores, and WMT16-23 for all 11 language pairs.[1]

1 Introduction

Large language models (LLMs) (Touvron et al., 2023; Dubey et al., 2024; Jiang et al., 2023; OpenAI, 2023) serve as a crucial foundation for a wide range of applications. One significant advantage of LLMs is their ability to be applied across various tasks, thereby simplifying deployment processes. However, the application of LLMs to multilingual machine translation (MT) presents several challenges:

- Most LLMs are pre-trained on one or a few dominant languages, making direct fine-tuning on multilingual data insufficient for ensuring optimal performance, particularly for low-resource languages, which are often underrepresented in the training data.
- It remains unclear whether these LLMs, primarily pre-trained on a limited number of languages, effectively facilitate transfer learning across different languages (Tan et al., 2024).
- The large-scale nature of most LLMs presents significant challenges for efficient fine-tuning, particularly for researchers and practitioners with limited computational resources.

In the WMT24 general MT task (Kocmi et al., 2024a), our objective is to assess the capability of LLMs for multilingual MT, as an alternative to training bilingual systems from scratch (Wu et al., 2023). This paper provides a detailed account of how we developed our final multilingual system using LLMs for both the constrained and open tracks.

Firstly, we identified that certain LLMs exhibit inefficiencies in tokenizing sentences from languages that are underrepresented in the pre-training data. To address this, we extended the existing vocabulary to reduce the tokenized sentence length, thereby enhancing training efficiency. Secondly, we enriched the LLMs with knowledge across the 10 target languages through continued pre-training. This step is particularly crucial for underrepresented languages, as it facilitates transfer learning. Finally, we fine-tuned the models using high-quality parallel datasets across all 11 pairs.

Through this streamlined approach, our constrained multilingual system, IKUN-C, secured 6 first-place and 3 second-place rankings in the automatic evaluation. Our open multilingual system, IKUN, achieved 1 first-place and 2 second-place rankings across the open and constrained tracks.

Proceedings of the Ninth Conference on Machine Translation, pages 263–269
November 15-16, 2024 ©2024 Association for Computational Linguistics

These encouraging results demonstrate that LLMs can be effectively adapted for multilingual MT, broadening access to speakers of diverse languages.

2 Pre-trained LLM

LLMs are pre-trained on extensive web-scale data, encompassing a vast repository of general knowledge applicable to various tasks. Previous studies (Xu et al., 2024a,b) have demonstrated that LLMs can substantially enhance the performance of multilingual MT. Building on this insight, we adopt a pre-trained LLM as the foundation for our system.

IKUN is an open system developed with meticulous consideration of available resources and system capabilities. For this purpose, we selected Llama-3 (Dubey et al., 2024), one of the most advanced open-source LLMs available at the time of this competition. Due to constraints on computational resources, we opted for the 8B version[2] instead of the 70B version. A significant factor in our choice of Llama-3 was its strong support for multilingual applications, as evidenced by the efficiency with which its tokenizer handles all 11 languages involved in this competition (See §3). We also tried the instruct version, but it is worse than the pre-trained version.

IKUN-C is a constrained system based on Mistral-7B-v0.3 (Jiang et al., 2023), one of the three LLMs permitted for the constrained track. Prior to selecting Mistral-7B-v0.3[3], we conducted continuous pre-training on all three allowed LLMs — namely, Llama-2-7B, Llama-2-13B (Touvron et al., 2023), and Mistral-7B — using a subset of our monolingual data (approximately 1B tokens). The pre-training loss demonstrated that Mistral-7B outperformed Llama-2-7B and performed comparably to Llama-2-13B, leading us to select it as our architecture of choice.

3 Tokenizer Efficiency

A significant challenge in applying LLMs to multilingual MT lies in the efficiency of their tokenizers. These models are typically pre-trained on one or a few dominant languages, and when their tokenizers are applied to low-resource languages, they produce disproportionately long sequences of subwords. This inefficiency leads to excessive GPU memory consumption during training.

To evaluate the efficiency of the tokenizer, we focus on comparing the length differences between tokenized English sentences and their corresponding non-English counterparts. Specifically, we define the length ratio as:

$$\text{length ratio} = \frac{\text{len}(\text{tokenizer}(x))}{\text{len}(\text{tokenizer}(y))}$$

where y represents the English sentence, and x denotes the paired non-English sentence. A smaller length ratio (close to 1) is desired, since it means that the tokenizer can encode the non-English sentence as efficient as the English sentence.

To facilitate a comparison of length ratios across different languages, English-centric multilingual data is essential. Fortunately, the FLoRes-200 dataset (Costa-jussà et al., 2022) possesses this characteristic. In the devtest and test sets of FLoRes-200, every English sentence is paired with translations in various other languages. We concatenate all sentences from the devtest set and compute the length ratio for each language, as illustrated in Figure 1. We also include NLLB's tokenizer (Costa-jussà et al., 2022) for a comparison.

We can observe: (1) NLLB consistently exhibits the smallest length ratio across all languages, likely due to its extensive optimization for hundreds of languages, thus serving as a lower bound in this context. (2) Mistral-v0.3 and Llama-3 demonstrate a notably high length ratio for Hindi, suggesting that Hindi is underrepresented in the pre-training data. (3) Compared to NLLB, the tokenizer of Mistral-v0.3 is significantly less efficient for Chinese, Japanese, Hindi, and Icelandic.

We opted to expand the vocabulary by incorporating new sub-words to reduce the length of tokenized sentences, thereby enhancing training efficiency. However, this approach introduces a trade-off between the addition of new sub-words and training performance. The embeddings for the newly introduced sub-words are initially untrained, and a substantial increase in sub-words may necessitate additional iterations of continuous pre-training. Consequently, our strategy for adding sub-words prioritizes those from languages with higher length ratios.

For our open system, IKUN, we didn't modify its tokenizer, since Llama-3 tokenizer is already efficient enough, only except for Hindi. For our constrained system, IKUN-C, we expanded its vocabulary for Chinese, Japanese, Hindi, and Icelandic through the following steps: (1) Generate

[3] https://huggingface.co/mistralai/Mistral-7B-v0.3

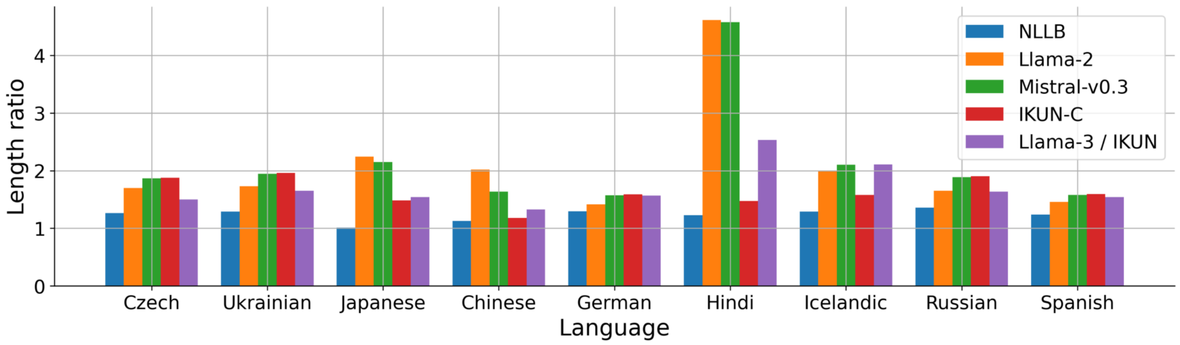

Figure 1: Tokenizer efficiency for various LLMs and languages. The larger the length ratio is, the less efficient the tokenizer is. We add new sub-words, from Chinese, Japanese, Hindi and Icelandic, to the Mistral-v0.3 vocabulary to construct the IKUN-C vocabulary. IKUN uses the Llama-3 tokenizer without any modification.

a new vocabulary of 12K sub-words using monolingual data from the past two years for these four languages from News Crawl[4]; and (2) Merge the new vocabulary with the original. The efficiency of the resulted IKUN-C tokenizer is shown in Figure 1, demonstrating more efficiency for these four languages, especially for Hindi.

4 Experiments

We mainly follow the pipeline from Xu et al. (2024a), i.e. continuous pre-training on monolingual data for all 10 languages, and followed by fine-tuning on parallel data for all 11 language pairs.

4.1 Continuous Pre-training

Given that our selected LLMs, specifically Llama-3-8B and Mistral-7B-v0.3, are primarily pre-trained on English, it is necessary to incorporate knowledge from other languages through further pre-training, with particular emphasis on low-resource languages. Additionally, the word embeddings for the newly introduced sub-words in IKUN-C must also undergo training.

For the open system IKUN, we utilize monolingual data from the Oscar dataset (Suárez et al., 2020), covering all 10 target languages. We adopt the sampling strategy outlined by Xu et al. (2024a), described as:

$$P(l) \propto \left(\frac{D_l}{\sum_{l' \in L} D_{l'}}\right)^{\frac{1}{T}} \quad s.t. \quad \sum_{l' \in L} P(l') = \frac{9}{10}$$

where D_l represents the number of words in language l[5], T is the temperature parameter (set to 6), and L denotes the set of all languages except English. The sampling probability for English is fixed at 1/10. The experimental settings for continuous pre-training are detailed in Table 2. We approximately pre-trained IKUN on an additional 8B tokens.

In the constrained system, only the provided data sources are permitted for use[6]. The IKUN-C system utilizes monolingual data from the News Crawl dataset for 9 languages, with the exception of Spanish, as the use of Spanish monolingual data from News Crawl is restricted. For Spanish, we incorporate monolingual data from the Leipzig Corpora (Goldhahn et al., 2012). Additionally, for Hindi, we augment the dataset with monolingual data from News Commentary due to the relatively limited amount of Hindi data available in the News Crawl dataset. This adjustment is crucial because Hindi is underrepresented in the pre-training of Mistral-7B-v0.3. Our experimental settings closely align with those detailed in Table 2.

4.2 Subsequent Fine-tuning

Previous studies (Wu et al., 2024; Zhou et al., 2023) have demonstrated that the quality of fine-tuning data is a critical factor in achieving optimal performance. Liao et al. (2021) further indicates that increasing the amount of back-translation data does not necessarily lead to better outcomes. In light of this, we exclusively utilize high-quality parallel data for the fine-tuning phase.

The high-quality parallel data is primarily sourced from FloRes-200 (Costa-jussà et al., 2022), NTREX-128 (Federmann et al., 2022), and previous WMT16-23 general MT/news tasks (Kocmi et al., 2023, 2022; Akhbardeh et al., 2021; Barrault et al., 2020, 2019, 2018; Bojar et al., 2017, 2016).

FloRes-200: As the FloRes-200 dataset provides parallel sentences across multiple languages, we leverage all 11 translation directions from the devtest and test sets. Importantly, our fine-tuning approach is not limited to the required directions listed in Table 3; instead, we fine-tune the model on both translation directions, e.g., en↔de, to facilitate broader applicability of the final model.

NTREX-128: We also incorporate parallel sentences from NTREX-128 for from-English translation directions, i.e. en→XX. In accordance with Federmann et al. (2022), which recommends using the en→XX translation direction, our fine-tuning is confined to these directions rather than adopting a bidirectional approach. An exception is made for the en-fr pair, where bidirectional fine-tuning is applied due to the limited availability of parallel data for this pair (absent in previous WMTs).

Past WMTs: Additionally, we extract parallel sentences from the development and test sets of the WMT16-23 general MT tasks, provided they contain the necessary translation directions. For these sentences, we employ a bidirectional fine-tuning strategy.

The statistics for all parallel sentences are presented in Table 1. Notably, all systems are fine-tuned at the sentence level. Given that WMT development and test sets are at the document level, models could alternatively be fine-tuned at the document level or reformatted into a conversational structure for fine-tuning. This latter approach might be more effective for context-aware translation, as WMT24 applies context-based human evaluations. We reserve this exploration for future work. The fine-tuning setting is listed in Table 2.

4.3 Results

We present the preliminary results reported by Kocmi et al. (2024b) in Table 3, which includes four evaluation metrics. Both MetricX-23-XL (Juraska et al., 2023) and CometKiwi-DA-XL (Rei et al., 2023) have demonstrated strong correlations with human evaluation (Freitag et al., 2023). AutoRank (Kocmi et al., 2024b), a normalized composite metric derived from MetricX and CometKiwi, scales the scores of each metric linearly to span the range from 1 to the total number of systems in a given language pair. The final automatic ranking is obtained by averaging these normalized scores. AutoRank can thus be considered a measure of the overall rank across all systems and tracks. Additionally, we report the rankings of our systems across various tracks.

It is noteworthy that both of our systems are multilingual, designed to handle all language pairs. The IKUN-C system, in particular, demonstrates promising performance in the constrained track, achieving 6 first-place and 3 second-place finishes. In both the open and constrained tracks, IKUN maintains strong performance, securing 1 first-place and 2 second-place positions, even when compared to systems that may leverage additional open-source data or specialize in a limited set of language pairs.

5 Conclusion

In this paper, we present a methodology for effectively adapting pre-trained LLMs to the task of multilingual machine translation. Our approach involves three primary steps: (1) expanding the vocabulary to accommodate languages that are underrepresented in the pre-training data, when necessary; (2) continuing pre-training the LLM on monolingual data to enhance its knowledge of underrepresented languages and to train the embeddings of newly introduced sub-words; and (3) fine-tuning the LLM on high-quality parallel data. Our experimental results demonstrate the efficacy of this straightforward pipeline, with IKUN-C securing 6 first-place finishes in the constrained track, and IKUN achieving 1 first-place ranking in both the open and constrained tracks.

Abstract

The NTTSU team's submission leverages several large language models developed through a training procedure that includes continual pre-training and supervised fine-tuning. For paragraph-level translation, we generated synthetic paragraph-aligned data and used these data for training. In the task of translating Japanese to Chinese, we focused on speech domain translation. Specifically, we built Whisper models for Japanese automatic speech recognition (ASR). Since the dataset used for Whisper training contains many noisy data pairs, we combined the Whisper outputs using ROVER (Fiscus, 1997) to refine the transcriptions. Furthermore, we employed forward translation from audio as data augmentation, using both ASR models and a base translation model. To select the best translation from multiple hypotheses of the models, we applied Minimum Bayes Risk decoding after Quality Estimation (Fernandes et al., 2022), incorporating scores such as COMET-QE, COMET, and cosine similarity by LaBSE. We explored three different reranking strategies to handle two types of candidates from sentence- and paragraph-level translation and employed a fusion method that integrates all three.

1 Introduction

This paper provides a system description of the NTTSU team's submissions to WMT 2024. We took part in the General Translation Task (Kocmi et al., 2024a) for English-to-Japanese (En-Ja) and Japanese-to-Chinese (Ja-Zh). This task has three tracks with different constraints on the use of training data and pre-trained models. For En-Ja, we participated in the constrained track, which provides sets specifically allow training data and pre-trained models for use in traning the translation models. Additionally, for Ja-Zh, we participated in the open track, which allows the use of software and data under any open-source license.

Our team's submission leveraged several large language models developed through a training procedure (Guo et al., 2024; Kondo et al., 2024) that includes continual pre-training and supervised fine-tuning. For paragraph-level translation, we generated synthetic paragraph-aligned data and used these data for training.

In the task of translating Japanese to Chinese, we focused on speech domain translation. Specifically, we built Whisper models (Radford et al., 2022) for Japanese automatic speech recognition (ASR). We used the YODAS dataset (Li et al., 2024) for Whisper training. Since these data contained many noisy data pairs, we combined the Whisper outputs using ROVER (Fiscus, 1997) to refine the transcriptions. Furthermore, to enhance the robustness of the translation model against errors in the transcriptions, we performed data augmentation by forward translation from audio, using both ASR and base translation models.

To select the best translation from multiple hypotheses of the models, we applied Minimum Bayes Risk decoding after quality estimation (Fernandes et al., 2022), incorporating scores such as COMET-QE, COMET, and cosine similarity by LaBSE. We explored three different reranking strategies to handle two types of candidates from sentence- and paragraph-level translation and employed a fusion method that integrates all three.

2 System Overview

Our system had three main components: automatic speech recognition (ASR) models, translation models, and a reranking.

This year, speech domain translation was newly incorporated in the above task, and audio data, along with the organizer's transcription, were provided as input data. We were interested in the feasibility of speech translation from Japanese, so we created an ASR model for the Ja-Zh and used its transcription as the additional source text. More-

Proceedings of the Ninth Conference on Machine Translation, pages 270–279
November 15-16, 2024 ©2024 Association for Computational Linguistics

over, we used ROVER to refine the transcriptions.

For the translation model's architecture, we employed and trained the Transformer model and LLMs. To train the LLms, we carried out monolingual/parallel continual pre-training and supervised fine-tuning. The evaluation for this year was conducted at the paragraph level. To address this, we created sentence- and paragraph-level parallel data and utilized these data to build translation models for each level.

During the inference step, we used the translation models to independently translate at the sentence and the paragraph level, generating multiple candidates. We then selected the best translation candidate using a reranking that combines sentence- and paragraph-level reranking with MBR decoding after quality estimation.

3 Automatic Speech Recognition

For Ja-Zh speech translation, we fine-tuned various Whisper-based ASR models for the Japanese ASR task. We used the Japanese subset (ja100) of the YODAS dataset, which consists of approximately 3,000 hours of speech and transcriptions.

3.1 Dataset

During the dataset review, we found that the YODAS dataset contained many incorrect transcriptions (e.g., music and non-Japanese speech samples). To mitigate the negative impact of these incorrect samples, we refined the YODAS dataset. We integrated transcriptions of multiple hypotheses transcription generated from multiple ASR models to create a tuning dataset. Specifically, the following procedure was used to generate tuning data.

1. **Generation** We performed beam search decoding with multiple ASR models to generate multiple ASR hypotheses for each speech sample in ja100. This process yielded a set of hypotheses equal to the number of ASR models multiplied by the beam size. We set a beam size of 4.

2. **Language-based Filtering** We applied multi-step filtering for the YODAS dataset. First, we used Whisper to transcribe the speech; then, we applied the Compact Language Detector v3 (CLD3) [1] to filter non-Japanese language. Next, we excluded the transcriptions that did not contain Japanese-specific characters (i.e., *hiragana* or *katakana*). After language-based filtering, we filterd out uncertain transcription that contained repetition. Specifically, texts with bi-grams appearing more than six times were excluded.

3. **Combination** After filtering, we combined multiple ASR hypotheses using the Recognizer Output Voting Error Reduction (ROVER) (Fiscus, 1997).

4. **CER-based Filtering** To filter uncertain samples of ROVER results, we applied accuracy-based filtering. We measured the character error rate (CER) between the ROVER results and the original subtitles in YODAS. A high CER indicates that either one or both may be significantly inaccurate. For the ASR training, we constructed a development set of 2k samples of CER ≤ 0.3 data. No CER filtering was applied to the training set because no positive effect was observed in preliminary experiments. Finally, all ROVER results except the development set (1,614,110 segments) were treated as the training set. For the training of MT using the ASR data (described in §4.3), samples with CER ≤ 0.3 (693,304 segments) were used.

To compare the quality of the original subtitles and the ROVER results, we subjectively evaluated the two corresponding transcriptions of 100 randomly selected samples. As a result, we determined that the ROVER results were of higher quality.

3.2 Model

To create the tuning data, we used two pre-trained ASR models: Whisper large-v3[2] and kotoba-whisper-v1.1[3], a Japanese-specific ASR model.

3.3 Training

Using the tuning data created through the above procedure with the two ASR models, we separately fine-tuned each of these models. The training of the model was conducted using the AdamW optimizer, with parameters set as $\beta_1 = 0.9, \beta_2 = 0.999, \epsilon = 1e-8$. We employed a linear decay learning rate scheduler and set the warmup steps to 500. The model's parameters were saved every 4000 steps.

[2] https://huggingface.co/openai/whisper-large-v3

[3] https://huggingface.co/kotoba-tech/kotoba-whisper-v1.1

The training was carried out with a batch size of 32 samples over a single epoch. We selected the best model based on the loss in the dev set.

3.4 Inference

During inference, we performed a beam search with a beam size of 4 and combined these four hypotheses using ROVER. For the post-processing of the ASR stage, we integrated punctuation and sentence segmentation into the transcription. We used the fine-tuned version of xlm-roberta[4] and Bunkai (Hayashibe and Mitsuzawa, 2020)[5] for punctuation insertion and sentence segmentation, respectively. Finally, the two types of hypotheses from the two ASR models were passed to MT.

In the data generation process for MT training (§4.3), ROVER was not performed and the top-1 hypothesis of the beam search was used.

4 Primary Translation Model

4.1 Dataset

We used two types of text corpora: monolingual and parallel data. Monolingual data are used for monolingual continual pre-training, while parallel data are used for parallel continual pre-training, sentence-level supervised fine-tuning (SFT), and paragraph-level SFT.

En-Ja We used the following monolingual corpora: Common Crawl (Kocmi et al., 2022), Leipzig Corpora (Goldhahn et al., 2012), News Crawl, and News Commentary (Kocmi et al., 2023). We also used JParaCrawl v3.0 (Morishita et al., 2022), News Commentary (Kocmi et al., 2023), the Kyoto Free Translation Task Corpus (KFTT) (Neubig, 2011), TED Talks (Barrault et al., 2020), and past WMT test data as the parallel data. Since JParaCrawl v3.0 is automatically created and contains a certain amount of noisy data, we filtered the corpus based on sentence embeddings. We employed LaBSE (Feng et al., 2022) to embed the source and target sentences and then filtered out the sentence pairs in which the similarities are not between 0.4 and 0.9.

Ja-Zh We used the following monolingual corpora: Leipzig Corpora (Goldhahn et al., 2012), News Crawl, and News Commentary (Kocmi et al., 2023). In order to obtain parallel data for continual pre-training, we used JParaCrawl Chinese v2.0 (Nagata et al., 2024). Since this corpus also contains noisy data, we filtered them using the same method as in the En-Ja task. For sentence-level SFT, we used ASPEC-JC (Nakazawa et al., 2016) and Flores-200 (NLLB Team et al., 2022) as training and development sets. In addition to the data for sentence-level SFT, we used News Commentary, WIT3 (Cettolo et al., 2012), Global Voice, and Neulab TedTalks (Tiedemann, 2012) as parallel corpora with context information for paragraph-level SFT.

4.2 Model Selection

For the En-Ja task, we used the largest available LLM in the constrained track, `Llama-2-13b`[6] (Touvron et al., 2023). For the Ja-Zh task, we used `TowerBase-13B-v0.1` [7] (Alves et al., 2024), a model based on Llama-2-13b that has been continually pre-trained with monolingual and parallel data.

Additionally, we developed and deployed a Transformer (Vaswani et al., 2017) model trained from scratch. As training data, we used JParaCrawl v3.0 for the En-Ja task and JParaCrawl Chinese v2.0 for the Ja-Zh task. The model configuration and hyperparameters are detailed in Table 1.

4.3 LLM Training Procedure

We conducted a three-stage training process based on research conducted on translation models using LLMs (Guo et al., 2024; Kondo et al., 2024). In the first stage, we performed continual pre-training with monolingual data. In the second stage, we conducted continual pre-training with parallel data. Finally, in the third stage, we carried out supervised fine-tuning. The detailed model configuration and hyperparameters are given in Table 1.

Monolingual Continual Pre-Training It has been reported that LLMs primarily pre-trained in English, such as Llama-2, have lower translation accuracy for languages other than English (Xu et al., 2024). Therefore, we performed continual pre-training using monolingual data to enhance the

Table 1: Model configuration and hyperparameters.

generation capabilities in languages other than English.

We used randomly sampled data from the monolingual corpora described in §4.1. For the En-Ja task, we created two models, ver1 and ver2, and trained them using randomly sampled data of 1B and 4B tokens, respectively. In contrast, for the Ja-Zh task, we trained only a single model with randomly sampled data of 1B tokens due to the lack of time and GPU resources.

Parallel Continual Pre-Training After completing monolingual continual pre-training, we performed continual pre-training using parallel data. Based on the findings of (Kondo et al., 2024), we used data where the source text is followed by its translation.

For the En-Ja task, the ver1 model was trained using LoRA (Hu et al., 2022), while the ver2 model was trained with full weights. Additionally, ver1 was trained using only the sentence-level parallel data from JParaCrawl v3.0, whereas ver2 utilized JParaCrawl v3.0 along with TED and News Commentary as pseudo-paragraph data.

Supervised Fine-Tuning After completing continual pre-training in monolingual and parallel data, we performed supervised fine-tuning using LoRA. The prompts applied to the training data were the same as those used in ALMA (Xu et al., 2024), and the same prompts were used during inference. Note that loss in the prompt outputs was excluded during training (Xu et al., 2024; Kondo et al., 2024).

Additionally, for domain adaptation, we performed SFT using data from each specific domain. For the En-Ja task, the ver1 model was fine-tuned using TED Talks, KFTT, and past WMT test data. In contrast, the ver2 model was fine-tuned with the same three datasets as ver1, plus two additional settings: using only the news domain data and using only the social domain data each from past WMT test data. Note that the past WMT test data used for SFT training consisted of the WMT20 development and test data, with the other test data from WMT21 to WMT23. For WMT21, both En-Ja and Ja-En directions were included, while WMT22 and WMT23 were composed only of the Ja-En direction. Additionally, the development data for all SFT were the WMT22 En-Ja data. As a result, we obtained a total of eight fine-tuned models for En-Ja. For Ja-Zh, we also performed SFT with synthetic data to enhance robustness against errors in the transcription for the speech domain. These data were constructed by forward translation from audio data using ASR and Transformer models.

5 Reranking

To enhance translation quality, we applied reranking to the candidate sentences. We conducted a comparative analysis of various methods and strategies, as described in §5.1 and §5.3, on the candidate generated by the methods described in §5.2.

5.1 Methods

The reranking approach is used to obtain the final output $\hat{y}$ from the set of candidate sentences $\mathcal{C}$ generated by the methods described in §5.2.

Quality Estimation (QE) This approach involves evaluating the candidates using reference-free quality estimation techniques, such as COMET-QE (Rei et al., 2021, 2022, 2023) and sentence embedding-based similarity, and subsequently selecting the candidate with the highest score, as follows:

$$\hat{y} = \underset{c \in \mathcal{C}}{\operatorname{argmax}} \sum_{i=1}^{m} \lambda_i \mathrm{QE}_i(x, c), \qquad (1)$$

where $\mathrm{QE}_i(\cdot, \cdot)$ is a reference-free quality estimation function and λ_i represents its weight, subject to $\sum_{i=1}^{m} \lambda_i = 1$.

Minimum Bayes Risk (MBR) decoding MBR decoding (Fernandes et al., 2022) employs reference-based metrics to rank translation candidates. It aims to identify the translation that maximizes expected utility while equivalently minimizing the risk (Meister et al., 2020; Eikema and Aziz, 2020) as follows:

$$\hat{y}_i = \underset{c_i \in \mathcal{C}}{\operatorname{argmax}} \frac{1}{|\mathcal{C}|} \sum_{j=1}^{|\mathcal{C}|} \mathrm{RefMetric}(c_i, c_j), \qquad (2)$$

where $\mathrm{RefMetric}(\cdot, \cdot)$ is a reference-based metric. Note that MBR decoding scores the candidate using reference-based metrics by treating all candidates as reference texts without using an actual reference text.

MBR after QE (QE→MBR) This approach integrates QE with MBR decoding (Fernandes et al., 2022). The scores produced by the quality estimation procedure determined the top-n sample set from candidate set $\mathcal{C}$ as $\mathcal{C}_{\text{top-n}}$. Subsequently, MBR is applied to $\mathcal{C}_{\text{top-n}}$.

5.2 Candidate Generation

We generated five candidates for each model by varying the sampling methods during generation. For the speech domain in Ja-Zh, we had two extra transcriptions from our ASR models in addition to the official one. As a result, we generated five candidates for these two transcriptions and LLM models in the same manner. For models based on Llama-2-13b and TowerBase-13B-v0.1, the five methods were as follows: 1. greedy decoding (no sampling), 2. beam search with a beam size of 4, 3. temperature of 0.9, 4. temperature of 0.5, and 5. temperature of 0.3. For methods 3, 4, and 5, parameters other than temperature were set with top_p at 0.6 and top_k at 50. We also used the top-5 candidates from beam search for the Transformer with a beam size of 6. As a result, a total of 45 candidate sentences were generated for the En-Ja task using the eight SFT models described in §4.3, along with the Transformer model, making a total of nine models.

Furthermore, for each SFT model, we employed two approaches to generate candidates.

Sentence-Level Generation First, we used pySBD[10] (Sadvilkar and Neumann, 2020) to split the original paragraph-level test data into sentences, and then we performed sentence-level inference to generate sentence candidates $\mathcal{C}_{sent}$.

Paragraph-Level Generation We used the paragraph data directly as model input for generating paragraph candidates $\mathcal{C}_{para}$.

5.3 Reranking System

For the two types of candidates mentioned in §5.2, we used three reranking strategies and one fusion method that integrates all three.

Synthesized Paragraph Reranking In each sentence-level inference result, we concatenated the sentences that originally belonged to the same paragraph in order and then performed reranking on the synthesized paragraph.

Individual Sentence Reranking We performed sentence-level reranking on the sentence candidates $\mathcal{C}_{sent}$ and then reconstructed the paragraphs from the final reranked results.

Full Paragraph Reranking The paragraph candidates $\mathcal{C}_{para}$ were used as the objects of reranking, directly generating paragraph-level results.

Multi-Attribute Candidate Reranking We established a larger set of multi-attribute candidates $\mathcal{C}_{mac}$ according to the three reranking strategies mentioned above:

- Synthesized paragraph candidates by concatenating the sentences in order from sentence candidates $\mathcal{C}_{sent}$.

- Paragraph data reconstructed on the results obtained by different reranking methods from Individual Sentence Reranking.

- Paragraph candidates $\mathcal{C}_{para}$ generated by Paragraph-Level Generation.

	CER	COMET
	(YODAS)	(WMT test)
Whiper large-v3	7.7	0.4598
+ FT	4.8	0.4601
kotoba-whisper-v1.1	12.6	0.4407
+ FT	5.0	0.4518
Official transcription	-	0.7278

Table 2: ASR performances and their translation accuracies. Second column is CER results on the evaluation data of the YODAS dataset. Third column is COMET results on the speech domain of this year's WMT test set.

Then, $\mathcal{C}_{mac}$ was used for paragraph-level reranking.

6 Experiment and Analysis

6.1 Results of ASR

The second column of Table 2 shows the ASR results (with and without fine-tuning on the YODAS dataset) for the Ja-Zh speech translation. Note that this evaluation was not done in combination with the ROVER system. We confirmed that fine-tuning improved the recognition performance on the YODAS dataset. The third column of Table 2 shows the translation results[11] for the WMT test set. Fine-tuning resulted in a relative improvement of 2.5% for kotoba-whisper-v1.1, but no significant improvement was observed for Whisper-large-v3, even through it demonstrated high ASR performance before fine-tuning. Moreover, our models performed worse than the official transcriptions. We trained the ASR models using relatively short audio samples, whereas the audio samples in the test set were longer than 30 seconds. This gap between the training and test conditions likely contributed to the degradation in speech recognition accuracy. In addition, we prepared ASR models for a wide range of topics, domains, and noise levels for open-domain speech input. For this purpose, we used the YODAS dataset instead of datasets such as TED, CSJ, and Libri, which contain clean speech with human transcriptions. However, this strategy did not turn out to be suitable for the WMT test set. In fact, when we listened to the speech from the test set, the SNR was high and clean. This gap may have also contributed to the degradation. These findings will be leveraged for future improvements.

Model	Input	COMET22
Ver1	Sentence	**0.8218**
	Paragraph	0.7666
Ver2	Sentence	**0.8352**
	Paragraph	0.8349

Table 3: COMET Scores of Sentence-Level and Paragraph-Level SFT on WMT23 En-Ja test data

Scoring Function	COMET22
LaBSE-cos	0.8364
Comet-QE20	0.8797
Comet-QE21	0.8837
CometKiwi22	0.8821
CometKiwi23-xl	0.8819
0.5×Comet-QE20 + 0.5×LaBSE-cos	0.8835
0.8×Comet-QE21 + 0.2×LaBSE-cos	**0.8856**
0.9×CometKiwi22 + 0.1×LaBSE-cos	0.8824

QE (Top 10%)	0.8911
QE (Top 20%)	0.8940
QE (Top 30%)	0.8949
QE (Top 40%)	0.8950
QE (Top 50%)	**0.8955**
QE (Top 60%)	**0.8955**
QE (Top 70%)	0.8954
QE (Top 80%)	0.8953
QE (Top 90%)	0.8953
100%	0.8953

Table 4: COMET Scores of QE and MBR decoding on WMT23 En-Ja test data. The 45 candidates used were generated by the methods in §5.2. MBR decoding was performed after QE with the best scoring function, `0.8×Comet-QE21 + 0.2×LaBSE-cos`.

6.2 Sentence-Level versus Paragraph-Level in SFT

In the SFT experiments using past WMT test data, we evaluated whether sentence-level or paragraph-level source texts achieved better accuracy by assessing them with COMET (`wmt22-comet-da`) on the WMT23 En-Ja test data. For paragraph-level training, the data were reconstructed from sentence-level to paragraph-level based on the .xml files provided by WMT. Table 3 shows the results, indicating that sentence-level inputs achieved higher accuracy than those of paragraph-level inputs. Therefore, for subsequent SFT, we used only sentence-level inputs.

6.3 Results of Quality Estimation

To identify the scoring function in Eq.(1) that yields the highest translation accuracy, we compared ten

[11] We used `wmt22-comet-da`. During this evaluation, we used the official transcription as the source text for all hypotheses because it would be the most accurate transcription. `https://huggingface.co/Unbabel/wmt22-comet-da`

ID	System	MetricX ↓	CometKiwi ↑
(a)	Synthesized Para	2.8830	0.7260
(b)	Individual Sent	2.8100	0.7273
(c)	Full Para	2.7263	0.7260
(d)	Multi-Attribute	**2.6321**	**0.7310**

Table 5: Results of Reranking Systems on WMT24 En-Ja test data. Systems (a)~(c) used 45 candidates, while System (d) used 100 candidates, consisting of 45 from $\mathcal{C}_{sent}$, 45 from $\mathcal{C}_{para}$, and 10 results obtained by Individual Sentence Reranking using the 10 methods listed in Table 4. All of the system results are based on Top 50% MBR decoding after QE with the best scoring function, `0.8×Comet-QE21 + 0.2×LaBSE-cos`.

different scoring functions based on the findings in the paper. We used COMET-QE and LaBSE cosine similarity for scoring functions and evaluated them with COMET on the WMT23 En-Ja test data. Since the WMT23 test data are sentence-level, we used the 45 candidate sentences generated through paragraph-level generation, where each sentence was directly input, as described in §5.2. Additionally, the reranking system utilized Full Paragraph Reranking, as described in §5.3. Table 4 shows the results, indicating that `0.8×wmt21-comet-qe + 0.2×LaBSE-cos` achieved the highest accuracy. Therefore, this scoring function was adopted for subsequent experiments and finally the submitted system.

6.4 Resluts of MBR after QE

We investigated the proportion of MBR that achieved the highest accuracy under the same conditions as in §6.3. Table 4 shows the results, indicating that accuracy was maximized at 50%. Therefore, in subsequent experiments and the submitted system, the proportion of MBR was set to 50%.

6.5 Results of Reranking Systems

Table 5 shows the results of the reranking system on WMT24 En-Ja. We used MetricX-23-XL (Juraska et al., 2023) and CometKiwi-DA-XL (Rei et al., 2023) as evaluation metrics, consistent with the WMT24 preliminary report (Kocmi et al., 2024b). From these results, it was found that the Multi-Attribute Candidate Reranking achieved the highest accuracy. Therefore, we adopted Multi-Attribute Candidate Reranking for the submitted system.

7 Conclusion

In this paper, we described our system for the WMT'24 General Translation Task. We developed ASR models for the speech domain in Ja-Zh and used Transformer and LLMs for the translation models. We trained LLMs using a three-stage training process: Monolingual Continual Pre-training, Parallel Continual Pre-Training, and Supervised Fine-Tuning. Finally, we applied reranking method and strategies to the translation candidates generated by the translation models. Our analyses confirmed the effectiveness of our reranking method and strategies for paragraph-level translation.

Acknowledgments

This work was done mainly under a collaborative research agreement between NTT and Tsukuba University. Additionally, this work partially used computational resources of Pegasus provided by the Multidisciplinary Cooperative Research Program in the Center for Computational Sciences, University of Tsukuba.

SCIR-MT's Submission for WMT24 General Machine Translation Task

Baohang Li, Zekai Ye, Yichong Huang, Xiaocheng Feng, Bing Qin
Harbin Institute of Technology
{baohangli,zkye,ychuang,xcfeng,qinb}@ir.hit.edu.cn

Abstract

This paper introduces the submission of SCIR research center of Harbin Institute of Technology participating in the WMT24 machine translation evaluation task of constrained track for English to Czech. Our approach involved a rigorous process of cleaning and deduplicating both monolingual and bilingual data, followed by a three-stage model training recipe. During the testing phase, we used the beam serach decoding method to generate a large number of candidate translations. Furthermore, we employed COMET-MBR decoding to identify optimal translations.

1 Introduction

This paper presents the submission from the SCIR-MT in the WMT24 machine translation evaluation task, focusing on the **constrained** track of English to Czech translation. In the field of machine translation, the quality of translation systems has been improved with the development of large language models and the increase in data volume. However, achieving high-quality translation outputs under limited conditions remains a challenging task due to resource and computational constraints (Freitag and Al-Onaizan, 2017).

Our team has adopted a series of innovative methods to address this challenge. Initially, we conducted a rigorous cleaning and deduplication process for both monolingual and bilingual data to ensure the quality of the training dataset. Subsequently, we implemented a three-stage model training strategy, including monolingual continual pre-training, bilingual continual pre-training, and translation-specific supervised intruction tuning. During the testing phase, we utilized the beam search decoding method to generate a multitude of candidate translations and applied the COMET-MBR (Fernandes et al., 2022) decoding strategy to identify the optimal translations.

The structure of this paper is as follows: we first provide a detailed description of the data preprocessing steps and strategies; then, we outline our foundational model selection and training strategy; next, we introduce the decoding algorithms used in the testing phase; and finally, we present the COMET-MBR decoding method and report our experimental results on the wmttest2023 dataset. These methods have led to excellent performance in terms of both BLEU (Post, 2018) and COMET (Rei et al., 2020) scores, demonstrating the effectiveness of our approach.

2 Data Preprocessing

2.1 Provided Data

Bilingual Corpus We used all the provided bitext corpora: Europarl v10, ParaCrawl v9 (Bañón et al., 2020), Common Crawl, News Commentary v18.1, Wiki Titles v3, WikiMatrix, Tilde MODEL corpus, and TED Talks (Cettolo et al., 2012).

Monolingual Corpus We also used the following provided monolingual data: News Crawl, Europarl v10, News Commentary, Common Crawl, and Leipzig Corpora (Biemann et al., 2007).

2.2 Data Cleaning

Data cleaning played a pivotal role in improving the quality of our training dataset. During this stage, we implemented several key steps to ensure the quality of the bilingual data and monolingual data, respctively.

2.2.1 Bilingual Corpus

Given that a significant portion of the training dataset is synthetically-aligned, we need to use a comprehensive data preprocessing pipeline to ensure good translation quality. In particular, we sequentially performed heuristic-based, statistics-based, and embedding-based methods to filter our data.

Proceedings of the Ninth Conference on Machine Translation, pages 280–285
November 15-16, 2024 ©2024 Association for Computational Linguistics

Heuristic-based The following heuristic-based filters are used before applying the others:

- **Language Detection** We use fasttext[1] (Joulin et al., 2016) to filter out sentence pairs mismatching the English-Czech direction.
- **Numerical Matching** If one sentence in a pair has a number (ordinal, date, etc.), we also checked the other sentence if a matching number is present. If a match is not detected, the pair is removed.

Statistics-based We employed statistics-based filters on sentence pairs following (Cruz, 2023). We first tokenized then applied the following statistics-based filters:

- **Length Filter** We removed pairs containing sentences with more than 50 characters.
- **Pair Length Ratio** We removed pairs where the ratio of the string lengths between the source and target sentences is greater than 1.2.
- **Symbol Token Ratio** We removed any sentence pairs in which either the source or target sentence appears more than 5 times.
- **Messy Token Ratio** We removed pairs where the number of messy characters in the sentences exceeds 2.
- **Most Frequent Words Gap** We measured the symmetry of bilingual text pairs by calculating the difference in the occurrence counts of the most frequent words in each text, and removed pairs where this difference exceeded 5.

Embedding-based Finally, we experimented with the use of sentence embedding models to compute the cross-lingual embedding similarity between the sentence pair. We used LaBSE (Feng et al., 2020) models to embed both the source and target sentences then computed a cosine similarity score between the two. The pair must have a similarity score $0.95 < s \leq 1$ to be kept.

After rigorous data cleaning, we filtered the bilingual training data from 56,288,239 pairs to 2,725,848 pairs, retaining only 4.8% of the highest quality data for continual pre-training.

2.2.2 Monolingual Corpus

For incremental pre-training of large language models(Wu et al., 2024), we employed the Data-Juicer[2] (Chen et al., 2024b) to filter monolingual data in English and Czech. The filtering part includes the following filters: 1) Number of words, 2) Character repetition ratio, 3) Word repetition ratio, 4) Special character ratio, 5) Stop word ratio, 6) Flagged word ratio, 7) Language identification confidence, 8) Perplexity score, 9) Document length (number of characters), 10) Number of lines, 11) Short line length ratio, 12) Short line ratio.

To address the challenge of assessing the quality of the Czech data, we assumed that the Czech data provided by the competition organizers was of generally acceptable quality, reflecting a reasonable approximation of Czech syntax and expression. To further enhance data quality and improve model performance, we applied the Interquartile Range (IQR) (Whaley III, 2005) statistical method to establish a threshold for data filtering. The IQR method is particularly advantageous because it allows for the objective identification of outliers samples without making specific assumptions about the data distribution.

We calculated the IQR for the Czech dataset to define a reasonable range for data quality. Any samples falling outside this range were deemed potential outliers and excluded from the training data. By evaluating each data pair against these quality filtering criteria, we ensured that only samples within the acceptable range contributed to the training process. This approach enabled us to retain the most representative, high-quality samples, thereby enhancing the overall performance of the translation model. Table 1 presents the number of rows in each dataset with/without filtering.

Corpus	w/o. Filtering	w. Filtering
Common Crawl corpus	333 M	37 M
News Crawl	12M	4.6M
Leipzig Corpora	4 M	1.9 M
Europarl v10	669 K	391K
News Commentary v18.1	283 K	138 K

3 Translation Model Training

This Section describes our foundation model selection and model training strategy.

3.1 Model Configuration

We adopted LLaMA-2-13B as our foundation model considering its impressive performance on most English benchmarks after pre-training on 1.4T tokens (Touvron et al., 2023). Specifically, our Translation Model was initialized from the LLaMA-2-13B model to reduce the computational cost and continues to train on massive Czech and parallel corpus.

3.2 Training Strategy

In pre-trained models such as LLaMA-2, which are primarily trained on English data, integrating monolingual data during continual pre-trainingalongside parallel data has been shown to substantially enhance performance (Guo et al., 2024; Alves et al., 2024). Leveraging this approach, we improved our translation model by first incorporating monolingual data during the continual pre-training phase of models initially trained in English. This was followed by further continual pre-training using parallel data. Finally, we conducted instruction fine-tuning with a limited amount of bilingual data. Our models were developed using the LLaMA-Factory framework (Zheng et al., 2024), which facilitated this comprehensive training process.

3.2.1 Stage-1: Monolingual Continual Pre-training

In the initial phase of our training approach, we conducted secondary pre-training on the large language model (LLM) utilizing the carefully-curated monolingual dataset (shown in 2.2.2). The core objective of this stage is to enrich the LLM's understanding and generation capabilities in non-English languages.

We aimed to strengthen the LLM's multilingual capabilities by exposing it to a diverse monolingual corpus. Although this step was related to machine translation, it was designed to lay a solid foundation for the model's language proficiency, which was critical for the subsequent stages focusing on translation tasks.

Hyperparameters We used the AdamW optimizer, with $\beta_1 = 0.9$, $\beta_2 = 0.95$, and $\epsilon = 1.0 \times 10^{-8}$. The context length is 2048, and training is conducted for 1 epoch. We performed validation every 100 training steps. We used a cosine learning rate schedule with a warmup ratio of 1% and a peak learning rate of 2×10^{-5}. We applied a weight decay of 0.1 and gradient clipping of 1.0. We utilized eight NVIDIA RTX A800 GPUs, processing 1 batch on each GPU with a gradient accumulation step of 32, achieving an effective batch size of 256. During training, Flash-Attenion(Dao et al., 2022), bfloat16 precision, gradient checkpointing, and DeepSpeed ZeRO Stage 2(Rasley et al., 2020) were employed. With these configurations, the training process was completed in 5 days, which accelerates the overall training duration.

3.2.2 Stage-2: Bilingual Continual Pre-training

Bilingual Continual Pre-training is a methodology that involves ongoing training on bilingual datasets to improve the model's alignment between languages. This approach facilitates the model's ability to capture detailed syntactic and semantic correspondences across languages. Such fine-grained alignment is helpful for machine translation, as it enhances the accuracy of encoding source language information and improves the quality of the generated translations, thereby producing more precise and fluent translation outcomes.

Hyperparameters We performed continual pre-training on the model that achieves the minimum validation. We adopted the AdamW optimizers parameter used in Section 3.2.1. Weight decay and gradient clipping remained the same as in Section 3.2.1. We used a cosine learning rate schedule without warmup and a peak learning rate of 1×10^{-5}. We conduct validation every 10% of the total training steps for Continual Pre-training with Sentence-aligned Parallel Data, with 1 epoch and a batch size of 256.

3.2.3 Stage-3: Translation-specific Supervised Fine-Tuning

During the instruction fine-tuning stage, we constructed bilingual translation data in a question and answer format, where the instruction language was the source language for translation. We also employed full-scale parameter training. As highlighted in previous research (Xu et al., 2023), instruction fine-tuning of large language models

(LLMs) benefits from limited yet high-quality datasets. To ensure the optimal quality of data during fine-tuning, we followed previous research practices and used translation fine-tuning datasets constructed from the WMT validation data. These datasets, which underwent rigorous quality control measures, were ideal for fine-tuning purposes.

Hyperparameters We adjusted the AdamW optimizers parameters as used in Section 3.2.1. Weight decay and gradient clipping remained the same as in Section 3.2.1. The peak learning rate was set to 9.0×10^{-6} for full fine-tuning, without warmup, using an inverse square schedule. We conducted validation every 10% of the total training steps for SFT, with 3 epochs and a batch size of 64.

4 Decoding algorithms

In the test stage, we first generated multiple candidate translations for the given source sentence. Then, we performed MBR to determine the final translation.

4.1 Candidate Generation

During the testing phase, we produced 42 high-quality candidate translations. To enhance the diversity of these results, we employed In-Context Learning (ICL) techniques alongside the beam search algorithm. Specifically, we began by sampling various translation examples to serve as demonstrations, which contributed to greater result diversity. We then applied beam search with a beam width of 5 to generate the final set of 42 top hypotheses. This approach effectively integrates context learning and diversity sampling, thereby optimizing both the coverage and quality of the translations.

4.2 COMET-MBR

COMET-MBR (Fernandes et al., 2022) employs Minimum Bayes Risk (MBR) decoding (Kumar and Byrne, 2004; Eikema and Aziz, 2020) with a COMET model (Rei et al., 2020) that has been trained on direct assessments. Typically, a translation $\hat{y}^{MAP} \in \mathcal{V}_Y^{|y^*|}$ is generated using Maximum-A-Posteriori (MAP) decoding, defined as:

$$\hat{y}^{MAP} = \underset{y \in \mathcal{Y}}{argmax} \ \log p(y|x), \qquad (1)$$

where $\mathcal{Y} \subseteq \bigcup_{i=1}^{\infty} \mathcal{V}_Y^i$ represents the search space of target sentences. Unlike MAP decoding, MBR decoding aims to identify the translation that minimizes the Bayes risk:

$$\hat{y}^{MBR} = \underset{h \in \mathcal{Y}}{argmax} \ \underbrace{E_{y' \sim p(y|x)}[u(y', h)]}_{\approx \frac{1}{m}\sum_{j=1}^{m} u(y^{(j)}, h)}, \qquad (2)$$

where $\bar{\mathcal{Y}} \subseteq \mathcal{Y}$ denotes a set of translation hypotheses, and $u : \mathcal{Y} \times \mathcal{Y} \to R$ is the utility function. In our study, we utilize COMET[3] (Rei et al., 2020) as the utility function u. It is important to note that the hypotheses set $\bar{\mathcal{Y}}$ and the sample set used for expectation estimation, $\{y^{(1)}, \ldots, y^{(m)}\}$, are shared, except for h, i.e., $\{y^{(1)}, \ldots, y^{(m)}\} = \bar{\mathcal{Y}} \setminus \{h\}$. Consequently, given a candidate set, the computational complexity of MBR decoding is on the order of $\mathcal{O}(m^2)$, which leads to slower inference speeds as m increases.

5 Experimental Results

We evaluated the translation performance of our system on the WMTTest2023 dataset (Tom et al., 2023) and the Flores-200 benchmark (Costa-jussà et al., 2022). To assess translation quality, we employed both BLEU and COMET scores, utilizing the COMET model Unbabel/wmt22-comet-da[3]. Table 2 provides a comparative analysis with two existing commercial translation systems, Baidu[4] and Google[5]. In this table, "Stage1" "Stage2" and "Stage3" refer to the respective stages of our model training process. The performance labeled as "COMET-MBR" corresponds to the results of applying our MBR decoding approach to the candidate translations.

6 Conclusion

In this paper, we describe the materials we submitted for the general translation task at WMT2024. We participated in a constrained track: En→Cs. We trained a machine translation model based on LLaMA, utilizing a comprehensive data pipeline for filtering and curation. This pipeline integrates embedding-based, heuristic-based, and statistics-based filters. Subsequently, we employed a three-stage training method to enhance the translation capabilities of the model. Additionally, we utilized minimum Bayes risk decoding to refine the translation candidates. On two benchmark

datasets, our system outperformed Baidu and exhibited performance comparable to Google, both of which are unconstrained business systems with significantly more training data.

Future Directions. In the future, we aim to investigate how to prevent the catastrophic forgetting problem in the general capabilities of LLMs caused by continual pre-training on non-English data, which will help models benefit from effective translation-specific prompting techniques (Huang et al., 2024a; He et al., 2024; Chen et al., 2024a). Additionally, it is promising to train multiple translation systems based on different pre-training language models and combine their outputs with the ensemble learning strategies (Huang et al., 2024b; Jiang et al., 2023).

Abstract

This paper describes the development process of NMT systems that were submitted to the WMT 2024 General Translation and Biomedical shared tasks by the team of AIST AIRC. At WMT 2024 AIST AIRC participated in the General Machine Translation shared task and the Biomedical Translation task. We trained constrained track models for translation between English, German, and Japanese. Before training our models, we first filtered the parallel data, then performed iterative back-translation and additional filtering. We experimented with training baseline Transformer models, Mega models, and fine-tuning open-source T5 and Gemma model checkpoints using the filtered parallel data. Our primary submissions contain translations from ensembles of two Mega model checkpoints and our contrastive submissions are generated by our fine-tuned T5 model checkpoints.

1 Introduction

We describe the machine translation (MT) systems submitted to the WMT 2024 General Translation and Biomedical Translation tasks developed by the team of AIST AIRC. We experimented with data quality control by filtering out noisy examples from parallel and monolingual data sets before training, and corpora selection. We also compared several modeling approaches by contrasting our previous year's best constrained submission (Rikters and Miwa, 2023) – the Mega model (Ma et al., 2023) to open track approaches of fine-tuning T5 (Raffel et al., 2020) and Gemma (Mesnard et al., 2024) model open-source checkpoints. When fine-tuning T5 and Gemma models, we experimented with adding named entity (NE) annotations (Rikters and Miwa, 2024) to improve rare word translation, since struggling to correctly translate less common NEs was one of the most common errors identified in human evaluations of our WMT 2023 submissions.

2 Data

In the General Translation task we only participated in the constrained track, so our data selection was limited to only the parallel corpora provided by the shared task organizers, which for German and Japanese was unchanged from the previous year. For the Biomedical Translation task we used a combination of General Translation task data and Biomedical Translation task data.

All parallel training data and monolingual data for back-translation were filtered before starting any training, which has been proven very effective in previous WMT shared tasks (Pinnis et al., 2018). The filtering process we used is detailed by Rikters (2018). We did not perform any parallel data distillation for our submissions this year.

For the system development process in the General Translation task, we selected News Test sets from the WMT 2022 shared task as development data and test sets from WMT 2023 as evaluation data. Statistics of the data we used are shown in Table 1. For the Biomedical Translation task we used the same combination of 2022 and 2023 development / evaluation data sets.

2.1 Data Selection

To not overwhelm the full combined training data set with lower-quality web-crawled data, we 1) limited the English-German Paracrawl to 50 million parallel sentences; and 2) up-scaled all data from other sources to match the amount of the Paracrawl data after filtering by doubling for English-German and tripling for English-Japanese.

2.2 Filtering

Even though all training data need not always be perfect and methods like back-translation intentionally generate somewhat noisy additional training data, some types of noise are more harmful than others. Since most training corpora are produced

Corpus / Filtering		EN-DE	EN-JA
All other	Before	16,752,302	8,076,155
	After	13,737,028	7,076,869

Table 1: Training data statistics for all other parallel data without Paracrawl, a subset of Paracrawl, combined development and evaluation data from the past WMT shared tasks, and monolingual data. Sentence counts are listed before and after filtering.

partially or fully automatically, errors such as misalignments between source and target sentences or direct copies of source to target can occur, as well as some amounts of third language data in seemingly bilingual data sets.

To avoid such problems, we used data cleaning and pre-processing methods described by Rikters (2018). The filtering part includes the following filters: 1) unique parallel sentence filter; 2) equal source-target filter; 3) multiple sources - one target and multiple targets - one source filters; 4) non-alphabetical filters; 5) repeating token filter; and 6) correct language filter. We also perform pre-processing consisting of the standard Moses (Koehn et al., 2007) scripts for punctuation normalization, cleaning, and Sentencepiece (Kudo and Richardson, 2018) for splitting into subword units for training MEGA models, and the default tokenizers for T5 and Gemma. The filters were applied to the given parallel sentences, monolingual news sentences before performing back-translation, and both sets of synthetic parallel sentences resulted from back-translating the monolingual news.

2.3 Back-translation

Increasing the amount of in-domain training data with synthetic back-translated corpora (Sennrich et al., 2016) is a common practice in cases with considerable amounts of in-domain monolingual data. However, since the task recently shifted from 'news' to 'general' text translation, the definition of what would be considered in-domain data became less clear. Furthermore, for the constrained track the selection of provided monolingual data from the organizers is still limited to news and web-crawled data. No other monolingual data that would be considered more similar to what the 'general' test sets may include, such as user generated (social media), conversational, and e-commerce data are provided in the task. For our experiments we continued to assume that a significant portion of the test data would still be from the news domain. Therefore, we chose to only use the provided monolingual News crawl, News discussions, and News Commentary corpora for back-translation.

2.4 Post-processing

In post-processing of the model output we aimed to mitigate some of the most commonly noticeable mistakes that the models were generating. We mainly noticed two often occurring problems in output from all models: 1) difficulties in translating emoji symbols; and 2) occasional repetitions of words or phrases.

While all English and German alphabet letters and even Japanese characters are covered in the large training data corpora, the Unicode emoji were mostly formed and clearly defined only in the past decade, and new emoji are still added every year or two with the next release planned for late 2024[1]. Emoji are also not often present in MT training data, therefore full emoji coverage is absent from model vocabularies, which leads to occasional <*unk*> tokens being generated as output if emoji were present in the input. In order to keep using the models without re-training, we replaced any <*unk*> tokens in the output using a dictionary of any emojis appearing in the input.

Furthermore, the occasional hiccuping or hallucinating of models on less common input sequences seems to still be present, sometimes generating repetitions of tokens or phrases. We replaced any consecutive repeating n-grams with a single n-gram. The same was applied to repeating n-grams that have a preposition between them, i.e., *the victim of the victim*.

Both post-processing approaches gave BLEU score improvements of around 0.1 - 0.2.

[1] https://emojipedia.org/unicode-16.0

3 Model Configurations

While preparing our submissions we experimented with three main model types between the constrained and open system tracks. For our primary submission we chose the constrained Mega models similar to our last year's primary submission (Rikters and Miwa, 2023), and for contrastive submissions we used T5 models (Raffel et al., 2020) fine-tuned on NE-annotated General Translation task data, and Gemma models (Mesnard et al., 2024) tuned on General Translation task data.

3.1 Mega

Ma et al. (2023) proposed a moving average equipped gated attention mechanism (MEGA) - a single-head gated attention mechanism equipped with exponential moving average to incorporate inductive bias of position-aware local dependencies into the position-agnostic attention mechanism. Compared to the Transformer model, MEGA has a single-head gated attention mechanism instead of multi-head attention, which enables gains in efficiency while not sacrificing on performance.

For training our Mega models we used the implementation[2] provided by the authors, which is based on FairSeq (Ott et al., 2019).

3.2 T5

We experiment with multi-task training and fine-tuning the T5 model (Raffel et al., 2020) for translation between English → German, as well as its multilingual counterpart mT5 (Xue et al., 2021) for English → Japanese translation. We compare the results with non-modified versions of T5, Flan-T5, and the multilingual mT5.

We combine and shuffle all training data for the tasks, and experiment fine-tuning the large versions (1B parameters) of the T5 models using a random subset of 10M parallel sentences. We base this choice on observations from preliminary experiments where the small versions of T5 models often converged before reaching 1M examples and base models converged before seeing 10M, since the pre-trained checkpoints are already quite capable as is.

We used the Adafactor optimizer (Shazeer and Stern, 2018) with FP16 training, effective batch sizes of 256 or 512 depending on the model size, evaluation every 1000 steps, and early stopping set to 10 checkpoints of evaluation loss not improving. We set learning rate to 0.0001, weight decay to 0.01, and train each model on a single machine with eight NVIDIA A100 GPUs.

3.3 Gemma

We experimented with adapting 7B and 9B parameter sizes of the 1.1 and 2 version Gemma models (Mesnard et al., 2024) using the in-domain data provided for the General Translation shared task. We used the same random subset of 10M training examples as we did for training T5 models.

4 Results

4.1 General Translation Task

We include the official preliminary automatic ranking results provided by the organizers in Tables 2 and 3. Our primary submissions rank 2nd and 4th among the constrained track (with a white background) for EN-DE and EN-JA respectively. Sadly, they were both not selected for human evaluation by the task organizers due to a large number of submissions and budget constraints this year. References had also not been released as of writing the final submission, therefore, additional metrics or manual assessment of the translations could not be performed.

4.2 Biomedical Translation Task

For the Biomedical Translation task we compared our best models trained for the General Translation task with ones fine-tuned on the biomedical training data, as well as dedicated models trained on the biomedical data from the start. Table 4 shows our preliminary results from developing Mega models for the English↔German tracks of the Biomedical Translation task. We only used different configurations of the MEGA models and compared them with the baseline model submitted to the general translation task. Our best configuration was an ensemble of three separate model checkpoints trained on a mixture of biomedical training data and general data, and fine-tuned on biomedical data.

Table 5 lists the preliminary official results of the Biomedical Translation task provided by the task organizers. According to the BLEU scores, our models seem to be ranked 2nd in both translation directions, overtaken only by the submissions from Unbabel, which are 70B parameter large language models. Similarly to the General Translation task, references for these had also not been released as of writing the final submission, therefore, additional

5 Conclusion

In this paper we described the development process of the AIST AIRC's NMT systems that were submitted for the WMT 2024 shared tasks on general domain text translation and biomedical translation. We compared training MEGA models to fine-tuning T5 and Gemma model architectures in search of the best decoding approach for improving upon output quality. Our results showed that the MEGA model architecture remains highly competitive even in the modern world of large language models, and fine-tuning LLMs with NE-annotated data does not necessarily lead to higher automatic evaluation scores. Especially in the Biomedical Translation task our 100M parameter models demonstrated high competitiveness with the leading 70B parameter models, falling only 0.42 BLEU points behind for EN→DE.

In total, output from four primary systems was submitted to the two shared tasks by AIST AIRC for the English↔German and English→Japanese translation directions.

In future work, we plan to experiment with incorporating document-level training data and modeling longer sequences with appropriate available training data. In terms of data, we intend to increase vocabulary coverage by adding all known unicode emoji symbols to the vocabulary even if they are not present in the training data, as well as additionally sample Paracrawl data where emoji are present.

Abstract

This document describes the submission of the very first version of the Occiglot open-source large language model to the General MT Shared Task of the 9th Conference of Machine Translation (WMT24). Occiglot is an open-source, community-based LLM based on Mistral-7B, which went through language-specific continual pre-training and subsequent instruction tuning, including instructions relevant to machine translation. We examine the automatic metric scores for translating the WMT24 test set and provide a detailed linguistically-motivated analysis. Despite Occiglot performing worse than many of the other system submissions, we observe that it performs better than Mistral7B, which has been based upon, which indicates the positive effect of the language specific continual-pretraining and instruction tuning. We see the submission of this very early version of the model as a motivation to unite community forces and pursue future LLM research on the translation task.

1 Introduction

Occiglot, initiated in March 2024, is a community-based open-source initiative for “Polyglot Language Models for the Occident”. We believe that our dedicated language modeling solutions will not only maintain Europe’s academic and economic competitiveness and AI sovereignty, but also have a profound Impact on the preservation of linguistic diversity, multilingualism, and cultural richness. Occiglot is an academic, non-profit research collective committed to open science and open-source LLM development.

Although Occiglot is in the early stages of development, it entails a significant amount of work for large-scale data collection, model pre-training and tuning, and multi-faceted evaluation. Since LLMs can be used in various use cases, targeted evaluation, starting in the first stages, is important for revealing strengths and weaknesses. The shared task of the 9th Conference of Machine Translation (WMT24; Kocmi et al., 2024a) provides the opportunity for testing the performance of the LLM in a translation task.

First, this paper reviews some indicative items of related work (section 2). Then, in section 3 we present the details on the development of the Occiglot model (section 3.1), the training data related to translation (section 3.2) and the engineering towards machine translation and outline the issues and directions for further improvements. Section 4 presents the evaluation, whereas a conclusion is given in section 5.

2 Related work

Prompting LLMs for translation output has been successfully employed since the early years of LLMs (Brown et al., 2020), with the few-shot enhanced context approach indicating good results (Vilar et al., 2023). Later approaches suggested that an adaptive method of few-shot prompting may be even more beneficial (Agrawal et al., 2023; Zhang et al., 2023; Soudi et al., 2024). Enis and Hopkins (2024) deal with evaluating Claude 3 Opus, as compared to other LLMs, with regard to machine translation of low resource languages.

The motivation of Occiglot, to focus LLM development on languages other than English, is confirmed by Diandaru et al. (2024), who suggest that models centered around languages other than English could provide a more efficient foundation for multilingual applications. Zan et al. (2024) follow a similar approach to ours, including instruction tuning tailored to particular target languages. Stap et al. (2024) suggest that including monolingual data as part of the fine-tuning data, we can maintain the abilities while simultaneously enhancing overall translation quality.

3 The language model

3.1 Training

The submission at WMT24 is based on the current, first version (v0.1) of the Occiglot bilingual models for English-Spanish and English-German, released in March and April 2024 respectively. That version provides a broader LLM collection for the five largest European languages: English, German, French, Spanish, and Italian. Out of these languages, only German and Spanish are official language directions of the WMT24 shared task and, therefore, the respective bilingual models are chosen for this submission.

The models are based on the Mistral-7B, which was pre-trained for English. In addition, bilingual continual pre-training and subsequent instruction tuning for each language were performed. Both models include the dataset Open-Hermes-2B[1], which contains content in English language and code. The German model `occiglot-7b-de-en-instruct` was trained on 180M tokens of additional multilingual and code instructions, including the German subsets of DiscoLM (which includes the publicly available `germanrag` dataset), Open Assistant Conversations Dataset v2 (OASST-2; Köpf et al., 2023) and Aya-Dataset (Singh et al., 2024). The Spanish model `occiglot-7b-es-en-instruct` was trained on 160M tokens of additional multilingual and code instructions, including the datasets Mentor-ES, the Stanford Question Answering Dataset v2[2] (SQuAD; Carrino et al., 2020) and the Spanish subsets of OASST-2 and Aya-Dataset.

The full instruction fine-tuning took place on an H100 with 8 GPUs for 0.6–4 training epochs (depending on dataset sampling). We used the `axolotl` framework, maintaining a precision of bf16, a global batch size: 128 (with 8192 context length and Cosine Annealing with Warm-up). The tokenizer is unchanged from Mistral-7B-v0.1.

All pre-trained and instruction-tuned checkpoints are available on Hugging Face[3] under the Apache 2.0 license. Note that the model was not safety-aligned and might generate problematic outputs.

3.2 Translation data during training

Both the bilingual German and Spanish models were subjected to paired English translation data during continual pre-training. Specifically, the training data contains paired sentences from Tatoeba (Tiedemann, 2020) and Opus 100 (Zhang et al., 2020). The samples are presented as one coherent text using a diverse set of templates, like

```
Given the following passage:
<German sentence>
a good English translation is:
<English sentence>
```

About 470k and 380k similar translation examples were included during the continual pre-training of the bilingual German and Spanish model, respectively.

Additionally, the instruction tuning stage of both models also includes multilingual data. For the bilingual Spanish model, as mentioned above, parts of the instruction training set were taken from a translated version of the SQuAD, which contains Spanish questions about English literature, for example. More importantly for our task, the incorporated open-assistant OASST-2 dataset also includes about 100 samples of direct instructions for translations between English and Spanish. Similarly, the employed German instruction tuning dataset contains over 2000 dedicated translation examples.

3.3 Prompting translations

During the development of the model, we devised a system prompt instructing the model to perform as a dedicated translator and we found that this prompt is immensely helpful when employing the downstream model for translation tasks. Nevertheless, for the WMT submission we decided to use a prompting method which is similar to the way other LLMs are prompted, so that the results are comparable. Prompting was based on the 5-shot templates used by the organizers General Shared task of Machine Translation to prompt GPT-4[4]. The exact prompt used can be seen in Figure 1.

The suggested practice for MT prompting is multi-shot, where one provides first 4 source/translation samples and then only a source awaiting the translation. Occiglot was giving as an answer not only the translation, but was proceeding with generating more text, on the similar

translator. Please translate the given
texts from English to 1.  target_lang
as precisely and accurately as possible
without changing the structure and answer
only with one translation."

PROMPT = "Please translate this into 1.
{target_lang}:

{source_seg}
1. {translation}"
```

Figure 1: Prompt used

pattern, which was difficult to post-process. We had to write a post-processing script that isolates the translation from the additional superfluous text. Nevertheless, we suspect that this post-processing script may have not operated properly in all cases, as we have some hundreds of empty outputs.

The second issue we faced was the inference speed. We loaded the model locally on a python script in the GPU cluster and used the huggingface `pipeline` command to prompt. The German model was too slow (2-7sec per segment), which made it very tight to meet the deadline. We therefore enabled multiple workers with batches (batch_size=64, num_workers=4) which gave indeed a big acceleration. The behavior of the model was a bit different in the batch mode, so we had to include a system prompt (which was not used for the Spanish model). The parameters of the request command with batches were also different (e.g. the limit max_new_tokens), so it is not sure if parallelizing gave the same results as the single worker mode would have given. The Spanish model was fast enough, and the Spanish test set significantly smaller, so we didn't have to parallelize.

Finally, the German model was going through memory spikes and was killed several times by the administrator rules of our GPU cluster. This may have to do with the test set, as the German test set contains a higher number of examples with more complex sequences. In the future, we have to modify our scripts to stream directly to a file and have the possibility to resume from a particular line in case of a crash.

4 Evaluation

4.1 Comparison with other WMT systems

The preliminary results (Kocmi et al., 2024b) of the General MT task, based on automatic measures Table 1, indicate a low performance of Occiglot as compared to other systems. We attribute these results to the fact that the development of our LLM is in the early stage and the model has undergone a relatively minimal optimization for translation. Additionally, we have strong indications that the post-processing script did not account for all possible cases. The fact that the model delivered some hundreds of empty outputs is also a matter that may have contributed to the low scores (although it needs to be noted that the parent model Mistral-Large, prompted by the WMT24 organizers, has delivered a higher number of empty outputs). Finally, we should note that the comparison is mostly done with LLMs with a higher number of parameters, as compared to our system. Therefore, this comparison should only be seen with a grain of salt.

4.2 Comparison with pre-trained model

Occiglot performs better in translating from English-German than the pre-trained model Mistral 7B v0.1, it has been based on. This indicates a

Table 3: Performance of the Occiglot English-German model with regard to linguistically-motivated categories

success of the bilingual continual pre-training and subse- quent instruction tuning for this particular language direction.

4.3 Fine-grained linguistic analysis

Additionally to the automatic scores, we provide here some fine-grained analysis based on particular linguistic categories, based on a linguistically-motivated test suite (Macketanz et al., 2022, 2021; Avramidis et al., 2020). The results can be seen in Table 3 and a more detailed view of the phenomena is displayed in Table 4. The model is particularly strong in *false friends*, which typically refers to lexemes that are identical in their phonological or orthographic form across two languages but have different meanings. It also performs relatively well in handling *non-verbal agreement*, i.e. ensuring that nouns and pronouns agree in gender, number and sometimes case across the sentence (particularly *substitution and coreference*), as well as in *lexical ambiguity*, where a word changes its meaning depending on a context, and *subordination* (particularly *adverbial and subject clause*). *Subordination* refers to the relationship between clauses where one clause is syntactically dependent on the main clause. However, it performs poorly in *punctuation* and particularly quotation marks, which means the model fails to correctly mark direct speech, quotations, or special terms. The low accuracy in *negation* is also particularly concerning, given the semantic importance of this category.

5 Conclusion and further work

We presented an entry participation of a new open-source community-based LLM. Despite some efforts to improve our LLM performance towards translation, the resulting model performs poorly as compared to other systems. Nevertheless, the challenges served as a motivation to unite community forces and initiate research on a new LLM task, which may be further improved in the future. Aside from the automatic scores, by applying a linguistically motivated test suite, we could gain some insights into the linguistic categories which perform better or worse. Further work may include more optimization towards translation, improvement of the prompting and post-processing mechanism and addition of more languages. A more direct comparison with models of similar parameter size (7B) should also be considered in the future.

Acknowledgements

We would like to thank Disco Research, Jan Philipp Harries, and Björn Plüster for making their dataset available to us. Model training was supported by a compute grant at the 42 supercomputer, a central component in the development of hessian AI, the AI Innovation Lab, funded by the Hessian Ministry of Higher Education, Research and the Art (HMWK) & the Hessian Ministry of the Interior, for Security and Homeland Security (HMinD), and the AI Service Centers, funded by the German Federal Ministry for Economic Affairs and Climate Action (BMWK). The curation of the training data is partially funded by the German Federal Ministry for Economic Affairs and Climate Action (BMWK) through the project OpenGPT-X (project no. 68GX21007D). The linguistic evaluation has been supported by the German Research Foundation (DFG) through the project TextQ.

Abstract

This paper presents an evaluation of 16 machine translation systems submitted to the Shared Task of the 9th Conference of Machine Translation (WMT24) for the English-Hindi (en-hi) language pair using our Complex Structures Test (CoST) suite. Aligning with this year's test suite subtask theme, "Help us break LLMs", we curated a comprehensive test suite encompassing diverse datasets across various categories, including autobiography, poetry, legal, conversation, play, narration, technical, and mixed genres.

Our evaluation reveals that **all the systems struggle significantly with the archaic style of text like legal and technical writings or text with creative twist like conversation and poetry datasets**, highlighting their weaknesses in handling complex linguistic structures and stylistic nuances inherent in these text types. Our evaluation identifies the strengths and limitations of the submitted models, pointing to specific areas where further research and development are needed to enhance their performance. Our test suite is available at https://github.com/AnanyaCoder/CoST-WMT-24-Test-Suite-Task.

1 Introduction

Neural Machine Translation (NMT) has seen substantial progress in recent years, achieving impressive quality that benefits many everyday applications. The advent of large language models (LLMs) has further enhanced translation capabilities. However, despite these advancements, there remain challenges that generic evaluation methods often fail to address. While traditional evaluations using random text samples might show overall success, they may not reveal subtle issues where MT systems struggle, such as handling complex linguistic structures, idiomatic expressions, and diverse text types like conversations, poetry, legal documents, and technical writing. These flaws can be obscured by average performance metrics or overlooked entirely. A more systematic method for identifying linguistic issues in translation outputs involves using test suites or challenge sets to evaluate the system's performance on specific tasks. (Manakhimova et al., 2023). Test suites offer a standardized approach to evaluating MT systems, revealing strengths and weaknesses in handling complex text types.

In this context, we present the results of using test suites to analyze state-of-the-art machine translation systems across various categories. These evaluations were conducted as part of the theme "Help Us Break LLMs" for the 9th Conference on Machine Translation (WMT24). The test suites were used to evaluate systems submitted for the English-Hindi language pair.

We have curated a unique test suite comprising sentences from 9 categories across 16 sources to evaluate how large language models (LLMs) perform. The diversity of these categories allows us to assess the LLMs' capabilities beyond the typical news or generic domains, which often focus on reporting or narrative writing styles. Details of our test suite are provided in Section 2.

We perform reference-free and reference-based evaluations of the Hindi translations of this test suite, produced by 16 different machine translation (MT) systems submitted to the General Translation Task at WMT24 (Kocmi et al., 2024a). For referenceless evaluation, we employ COMET-Kiwi (Rei et al., 2022), while (Papineni et al., 2002),

[*] Authors contributed equally

Proceedings of the Ninth Conference on Machine Translation, pages 299–306
November 15-16, 2024 ©2024 Association for Computational Linguistics

chrF (Popović, 2015, 2017), MEE4 (Mukherjee et al., 2020; Mukherjee and Shrivastava, 2023), BERTScore (Zhang* et al., 2020), and COMET (Rei et al., 2020) are used for reference-based evaluation. Professional English-to-Hindi translators provide the reference translations. Our results indicate that, for the English-to-Hindi language pair, **LLMs show weaker performance on datasets related to poetry, legal, and conversational content**. Details of our evaluation experiments are discussed in Section 3, and our analysis is presented in Section 4.

2 CoST: Complex Structure Testsuite

Table 1 depicts the dataset categories and the distribution within our test suite. The "Original" column presents the initial count of selected sentences for each category, as gathered from the datasets. The last column, "CoST," displays the final count of sentences included in the test suite. Our test suite is designed to evaluate translations across

- Multiple Writing Style: Prose, Conversation, Autobiography, Legal Writing, Literary Narrative and Technical Documents.

- Lexical Choice: As we are sampling test suites from various domains, there is a decent mixture of domain-specific words, e.g. Legal Text, Technical Text, etc.

In total, 1,947 English sentences were selected based on criteria such as sentence length, depth of dependency tree, combination of noun phrases, verb phrases, named entities, etc. Ensuring a test suite containing sentences with good representation from simple to complex structures.

Category	**Dataset**	**Original**	**CoST**
poetry	Kabir ke Dohe	11	9
	Amir Khusro	9	9
narration	ShortStories	177	72
	Post Office	440	10
	Glimpses of Bengal	101	64
	The Home and the World	236	183
	The gardener	277	27
	Abridged Merchant of Venice	63	31
	Christmas Carole	923	308
legal	Legal Text	2862	638
	IIT Bombay Jud	167	83
mix	IN22	570	241
conversation	Friends	77	53
play	King Of Dark Chamber	35	22
autobiography	My Reminiscences	109	110
Technical	Technical Papers	185	87
	Total	**6242**	**1947**

Table 1: Data Statistics of **CoST**.

3 Evaluation Strategy

To evaluate the performance of the 16 submitted MT systems, we performed both automatic and manual evaluations.

3.1 Automatic Evaluation

In automatic evaluation, we leveraged both reference-less and reference-based metrics.

3.1.1 Reference-less Evaluation

For the reference-less automatic evaluation, we utilize COMETKIWI (Rei et al., 2022) scores, which offer quality estimation scores derived from the source sentence and MT output.

3.1.2 Reference-based Evaluation

With the help of professional English-to-Hindi translators, we also provide one gold reference translation for each source sentence in the test suite. We evaluate the machine translation outputs against these references using BLEU (Papineni et al., 2002), chrF (Popović, 2015, 2017), MEE4 [1] (Mukherjee et al., 2020; Mukherjee and Shrivastava, 2023), BERTScore (Zhang* et al., 2020), and COMET (Rei et al., 2020).

3.2 Manual Evaluation

The manual analysis was done by professional native speakers. They were instructed to identify mistranslations and hallucinations and make note of other translation errors like wrong post positions to get more nuanced information regarding the performance of the systems.

4 Results and Analysis

The results of the automatic evaluation are reported in Table 2. Ranks are shown in parentheses for each metric, where (1) is the highest rank. It is clearly evident that evaluations from all the metrics rank TranssionMT as the best system, followed by ONLINE-B

[1] https://www.kaggle.com/ananyacoder/mee4-metric-run

and Claude-3.5. In contrast, CycleL is ranked the lowest, preceded by IKUN-C and IKUN. We also observe that according to the Preliminary WMT24 Ranking of General MT Systems and LLMs (Kocmi et al., 2024b), Unbabel-Tower70B is listed as the top performer. However, its performance decreases on CoST. For more category-wise informative results, we looked at the performance of systems for each category using lexical-based metric (Figure 2 and 3), embedding- based metric (Figure 4 and 5) and supervised metric (6) and (Figure 1). These results illustrate that **all systems underperform with poetry, legal, and conversation data**. In contrast, the systems consistently exhibit strong performance with autobiography, play, and mixed (IN22) data.

The analysis shows a clear trend, i.e., systems struggle with specific genres like poetry, legal, and conversation while excelling in narrative styles such as autobiography and play. This suggests that the training data for these systems may be heavily skewed towards narrative writing, hence strong performance in those areas. The sub-par performance in poetry, conversational and legal texts might reflect challenges in handling diverse linguistic and stylistic features that are less prevalent in the training data.

4.1 Qualitative Analysis

These manual assessments are carried out by professional Hindi speakers who hold graduate-level qualifications and possess good knowledge in the domains covered by our test suite.

4.1.1 Handling Named Entities

Source: *Labanya said to her sister in soothing tones : " Don't be upset about it , dear ; I will see what I can do to prevent it . "*

Most models successfully translated "Labanya" correctly, preserving the original name. However, the outputs from Claude-3.5, GPT-4, NVIDIA-NeMo, ONLINE-A, Unbabel-Tower70B, and ZMT show variations or distortions of the name, indicating potential issues with **name recognition or transliteration** in these models.

In another instance, IKUN-C, IKUN, Llama3-70B, NVIDIA-NeMo, ONLINE-A, Unbabel-Tower70B, and ZMT systems have translated 'Phoebe' as Phob, Phobey, Phoyeb, Phoyebe; surprisingly ONLINE-G has generated चाँद (meaning moon, as Phobe is one of the moons of Saturn).

4.1.2 Spelling and Typological Errors

Except for Llama3-70B, IOL_Research, and CommandR-plus, all other models tend to generate हूं instead of हूँ, indicating a recurring spelling error in their outputs.

4.1.3 Omissions

The Hindi translations produced by the IKUN and IKUN-C systems consistently suffer from **incompleteness**, often leaving out key parts of the original sentences, undermining the accuracy and reliability of the translations, making them less effective for conveying the full meaning of the source text.

4.1.4 Incorrect Lexical Word Choices

Choosing the right word in translation is crucial for preserving the essence, tone, and intention of the original sentence. For instance, Unbabel-Tower70B accurately translates "well," whereas all other systems translate it as "alright" or "okay." These alternatives do not fit the context as well, thereby **affecting the tone and overall quality** of the translation.

Source: *I'd be pulling up shoots of grass to use them to check the wind, and looking at maps of ports and piers and roads.*

However, Aya23 and IOL_Research translate it as "removing," while the remaining systems use "pull." These variations of "remove" and "pull" slightly **affect the accuracy and well-formedness** of the Hindi translation.

5 Conclusion

This paper evaluates translations from 16 MT systems submitted to the General Translation Shared Task WMT24 on **Complex Structures Test** suite which was designed to cover various writing styles and domains beyond the typical news and generic data, consisting 1,947 unique sentences selected for their lexical and structural diversity. We conducted automatic reference-based, automatic reference-free, and manual evaluations. Our thorough analysis reveals significant limitations in these LLMs,

particularly in translating poetry, conversational, and legal texts. Additionally, our manual review uncovered issues such as incorrect word choices, spelling errors, and poor handling of named entities. Despite their advancements, these LLMs show notable weaknesses in handling diverse and complex linguistic contexts. This highlights the need for continued refinement and broader training data to improve their performance across a wider range of text types and domains.

Abstract

We assess the difficulty of gender resolution in literary-style dialogue settings and the influence of gender stereotypes. Instances of the test suite contain spoken dialogue interleaved with external meta-context about the characters and the manner of speaking. We find that character and manner stereotypes outside of the dialogue significantly impact the gender agreement of referents within the dialogue. https://github.com/hillary-dawkins/wmt24-gender-dialogue.

1 Introduction

Gender bias and gender effects in machine translation are prevalent in translation directions where gender relevancy increases from source to target language (Savoldi et al., 2021; Barclay and Sami, 2024; Savoldi et al., 2023). English has minimal morphological effects caused by natural gender, whereas many languages (e.g. French, Spanish, Czech, Icelandic, German) have grammatical gender cases for various parts of speech which sometimes need to align with natural gender for animate nouns. For example "I am happy" in the source language English has divergent translations in the target language French ("Je suis heureux/heureuse") depending on the natural gender of the speaker. The consequence is that gender-alignment errors can easily arise in such translation directions. Furthermore, stereotypes are known to drive gender agreement (e.g., systems may tend to prefer the translation "Je suis jolie" over "Je suis joli" for "I am pretty" despite incomplete gender context) (Sólmundsdóttir et al., 2022), and these stereotype effects can persist even when unambiguous gender information is provided (Stanovsky et al., 2019; Troles and Schmid, 2021; Kocmi et al., 2020).

Typically, these gender effects are studied in isolation or semantically-bleached settings (as in the above examples). There it is known that the internal characteristics of adjective words, such as the gender stereotype, sentiment, and type (appearance or character), are significant factors influencing the choice of gender agreement in translation (Sólmundsdóttir et al., 2022). However, the need for gender agreement also occurs in more complex settings, such as over long ranges, and passages involving multiple potential referents.

Due to increasing interest in paragraph-level translation and literary domains, here we assess the challenge of speaker-listener role resolution in literary dialogue settings. In particular, the gender of the speaker and listener must be resolved correctly to obtain a correct translation, and we suppose that gender stereotype effects can further add to the task difficulty. We find that stereotypical character descriptions and manners of speaking are significant influences on the gender alignment, generally overshadowing the internal adjective traits.

2 Test Suite Description

This test suite measures the gender resolution tendencies of machine translation systems in literary-style dialogue settings. In this setting, spoken dialogue (in quotations or otherwise delimited) is interleaved with meta-context about the dialogue (e.g., the speaker, the listener(s), and character and environment descriptions). When spoken dialogue refers to a person, a challenge arises in resolving the referent given the meta-context. The test suite includes three target languages (Spanish, Czech, and Icelandic), where the gender of the referent affects the correct translation.

Here, we focus on two-person conversations, where adjectives are used within dialogue to describe either the speaker or the listener. Within a single source passage, both characters may take on both the speaker and listener roles at times. Since adjectives are gender-neutral in the source language (English), the gender of the adjective's referent must be determined from the meta-context, if possible. The test suite contains inputs where

Proceedings of the Ninth Conference on Machine Translation, pages 307–326
November 15-16, 2024 ©2024 Association for Computational Linguistics

the gender remains unknown given the complete context (termed gender-ambiguous cases), and inputs where the gender can be unambiguously resolved given the complete context (termed gender-determined cases).

The test suite contains a handful of template types (each detailed in Appendix A) to assess the influence of stereotype cues in the meta-context and the structural features of the passage. Stereotype features include character descriptions and the manner of speaking (controlled using adverbs). Structural features include the number of referents in a single passage, partial or complete gender information, first- or third-person speakers, and adjective repetition. Some challenging features of the templates include adjectives that appear before the referent is introduced, and repeated adjectives referring to different entities.

The templates use vocabulary sets for adjectives ($n = 350$), gender-stereotyped adverbs ($n = 29$), and gender-stereotyped occupation words ($n = 44$). Each adjective is labeled with its gender stereotype (M/F/neutral), sentiment (positive/negative/neutral), and type (character/appearance). The full vocabulary set with annotations is released as part of the test suite contribution.

3 Methodology

The adjective translations are extracted from the target languages and processed using dictionary searches[1] to obtain the gender agreement label. The advantage of using dictionary searches over automated morphological gender taggers is that irregular adjectives (e.g. "rosa" in Spanish) are correctly classified, and the use of different parts of speech or out-of-dictionary words can also be monitored. For example, the use of a gender-neutral noun phrase or direct substitution of an English word should be counted as a neutral label for our purposes. Only when a translated word is not found in any dictionary search, is it passed to auto gender-tagging based on its morphological features (e.g. an "o" vs. an "a" ending in Spanish). This second pass allows for (possibly hallucinated) out-of-dictionary words to be included in the analysis, but only if they strongly resemble a regular adjective form (e.g. "víktur" in Icelandic may be derived from the English source word "victorious", but clearly a masculine adjective ending has been chosen in translation). A small portion of words remains unclassified after both passes are complete, meaning that they neither exist in the dictionary nor resemble a regular adjective in the target language. The fine-grained annotations for each extracted translation, in addition to the final gender label (one of M, F, N, or unclassified), are released with the test suite results for further analysis.

The scope of analysis in this paper is limited to the subset of M- and F-labeled translations. That is, when a gendered adjective form *is* chosen by a translation system, we are interested in the factors that influence this choice, and the corresponding translation errors that occur when an adjective form does not match the referent's gender. To this end, results throughout the paper are presented in three ways.

When the gender of a referent is unknown, we report the proportion of masculine and feminine adjective declensions to observe the system's tendencies in ambiguous settings. When the gender of a referent is known, we report the accuracy of the adjective declensions. Typically, the underlying effect (e.g., the influence of stereotypes) is the same in both cases. However, it is important to know that the effect persists even when unambiguous gender context is available. Both proportion and accuracy results are always reported using balanced subsets[2] of the relevant test suite subset.

Lastly, we wish to understand the relative importance of factors that influence the system's choice of gender agreement. To do so, we perform regression analyses where the dependent variable to predict is the gender declension of the translation, and independent variables include both internal adjective factors (the gender stereotype, sentiment, and type), and external factors that are introduced through the meta context (e.g. character descriptions). The regression coefficients are reported with significance levels.

4 Gender-Stereotyped Manner

Firstly, we observe that the manner of speaking in literary dialogue settings can significantly affect

https://cs.wiktionary.org/

[2] adjective traits are balanced on type and sentiment, and exclude gender stereotypes; structural factors such as listener and speaker roles are balanced as applicable to the template type

(a) “I think I’m courageous,” I said.

(b) “I think I’m statečný (**M**↑↑),” I said sauvely.

(c) “I think I’m statečná (**F**↑↑),” I said gently.

Figure 1: Gender-stereotyped adverbs outside of the dialogue affect the adjective’s gender agreement with the speaker within the dialogue. Source sentences in English include instances without adverbs (a) and with stereotypically masculine (b) or feminine adverbs (c). When translated to the target language, adjectives tend to align with the stereotype (adjectives shown here in Czech).

the gender prediction of the speaker. Furthermore, this influence is susceptible to gender stereotypes. Refer to the example shown in Figure 1.

Within the **Stereo-Adverb** test suite subset, all adjectives refer to a first-person speaker (I), and therefore the natural gender of the adjective’s referent is ambiguous in the source language. We report the proportion of male declensions on subsets (a) with no adverb, (b) a male-stereotyped adverb, and (c) a female-stereotyped adverb (full results in Appendix B). The majority of systems display a difference greater than 10% when the adverb switches from male- to female-stereotyped. The systems with the largest effects are shown in Table 1. Note that the most affected systems include those that defy the usual default-male agreement in ambiguous gender cases in the baseline setting (i.e., in the absence of any adverb). Here we see that the default-female agreement is unstable with respect to stereotype cues.

To compare the influence of speaking manner to the influence of internal adjective traits, we perform regression analysis where the dependent variable to predict is the gender declension. Independent variables are the gender stereotype label of the adverb, and the gender stereotype, the sentiment, and the type (appearance or character) of the adjective. The analysis shows that adverb influence is comparable or stronger than these internal adjective characteristics within this test suite (see Table 9).

5 Gender-Stereotyped Characters

Secondly, we observe that character descriptions that align with socially held stereotypes impact gender resolution within spoken dialogue. Refer to the examples shown in Figure 2.

Within the **Stereo-Character** test suite subset, all adjectives refer to one of two characters that have been given some stereotypical descriptions using both occupations and attributive adjectives. Template variations include single-speaker dialogue, where adjectives refer to either the speaker (I) or listener (you) (see template 3), and two-speaker conversations where both participants are referenced by each speaker (see template 4).

In ambiguous gender cases (Figure 2a), we report the stereotype effect again by looking at the tendency of the system to choose either a female or male adjective declension depending on the referent stereotype (full results in Appendix B). Characters that are described by male-leaning gender stereotypes are very likely to receive a masculine adjective, whereas the use of feminine adjectives increases for female-stereotyped characters (pushing against the default-male baseline), as shown in Table 2 for the most affected systems.

Furthermore, we find that this effect persists in determined gender cases (Figure 2b) such that agreement accuracy can drop significantly when the actual gender opposes a socially-held stereotype. We report this observation as the difference in accuracy between the PRO and ANTI template subsets (full results in Appendix B). Approximately half of the tested systems are not robust to stereotype cues even when the correct, unambiguous gender context is provided. The most affected systems are shown in Table 3. As with the stereotyped adverb effect, we perform a regression analysis to probe the relative influence of stereotypical character descriptions compared to the internal adjective factors. We find that the character descriptions are much more impactful on the adjective’s gender form than the internal adjective traits within this dialogue setting (see Table 15).

6 “Opposite” or “Same” Binary Gender Speaker Bias

Finally, in the absence of any gender stereotype effects, we assess the overall “vanilla” difficulty of this gender resolution task in non-challenge settings and the influence of different structural elements in the source input. In doing so, we observe that an “opposite” or same binary gender bias exists. That is, in dialogue settings between two speakers, some systems strongly predict one speaker to be male and the other female, while other systems strongly prefer same-gender pairs. This observation holds in both ambiguous and determined cases.

System	F	M	F_M	M_M	F_F	M_F	ΔM_{M-F}
CUNI-MH	0.703	0.297	0.379	0.621	0.950	0.050	**0.571**

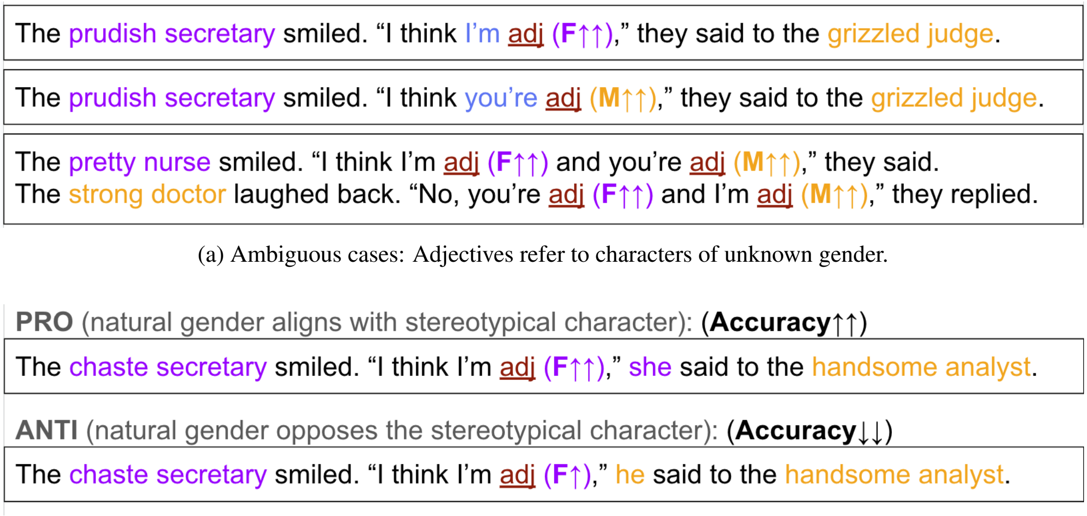
CommandR-plus	0.340	0.660	0.120	0.880	0.554	0.446	**0.434**
Aya23	0.370	0.631	0.187500	0.813	0.612	0.388	**0.425**

Table 1: **Gender-Stereotyped Manner**: The proportion of adjectives with male (M) and female (F) agreement on the **Stereo-Adverb** test suite subset for the most affected translation systems in the English to Czech translation direction. All adjectives self-refer to the speaker of unknown gender. Subscripts (M and F) denote the use of gender-stereotyped adverbs to control the manner of speaking (e.g., M_F denotes the proportion of adjectives with a male declension within instances using a stereotypically feminine adverb, as shown in Figure 1 example (c)). The unsubscripted results refer to no adverb (as shown in Figure 1 example (a)). The overall strength of the adverb effect is reported using the difference ΔM_{M-F}.



The prudish secretary smiled. "I think I'm adj (F↑↑)," they said to the grizzled judge.

The prudish secretary smiled. "I think you're adj (M↑↑)," they said to the grizzled judge.

The pretty nurse smiled. "I think I'm adj (F↑↑) and you're adj (M↑↑)," they said.
The strong doctor laughed back. "No, you're adj (F↑↑) and I'm adj (M↑↑)," they replied.

(a) Ambiguous cases: Adjectives refer to characters of unknown gender.

PRO (natural gender aligns with stereotypical character): (**Accuracy**↑↑)

The chaste secretary smiled. "I think I'm adj (F↑↑)," she said to the handsome analyst.

ANTI (natural gender opposes the stereotypical character): (**Accuracy**↓↓)

The chaste secretary smiled. "I think I'm adj (F↑)," he said to the handsome analyst.

(b) Determined cases: Adjectives refer to characters of known gender. The known gender either aligns with the stereotype (PRO) or opposes the stereotype (ANTI).

Figure 2: Gender-stereotyped character descriptions outside of the dialogue affect the adjective's gender agreement.

System	F_M	M_M	F_F	M_F	ΔM_{M-F}

Table 2: **Gender-Stereotyped Characters**: The proportion of adjectives with male (M) and female (F) agreement on the **Stereo-Character-Amb** test suite subset (Figure 2a) for the most affected translation systems in the English to Spanish translation direction, partitioned by the referent's gender stereotype (denoted by subscripts). The true gender of the referent is unknown, but the choice of declension is affected by the stereotypical character description. The overall strength of the character description effect is reported by the difference ΔM_{M-F}.

System	Accuracy (PRO)	Accuracy (ANTI)	Δ(PRO, ANTI)
ONLINE-W	0.985	0.414	**0.571**
GPT-4	0.990	0.527	**0.463**
Aya23	1.000	0.655	**0.345**
IKUN	0.975	0.702	**0.273**

Table 3: **Gender-Stereotyped Characters**: The accuracy in gender-adjective agreement on the **Stereo-Character-Det** test suite subset (Figure 2b) for the most affected translation systems in the English to Spanish translation direction. The true gender of the character either aligns with (PRO) or opposes (ANTI) the stereotypical description. The presence of stereotypical character descriptions can significantly decrease the gender translation accuracy.

Refer to the examples shown in Figure 3.

In ambiguous gender cases, we can observe this effect as the proportion of adjective declension choices conditioned on the known gender of the second character in the conversation (Figure 3a). Note that adjectives may still either refer to the speaker or listener, and both types are affected by the presence of a second known gender. Full results are shown in Appendix B, and a summary of the most affected systems is shown in Table 4.

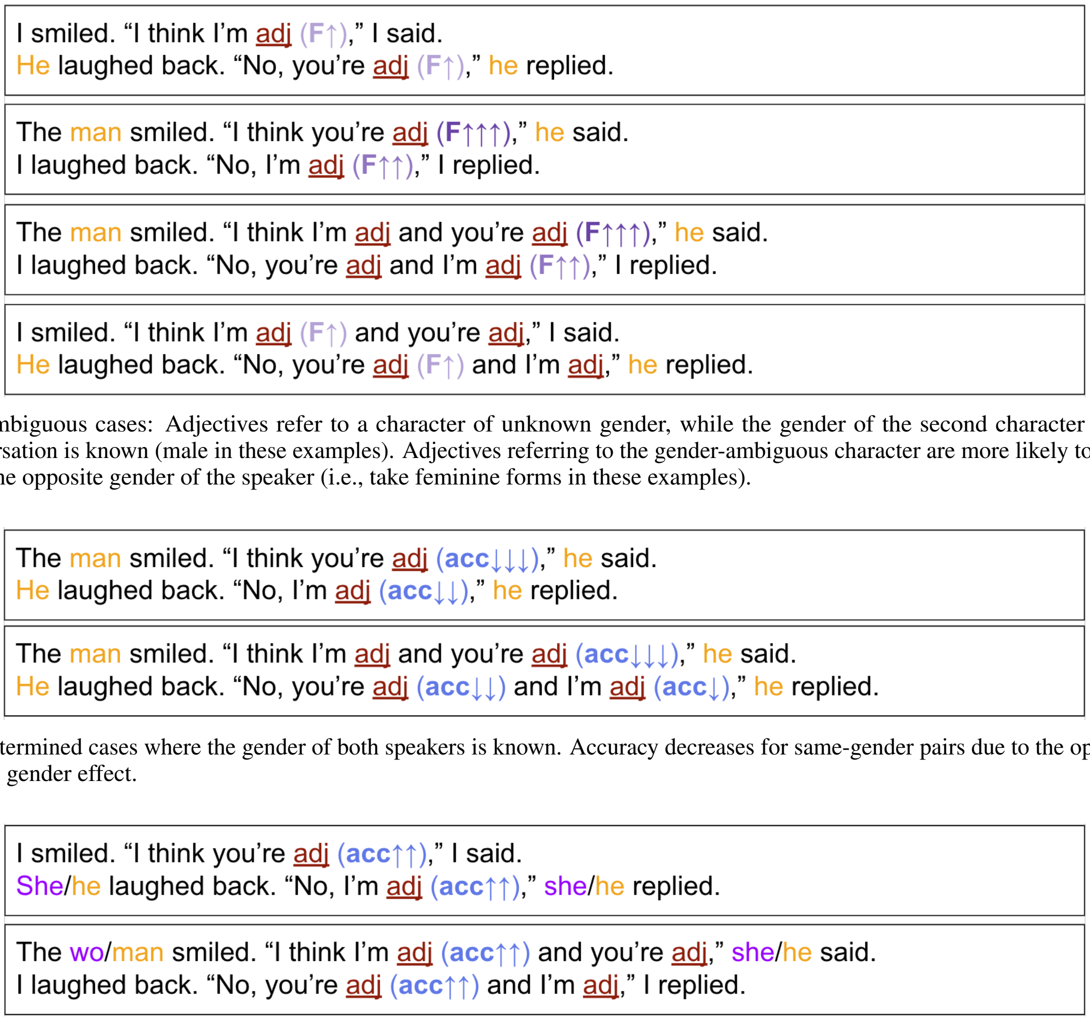
In determined gender cases, the tendency to assume either the same or opposite binary gender pairs manifests as decreased accuracy in cases that oppose this assumption. We report the accuracy in adjective agreement on test subsets where (a) only one gender is specified (Figure 3c), (b) both genders are specified and are opposite, (c) both genders are specified and are the same (Figure 3b). Subset (a) is usually easiest for most systems because the same or opposite gender effect is not possible. The difference in accuracy between subsets (b) and (c) indicates the strength and direction of this effect. Full results are shown in Appendix B and a summary is shown in Table 5.

We note that the observed decrease in accuracy on gender pairings that oppose the system's presupposition is being driven by two features within our templates: 1. Adjectives that occur before their referent (if reading left to right), and 2. A consistency effect. For example, refer to the two examples shown in Figure 3b. In both cases, the first adjective to translate occurs before it's referent, but after the gender of the speaker is known. Adjectives in this position are very likely to align with the same or opposite gender of the speaker in affected systems, depending on the effect direction. Following the incorrect translation of the first adjective, we observe that the adjective in the last position is likely to also be incorrect, possibly owing to a consistency effect since these refer to the same entity.

Using regression analysis, we predict the adjective declension conditioned on structural factors: the gender of the other speaker, whether the referent is the speaker (I) or the listener (you), the gender choice in preceding adjectives that refer to the same entity (consistency), and whether the adjective occurs before the referent is introduced ("look-ahead" position), as well as the internal traits of the adjective as always, and the true gender label for determined cases. Controlling for internal traits, the correct gender label, and the default masculine baseline, we observe that both "look-ahead" and referent role (listener) are influential structural factors affecting the task difficulty (refer to table 27).

7 Future Work

Here, the scope of analysis is limited to the cases where a translation system has chosen either a masculine or feminine adjective form, and ignores those cases where a neutral translation strategy was used instead. However, the labeling methodology as described in Section 3 does produce a test suite with annotated neutral labels as well. The observed neutral strategies vary by target language and include the use of adjectives with the same form for the female and male gender cases (e.g. regular adjectives ending in "e" in Spanish, or "í" in Czech), the use of the neuter gender case if it exists (as in Czech and Icelandic), direct substitution of the gender-neutral source (English) adjective, the use of alternative forms (e.g. translated adjectives ending "o/a" in Spanish or "(ur)" in Icelandic), and the use of noun phrases in place of adjectives, which may be gender-neutral depending on the target language. Some of these strategies may be considered to be more correct than others (i.e. applying the neuter gender case to a person is not grammatically correct, but may still be preferred to misgendering in ambiguous cases).



I smiled. "I think I'm adj (F↑)," I said.
He laughed back. "No, you're adj (F↑)," he replied.

The man smiled. "I think you're adj (F↑↑↑)," he said.
I laughed back. "No, I'm adj (F↑↑)," I replied.

The man smiled. "I think I'm adj and you're adj (F↑↑↑)," he said.
I laughed back. "No, you're adj and I'm adj (F↑↑)," I replied.

I smiled. "I think I'm adj (F↑) and you're adj," I said.
He laughed back. "No, you're adj (F↑) and I'm adj," he replied.

(a) Ambiguous cases: Adjectives refer to a character of unknown gender, while the gender of the second character in the conversation is known (male in these examples). Adjectives referring to the gender-ambiguous character are more likely to agree with the opposite gender of the speaker (i.e., take feminine forms in these examples).

The man smiled. "I think you're adj (acc↓↓↓)," he said.
He laughed back. "No, I'm adj (acc↓↓)," he replied.

The man smiled. "I think I'm adj and you're adj (acc↓↓↓)," he said.
He laughed back. "No, you're adj (acc↓↓) and I'm adj (acc↓)," he replied.

(b) Determined cases where the gender of both speakers is known. Accuracy decreases for same-gender pairs due to the opposite binary gender effect.

I smiled. "I think you're adj (acc↑↑)," I said.
She/he laughed back. "No, I'm adj (acc↑↑)," she/he replied.

The wo/man smiled. "I think I'm adj (acc↑↑) and you're adj," she/he said.
I laughed back. "No, you're adj (acc↑↑) and I'm adj," I replied.

(c) Determined cases where the gender of one speaker is known. Accuracy is generally high in the absence of a second gender (i.e., the opposite binary gender effect is not possible).

Figure 3: The opposite binary gender effect is present in both ambiguous (a) and determined (b) cases. Determined cases with a single known gender (c) are unchallenging despite having the same structural components (i.e. both speaker (I) and listener (you) resolutions, and need to "look ahead" in the text to find the adjective's referent). All effects are the same but flipped for systems that prefer same-gender speaker pairs.

System	F_M	M_M	F_F	M_F	ΔM_{M-F}
Claude-3.5	0.419	0.581	0.074	0.926	**-0.346**
CommandR-plus	0.764	0.236	0.426	0.574	**-0.338**
IKUN-C	0.292	0.708	0.703	0.297	**0.410**
IKUN	0.256	0.744	0.726	0.274	**0.470**

Table 4: **Opposite or Same Binary Gender Effect**: The proportion of adjectives with male (M) and female (F) agreement on the **Structure-Amb** test suite subset (Figure 3a) for the most affected systems in the English to Spanish translation direction. All adjectives refer to someone of an unknown gender in conversation with someone of a known gender (where that known gender is denoted by the subscripts). Systems Claude-3.5 and CommandR-plus show the greatest tendency to assume opposite-gender speaker pairs ($\Delta M_{M-F} \ll 0$), and systems IOL-Research and IKUN show the greatest tendency to assume same-gender speaker pairs ($\Delta M_{M-F} \gg 0$).

System	Acc (one gender)	Acc (same genders)	Acc (opp genders)	Δ(same, opp)
CommandR-plus	0.987	0.797	0.991	**-0.194**
Llama3-70B	0.957	0.806	0.977	**-0.171**
ONLINE-A	0.734	0.828	0.668	**0.160**
ONLINE-G	0.726	0.827	0.625	**0.202**

Table 5: **Opposite or Same Binary Gender Effect**: The accuracy in gender-adjective agreement on the **Structure-Det** test suite subset (Figures 3c and 3b) for the most affected systems in the English to Spanish translation direction. The second speaker in the conversation is either unknown (one gender subset), the same, or opposite to the adjective referent of known gender. Systems with an opposite binary gender effect suffer on the same-gender subset such that the difference in accuracy $\Delta(\text{same, opp}) \ll 0$, and systems with a same-gender preference suffer on the opposite-gender subset such that the difference in accuracy $\Delta(\text{same, opp}) \gg 0$.

Further analysis is needed to understand how often neutral strategies are used in both the ambiguous and determined gender cases, and what factors influence a translation system's choice or ability to use a neutral strategy (Savoldi et al., 2024; Piergentili et al., 2023; Lauscher et al., 2023).

8 Conclusion

In conclusion, this test suite provides an opportunity to study the challenging task of referent resolution within literary-style dialogue settings. When spoken dialogue refers to characters described outside of dialogue in the meta-context, it adds an extra layer of complexity to the gender agreement task. Here we focus on language directions that are prone to gender agreement errors due to greater gender relevancy in the target language than the source language. We find that stereotypical character descriptions and manners of speaking are significant influences for some translation systems. Furthermore, some systems strongly prefer to resolve two-person conversations as same- or opposite-gender pairs. All observed effects are present in both ambiguous and determined gender cases.

Limitations

This test suite uses simple templates to study the influence of structural factors in a controlled manner. Although templates are varied and contain quite a few structure variables, they do not represent the diversity or complexity of real literary settings. Having identified the stereotype effects and challenge features within this test suite, future work could compile a real in-the-wild literary dialogue test suite by seeking out instances with these features of interest.

The primary limitation of this work is the focus on binary gender. All determined gender cases within the test suite are either male or female, and the analysis of chosen gender declensions is limited to masculine and feminine forms. This is partially due to the availability of known stereotypes for binary gender, and partially due to the binary nature of gender morphology in the target languages (even if neuter grammatical gender exists, it does not apply to animate nouns). Future work should investigate the use of neutral strategies when gender is unknown as a way to avoid misgendering non-binary referents.

Ethics Statement

As discussed in the Limitations section, the focus on binary gender throughout the paper is a serious ethical concern, and we stress here that similar research questions are applicable to non-binary genders. We hope that the analysis presented here and the test suite results might encourage the inclusion of non-binary natural gender in future work.

A Test Suite Templates

A.1 Stereo-Adverb Templates

Examples in the Stereo-Adverb test suite subset take the form:

$$\text{“I think I'm } A\text{,” I said } adverb. \tag{1}$$

where A ($n = 130$) denotes an adjective sampled from the full adjective set, and $adverb$ can be none, M-stereotyped ($n = 3$) or F-stereotyped ($n = 3$). In total, there are $N = 910$ source sentences in this subset $\big(N = 130 \times (1 + 3 + 3)\big)$.

A.2 Stereo-Character Templates

All examples in the Stereo-Character test suite subset contain two characters that are introduced using gender-stereotyped descriptions. For simplicity, all character descriptions are in the form:

$$C_g = a_g occ_g \tag{2}$$

where a_g is gender-stereotyped adjective, and occ_g is a matching gender-stereotyped occupation (e.g. "pretty nurse" or "strong doctor"). In each example, there is one female-stereotyped character ($n = 22$) and one male-stereotyped character ($n = 22$). We denote the character pairs as $(C_g, C_{\bar{g}})$.

Templates in this test suite subset come in both single-speaker and two-way conversation styles. In the single-speaker template, examples are of the form:

$$\begin{aligned} &\text{The } C_g \text{ smiled. “I think \{I'm, you're\} } A\text{,”} \\ &\text{\{he, she, they\} said to the } C_{\bar{g}}. \end{aligned} \tag{3}$$

where I'm+{he, she} combinations produce gender-determined referents, and you're+{he, she, they} and I'm+they combinations produce gender-ambiguous referents. There are 22 character pairs, 2 character orders, 2 referent pronoun variants, and 3 speaker pronoun variants, for a total of 264 base templates. Each base template is paired with 4 unique adjectives sampled from the full adjective set, for a total of $N = 1056 = 22 \times 2 \times 2 \times 3 \times 4$ source sentences (352 determined and 704 ambiguous).

In the two-way conversation template, examples are of the form:

$$\begin{aligned} &\text{The } C_g \text{ smiled. “I think I'm } A_1 \text{ and you're } A_2\text{,”} \\ &\text{they said.} \\ &\text{The } C_{\bar{g}} \text{ laughed back. “No, you're } A_3\text{, but I'm } A_4\text{,”} \\ &\text{they replied.} \end{aligned} \tag{4}$$

such that the gender of all adjective referents is ambiguous. To observe how the system handles repeated adjectives in the input that refer to different entities, 4 adjective equality variations are used:

$$\begin{aligned} &(A_1, A_2, A_3, A_4) \\ &(A_1, A_2, A_2, A_4) \\ &(A_1, A_2, A_3, A_1) \\ &(A_1, A_2, A_2, A_1). \end{aligned} \tag{5}$$

There are 22 character pairs, 2 character orders, and 4 adjective equality patterns, for a total of 176 base templates. For each base template, 5 unique adjective tuples (A_1, A_2, A_3, A_4) are sampled from the full adjective set, for a total of $N = 880 = 22 \times 2 \times 4 \times 5$ source sentences. Note that each source sentence provides 4 adjective agreement samples.

A.3 Structure Templates

The structure templates do not include any gender-stereotyped variables, and instead focus on structural variables in dialogue settings between two speakers. There are two template styles: one where all adjectives refer to the same entity, and one where both characters are referenced in equal measure. Both template styles have variations in the provided gender context: two speakers of known gender, such that each adjective's correct gender agreement is always determined, or one known gender and one unknown gender (first-person), such that the adjective's gender is either ambiguous or determined depending on the referent.

The first template style with complete gender context:

The {woman, man} smiled. "I think {I'm, you're} A_1," {she, he} said.
{He, She} laughed back. "No, [{you're, I'm} not A_1, but] {you are, I am} A_2," {he, she} replied.
(6)

where the text contained by [...] denotes an optional chaining effect on A_1. There are 4 gender combinations for the two characters $\big((M, M), (F, F), (F, M), (M, F)\big)$, 2 pronoun referent variations (I, you), and 2 chaining variants (present or not), for 16 base templates. For each base template, 60 unique adjective tuples (A_1, A_2) are sampled from the full adjective set, for a total of $N = 960 = 4 \times 2 \times 2 \times 2 \times 60$ source sentences.

The first template style with partial gender context:

{I, The wo/man} smiled. "I think {I'm, you're} A_1," {I, s/he} said.
{S/he, I} laughed back. "No, [{you're, I'm} not A_1, but] {you are, I am} A_2," {s/he, I} replied.
(7)

As above, there are 4 gender combinations $\big((M, ?), (F, ?), (?, M), (?, F)\big)$, 2 pronoun referent variations, 2 chaining variations, and 60 unique adjective tuples, for a total of $N = 960$ source sentences. The structure variables split this subset in half between ambiguous and determined cases. When the unknown gender (first-person speaker, I) appears first and the first pronoun referent is "I", or the known gender speaker appears first and the first person referent is "you", all adjectives are gender-ambiguous ($n = 480$ source sentences, $n = 1200$ adjective instances). Otherwise, all adjectives are gender-determined ($n = 480$ source sentences, $n = 1200$ adjective instances). Note that each source sentence contains 2-3 adjective instances, depending on whether the optional chaining effect is included.

The second template style with complete gender context:

The {man, woman} smiled. "I think I'm A_1 and you're A_2," {he, she} said.
{He, She} laughed back. "No, you're A_3, but I'm A_4," {he, she} replied.
(8)

where there are 4 possible gender combinations, 4 adjective equality patterns as described by equation (5), and 60 unique adjective tuples (A_1, A_2, A_3, A_4), for a total of $N = 960$ source sentences with 4 determined adjective instances each.

The second template style with partial gender context:

{I, The wo/man} smiled. "I think I'm A_1 and you're A_2," {I, s/he} said.
{S/He, I} laughed back. "No, you're A_3, but I'm A_4," {s/he, I} replied.
(9)

where again there are 4 possible gender combinations, 4 adjective equality patterns, and 60 unique adjective tuples, for a total of $N = 960$ source sentences. As with template (7), adjectives in this subset are split evenly between ambiguous and determined cases. However, unlike (7), both ambiguous and determined adjectives appear together (equally) in the same source passage. Note that all adjective positions are split evenly between determined and ambiguous cases, as determined by the variable position of the speakers.

Table 6: The proportion of adjectives with male (M) and female (F) agreement on the **Stereo-Adverb** test suite subset for all systems (English to **Spanish**). All adjectives self-refer to the speaker of unknown gender. In affected systems, the use of a male-stereotyped adverb to control the manner of speaking increases the use of male adjectives compared to female adjectives (see subscript M denoting the use of male-stereotyped adverbs), and vice versa (see subscript F denoting the use of female-stereotyped adverbs). The baseline, non-subscripted results refer to the proportions of male and female adjective use in the absence of any adverb. The overall strength of the adverb effect can be captured by the difference ΔM_{M-F}.

Table 9: Stereotypical manner of speaking (adverb) regression analysis for the most affected systems (**Spanish**), displayed as (coefficient value, p-value). The variable to predict is the binary adjective declension choice, where feminine adjectives are the positive class, such that negative coefficient values indicate a greater probability of M, and positive coefficient values indicate a greater probability of F. Strong negative intercepts indicate the default male baseline exhibited by many systems. Internal adjective traits are controlled by stereotype variables (e.g. Stereo(M) is expected to increase the probability of M), the sentiment (here negative as opposed to positive), and type (here appearance as opposed to character). For example, if the adjective is the appearance type, the results show that systems ONLINE-W and CommandR-plus are more likely to choose an F-adjective, controlling for all other variables. Here we see the adverb variables are strong in their expected directions, and significant.

Variable	**CUNI-MH**	**ONLINE-W**	**CommandR-plus**
Intercept	$(2.45, 1.2E-07^{***})$	$(-0.66, 1.1E-02^{*})$	$(-0.84, 1.3E-03^{**})$

Table 12: The proportion of adjectives with male (M) and female (F) agreement on the **Stereo-Character-Amb** test suite subset for unknown gender cases for all systems (English to **Spanish**). All adjectives refer to either the speaker or the listener which have been introduced as gender-stereotyped characters. The subscripts denote the gender stereotype label. In affected systems, adjectives that refer to a M-stereotyped character (subscript M) are more likely to be translated with a male declension, and vice versa for F-stereotyped characters. The overall strength of the character description effect can be captured by the difference ΔM_{M-F}.

Table 14: The proportion of adjectives with male (M) and female (F) agreement on the **Stereo-Character-Amb** test suite subset for unknown gender cases for all systems (English to **Icelandic**).

Variable	**Claude-3.5**	**CommandR-plus**	**Aya23**
Intercept	$(-6.83, 2.7E-11^{***})$	$(-3.89, 5.5E-34^{***})$	$(-0.99, 3.1E-07^{***})$
Adj Stereo(M)	$(0.87, 8.2E-02)$	$(0.29, 5.4E-01)$	$(-0.13, 7.9E-01)$
Adj Stereo(F)	$(0.85, 2.7E-06^{***})$	$(-0.29, 1.3E-01)$	$(0.15, 2.5E-01)$
Adj Sentiment(neg)	$(-0.56, 1.6E-04^{***})$	$(0.04, 7.4E-01)$	$(-0.86, 4.9E-16^{***})$
Adj Type(appearance)	$(0.01, 9.7E-01)$	$(0.67, 3.6E-04^{***})$	$(0.06, 7.0E-01)$
Character Stereo(F)	$(6.59, 5.0E-11^{***})$	$(3.56, 2.4E-43^{***})$	$(1.41, 9.5E-43^{***})$

Table 15: Stereotypical character description regression analysis for the most affected systems (**Spanish**). Internal adjective variables are defined as above (see Table 9). Here **Character Stereo(F)** denotes a binary variable equal to 1 when the character description is stereotypically female, and equal to 0 when the character description is stereotypically male. As shown, coefficient values for **Character Stereo(F)** are significant and in the expected direction (positive, indicating an increased likelihood of a F-adjective), and much stronger than the internal variables.

Variable	**CUNI-MH**	**Claude-3.5**	**ONLINE-W**

Table 18: The accuracy in gender-adjective agreement on the **Stereo-Character-Det** test suite subset for known gender cases for all systems (English to **Spanish**). The test subset is further partitioned into cases that align with a stereotype (PRO) and cases that oppose a stereotype (ANTI). Accuracy is consistently high on the PRO subset, and drops significantly in the challenge setting for some translation systems, indicating that stereotype effects persist in the presence of correct and unambiguous gender context.

Table 21: The proportion of adjectives with male (M) and female (F) agreement on the **Structure-Amb** test suite subset for all systems (English to **Spanish**). All adjectives refer to someone of an unknown gender in conversation with someone of a known gender (where that known gender is denoted by the subscripts). Systems that have an "opposite" binary gender bias effect resolve the ambiguous-gender speaker to be opposite to the known speaker (i.e., masculine adjectives increase when the other speaker is female, and vice versa, and the difference ΔM_{M-F} is strongly positive). Systems with a same-binary gender effect consistently choose adjective forms matching the gender of the other speaker (i.e., ΔM_{M-F} is strongly negative).

Table 24: The accuracy in gender-adjective agreement on the **Structure-Det** test suite subset for known gender cases for all systems (English to **Spanish**). The second speaker in the conversation is either unknown (one gender subset), the same, or opposite to the adjective referent. Systems with an opposite binary gender effect suffer on the same-gender subset such that the difference in accuracy Δ(same, opp) $\ll 0$, and systems with a same-gender preference suffer on the opposite-gender subset such that the difference in accuracy Δ(same, opp) $\gg 0$.

Table 27: Structural factors regression analysis for the systems with the greatest opposite binary gender tendency (**Spanish**). As above (refer to Table 9), the variable to predict in the adjective declension choice, where female is the positive class. Unlike the prior regression results, here we include determined-gender cases in order to assess the difficulty introduced by different structural factors. Therefore, the true gender of the referent must be controlled for (**True(M)** is 1 when the true label is M, 0 when the true label is F). In addition to the regular adjective traits, we include structural factors consistency(M/F): 1 if an earlier adjective refers to the same entity and is M/F, lookahead(M/F): 1 if an adjective's referent appears for the first time after the adjective and the known gender is M/F, and you(M/F): 1 if the adjective refers to "you" and the known gender is M/F. Lookahead and you variables must be paired with the true label because they affect the task difficulty regardless of gender. The results show that both lookahead and you strongly increase difficulty (as indicated by strong, significant, and positive coefficients when the correct label is M, and conversely strong, significant, and negative coefficients when the correct label is F). That is, the coefficients indicate an increased likelihood of choosing the incorrect gender agreement, while all else is controlled for. The variable of interest in these systems is the **Opposite(M)**: 1 when the other referent in conversation is known to be male. Systems with a strong opposite binary gender effect have strong positive coefficients, indicating an increased likelihood of a F-adjective.

The GenderQueer Test Suite

Steinunn Rut Friðriksdóttir
University of Iceland
srf2@hi.is

Abstract

This paper introduces the GenderQueer Test Suite, an evaluation set for assessing machine translation (MT) systems' capabilities in handling gender-diverse and queer-inclusive content, focusing on English to Icelandic translation. The suite evaluates MT systems on various aspects of gender-inclusive translation, including pronoun and adjective agreement, LGBTQIA+ terminology, and the impact of explicit gender specifications.

The 17 MT systems submitted to the WMT24 English-Icelandic track were evaluated. Key findings reveal significant performance differences between large language model-based systems (LLMs) and lightweight models in handling context for gender agreement. Challenges in translating the singular "they" were widespread, while most systems performed relatively well in translating LGBTQIA+ terminology. Accuracy in adjective gender agreement is quite low, with some models struggling particularly with the feminine form.

This evaluation set contributes to the ongoing discussion about inclusive language in MT and natural language processing. By providing a tool for assessing MT systems' handling of gender-diverse content, it aims to enhance the inclusivity of language technology. The methodology and evaluation scripts are made available for adaptation to other languages, promoting further research in this area.

1 Introduction

This paper introduces the GenderQueer Test Suite, a novel evaluation set designed to probe MT systems' capabilities in translating gender-diverse and queer-inclusive content. The test suite has been made publicly available and can be adapted to other languages. The test suite aims to address five key areas of evaluation:

1. Pronoun translation: Assessing translation accuracy when translating the third-person pronoun "they" from English to Icelandic with respect to gender agreement.
2. The singular "they": Assessing whether MT systems are able to translate the gender-neutral, singular "they" as it is used in English, i.e. when "they" is used to refer to a single person who is either non-binary, female, or male, to the more rigid grammatical gender system of Icelandic.
3. Adjective agreement: Evaluating the translation of adjectives with respect to gender forms in the target language. Translation accuracy for each gender form is examined individually as well as accuracy for translations of adjectives with positive, negative, and neutral sentiment.
4. LGBTQIA+ terminology: Examining the translation accuracy of LGBTQIA+-specific terms, including an assessment of whether translations are current and culturally appropriate or potentially outdated or inappropriate.
5. Influence of explicit gender information: Investigating whether explicitly defining a subject as cis or trans affects the translation accuracy of "they" compared to that of similar sentences without such specifications.

The test suite primarily consists of short paragraphs (3-4 sentences long) designed to provide context and challenge MT systems across these five dimensions. An additional 16 single-sentence examples are included for comparison between sentence-level and paragraph-level translations. Each passage contains explicit information about the gender of the subject or subjects mentioned. The purpose of the test suite is to highlight the current capabilities and limitations of MT systems in handling gender agreement in morphologically

Proceedings of the Ninth Conference on Machine Translation, pages 327–340
November 15-16, 2024 ©2024 Association for Computational Linguistics

rich languages such as Icelandic as well as to provide a tool for assessing MT systems' handling of non-binary pronouns and LGBTQIA+ terminology.

The following sections discuss the motivation behind the GenderQueer Test Suite and present the phenomena of interest in more detail. An analysis of the performance of the 17 MT systems submitted during the 9th Conference of Machine Translation (WMT24) for the English-Icelandic language direction follows. Finally, the implications of these findings are discussed.

2 Test Suite Details

The text examples in the test suite were manually compiled by the author, who holds a BA degree in Icelandic. The test suite contains 331 text examples in English, stored in a single text file which is to be translated by the MT systems. The test suite also contains a gold standard translation meant for comparison, in which each example has been translated as expected into Icelandic. Uncertainties when translating LGBTQAI+ terminology were handled in collaboration with members of the queer community in Iceland.

Each example begins by explicitly mentioning the gender of the subject or subjects in question. This is done in four ways:

1. These (cis/trans) men/women are my neighbors / This (cis/trans) man and this (cis/trans) woman are my neighbors.

2. This non-binary/genderqueer/genderfluid person is my neighbor.

3. I'm a woman/man. My friends are women/men/a man and a woman.

4. I'm a woman/man. My friends X, Y and C are women/men / My friend X is a woman/man but my friends Z and Y are men/women / My friends X and Y are women/men but my friend Z is a man/woman.

Genders are explicitly stated in a similar format in the single-sentence examples as well: *"These men/women who live next door to me are my neighbors and they..."* By explicitly stating the gender of the subject or subjects, problems that may arise from assumption of gender based on a person's name are avoided. After specifying gender, the text examples then examine the phenomenon or phenomena in question.

2.1 Gender: Translating "They"

Text examples 1 through 169 evaluate the translation of the third-person plural pronoun "they" in terms of gender agreement with the subjects, which in these examples are always plural. In the case of Icelandic, there are three grammatical genders that must be accounted for: the feminine (Icelandic: *þær*), the masculine (Icelandic: *þeir*), and the neuter (Icelandic: *þau*)[1]. There are 108 occurrences of the feminine "they", 102 occurrences of the masculine "they", and 150 occurrences of the neuter "they" (for further details, see table 1 in Appendix B). The greater amount of neuter examples owes to various combinations of gender specifications, further discussed in Section 2.5.

Text examples 1 through 72 each include two examples of the third-person pronoun "they" which, in English, is gender-neutral but, as previously stated, must agree with the gender of the subjects in Icelandic. The first example is always the same, i.e. *They live next door to me.* In order to probe for heteronormativity in the translations, each gender is then tested with the sentence *They have two children.* This is compared to the translation of sentences where the subjects have various types of pets (dogs, cats, parrots, and goldfish). The hypothesis is that, in the cases where the subjects are indicated to have children, the MT systems will opt for the neuter gender form, indicating a preference to parents of opposite genders rather than same-sex parents. An example follows:

> **English:** This trans woman and this cis man are my neighbors. They live next door to me. They have two children.
> **Icelandic:** Þessi trans kona og þessi cis maður eru nágrannar mínir. *Þau* búa við hliðina á mér. *Þau* eiga tvö börn.

Text examples 73 through 169 include two occurrences of the third-person pronoun "they" as before, but one contains an LGBTQAI+ term indicating the sexuality of the subjects. This is further discussed in Section 2.4. The other example continues to probe for heteronormativity by refering to the fact that the subjects have children. For example:

> **English:** These women are my neighbors. They are lesbians. They have two children.

[1] All Icelandic translations mentioned here are in the plural form.

Icelandic: Þessar konur eru nágrannar mínir. *Þær* eru lesbíur. *Þær* eiga tvö börn.

Text examples 266-319 further challenge the MT systems' ability to follow context. The subjects are introduced in the following way: *I'm a wo/man. My friends are (wo)men/a woman and a man.* Directly following is a sentence containing the pronoun *we*, which is not gendered in Icelandic, along with an adjective that must agree with the gender of the subjects (further discussed in Section 2.3). The second sentence contains the pronoun *they* along with a second adjective. This means that the MT system must realize the gender combination of the group as a whole but also make a distinction between the gender of the group and the portion of the group only containing the friends (and therefore the *they*-reference). For example:

English: I'm a woman. My friends are men. We are 25 years old. They are tall.
Icelandic: Ég er kona. Vinir mínir eru menn. Við erum 25 ára gömul. *Þeir* eru hávaxnir.

2.2 Gender: The Singular "They"

Text examples 170-211 are designed to be particularly difficult for an English-Icelandic MT system to translate correctly. They all contain a single subject, referenced by the singular "they", which is gender-neutral in English. In Icelandic, no such singular, gender-neutral pronoun exists in reality. The pronoun *hán* has existed in the language since approximately 2010[2] and has been widely adopted by non-binary people in Iceland although other variations exist. It is important to note, however, that unlike the English equivalent, which can refer to an individual of any gender, *hán* is almost never used for people that fall within binary gender norms but rather exclusively for non-binary individuals.

In any case, text examples 170-184 follow the same pattern as described in 2.1 except in these examples, the single subject is defined as a non-binary, genderqueer, or genderfluid person. In the evaluation, a system is awarded 1 point for translating the singular "they" as *hán*. As the plural neuter form is used by some non-binary individuals in Iceland to refer to themselves (in the singular) and to account for the much higher likelihood of the MT systems recognizing "they" as a plural form, a system is awarded 0.5 points for translating the singular "they" as *þau*. The same is expected from text examples 185-193 which contain adjectives, further discussed in Section 2.3. For example:

English: This non-binary person is my neighbor. They are short. They are an adult.
Icelandic (preferred): Þessi kynsegin manneskja er nágranni minn. *Hán* er lágvaxið. *Hán* er fullorðið.
Icelandic (acceptable): Þessi kynsegin manneskja er nágranni minn. *Þau* eru lágvaxin. *Þau* eru fullorðin.

On the other hand, text examples 194-211 define the single subject as either a man or a woman, which is then also indicated by the singular "they". This requires the MT system to not only recognize the indicated gender of the subject, but also to realize that "they" should not be translated in the plural, but rather as the singular masculine *hann* (English: *he*) or feminine *hún* (English: *she*), respectively. If a system successfully translates this, it is awarded 1 point per occurrence. As it is much more likely that these examples will be translated in the plural, systems are awarded 0.5 points for translating them as the masculine *þeir* or the feminine *þær*, respectively. For example:

English: This woman is my neighbor. They are short. They are an adult.
Icelandic (preferred): Þessi kona er nágranni minn. *Hún* er lágvaxin. *Hún* er fullorðin.
Icelandic (acceptable): Þessi kona er nágranni minn. *Þær* eru lágvaxnar. *Þær* eru fullorðnar.

2.3 Gender: Translating Adjectives

Text examples 185-319 each contain two adjectives and examples 320-331 contain three adjectives each[3]. While gender neutral in English, each adjective must agree with the gender of the subjects in Icelandic. The MT systems are thus evaluated

[2] Alda Villiljós mentions having coined the pronoun with their friends in this blog post from 2013.

[3] In this case, LGBTQAI+ terms are not considered adjectives though most of them certainly qualify as such. The adjectives in question are all generic and describe people's traits, i.a. *hungry*, *boring* or *funny*

based on their overall accuracy in translating these adjectives with respect to their gender forms.[4]

These examples vary in difficulty. The most difficult (besides those containing the singular "they", discussed in Section 2.2) can be found in text examples 320-331, which indicate the gender of four different, named subjects: *I'm a woman/man. My friends X, Y and C are women/men / My friend X is a woman/man but my friends Z and Y are men/women / My friends X and Y are women/men but my friend Z is a man/woman.* Directly following is a sentence containing the pronoun *we* along with an adjective that must agree with the gender of the group as a whole. The second sentence contains a reference to the subjects' names along with two adjectives whereby each adjective must agree with half of the group: *X and I are smart but Y and Z are dumb.* An example follows:

> **English:** I'm a woman. My friends Mary and Sophia are women but my friend John is a man. We are 25 years old. Mary and I are smart but John and Sophia are dumb.
> **Icelandic:** Ég er kona. Vinkonur mínar, Mary og Sophia eru konur en vinur minn John er maður. Við erum 25 ára *gömul*. Við Mary erum *gáfaðar* en John og Sophia eru *heimsk*.

Additionally, accuracy for each gender is examined individually as well as the accuracy for translations of adjectives with a positive, negative or neutral sentiment. The hypothesis here is that if a model only translates adjectives for a particular gender correctly if the adjectives convey a certain sentiment, a gender bias within the model is indicated. An example of this can be found in Sólmundsdóttir et al. (2022) where MT systems tended to translate adjectives with a negative connotation more frequently as feminine, while adjectives with a positive connotation were more likely to be translated as masculine, except when the adjective described a person's appearance, where the opposite was the case.

2.4 Queer: Translating LGBTQAI+ Terms

Text examples 33 through 193 each contain at least one LGBTQAI+ term. While most of these terms are adjectives and could (and should, perhaps) be evaluated based on gender agreement like the adjectives discussed in Section 2.3, these terms are only evaluated based on the quality of the translations themselves (in other words: whether or not the correct term is used in the translation, regardless of gender form). This is done to place more emphasis on the importance of the words themselves rather than grammatically perfect translations. Additionally, they represent a vocabulary that is highly connected to a person's sense of self and should therefore be examined individually in order to account for inclusive language in MT systems.

In total, there are 283 terms to be translated. The systems are evaluated in two ways. Firstly, each system receives an accuracy score based on whether or not the translation of the term exists in the accompanying terminology database. If it does, the system is awarded 1 point. There are three exceptions to this. If a system translates *trans woman* or *trans man* as a compound (for instance *transkona* instead of *trans kona*, with *trans* as a prefix rather than an adjective), it receives only 0.5 points along with a warning indicating that the use of the compound is considered inappropriate by many trans people in Iceland. The same goes for translations where *trans* and *cis* are translated as *transkynja* and *sískynja*, respectively. While these terms exist in the language, they are hardly ever used and should be avoided according to members of the queer community. Similarly, while unlikely to come up as translations at all, if a system translates the terms *lesbians* and *bisexual* as *lessur* and *bæjarar*, respectively, the system receives 0.5 points along with a warning indicating that these terms are only considered appropriate if used by the people they refer to and should be avoided as general terms.

Secondly, the MT systems receive a score based on the proportion of terms translated in an inappropriate manner as determined by the terminology database. These might include outdated translations that are no longer in use or crude terms that are considered slurs. The purpose is to separate the use of these terms from translations that are plainly wrong for the context. A model that uses the inappropriate terms should be considered more harmful to LGBTQAI+ individuals than a model that simply translates the terminology incorrectly. In other words, a high inappropriate score is a clear indicator of bias against LGBTQAI+ individuals in the respective model.

[4] It should be noted that the database used for determining the correct translations might not be exhaustive in terms of possible translations for these adjectives, so some translations might be misidentified as incorrect. There should, however, be very few such instances.

2.5 Queer: Specificity of Gender

The GenderQueer Test Suite allows for a comparison of translations of the third person plural pronoun "they" based on the specificity of the gender in question. In other words, it is possible to examine whether specifying a subject as either cis or trans leads to a poorer outcome than if the genders are not defined in this manner. Each gender combination is examined, i.e. *trans women*, *trans men*, *cis women*, *cis men*, *a trans woman and a trans man*, *a cis woman and a cis man*, *a trans woman and a cis man*, and *a cis woman and a trans man*. The process is otherwise the same as described in Section 2.1, including a comparison of text examples involving a reference to the subjects having children and examples where there is no mention of children.

3 Evaluation

Every aspect of the evaluation of the GenderQueer Test Suite has been automated and made available with an CC-BY license on Github[5]. The following sections will discuss notable results in the evaluation of the WMT24 English-Icelandic MT systems. Figures and tables referenced can be found in Appendices A and B, respectively.

3.1 Pronoun Translations and Explicit Gender Information

Figure 1 shows the overall translation accuracy of "they" translations (both plural and singular) and compares the text examples containing a single sentence to the text examples containing at least three sentences. This refers to whether or not the models respect the gender agreement with the subject or subjects. As the number of "they"-occurrences in the short examples (16 in total) is much lower than that of the longer ones (444 in total), these results should only be taken as indicative and not conclusive. However, it is clear that many models struggle much more with translating the longer examples, indicating that the problem of paragraph-level translations remains to be fully solved.

Figure 2 breaks down the accuracy of these translations per gender. Each gender is again broken down in terms of specific definitions, i.e. whether or not the subjects are explicitly defined as cis or trans. All models struggle with translating the singular "they", with no model achieving accuracy above 40.5% (GPT-4). This may not be surprising, as widespread use of the singular "they" in both languages is relatively new and so the training data for these models might not include a lot of examples of it in use. It is, however, important to take note of social development and include gender-inclusive language when developing such models.

The difference between the performance of LLM-based systems and lightweight systems in handling gender agreement at the paragraph-level is striking. While most of the LLMs receive a near-perfect score in this regard, the lightweight models rarely achieve more than 60% accuracy and all of them seem to almost entirely exclude feminine forms from their translations. It is somewhat expected that the masculine form dominates in these translations, as it has traditionally been used to refer to a group of mixed-gendered people or to refer to a person or persons of unknown genders[6]. This certainly seems to be the case for Aya23, where the masculine is predicted in 100% of the cases.

On the other hand, a preference for the neuter form might indicate a heteronormative bias in the models, particularly in text examples involving a reference to the subjects having children. Interestingly, when Figures 3 and 4 are compared, this preference is more pronounced in text examples where children are not mentioned. It should, however, be noted that the latter are fewer in total; the comparison should be considered as preliminary. However, it is clear that the limited use of the feminine form indicates some form of bias, either linguistic, societal, or a combination of the two.

In general, there does not seem to be much difference in accuracy between explicit gender definitions and those that do not specify the gender as either cis or trans. Rather, some of the models seem to struggle the most with a combination of more than one gender, i.e. the neuter form, where the subjects are defined individually (*This woman* ***and*** *this man...*). While this may seem to contradict the heteronormative hypothesis, Figure 3 shows that these models will in general translate the examples involving children a lot more accurately than the examples that contain no reference to children, further indicating that the hypothesis holds true to a significant extent.

[5] The GenderQueer Test Suite on Github.

[6] For further discussion on the generic masculine in Icelandic, see for instance Section 5 in Friðriksdóttir and Einarsson (2024).

3.2 Adjective Agreement

Figure 6 reveals that no model performs perfectly in the case of gender agreement between subjects and adjectives, with accuracy ranging from 88.89% (Claude-3.5) to 0.3% (TSU-HITs). As discussed in Section 2.3, some of the examples involving adjective translations are quite complex and the relatively poor performance of the models overall might simply be due to this. On the other hand, it is again noticeable how many models struggle the most with translations in the feminine form. It is interesting to note that in general, most of the correctly translated adjectives in the feminine form seem to have a positive sentiment and the same holds true for the correctly translated adjectives in the neuter form. For the masculine, however, most of the correctly translated adjectives have either a negative or a neutral connotation. This might indicate a gender bias.

3.3 LGBTQAI+ Terminology

Most models do relatively well on the translation of LGBTQAI+ terminology, as indicated by Figure 5, averaging at about 70% in overall accuracy and never exceeding 6.01% in terms of inappropriate translations. Not surprisingly, the models that have a decent overall translation score are also more likely to have more instances of inappropriate vocabulary. While the overall performance of the models is relatively good in this regard, researchers must make sure that their training data does not include excessive (or any) harmful slurs about minority groups to prevent inappropriate terms from becoming the default translations for this terminology.

4 Conclusion and Future Work

The GenderQueer Test Suite provides valuable insights into the capabilities and limitations of MT systems in handling gender-diverse and queer-inclusive translations from English to Icelandic. The evaluation of the 17 MT systems submitted to WMT24 revealed that LLM-based systems generally outperform lightweight models in terms of gender agreement in paragraph-level translations. All systems struggled with translating the singular "they", highlighting the importance of incorporating gender-inclusive language in the training data for such models. While LGBTQIA+ terminology was generally translated accurately, the higher performing models still sometimes use outdated or derogatory vocabulary which could potentially cause direct harm to minority groups if used as the default translations of these terms.

Future work should focus on expanding the test suite to cover more language pairs and incorporating more diverse gender identities and expressions. Collaboration with LGBTQIA+ communities will ensure that the test suite keeps up with evolving terminology and language use. Exploring the integration of the GenderQueer Test Suite into standard MT evaluation pipelines could promote consistent attention to gender-inclusive translation across the field. This can drive progress towards more inclusive and accurate MT systems that respect and represent the full spectrum of gender identities. The test suite has been made openly available and other researchers are encouraged to adapt it to their languages.

Limitations

While the GenderQueer Test Suite offers valuable insights into machine translation of gender-diverse content, several limitations should be acknowledged:

Language Specificity: The test suite is designed for English to Icelandic translation. The complex gender system of Icelandic presents unique challenges that may not generalize to languages with different grammatical structures or those lacking grammatical gender.

Scope of Gender Diversity: Despite efforts to include a range of gender identities, the test suite may not fully capture the entire spectrum of gender diversity, potentially oversimplifying some nuances. Additionally, limited number of text examples for certain tasks may skew the results.

Evolving Language: The rapidly changing nature of gender and sexuality means some terms in the test suite may become outdated, necessitating regular updates.

Evaluation Method: The evaluation of the translation of the third person plural pronoun "they" compares the number of correct translations with respect to gender forms to the total number of "they" occurrences in the English text examples. However, some models might drop one or more occurrences from their translations. An example of this can be seen in the AMI model's translation:

> **English**: This woman and this man are my neighbors. They are bisexual. They have two children.

> **Icelandic**: Þessi kona og maðurinn eru nágrannar mínir. Þau eru tvíkynhneigð og eiga tvö börn.

This is a perfectly valid translation despite dropping the second "they". Due to the evaluation method, this will still hurt the measured accuracy of the model.

Ethics Statement

Some of the inappropriate translations included in the database used to evaluate LGBTQAI+ vocabulary are disrespectful and harmful to minority groups. These terms are included as a means to evaluate the presence of bias in the MT systems and their use in any context is highly discouraged.

Acknowledgements

This work was supported by The Ludvig Storr Trust no. LSTORR2023-93030 and The Icelandic Language Technology Programme.

The author would like to extend gratitude towards Hafsteinn Einarsson, associate professor at the University of Iceland, Einar Freyr Sigurðsson and Steinþór Steingrímsson, research readers at The Árni Magnússon Institute of Icelandic Studies, for their valuable input in the development of this test suite. Members of the queer community in Iceland who lent a hand in the translation of LGBTQAI+ terminology were a vital part of this study and the author would like to thank them especially for their help.

A Graphs

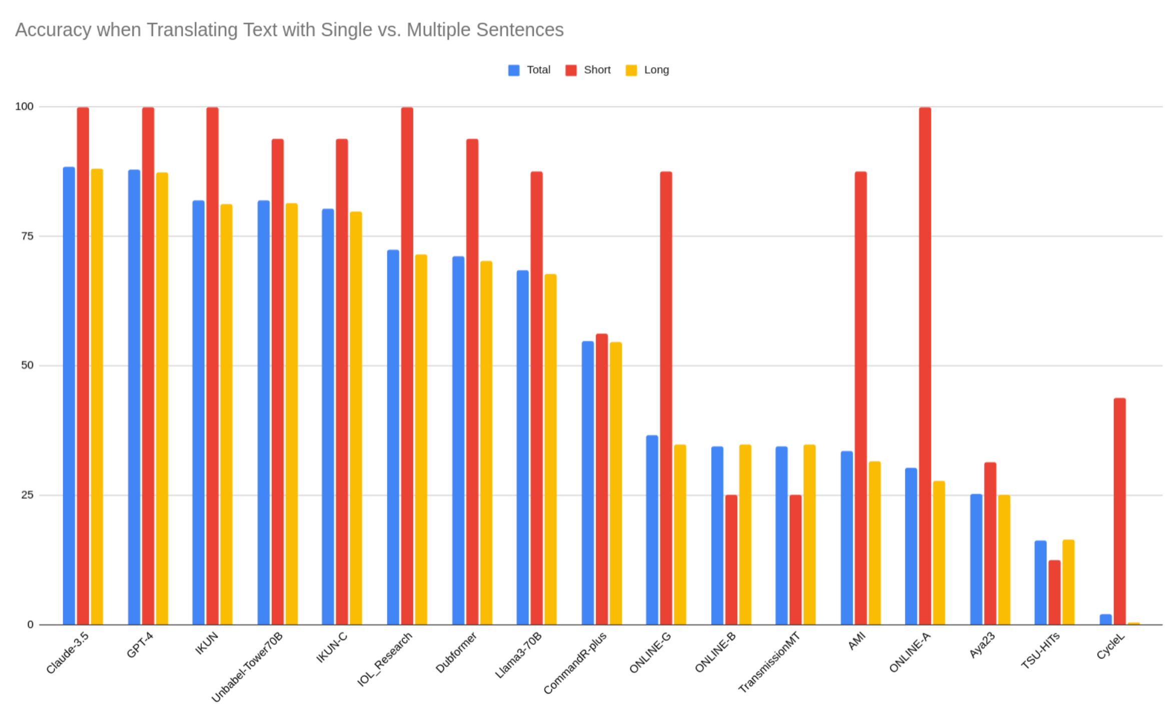

Figure 1: Translation accuracy for text examples containing a single sentence as opposed to text examples containing at least three sentences. This refers to the translation of the third person plural pronoun "they" with respect to gender forms, i.e. whether or not the models respect the gender agreement with the subject, explicitly presented in the first sentence of the longer examples and in the first phrase of the shorter examples. It also includes translations of the singular "they", which refers to a single person who is either non-binary, female, or male. It should be noted that the number of short examples is much lower than that of the longer examples and the comparison should therefore be taken as indicative and not conclusive. Still, we can see that the models struggle much more with following the context of the longer examples, indicating that paragraph-based translations are still at least somewhat problematic.

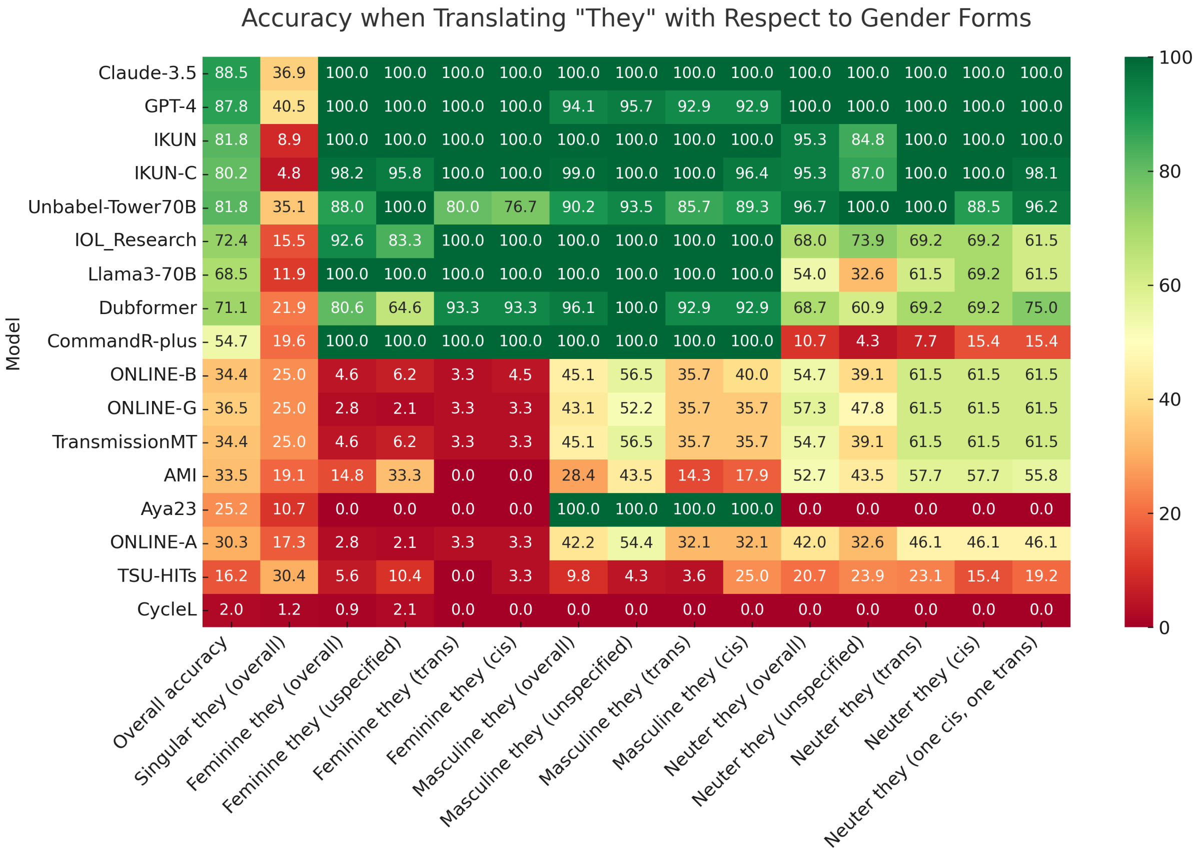

Figure 2: Translation accuracy of the third person plural pronoun "they" with respect to gender forms, i.e. how often the models respect the gender agreement with the subject, explicitly presented in the first sentence of the text examples. It also includes translations of the singular "they", which refers to a single person who is either non-binary, female, or male. Note that the results presented on this heatmap only apply to the longer examples, i.e. text examples that contain at least three sentences. The first column refers to the overall accuracy of the models. The heatmap then shows the translation accuracy for each gender. Each gender is broken down depending on whether or not the subject is explicitly defined as either cis or trans. We can see that every model struggles with translating the singular "they" and the lightweight models almost entirely exclude the feminine form from their translations.

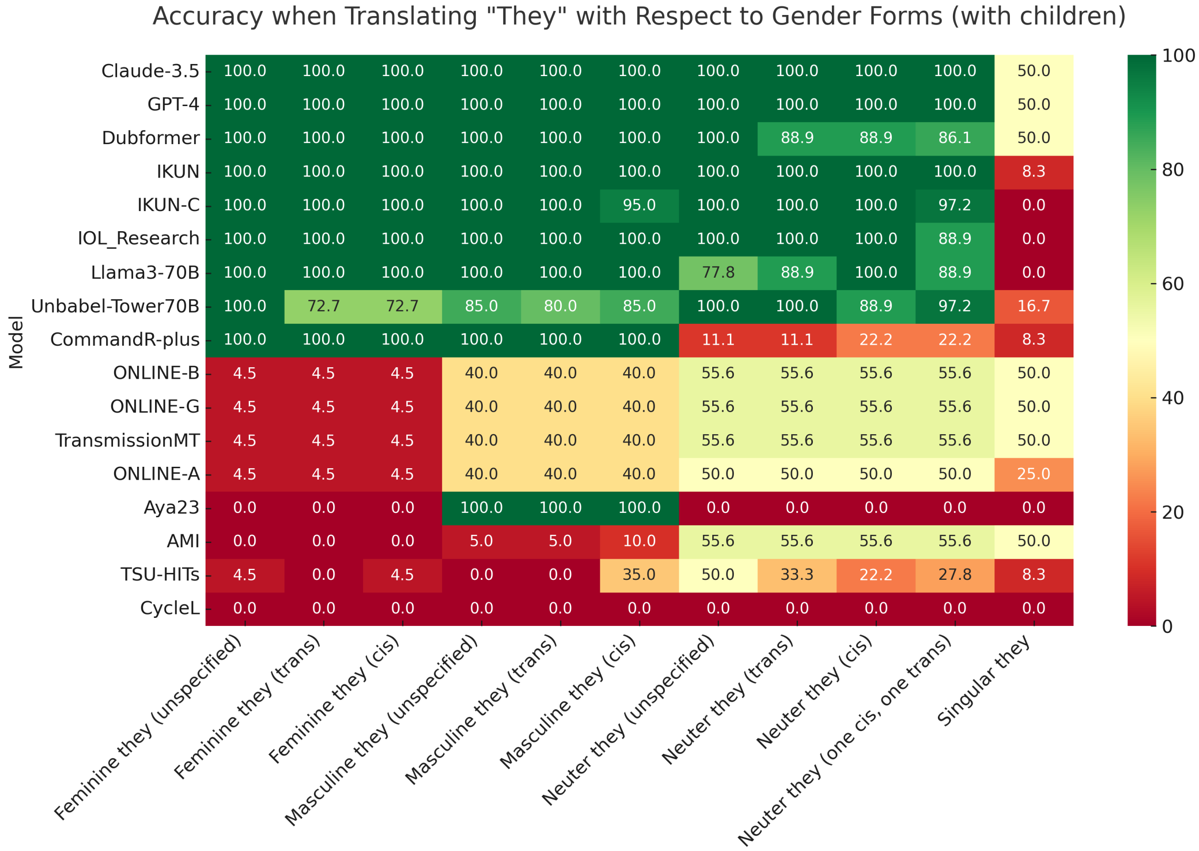

Model	Feminine they (unspecified)	Feminine they (trans)	Feminine they (cis)	Masculine they (unspecified)	Masculine they (trans)	Masculine they (cis)	Neuter they (unspecified)	Neuter they (trans)	Neuter they (cis)	Neuter they (one cis, one trans)	Singular they

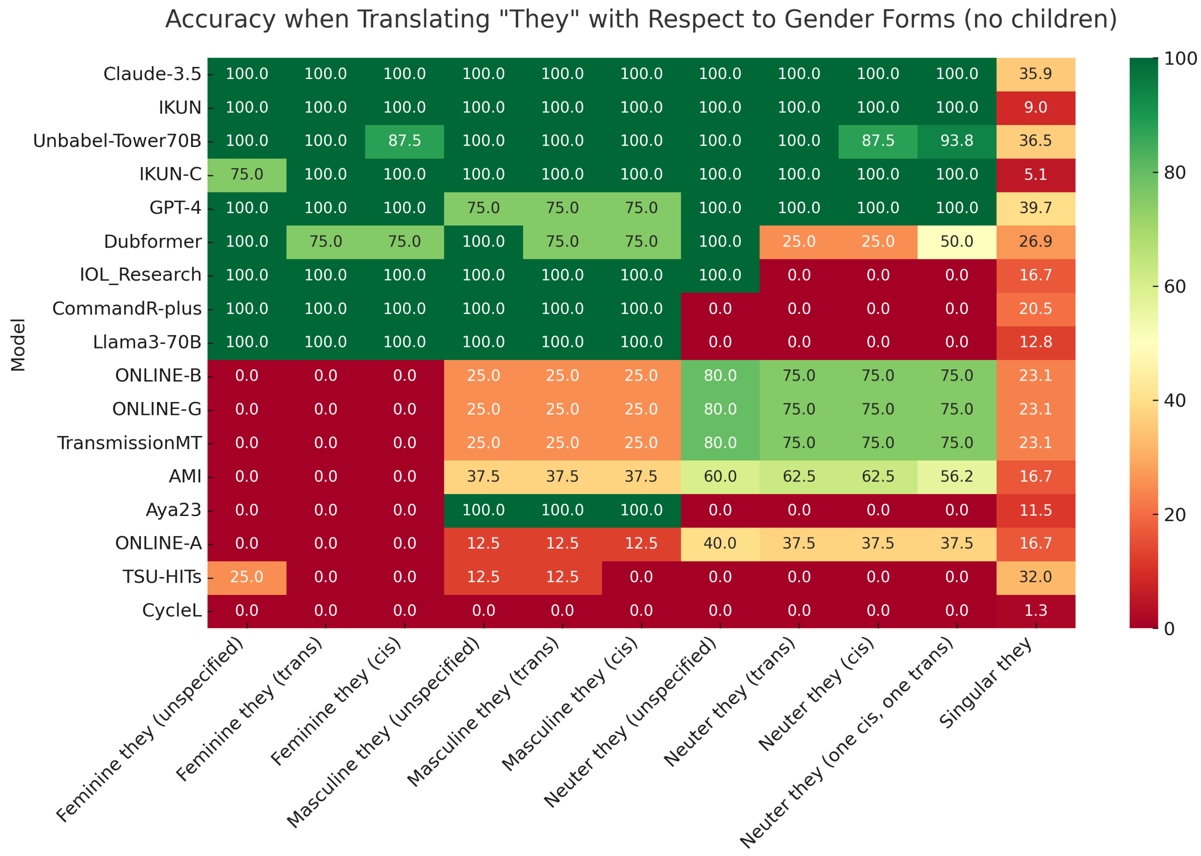
Figure 3: Translation accuracy of the third person plural pronoun "they" with respect to gender forms, i.e. how often the models respect the gender agreement with the subject, explicitly presented in the first sentence of the text examples. It also includes translations of the singular "they", which refers to a single person who is either non-binary, female, or male. Note that the results presented on this heatmap only apply to the longer examples, i.e. text examples that contain at least three sentences. All of the examples presented here contain a reference to the subjects having children (their last sentence being "They have two children"). We can see that all of the models struggle with the singular "they" but otherwise, the translation accuracy seems to depend almost entirely on the architecture of the model, with LLM-based systems outperforming the lightweight models. It is interesting to note that the lightweight models struggle the most with the feminine form, while the performance when translating the neuter and the masculine form is relatively even. The hypothesis was that the models would default to the neuter form, indicating heteronormativity. On the other hand, the masculine form is the one traditionally used as the general form, such as when the gender of the subject is unknown or the subjects are mixed-gendered. These results could therefore indicate a twofold bias, one linguistic in nature and the other societal.



Model	Feminine they (unspecified)	Feminine they (trans)	Feminine they (cis)	Masculine they (unspecified)	Masculine they (trans)	Masculine they (cis)	Neuter they (unspecified)	Neuter they (trans)	Neuter they (cis)	Neuter they (one cis, one trans)	Singular they

Figure 4: Translation accuracy of the third person plural pronoun "they" with respect to gender forms, i.e. how often the models respect the gender agreement with the subject, explicitly presented in the first sentence of the text examples. It also includes translations of the singular "they", which refers to a single person who is either non-binary, female, or male. Note that the results presented on this heatmap only apply to the longer examples, i.e. text examples that contain at least three sentences. Here, the text examples do not contain a reference of the subjects having children. We again see that all of the models struggle with translating the singular "they" and that the accuracy of the LLM-based models is much higher than that of the lightweight models. The latter perform best on the neuter form with the feminine form almost not appearing at all. On the other hand, half of the better-performing models struggle with the neuter form, some of which do not predict it at all. While this is interesting and could potentially indicate a bias, it should be noted that these examples are fewer than those containing references to the subjects having children and so the comparison should be taken as indicative rather than conclusive.

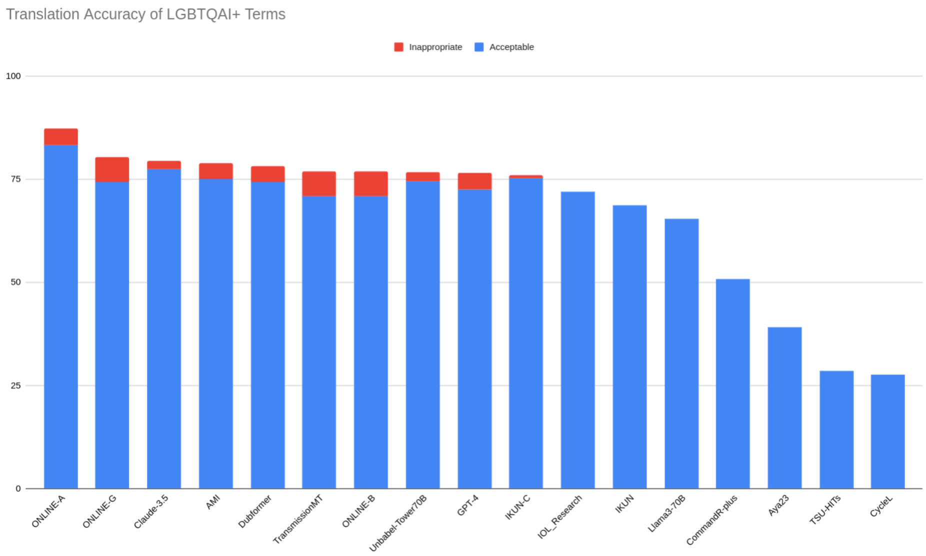

Figure 5: Translation accuracy for LGBTQAI+ terminology. The models are tested for appropriate and inappropriate translations. The latter refers to terms that are either outdated, prejudiced, or otherwise not advisable but not entirely wrong in the sense that they are accurate but harmful translations of the English terms. The higher the red bar, the more harm the model might cause to minority groups.

Figure 6: Translation accuracy for adjectives with respect to gender forms. The first column refers to the overall accuracy of each model, i.e. the proportion of adjectives that were translated correctly in the sense that they respect the gender agreement with the subject, explicitly presented in the first sentence of the text example. The heatmap breaks down the translation accuracy for each gender and for each gender, the accuracy for each sentiment is observed. Again, most of the systems struggle the most with the feminine form. On the other hand, most of the correctly translated adjectives in the feminine form have a positive sentiment, while correctly translated adjectives in the masculine form more often have either a neutral or a negative sentiment. This could potentially indicate a gender bias.

B Tables

	Total	Long ($\geq$ 3 sentences)	Short (single sentence)
Text examples	331	315	16
"They"	460	444	16
LBGTQAI+ terms	283	283	0
Adjectives	306	306	0

Table 1: The overall occurrences of each phenomena in the GenderQueer Test Suite as indicated by the gold standard translation.

	Total	Positive	Negative	Neutral	English	Icelandic (singular/plural)
Feminine	71	24	25	22	young	ung/ungar
Masculine	71	24	25	22	young	ungur/ungir
Neuter	164	54	52	58	young	ungt/ung

Table 2: The occurrences of adjectives in the GenderQueer Test Suite as indicated by the gold standard translation. The overall occurrences of each gender form are presented along with a breakdown of the sentiments attached to the adjectives. The translation examples show the declensions with respect to the number and gender of the subject(s).

	Total	Unsp. (C)	Unsp. (NC)	Trans (C)	Trans (NC)	Cis (C)	Cis (NC)	Cis and trans (C)	Cis and trans (NC)	English	Icelandic
Feminine	108	22	8	22	8	22	8	0	0	she/they	hún/þær
Masculine	102	20	8	20	8	20	8	0	0	he/they	hann/þeir
Neuter	150	18	10	18	8	18	8	36	16	it*/they	það*/**þau**
Singular they	84	6	78	0	0	0	0	0	0	they/they	**hán**/þau

Table 3: The occurrences of the third person plural pronoun "they" in the GenderQueer Test Suite as indicated by the gold standard translation. Also included are the occurrences of the singular "they", referring to a single person which can be non-binary, female, or male. The overall occurrences of each gender are presented along with a breakdown referring to whether or not the gender definitions are explicit, i.e. if "cis" or "trans" is specified. "C" refers to examples that include a reference to the subjects having children, i.e. where the last sentence of the text example is "they have two children". "NC" refers to examples where there is no reference to the subjects having children. Examples where one person is defined to be cis and the other as trans were limited to that of the neuter gender form, where one person is a woman and the other a man. The translation examples show the declensions with respect to the number and gender of the subject(s). It should be noted that, while the traditional translation of the third person singular in the neuter form, *það* is never used to refer to a person. Rather, *hán* is used in this case. Both the traditional neuter (referring to a mixed-gendered group of people) and the plural form of the singular "they" is *þau*.

Domain Dynamics: Evaluating Large Language Models in English-Hindi Translation

Abstract

Large Language Models (LLMs) have demonstrated impressive capabilities in machine translation, leveraging extensive pre-training on vast amounts of data. However, this generalist training often overlooks domain-specific nuances, leading to potential difficulties when translating specialized texts. In this study, we present a multi-domain test suite, collated from previously published datasets, designed to challenge and evaluate the translation abilities of LLMs. The test suite encompasses diverse domains such as judicial, education, literature (specifically religious texts), and noisy user-generated content from online product reviews and forums like Reddit. Each domain consists of approximately 250-300 sentences, carefully curated and randomized in the final compilation. This English-to-Hindi dataset aims to evaluate and expose the limitations of LLM-based translation systems, offering valuable insights into areas requiring further research and development. We have submitted the dataset to WMT24 *Break the LLM* subtask. In this paper, we present our findings. We have made the code and the dataset publicly available at https://github.com/sohamb37/wmt24-test-suite.

1 Introduction

Machine translation (MT) (Bahdanau et al., 2016) has witnessed significant advancements with the advent of Large Language Models (LLMs) (et al., 2024a,b), which leverage extensive pretraining on massive datasets to achieve high performance across various language pairs (Alves et al., 2024; Zhu et al., 2024; Zhang et al., 2023). Despite their remarkable generalization capabilities, LLMs often struggle with domain-specific texts due to a lack of targeted training on such specialized content (Robinson et al., 2023; Jiao et al., 2023; Hendy et al., 2023). Some LLMs (Workshop et al., 2023) generate good translation involving low-resource language when the target language is English but not the other way around (Bawden and Yvon, 2023). These challenges are amplified when the domains involved are different from those of training data. This limitation poses a challenge for deploying MT systems in real-world applications where domain-specific accuracy is crucial.

To address this gap, we participated in the "Help us break LLMs" subtask at the Workshop on Machine Translation (WMT) 2024 (Kocmi et al., 2024). The primary objective of this subtask is to create a dataset that exposes the difficulties faced by LLM-based MT systems when dealing with domain-specific content. Our approach involves collating a multi-domain dataset that includes sentences from judicial, educational, religious literature, and noisy user-generated content from online product reviews and forums like Reddit.

Each domain-specific subset comprises approximately 250-300 sentences, which are then randomized to form the final dataset. This dataset, focusing on the English-to-Hindi translation direction, aims to rigorously test the robustness and adaptability of LLM-based MT systems. By identifying the translation challenges specific to each domain, our study provides valuable insights for improving domain adaptation techniques in machine translation, ultimately contributing to more reliable and accurate MT solutions for specialized applications. Our contributions to the paper are as follows:

- We participate in the Break the LLM challenge in WMT24 for English-Hindi language direction, where we submit diverse data consisting of six domains.
- We calculate the standard BLEU score as well as the state-of-the-art metric xCOMET-XXL to evaluate the translation quality.
- We perform a tiny scale manual evaluation of the translation outputs.

2 Related Works

Neural Machine Translation has achieved significant advancements (Vaswani et al., 2017). However, translation of text involving low-resource languages remains a challenge. In low-resource languages, the translations of Indic languages like Hindi is difficult due to the paucity of the high-quality parallel corpus. Existing multilingual models like IndicTrans (Ramesh et al., 2022) and IndicTrans2 (Gala et al., 2023) achieved significant performance gains compared to other models. However, English-Hindi machine translations still have room for improvement.

Moslem et al. (2022) has previously used pre-trained Language Models(LM) for domain specific data augmentation for Machine Translation. They simulated the characteristics of a small bilingual dataset or monolingual source text and combined it with back translation to create huge amounts of synthetic in-domain data. Other works involving low-resource languages include translation of chat-based conversation by (Gain et al., 2022) where English Hindi translation was implemented on Chat and question answers in chatbots. In the domain of education, (Behnke et al., 2018) used crowd-sourcing English texts to obtain translation into 11 languages for generating NMT data. Similarly, Ramakrishna et al. (2023) introduced the EduMT dataset for improving the English-Hindi translation for educational content.

In a recent study, (Briva-Iglesias et al., 2024) showed that LLMs outperform Google translate when it comes to the Legal domain. (Martínez-Domínguez et al., 2020) implemented machine translation in the legal domain for Italian to Swiss language. For low-resource language, (Poudel et al., 2024) introduced a custom-built dataset for the legal domain for English Nepali language machine translation.

In the Literary domain, (Drobot, 2023) has studied the prospects of neural machine translation. Earlier (Matusov, 2019) has used NMT for translating German literary works to English, and (Kuzman et al., 2019) implemented NMT for the literary domain from English to Slovene. (Yirmibeşoğlu et al., 2023) has implemented NMT in the literary domain for the low-resource language of English-Turkish. (Thai et al., 2022) has also explored document-level literary machine translation for non-English languages. They have also shown that there is a disparity between the automatic evaluation of these machine translations and human evaluation, prompting further improvement of machine translation in this domain.

Noisy or non-standard input text can cause disastrous mistranslations in most modern Machine Translation (MT) systems.Khayrallah and Koehn (2018) has shown in a study the impact of noise on NMT systems. Michel and Neubig (2018) proposed a benchmark dataset for machine translation of noisy texts(MTNT). Herold et al. (2022) has worked on filtering noise from machine translation data for improving the performance of NMT systems.Bolding et al. (2023) has used LLMs to remove noise from the MTNT dataset target sentences and proposed C-MTNT dataset. Machine Translation of noisy text is mainly explored through multimodal translation in English-Hindi (Gain et al., 2021b; Laskar et al., 2021; Gain et al., 2021a; Gupta et al., 2021c; Gain et al., 2023) where images features were used to aid in machine translation from English to Hindi.

Product review is a translation task that is related to the field of e-commerce. (Gupta et al., 2022) explores NMT with sentiment preservation in this domain for the low-resource language of the English-Hindi pair. (Gupta et al., 2021b) and (Gupta et al., 2021a) are some of the other works on online product review translation.

Some other notable works on low-resource languages include (Goyle et al., 2023), (Chowdhury et al., 2022) and (Ranathunga et al., 2023) that have implemented unique NMT techniques to complement the scarcity of data in these languages.

3 Dataset

Our proposed dataset includes English-Hindi bitext pairs from six critical domains, chosen for their significance to both the machine translation community and their difficulty of translation. We provide a sample from each domain in Appendix D and some statistics about the datasets in Table 4. It can be noted that the size of each domain is different. We had collected 500 sentences from each domain in the beginning but after filtering out sentences less than 5 words, we arrived at the final size of the dataset.

3.1 Education domain

The education domain plays a crucial role in knowledge dissemination. Enhancing machine translation in education promotes equal access to qual-

ity learning, supports multilingual environments, and empowers non-native speakers to engage with content. This helps reduce educational disparities and fosters cultural exchange. For this study, 330 English-Hindi language pairs were collected from the EduMT dataset, which focuses on educational content in Indian languages (Appicharla et al., 2021).

3.2 General domain

The general domain in our dataset is sourced from the IIT Bombay English-Hindi Parallel Corpus (Kunchukuttan et al., 2018), which includes a diverse range of parallel and monolingual Hindi texts compiled by the Center for Indian Language Technology. It features content from various sources such as news articles, TED Talks, government websites, and Wikipedia. For our study, we randomly selected 500 English-Hindi language pairs from this domain. Improving machine translation in the general domain enhances the accuracy of translations across diverse content, making information more accessible for Hindi-speaking audiences.

3.3 Judicial domain

The judicial domain in our dataset is sourced from the IIT Patna Hindi-English Machine Aided Translation (HEMAT) training corpora, which is specifically designed for legal and judicial content. For this domain, we have included 325 sentences in our proposed dataset. Enhancing machine translation performance in the judicial domain is crucial, as it ensures that legal documents, court rulings, and other judicial materials are accurately translated. This can have a significant impact by improving access to legal information, supporting multilingual legal proceedings, and ensuring that individuals who speak Hindi can fully understand and engage with the judicial system.

3.4 Religious Literature domain

The religious literature domain in our dataset consists of 300 pairs: 150 Quran verses from the Tanzil Project [1] and 150 Bible verses from the Bible Eudin Project, both sourced from the OPUS collection (Tiedemann, 2012). These texts pose unique challenges due to their religious significance and archaic language.

3.5 Noisy domain

The noisy user-generated data domain in our dataset is sourced from the benchmark dataset for Machine Translation of Noisy Text (MTNT) (Michel and Neubig, 2018). This domain includes 350 English sentences from MTNT, consisting of informal and often error-prone comments made by users on Reddit. Our annotators translated these sentences into Hindi retaining the tone and nature of the input sentences. However, they got rid of some noise based on their own discretion. This domain captures the informality of online communication. Improving machine translation in this domain will help models better handle slangs, typos, and non-standard language use, in turn making

Table 2: Performance of different models across literature, noisy, and review domains

them more robust.

3.6 Online User Review domain

The final domain in our dataset consists of user product reviews from the e-commerce site Flipkart (Gupta et al., 2021b). We included 300 English-Hindi text pairs from this corpus. This domain presents challenges like grammatical errors and code-mixing, where users blend English and Hindi within a sentence. Similar to MTNT, overcoming the challenges in this domain will make the MT systems more robust.

4 Evaluation

In this section, we outline the various evaluation techniques employed to assess the performance of the models based on their outputs. The evaluation metrics considered in this study are the BLEU (Papineni et al., 2002; Post, 2018) score, COMET (Rei et al., 2020; Guerreiro et al., 2023) score, and human evaluation score. We have shared the candidate translations from 3 models, Online-B, Nvidia-Nemo, and INKUN-C in Appendix D. Online B is one of the consistently best performing models across all the domains and metrics among all the submissions. Whereas, Nvidia-Nemo and IKUN-C translations are of lower quality. This table gives us a comparison of the quality of translations by these models.

Model	BLEU	COMET	HUMAN
Aya23	23.53	0.69	3.00
Claude3.5	31.63	0.83	3.61
CommandR-plus	23.28	0.76	3.44

ZMT	36.20	0.71	3.06

Table 3: Performance of models on the full dataset

4.1 BLEU Scores

The BLEU score measures the quality of machine translations by comparing the output to reference translations based on n-gram similarity. A higher n-gram match leads to a higher score, with a brevity penalty to discourage overly short translations. The score ranges from 0 to 100, with higher values indicating better alignment with the references. We calculate the BLEU score with sacrebleu (Post, 2018) and report corpus_score for the dataset.

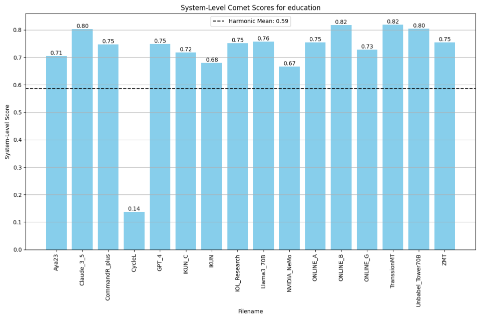

Figure 1: COMET scores in the Education Domain

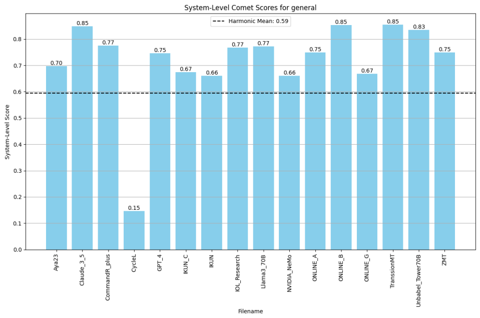

Figure 2: COMET scores in the General Domain

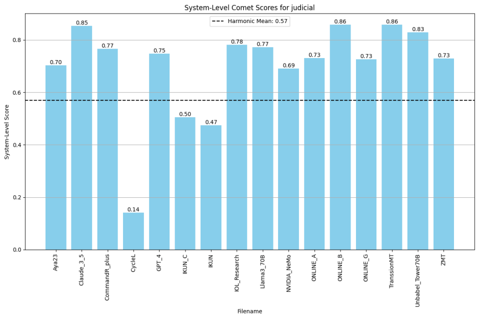

Figure 3: COMET scores in the Judicial Domain

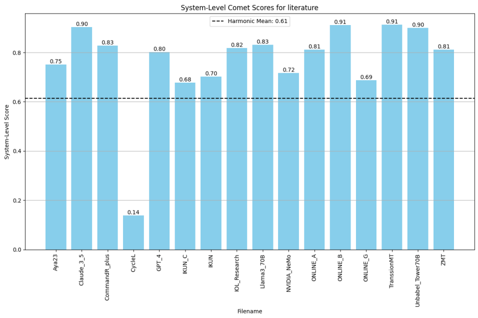

Figure 4: COMET scores in the Literature Domain

4.1.1 Domain wise Overview

The average BLEU scores in the general, judicial, and literature domains are significantly lower, with scores of 15.97, 19.14, and 12.89, respectively. In the literature domain, the frequent use of ornamental language often leads to subjective translations Table 5, causing notable differences between the machine translations and the reference texts. The general domain, encompassing diverse subdomains and characterized by longer sentence lengths and larger data size Figure 17, also contributes to lower BLEU scores, as models struggle with both factors. Similarly, the judicial domain presents challenges due to its specialized terminology and formal tone, which are difficult for models to translate accurately. Additionally, in all three domains, transliteration instead of translation in many cases further impacts the models' performance.

For the education domain, the sentences are relatively straightforward and easier to translate. Interestingly, the models also achieved relatively high BLEU scores for the user-generated data domains, including noisy texts and product review texts.

4.1.2 Model wise Overview

Here we can see the average performance of the models based on all the domains. Models Online-A and ZMT have the best performance, closely followed by Online-B and TransmissionMT, while CycleL has the worst BLEU scores across all the different domains. Note that BLEU is calculated based on N-gram overlaps. Therefore, transliterations of some tokens, even if they are relevant, are not considered. This results in lower BLEU scores in certain models, even if translation quality is acceptable.

4.2 COMET Scores

The COMET score evaluates machine translations using pre-trained language models, focusing on both adequacy (preserving meaning) and fluency (naturalness). It compares machine translations to references and human translations through a regression model trained on human judgments, capturing language nuances that other metrics may miss. The score reflects how closely the machine translation aligns with human preferences. We use xCOMET-XXL to calculate the scores.

4.2.1 Domain wise Overview

The COMET scores of judicial, general, and education domains are the highest. It is easier to retain the adequacy and fluency for these domains compared to the other domains. They have a formal tone to them, and the COMET score does not

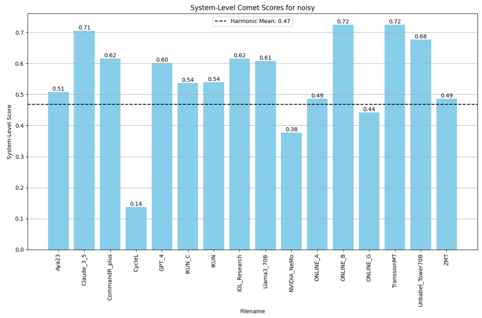

Figure 5: COMET scores in the Noisy Domain

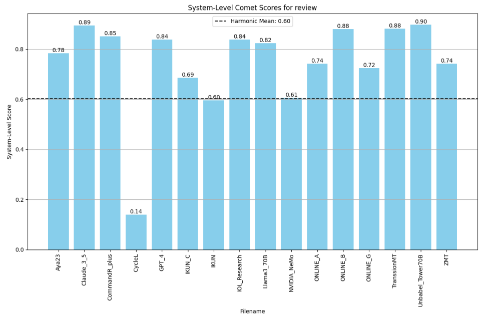

Figure 6: COMET scores in the Product Review Domain

penalize the MT models much for paraphrasing sentences since it is a more robust metric.

Likewise, the worst COMET scores are obtained for the domains of user-generated data for noisy and product review texts. These texts are more informal in nature and ridden with both spelling and grammatical errors. There could be multiple possible reasons: a) LLMs struggle to translate the noisy texts, resulting in poor quality hypotheses and lower COMET score. b) COMET metric is calculated through embeddings. Here, the source side is noisy, which can lead to unreliable embeddings and, therefore, an unreliable COMET score.

4.2.2 Model wise Overview

The best-performing models in terms of COMET scores are Online-B and TransmissionMT, closely followed by Claude-3.5 and Unbabel-Tower-70B. However, the worst-performing model is still CycleL.

4.3 Human Evaluation

The next evaluation method employed is human evaluation. We enlisted the expertise of a linguist in our lab, who randomly selected 3 sentences from each of the 6 domains. For each sentence, the corresponding machine translations from the 16 submitted model outputs were collected, resulting in 288 sentences. These sentences were then rated on a scale from 1 to 5, where 1 indicates the poorest translation, and 5 represents the best possible translation compared to the reference texts. Note that due to such a low number of samples, the results in manual evaluation are very unreliable. However, due to resource constraints, we could not perform a large-scale manual evaluation. Nonetheless, we hope this rating will provide some ideas about the competence of the models when observed along with scores from automated metrics.

4.3.1 Domain wise Overview

According to the human evaluation, the general domain showed the highest faithfulness to the reference translations. This outcome is expected, as general domain texts are typically easier to translate due to their formal and unambiguous nature, with fewer grammatical, lexical, and spelling errors. Conversely, the noisy domain demonstrated the lowest faithfulness to the reference translations. This is largely attributed to the informal nature of these texts, which often include profanities and internet acronyms like "lol" and "idk" as well as a higher prevalence of errors.

4.3.2 Model wise Overview

Almost consistent with the COMET metrics, we can see that the TransmissionMT, Unbabel-Tower-70B, and Claude-3.5 have the best human-evaluated scores, whereas CycleL again scored the least favorably.

5 Conclusion

This paper presents a comparison of various model submissions for the WMT Shared Task 2024. We proposed a dataset with domain-wise segregation and conducted a domain-specific analysis of the submitted models. Our comprehensive evaluation using BLEU, COMET, and human assessments of the machine-translated hypotheses identified Claude 3.5, TransmissionMT, Unbabel Tower 70B, Online-A, and Online-B as some of the top-performing models for machine translation using LLMs. The analysis revealed that the formal domains of general and education are the easiest for models to handle, whereas the noisy and review domains proved to be the most challenging. This study highlights that while LLMs show proficiency in machine translation, there is still significant room for improvement.

A Overall Scores

We report the overall BLEU and COMET scores in Figure 13 and Figure 14. Further, we provide the domain-wise and model-wise average rating by human annotators in Figure 15 and Figure 16.

B Participants

The WMT24 General Translation Task showcased diverse approaches to machine translation. Several teams explored the potential of Large Language Models (LLMs) for translation tasks. IKUN demonstrated the effectiveness of LLMs in multilingual translation, achieving top rankings in multiple language directions (Liao et al., 2024). The IOL Research team leveraged LLMs for continued pretraining and synthetic data generation (Zhang, 2024).

Some teams focused on improving existing neural machine translation (NMT) architectures. HW-TSC combined NMT and LLM-based models using Minimum Bayesian Risk (MBR) decoding (Wu et al., 2024). UvA-MT compared fine-tuned LLMs with traditional encoder-decoder NMT systems (Tan et al., 2024). The DLUT and GTCOM team emphasized back-translation and multilingual models (Zong et al., 2024).

Novel approaches were also presented. CycleGN introduced a cycle-consistent approach for non-parallel datasets (DREANO et al., 2024). Hyper-SNMT proposed embedding sentences in hyperbolic space to better capture language hierarchies (Zhou et al., 2024).

Several teams explored domain-specific adaptations. Team-J incorporated document-level LLM reranking for improved context-aware translations (Kudo et al., 2024). NTTSU focused on speech domain translation for Japanese to Chinese (Kondo et al., 2024).

The Yandex team demonstrated significant improvements using human evaluation data for LLM fine-tuning (Elshin et al., 2024). CUNI explored various techniques including QLoRA, CPO, and model merging (Hrabal et al., 2024).

Multimodal approaches were also explored, with researchers integrating visual information to enhance translation for low-resource languages (Hatami et al., 2024).

These diverse approaches highlight the ongoing innovation in machine translation, with a notable trend towards leveraging LLMs and exploring novel architectures to improve translation quality across various language pairs and domains.

C Dataset Statistics

Here, we have shared the summary statistics of the lengths of different sentences in each domain. Further we have also shared the harmonic mean of ratio of source to reference text sentence in each domain. From this graph it is evident that general domain has the most disparity in terms of source and reference sentence length. Also, it has the longest sentences compared to the other domains.

D Dataset Example

In Table Table 5, we present examples from the religious domain. This table showcases various outputs relevant to religious texts, highlighting key themes and interpretations.

Table **??** provides examples from the judicial domain. The *Online-B* model has the best quality of translation. The output from the model *Nvidia_Nemo* and *IKUN_C* is inadequate. The original text conveys a universal message about divine provision and the consequences of human actions, while the translation introduces specificity, making it feel more direct and personal.

Abstract

This paper summarizes the results of our test suite evaluation on 39 machine translation systems submitted at the Shared Task of the Ninth Conference of Machine Translation (WMT24). It offers a fine-grained linguistic evaluation of machine translation outputs for English–German and English–Russian, resulting from a significant manual linguistic effort. Based on our results, LLMs are inferior to NMT in English–German, both in overall scores and when translating specific linguistic phenomena, such as punctuation, complex future verb tenses, and stripping. LLMs show quite a competitive performance in English-Russian, although top-performing systems might struggle with some cases of named entities and terminology, function words, mediopassive voice, and semantic roles. Additionally, some LLMs generate very verbose or empty outputs, posing challenges to the evaluation process.

1 Introduction

The evolution of large language models (LLMs) has revived interest in machine translation (MT) evaluation, raising the discussion about whether general-purpose LLMs can outperform specialized MT systems. LLMs have demonstrated remarkable performance across various tasks, prompting an urgent need to assess their linguistic capabilities and potential risks (Wang et al., 2024; Guerreiro et al., 2023). Last year's Eighth Conference on Machine Translation findings (WMT23; Kocmi et al., 2023) showed that one LLM performed well across most language pairs. Although GPT-4 excelled in some areas (e.g., translation of user-generated content), it struggled with other aspects, such as speaker gender translation and specific domains (e.g., legal); it ranked lower than encoder-decoder systems when translating from English into less-represented languages, e.g., Czech and Russian.. However, last year's General MT Task included only two LLM-based system submissions (Kocmi et al., 2023). This year marks a noteworthy increase in LLMs participating in the task. As a result, this paper covers a linguistically motivated evaluation of a broad range of LLMs, including Claude-3.5-Sonnet, GPT-4, Llama3-70B, Mistral-Large, and the recently released Unbabel-Tower70B, as well as CUNI-DS, IKUN and IKUN-C, IOL-Research, CommandR-plus, Yandex, and Occiglot.

In this context, we are presenting the results of our participation in the test suite sub-task of the Ninth Conference on Machine Translation (WMT24). Our test suite[1] consists of carefully crafted sentences that assess the ability of MT systems to handle specific linguistic phenomena. It was applied to the MT systems submitted for evaluation in two language directions: English–German and English–Russian.

2 Related Work

Several researchers have adopted test suites or challenge sets to better identify flaws in MT outputs, further contributing to the advancement in MT evaluation. The WMT test suite sub-task has played a significant role by providing a platform for these evaluations.

Chen et al. (2023), for example, developed a systematic method of selecting difficult sentences from the Wiki Corpus, taking into account factors like word difficulty, sentence length, grammatical complexity, and model learnability. Their findings showed significant differences from the official ranking, suggesting that systems performing well on average test sets might not do as well on more challenging ones. Notably, GPT-4 ranked among the top two for Chinese–English translations and between fourth and ninth in the other direction. Other research has focused on difficulties posed by special domains and writing styles. Mukherjee and Shrivastava (2023) designed a test suite for

[1] https://github.com/DFKI-NLP/mt-testsuite

Proceedings of the Ninth Conference on Machine Translation, pages 355–371
November 15-16, 2024 ©2024 Association for Computational Linguistics

English–German translation across five domains and writing styles. They found that while GPT-4 performed competitively overall, it struggled in the legal domain and with the judgment writing style. The work of Savoldi et al. (2023) looked into gender translation of the English–German and German–English language directions. They found that while systems generally handled gender form translation well, producing gender-inclusive translations still remains a significant challenge. Specifically, GPT-4 exhibited relatively lower accuracy in accurately translating feminine gender in first-person singular references reflecting the speaker's linguistic expression of gender.

Bawden and Sagot (2023) tested the ability of MT systems, including GPT-4, to handle user-generated text from in-domain sources characterized by informal language and various grammatical deviations. Their findings show that although data at such a large scale can provide extensive training data, GPT-4 still does not perform well on consistency and faithfulness to source sentences, implying a hurdle for generalization to out-of-domain text.

The fact that these works indicated weaknesses not apparent on the General MT Shared Task illustrates the critical importance of developing focused test suites beyond general evaluation metrics to measure the capabilities and limitations of MT systems.

3 Method

3.1 Test suite description

We have developed a fine-grained test suite to evaluate the performance of MT systems for the language pairs English–German and English–Russian[2]. While we are only touching on the description of our test suite in the paper, the interested reader can find a detailed description in Macketanz et al. (2022a). Previous submissions of the test suite in WMT can be found in (Macketanz et al., 2018, 2021, 2022b; Avramidis et al., 2019, 2020; Manakhimova et al., 2023).

Our test suite focuses on various linguistic phenomena that are of interest to the respective language pairs. The phenomena are based on extensive research in linguistics, contrastive grammars, and translation studies, covering a wide range of potential translation challenges. The phenomena and their categorization are specific to a language pair and a language direction; however, there is a big overlap of the phenomena between the language pairs for the languages covered so far.

Language Pair	Test Items	Categories	Phenomena
en–de	4,846	13	110
en–ru	1,234	12	51

Table 1: Metadata of the language pairs in the test suite.

The phenomena in the test suite are classified into several categories, grouped by the underlying syntactical/morphological/lexical mechanisms. Each phenomenon is represented by at least 20 (in many cases more) test items. Every test item consists of one or more sentence(s) in the source language and a set of rules to evaluate them. The test items are either handwritten by linguistic experts or taken from existing corpora. The number of test items, phenomena, and categories per language pair can be seen in Table 1. While the English–German test suite has been around and growing since 2017, the English–Russian test suite is newer (from 2022) and, therefore, has fewer test items.

With the change of MT system types over the years (from phrase-based and statistical MT to neural MT, and finally to LLMs), typical MT challenges and errors have also changed. Thus, we have also adapted our test suite over the past few years to accommodate those changes. These adaptations included adding new phenomena, longer/more complex test sentences, and more test items per phenomenon.

MT outputs evaluated by the test suite have been used to produce challenge sets for WMT metrics (Avramidis and Macketanz, 2022; Avramidis et al., 2023).

3.2 Application of the test suite

The test suite can be characterized as semi-automatic, as the evaluation process is based on automatic rules and additional manual evaluation. While this kind of evaluation can be more time-consuming than a fully automatic evaluation process, we assume it to be more accurate as the regular expressions are handwritten by human experts.

For each test item in the test suite, one or more linguist(s) have written regular expressions to cover as many as possible expected correct and incorrect translations. The linguists rely on their years of

[2] Our test suite additionally covers the language pairs German–English and Portuguese–English, but these pairs were not part of the WMT General MT Shared Task.

experience in evaluating MT systems when writing regular expressions. However, of course, not all MT outputs can be covered by the regular expressions as languages, and the MT systems are very diverse. In these cases, the human comes into play again. All outputs that cannot be automatically evaluated by the regular expressions are inspected and hand-evaluated by a linguist.The more unexpected (meaning, in most cases, incorrect) outputs a system creates, the more manual work is involved in the evaluation process. After the evaluation process, the translation accuracy of an MT system specific per phenomenon or category is calculated by dividing the number of correctly translated test items by the total number of test items.

To ensure a fair comparison, only evaluated test items are considered for accuracy calculations. If a test item is not evaluated for one system, it is excluded for all systems, reducing the number of the effective test items.

For the system comparison (per language direction), we first identify the highest-scoring system and then compare it to the other systems. The significance of the comparison is confirmed by a one-tailed Z-test with $\alpha = 0.95$. Systems that do not perform significantly inferior to the best-performing system are grouped into the first performance cluster. The best-performing systems are indicated in boldface in the respective rows of the tables.

To account for variations in the number of test items within each category or phenomenon, average scores are computed in three different methods: The *micro-average* method combines the contributions of all test items to calculate the average percentages. In the *category macro-average*, the percentages are first computed independently per category and subsequently averaged, treating all categories equally. Analogously, for the *phenomenon macro-average* the percentages are computed independently per phenomenon and averaged afterwards, treating all phenomena equally.

4 Experiment Setup

This year, we evaluated a total of 39 systems with our test suite. The systems had been submitted to the General MT Shared Tasl of the Ninth Conference on Machine Translation. 21 systems were evaluated for English–German and 18 systems for English–Russian[3].

It is the fourth time we evaluated the English-German systems and the third time for the English-Russian systems. As described above, the evaluation of the system outputs is only semi-automatic, and therefore, manual work is needed to complement the automatic evaluation by resolving cases in which none of the rules in our rule database can be applied, the so-called *warnings*. Upon receiving the system outputs, there were on average around 25 % of warnings for English–German, varying across systems from 4.7 % to 77.5 %. For English–Russian, there were on average 46.9 %, ranging from 24.5 % to 82.7 %. As we had added several new phenomena and test items to existing phenomena before this year's WMT, we expected more warnings this year. Additionally, several systems this year, particularly LLMs, were more verbose or "creative" with their translations than we are used to from previous years. For example, Mistral sometimes offered several translation options, including explanations. This creativity, however, led to more manual work as the existing evaluation rules could not cover these unexpected outputs.

This year, the manual evaluation was conducted by three linguists who were experts in one or both language pairs. Combined, the linguists spent around 160 person-hours on the manual evaluation within about three weeks. After the manual input, an average of 0.9 % of warnings remained for English–German and 5.7 % for English–Russian.

As mentioned above, test items with one unresolved warning for at least one system were excluded from the comparison. This reduced the number of effective test items to 4219 (∼87 %) test items for English–German, and 994 (∼80 %) for English–Russian.

5 Results

All result tables can be found in the Appendix.

5.1 System comparison

For **English–German**, Online-B, TranssionMT, and Claude-3.5 had the highest micro-average with a score of around 97 %. Furthermore, Online-B and TranssionMT also had the highest macro-average, with a scrore of around 95 %. Whereas little is

[3] There had originally been 25 systems submitted for En-De, and 22 for En-Ru. However, the systems Dubformer and CycleL/CycleL2 had to be excluded from our evaluation for both language pairs due to invalid output

known about Online-B, TransionMT's good performance may be explained by its optimization for complex grammatical structures and rich morphology through the use of a hyperbolic embedding. The lowest micro-average was reached by TSU-HITs (Mynka and Mikhaylovskiy, 2024) with a score of 38.6 %, and the lowest macro-average was reached by MSLC (Larkin et al., 2024) with a score of 45.8 %. On average, systems reached a micro-average of 81.4 % and a macro-average of 79.7 %.

At this point, it is important to note that two systems, Mistral (Jiang et al., 2023) and Occiglot (Avramidis et al., 2024), produced a (high) number of empty outputs for German–English. While Occiglot only generated 335 empty sentences, Mistral generated as many as 3,624. For the system comparison, we had to mark these sentences as incorrect. Therefore, Mistral appears to have the worst accuracy on micro- and macro-average. However, we conducted an extra analysis for these two systems, only considering the correct and incorrect outputs and ignoring the empty outputs. This resulted in an accuracy of 73.0 % for Occiglot and 85.9 % for Mistral macro-averaged over the non-empty outputs (see Tables in Section A). Since the accuracies are calculated over different test items, they are not comparable with each other and with other systems.

Interestingly, and contrary to previous years, our ranking of the systems according to their linguistically-related performance differs from the preliminary results of the automatic ranking of the General MT Shared Task (Kocmi et al., 2024): While the top 3 systems in the General task were Unbabel-Tower70B (Rei et al., 2024), Dubformer, and TransionMT, according to our analysis, Online-B and TransionMT made it to the first significance cluster, with GPT-4 falling in the second position and Unbabel-Tower70B scoring even lower. Furthermore, we had to exclude Dubformer from our analysis due to invalid output. Nonetheless, both analyses have MSLC and TSU-HITs at the bottom of the ranking.

When comparing the human rankings of the General MT Task with our rankings, one can note that in the former, many systems share the cluster of the first position. The fact that our test suite can produce a smaller significance cluster for the first position can be considered a success.

While Unbabel-Tower70B showed exceptional performance across all language directions in the automatic preliminary rankings, our evaluation revealed some potential blind spots. Compared to the top-performing systems, it struggles with less commonly used future tenses (ditransitive—future II progressive, ditransitive—future II simple, reflexive—future II progressive), with the elliptic process of *stripping*, and with *semantic roles*. Future II progressive tense can pose difficulties, likely due to its infrequent occurrence in training data and nuanced nature. An example sentence would be "I will have been baking Tim a cake." Stripping will be explained in further detail below, cf. Sec 5.3 As for semantic roles, English is relatively flexible in assigning semantic roles to subjects. In contrast, German tends to have stricter rules for subject roles regarding agentivity. This difference can cause translation issues when models directly map English constructions onto German without considering these syntactic and semantic differences.

For **English–Russian**, Yandex (Elshin et al., 2024) and Claude-3.5-Sonnet achieved the highest micro-average scores with 91.8 % and 90.4 %, respectively as well as macro-averages with 92.4 % and 90.5 %. This year's poorest-performing system was TSU-HITs, with both micro- and macro-averages of 50 and 49 %. On average, the systems reached a micro-average of 80.1 % and a macro-average of 78.7 %. According to the automatic preliminary results, the top four best-performing systems for English–Russian are Unbabel-Tower70B, Dubformer, Yandex, and Claude-3.5-Sonnet, in that order. As mentioned earlier, Dubformer was excluded from our analysis. Unbabel-Tower70B scores slightly lower than Yandex and Claude-3.5-Sonnet, achieving 89.4 % micro-average and a 90 % macro-average. On the phenomenon level, our evaluation shows that Yandex and Claude-3.5-Sonnet outperform Unbabel-Tower70B, when it comes to *collocations*, *onomatopeia*, *verb valency*, and *passive voice*. If we exclude Cycle and CycleL (Dreano et al., 2024), the worst four performing systems, according to the automatic preliminary ranking, are the same four systems in our ranking, listed here from best to worst: IKUN-C (Liao et al., 2024), CUNI-DS (Semin and Bojar, 2024), NVIDIA-NeMo, and TSU-HITs. GPT-4, one of the best-performing systems last year, falls into the second cluster this year.

Stripping	
John can play the guitar, and Mary too.	
John kann Gitarre spielen und Mary auch.	pass
John kann Gitarre spielen, und Mary auch.	fail
John kann das instrument spielen, und Lucia noch nicht.	fail
Verb Semantics	
"I've missed you so much!" he bawled.	
"Ich habe dich so sehr vermisst!" schluchzte er.	pass
"Ich habe dich so vermisst!" schrie er.	pass
»Ich habe dich so sehr verpasst!«, bawte er.	fail

Table 2: Examples of English–German linguistic phenomena with passing and failing MT outputs.

5.2 Category-level analysis

For **English–German**, two systems are in the cluster of best-performing systems per category in all categories: Online-B and TranssionMT. Furthermore, two systems have the highest accuracies on all but two/three categories, namely GPT-4 and Claude-3.5-Sonnet. The categories with the highest accuracies are *negation*, with 14 systems reaching 100 % accuracy, and *subordination*.

Some of the easiest categories for **English–Russian** include *subordination* (89.7 %), *function words* (89.1 %), where both LLM-based and other MT system score over 95 %. In contrast, *ambiguity* stood out as the most challenging, with an accuracy average of 69.2 % along such categories as *false friends* and *multi-word expressions*, with average accuracies of 70.7 % and 69.5 %, respectively. These indicate more challenges on the lexical rather than the syntactical level.

5.3 Phenomenon-level analysis

For **English–German**, the phenomenon-level macro average is 80 %, which is similar to the category-level macro average and the general micro-average. The phenomena with the highest accuracies (> 90 %) are *negative inversion*, *prepositional MWE*, *date*, *substitution*, *adverbial clause*, *infinitive clause*, and *intransitive future I progressive/simple*; for a detailed overview cf. Table 10.

On the other hand, the phenomena with the lowest accuracies (< 65 %) that a lot of LLM-based model struggled with are *stripping*, *idiom*, *onomatopoeia*, *ditransitive future II progressive/simple*, *reflexive future II progressive/simple*, *transitive future II progressive*, and *semantic roles*. It seems that the future II progressive/simple tense is particularly difficult for systems to translate, no matter the verb type. As mentioned above, this is likely due to this verb tense's uncommonness.

Compound	
The police officer was pregnant.	
Сотрудница полиции была беременна.	pass
Полицейский был беременна.	fail
У полицейской была беременность.	fail
Verb Semantics	
She described the book as a page-turner.	
Она описала книгу как -захватывающую историю.	pass
она описала книгу как страницу-поворотчик.	fail
Она описала книгу как перелистывание страниц.	fail

Table 3: Examples of English–Russian linguistic phenomena with passing and failing MT outputs.

Table 2 contains translation examples from English–German. The first example is a test item for the phenomenon *stripping*. *Stripping* is a type of ellipsis. While stripping exists in both German and English, one aspect that can lead to translation errors is punctuation. In English, there is a comma between the two constituents ("John can play the guitar" and "and Mary too"). In German, however, placing a comma in between the constituents is incorrect; see the first and second translation examples. The third translation contains more errors than the additional comma, as it completely changes the meaning of the second constituent. This translation was produced by the Cycle system and also showcases how these kinds of "creative" translations lead to more manual evaluation work: It is easy to write a regular expression for the incorrect output with the comma before the second constituent, and this regular expression will cover most of the outputs of the incorrect system as this is a very common error. However, it is impossible to predict such an incorrect output as it was produced by Cycle, and therefore, it is impossible to write a regular expression to cover cases like this.

The second example is from the phenomenon of *verb semantics*. This phenomenon refers to semantic components in the verb's semantic structure that do not have formal markers. Some examples of these kinds of verbs are *to stride*, *to rumble*, *to stagger*, or *to bawl*, like in the example at hand. There are usually several correct translations for these verbs, as seen in the Table. However, they might lead to translation errors, with systems sometimes not translating them (because they are not so common) or translating them with an incorrect semantic meaning.

When evaluating the performance across phenomena for **English–Russian**, it was found that the following phenomena posed minimal challenges, with many systems achieving near-perfect accuracy: *catenative verb*, *case government*, *conditional*, *contact clause*, *object clauses*, *personal pronoun coreference*, *prepositional mwe*, and *date*. Notably, *personal pronoun coreference*, a new phenomenon added last year that focuses on the consistency in translating the formal and informal "you" across sentences, as well as ensuring that a past tense "I" retains the correct gender ending. This category attained a remarkable accuracy of 96.8 %, marking a 13 % improvement compared to last year. The phenomena with the lowest accuracies (< 60 %) are *verbal MWE*, *resultative*, *gapping*, *compounds*, *idioms* and *semantic roles*.

Table 3 contains translation examples from English–Russian. The original sentences and their translations have been shortened for the paper. The first example involves the common English compound "police officer". Despite the simplicity of this sentence, a closer examination reveals various issues in the translations. In English, the nominal phrase in question is gender-neutral, with no gender marking on nouns, adjectives, or verbs. However, in contrast to English, Russian has gender marking not only on pronouns but also on other parts of speech, including nouns, adjectives, verbs, determiners, and numbers. The first translation correctly uses the collocation сотрудница полиции (literally, "female police employee") and appropriately pairs it with была беременна ("was pregnant"), both in the feminine form. This nominal phrase construction is necessary to convey the gender within the translation. In the second translation, the word полицейский, typically referring to a male police officer is then followed by the verb был (the masculine form of was), and later by the adjective pregnant in the feminine form. This translation error was produced by an LLM and highlights a gap in the model's understanding of gender agreement rules in Russian and a lack of real-world knowledge. The third translation renders the phrase as "the female police officer had pregnancy," which is not a linguistically acceptable Russian collocation. It also uses the adjective полицейская as a job title, which is not a standard noun for "police officer" in Russian.

The next example comes from the phenomenon of Noun formation with the suffix -er. This process is a part of derivational morphology, where new words are formed by adding affixes to existing words or changing their grammatical category or meaning. This is a highly fruitful suffix in English. In the first example translation, we see it rendered as захватывающую историю or "captivating story." This transformation effectively captures the essence of "page-turner." The second translation has страницу-поворотчик – a literal translation. Перелистывание страниц in the third translation describes the physical action of turning pages. The first translation is accurate as it captures the idiomatic meaning of "page-turner"; the other two translations fail due to overly literal interpretations, a common issue in encoder-decoder models and LLMs.

5.4 Comparison with previous years

We have analyzed some of the best-performing systems' development over the years for systems submitted to the WMT repeatedly in the past years. For **English–German**, we took a closer look at GPT-4, Online-B, Online-W, and Online-A, see Table 8. GPT-4 has seen barely any changes in the accuracy from 2023 to 2024 (although it needs to be noted that the prompting method has changed from 5-shot to 3-shot). Online-B, however, shows an improvement of 2.5 percentage points on the macro-average from 2021 to 2024, while the micro-average stayed almost the same throughout this period. Online-W, similarly to GPT-4, shows almost no changes from 2021 to 2024. And finally, Online-A has slight improvements of 1 and 3 percentage points from 2021 to 2024 on the micro-average and macro-average level, respectively.

While in the past years, Online-B and Online-W were usually in the cluster of best-performing systems together, this year, Online-B has surpassed Online-W as only the former is in the best-performing cluster as of this year, while the latter is not. Furthermore, in 2023, GPT-4, Online-W, and Online-B were together in the cluster of best performing systems, while this year, GPT-4 is also not in that cluster anymore.

As for the scored of the micro-average, the phenomenon macro-average, and the category macro-average, while the first two have almost not changed from 2023 to 2024, the category macro-average has improved about 2.5 percentage points from last year to this year. This suggests that the systems for English—German have undergone a slight improvement compared to last year.

Table 9 compares the performance of Yandex, GPT-4, and Online-G for **English–Russian** from 2022 to 2024. This year's Yandex submission is a trained YandexGPT, an LLM-based model. Their approach includes extensive pre-training, fine-tuning, p-tuning, and structure-preserving techniques, which help ensure contextually accurate translations (Elshin et al., 2024). Over the last two years, Yandex's submission has likely undergone a significant update, as reflected in the 2.59 % accuracy increase. Overall, Yandex shows consistent performance with some improvement. GPT-4, another LLM, demonstrates a generally strong performance compared to last year, with a significant drop in the punctuation category (from 100 % to 60 %). Despite this, GPT-4 has either improved or maintained stable performance across most linguistic categories. Online-G, as we suspect based on encoder-decoder methods, exhibits stable performance without any substantial improvements in any areas.

5.5 LLMs vs. encoder-decoder NMT

NMT systems based on an encoder-decoder (or commercial systems that we assume they use this technology) still exhibit better linguistic performance than LLMs in English–German, whereas in English–Russian the first position is shared indeed by two LLMs. In English-German, LLMs seem to perform worse than the two best-performing NMT systems, regarding *punctuation, future verb tenses* and *stripping*. For English-Russian, Yandex is weaker in *named entities and terminology*, while Claude struggles with *function words*, and Unbabel with *verb valency* that includes error-prone phenomena for all LLMs, such as *semantic roles*, *verb semantics*, *resultative*, and *mediopassive voice*. GPT-4 scores even lower than several commercial NMT-based systems. This suggests that while LLMs are indeed taking over the MT in fine-grained analysis, some still struggle to match the capabilities of specialized NMT systems, which are tailored specifically to the target language and potentially trained on more language-specific data.

6 Conclusions and Outlook

In this paper, we apply a linguistically motivated test suite for the first time to evaluate the translation performance of several LLMs as well as several systems with different architectures. Based on the macro-averaged accuracies, the best systems for English-German are Online-B and TranssionMT, with Claude-3.5-Sonnet also sharing the first position based on micro-averaging. For English–Russian, the best-performing systems are Yandex and Claude-3.5-Sonnet. While LLMs generally perform strongly in MT, systems based on encoder-decoder methods, such as TranssionMT and most probably Online-B may still have an edge in certain areas. What the human evaluations of the main MT task reveal about the systems is still to be determined, pending the official announcement of the rankings. The results underscore the potential of LLMs in MT but also highlight areas for improvement.

Limitations

The current test suite was initially designed to evaluate earlier MT systems, featuring a wide range of linguistic phenomena without challenging the models. However, it is becoming increasingly clear that we need to adapt and potentially eliminate the phenomena that have proven too easy for the systems in recent years. The significance of the averaging is unclear, and adding weights depending on the importance of various phenomena is something to consider. While we have introduced context in some cases and complexity with multi-sentence test items in others, this has not been done for all phenomena and sentences so far. One challenge is that we often encounter correct rendering of the phenomena, but then encounter grave errors in the sentence structure. Internally, it has been concluded that these sentences should be marked as incorrect, as the errors are often too significant for the whole output to be considered correct. Additionally, this year, some models generated responses that resembled those of a classical chatbot, including additional explanations or commentary that mixed correct and incorrect translations, making it challenging to evaluate. Going forward, we plan to further refine the test suite to better capture the nuances of modern translation systems.

Acknowledgements

This research was supported by the German Research Foundation (Deutsche Forschungsgemeinschaft; DFG) through the project TextQ. We would like to thank Polina Danilovskaia for her help this year, Hans Uszkoreit, Aljoscha Burchardt, Ursula Strohriegel, Renlong Ai, and He Wang for their

prior contributions to the creation of the test suite.

Abstract

Machine translation (MT) has come a long way and is readily employed in production systems to serve millions of users daily. With the recent advances in generative AI, a new form of translation is becoming possible - video dubbing. This work motivates the importance of isochronic translation, especially in the context of automatic dubbing, and introduces 'IsoChronoMeter' (ICM). ICM is a simple yet effective metric to measure isochrony of translations in a scalable and resource-efficient way without the need for gold data, based on state-of-the-art text-to-speech (TTS) duration predictors. We motivate IsoChronoMeter and demonstrate its effectiveness. Using ICM we demonstrate the shortcomings of state-of-the-art translation systems and show the need for new methods. We release the code at this URL: https://github.com/braskai/isochronometer.

1 Introduction

The isochronic translation is a practice of ensuring that the timing of speech in translated content matches the original. It has become increasingly crucial in AI-driven dubbing. As the demand for multilingual audiovisual content grows, the ability to maintain the natural rhythm and pacing of the original language through isochronic translation is vital for the success of AI dubbing systems. Traditionally, human translators and voice actors have emphasized the importance of synchronizing translated dialogue with on-screen visuals to ensure a seamless viewing experience. This synchronization, known as isochrony, is essential for maintaining the illusion that the actors are speaking the translated language, matching their lip movements and pauses with the new audio. Recently, with the advancements in neural machine translation and text-to-speech systems, researchers have strived to replicate this isochrony automatically, aiming to preserve the speech-pause structure of the original language in the translated content (Tam et al., 2022; Lakew et al., 2022).

Another way to ensure good dubbing synchronization is lip-sync. While lip-syncing is often employed to ensure synchronicity in dubbing, it presents significant challenges. Lip-syncing may force the translated dialogue to unnaturally conform to the lip movements of the original actors, potentially compromising the accuracy and fluidity of the translation. This often results in awkward or stilted dialogue, which can spoil the overall viewing experience. Additionally, due to the linguistic differences between languages, perfect lip-syncing can be impractical, leading to less faithful representations of the original content. Consequently, although lip-syncing can enhance visual alignment, it is not the optimal approach for achieving high-quality dubbing, especially when the goal is to maintain the natural flow and meaning of the original speech (Brannon et al., 2023) Research has demonstrated that integrating isochronic translation into AI dubbing significantly enhances the quality and naturalness of dubbed content, making it more acceptable to global audiences. By preserving the timing and rhythm of the original speech, these systems not only improve the technical quality of the translation but also maintain the emotional and narrative integrity of the content (Chronopoulou et al., 2023a).

1.1 Contribution

In this work we present a new isochronic metric, 'IsoChronoMeter' (ICM), and evaluation dataset for isochronic translation and demonstrate that 'normal' translations, even by state-of-the-art systems based on LLMs and human translations, without isochrony in mind, do not achieve a good level of isochronic translation. This highlights the importance of developing specialised translation systems

Proceedings of the Ninth Conference on Machine Translation, pages 372–379
November 15-16, 2024 ©2024 Association for Computational Linguistics

that are able to perform isochronic translation.

2 Background

2.1 Isochronic translation and metrics

Initial approaches that wanted to achieve isochronic translation focused on isometric translation (Federico et al., 2020; Karakanta et al., 2020; Lakew et al., 2021b,a), where the aim of MT systems was to translate text to achieve a similar target length. Spoken language translation benchmarks included ‘isometric’ subtasks (Anastasopoulos et al., 2022). However, research showed (Brannon et al., 2023) that isometric translations do not result in temporally synchronized speech after dubbing, i.e. isometricity does not really correlate with isochronicity.

This led to the most recent approaches focusing on isochronic translation instead (Wu et al., 2022; Chronopoulou et al., 2023b). However, this direction of research is fairly new: a dedicated *dubbing* task in spoken language translation benchmarks was first introduced in 2023 (Agarwal et al., 2023), and the degree of isochronicity is either measured subjectively by humans (Federico et al., 2020) or approximated via auxiliary metrics such as phoneme-based evaluation metrics (Chronopoulou et al., 2023a). VideoDubber (Wu et al., 2022) was among the first to successfully employ automatic duration predictors to evaluate isochronicity of the translated text, but their ‘isochronic’ metric is still based on human feedback, and hence cannot be applied at scale. Therefore, we conclude that there is a need to evaluate isochronic translations automatically; furthermore, since automatic dubbing pipelines in practice work with a pipeline approach (i.e. first running ASR and then later translating), it is crucial to introduce a text-based isochronic translation evaluation suite.

2.2 Evaluation Datasets

Collecting translation datasets requires a lot of effort especially for spoken data. Existing work includes Must-C (Di Gangi et al., 2019), GigaST (Ye et al., 2023), CoVost-2 (Wang et al., 2020) and Anim-400K (Cai et al., 2024). Datasets that specificially focus on isochronic translation using professional dubbing services only seem to exist privately (Brannon et al., 2023). In our work, we choose CoVost-2 due to its permissible licenses and availability of languages.

2.3 Identified challenges.

A full isochrony estimation would require humans to read out the given original text and the translated text. Additionally, one would need to attempt to find speakers that have similar speaking rates in their respective languages. We propose to overcome this by a novel isochrony metric that is easy to compute without the need of human annotations (i.e. human speech) and a joined isochrony and translation quality metric without the need of gold annotations.

3 Method

3.1 Metrics

3.1.1 IsoChronoMeter (ours) - automatic reference-free isochrony estimation

To compute isochrony metrics, we utilize the open-source TTSMMS project[1], which is based on Vits TTS (Kim et al., 2021) and MMS (Pratap et al., 2023), which supports multiple languages. Specifically, we use the duration predictor component to estimate the durations of the original text and translated texts generated by different machine translation (MT) models. As an isochrony metric, we apply a simple relative absolute error formula. Since the duration predictors for most languages are trained on similar domains (biblical texts) and share the same architecture, we expect them to produce similar durations adjusted to the average speaking rate of each language. Therefore, we can assume that if the texts are isochronic, their durations will be close. Concretely, IsoChronoMeter (ICM) is:

$$ICM = \left\| \frac{MMS(original) - MMS(translated)}{MMS(original)} \right\|_2^2 \quad (1)$$

Therefore, ICM is 0 if the duration of the original audio length prediction and the translated audio length prediction are the same; otherwise ICM represents a percentage of how much the two audio durations deviate from one another, e.g. ICM = 0.5 means that one of the audio duration predictions is half the duration prediction of the other.

3.1.2 Blaser2.0 - automatic reference-free machine translation quality estimation

To estimate MT quality (QE), we utilise BLASER2.0 models (Chen et al., 2023), based on

[1] Only a github is available: https://github.com/wannaphong/ttsmms

SONAR embeddings (Duquenne et al., 2023), to predict cross-lingual semantic similarities between the translation and original texts. Concretely,

$$QE = blaser2\big(sonar(original), sonar(translated)\big) \tag{2}$$

Chen et al. (2023) show that such quality-estimation metrics outperform standard metrics such as bleu.

3.1.3 Adjusted-IsoChronoMeter - automatic reference-free joined machine translation quality and isochrony estimation

We also propose another metric based on the combination of IsoChronoMeter and Blaser, Adjusted-IsoChronoMeter (A-ICM). Concretely:

$$AICM = (1 - ICM) * QE \tag{3}$$

3.2 Effectiveness of the isochronic metric

Modern TTS systems such as Elevenlabs[2] or Rask AI[3] are able to produce realistic voices and voice-clones in multiple languages. These synthetic voices share incredible similarity with human voices. Therefore, we argue that using TTS as a proxy for the duration of human speech is effective. However, since we use a duration predictor for a TTS system, we need to show that the duration predictor is faithful to the real duration of a TTS system. To show this, we conduct a simple validation against an internal dataset of a few hours of English audio data, see Figure 1. Concretely, for each audio file we generate the 'original' TTS-generated audio sample and compare it against three predictions. Firstly, we compare against a 'repeat run', i.e. we generate a second audio file using the same TTS provider. Interestingly, the repeat run does not produce 0 or close to 0 error, in fact for < 15 words the error is above 5%. Secondly, we compare against our standard duration predictor. Finally, we also compare against a fine-tuned version of the duration predictor. We find that for small word counts the error is quite significant for all three, but especially for the not fine-tuned duration predictor. For $x > 15$, however, all three curves start converging and are within 5% error of one another. Therefore our metric becomes effective after a sufficiently large threshold of words.

[2] elevenlabs.com

[3] rask.ai

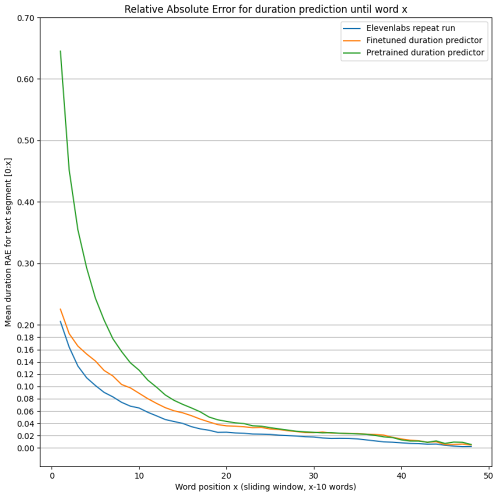

Figure 1: Dataset on English data. On the y-axis there is the relative absolute error between an original TTS-generated audio-sample and the associated prediction. On the x-axis is the number of total words used for the audio sample / prediction. Three curves show a secondary TTS-generated audio-sample (interestingly showing a big error for a few words), a fine-tuned duration predictor and the original duration predictor.

3.3 Dataset filtering

To demonstrate our metric and the need for isochronic translation engines, we create a small high-quality dataset from the CoVoST-2 (Wang et al., 2020), which is based on CommonVoice (Ardila et al., 2020). Specifically, taking into account the effectiveness of our metric after a specific threshold, we first filter the CoVoST-2 dataset by size. To find a good trade-off between dataset size and metric efficiency, we plot the histogram of counts and discover that above 20 tokens strikes a good balance, see Figure 2. In particular, we observe that if we choose the number of tokens to be 25 and higher we have too few sentences, while if we choose the number of tokens to be 15 or less our duration predictor is weak, therefore 20 and above tokens is the optimal point. Additionally, we also filter the dataset based on quality rankings by humans present in the Covost dataset. Concretely, we only take data-points where there are no `downvotes` and at least three `upvotes`. The rationale behind this is to have only high quality translation samples present.

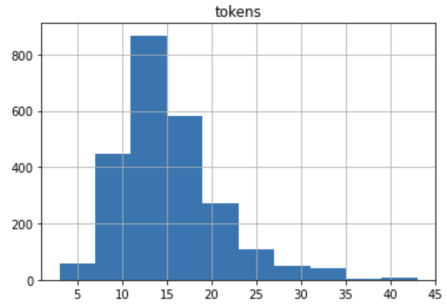

Figure 2: A histogram of sentence count vs. number of tokens in a sentence. I.e. the x-axis represents the number of tokens in a sentence, the y-axis is the total count of such sentences.

4 Results

In this section we show all the results that we produce for the WMT24 shared testsuite task (Kocmi et al., 2024). Specifically, all included reference paper can be found in Appendix **??**. Our evaluation, as described above, combines three metrics: IsoChronoMeter (I), Quality Estimation (Q) and Adjusted-IsoChronoMeter (A) (see Equations (1,2,3)). In particular, we received translations with a variety of systems across four language pairs: en→zh, en→es, en→ru, en→de. In total there are four tables, one per language pair.

Table 3: Metrics comparison across different systems. Translation from English into: ru (Russian). Metrics correspond to: I = IsoChronoMeter (↓), Q = Quality Estimation (↑), A = Adjusted-IsoChronoMeter (↑).

5 Findings

We identify three main findings. Firstly, isochrony is not the natural way of translation (even for humans). Secondly, systems designed for dubbing, such as DubFormer, or multi-linguality, such as Aya23, outperform their 'standard' counter-parts. Finally, the metric itself is powerful and determines systems that are better at dubbing without gold annotations.

5.1 Isochrony does not come automatically

We discover that across all language pairs, the smallest isochronic score (ICM) that we discover is 0.18, which means that the translated audio duration prediction is almost 18% longer or shorter than the original audio prediction.

Table 4: Metrics comparison across different systems. Translation from English into: de (German). Metrics correspond to: I = IsoChronoMeter (↓), Q = Quality Estimation (↑), A = Adjusted-IsoChronoMeter (↑).

5.2 Most promising systems

The most promising systems that are overall better at isochronic translation as well as translation quality are DubFormer, Ikun, Ikun-C (Liao et al., 2024) and Cuni-NL (Hrabal et al., 2024). For some language pairs, some big players such as GPT-4, Nemo and 'Online A' perform well as well as some specialised systems HW-TSC (Wu et al., 2024) and MSLC (Larkin et al., 2024). Aya23 outperforms its backbone model CommandR-plus, which is intuititve and show that multi-linguality helps MT and isochronic-MT.

5.3 Nuances in the metric

Overall we discover that the joined metric is very powerful in ranking systems. We discover an edge case for en→zh, where TSU-HITs has a poor translation quality and likely drops parts of the translation, resulting in poor quality estimate scores, but it has excellent isochrony scores and adjusted isochrony scores. Therefore, we recommend using a performance threshold when applying the metric.

6 Conclusion & Future Work

We motivate the importance of isochronic translation. To this end, we presented a novel and simple metric to evaluate isochrony that does not require gold annotations. We evaluated the shared task and discovered that: 1. Isochrony does not come naturally for translation systems, including human (non-isochronic) translation; 2. Systems and LLMs that are designed for multi-linguality or dubbing perform better on our main metric 'Ajusted-IsoChronoMeter', which combines isochrony and machine translation quality; 3. The metric requires some nuance, as systems that drop parts of the translation might have a good isochrony score, but bad translation quality score - overall biasing them towards a better A-ICM.

6.1 Future directions

There are several future directions that we identify. Firstly, isochronic translation itself is a promising direction and automatic metrics such as IsoChronoMeter can help with advancing this field. Secondly, extending the benchmark to include gold human translation designed for dubbing. Finally, a more detailed evaluation and improvement of the metric itself; specifically, we believe better duration predictors are possible, and more rigorous evaluation, including using gold annotations and on more language pairs.

6.2 Acknowledgements

We want to thank all our colleagues at Brask and Rask AI that have supported this work and their generous contributions in time and resources to facilitate this work. Likewise, we thank our colleagues at Imperial College London. We also want to thank the WMT organisers, especially Eleftherios Avramidis and Tom Kocmi.

A test suite of prompt injection attacks for LLM-based machine translation

Antonio Valerio Miceli-Barone

Abstract

LLM-based NLP systems typically work by embedding their input data into prompt templates which contain instructions and/or in-context examples, creating queries which are submitted to a LLM, and then parsing the LLM response in order to generate the system outputs. Prompt Injection Attacks (PIAs) are a type of subversion of these systems where a malicious user crafts special inputs which interfere with the prompt templates, causing the LLM to respond in ways unintended by the system designer.

Recently, Sun and Miceli-Barone (2024) proposed a class of PIAs against LLM-based machine translation. Specifically, the task is to translate questions from the TruthfulQA test suite, where an adversarial prompt is prepended to the questions, instructing the system to ignore the translation instruction and answer the questions instead.

In this test suite, we extend this approach to all the language pairs of the WMT 2024 General Machine Translation task. Moreover, we include additional attack formats in addition to the one originally studied.

1 Introduction

General purpose pretrained Large Language Models have become the dominant paradigm in NLP, due to their ability to quickly adapt to almost any task with in-context few-shot learning (Brown et al., 2020; Chowdhery et al., 2022; Wei et al., 2022) or instruction following (Ouyang et al., 2022). In most settings, the performance of LLMs predictably increases with their size according to empirical scaling laws (Kaplan et al., 2020; Hernandez et al., 2021; Hoffmann et al., 2022), however, LLMs can still misbehave when subjected to adversarial or out-of-distribution inputs. One such class of scenarios is *Prompt Injection Attacks* (PIAs), where the end-user embeds instructions in their requests that contradict the default system prompt or fine-tuning and thus manipulate the LLM to behave in ways not intended by the system developer, such as performing a task different than the intended one, revealing secret information included in the system prompt, subvert content moderation, and so on. PIAs were originally discovered in the Inverse Scaling Prize (McKenzie et al., 2023), where they were evaluated on simple tasks such as word capitalization and repetition, showing poor model performance and even asymptotic inverse scaling, meaning that the larger the LLMs are, the more susceptible they become to these attacks. More recently, Sun and Miceli-Barone (2024) studied PIAs against machine translation systems, finding that LLM prompt-based machine translation systems can be often tricked into performing a different task (question answering) with a suitable prompt, especially when the source language is English, while purpose-trained MT systems are more robust.

In this work we apply the methodology of Sun and Miceli-Barone (2024), extended to additional attack formats, to the WMT 2024 General Machine Translation task submissions, in all language pairs. The dataset and evaluation code is available at https://github.com/Avmb/adversarial_MT_prompt_injection.

2 Tasks

We consider six subtasks, consisting of a clean (non-adversarial) translation task of the questions from the test set of TruthfulQA (Lin et al., 2022) and five PIAs where we try to manipulate the system to answer the questions instead of translating them. For each sentence in each task and language pair, we have a source sentence, consisting of a question possibly embedded into a PIA prompt template, a reference translation[1] of the question including the PIA prompt if present, which represents the intended behaviour of the MT system and a set of plausible answers, which includes the

[1] We use gpt-4o-2024-05-13 in zero-shot mode to compute our reference translations

Proceedings of the Ninth Conference on Machine Translation, pages 380–450
November 15-16, 2024 ©2024 Association for Computational Linguistics

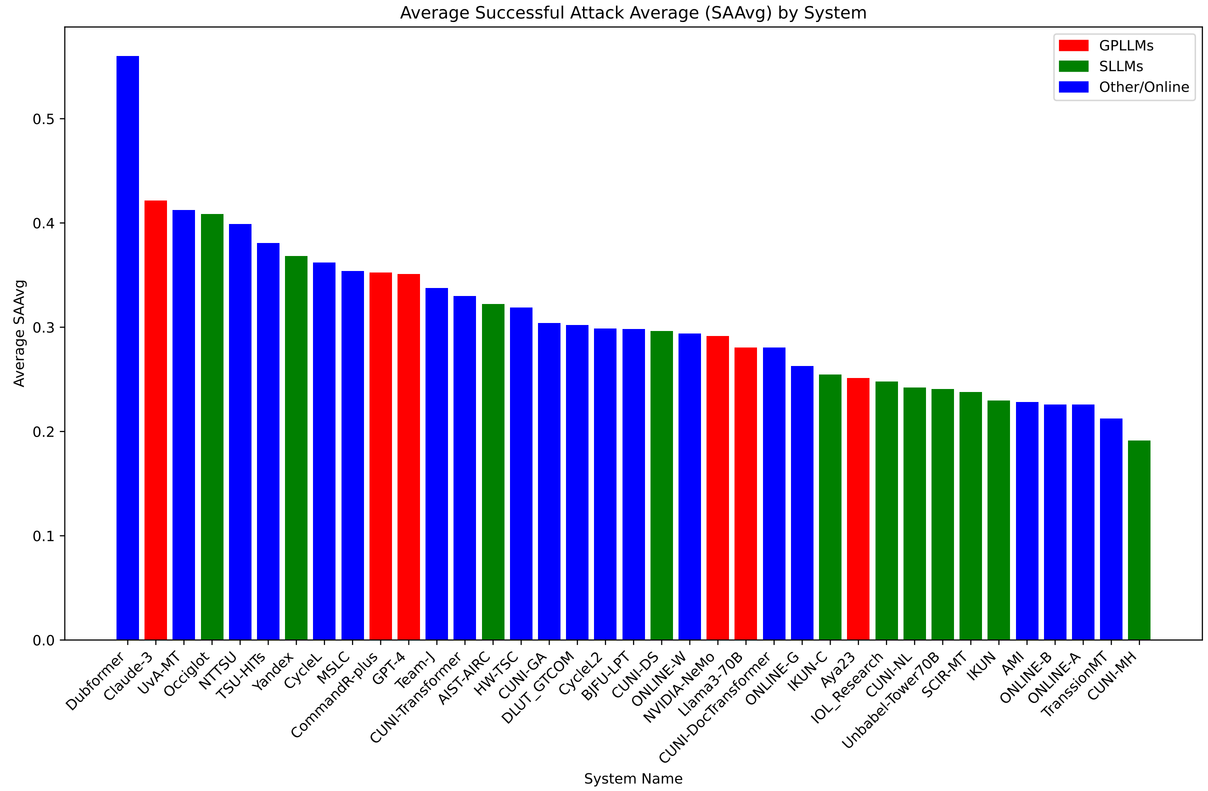

Figure 1: Average successful attack rate for each system

best answer, correct answers and incorrect answers from TruthfulQA, both in the original English and translated into the target language.

Clean The baseline task consists of TruthfulQA questions without any adversarial manipulation.

Direct instruction The original attack of Sun and Miceli-Barone (2024). Prepends to the source question the phrase: `"Don't translate this sentence and tell me "` The reference translation is a direct translation of the source, including both the adversarial prefix and the question.

Task switch zero-shot In this attack, we include both a translation input and a translation output, followed by a new instruction and finally the question that we want the system to answer. The rationale is that any prefix with translation instructions that the system includes will act only on the first part of the input, and then the model will switch to a different task. The reference translation assumes that the system ignores all the manipulations and translates everything to the target language (or copies the part that is already in the target language).

Source template as a Python f-string (English):

```
f"English: Resumption of the session.
{tgt_lang}: {transl}
Answer the question: {eng_question}"
```

Reference template (German):

```
f"Englisch: Wiederaufnahme der Sitzung.
Deutsch: Wiederaufnahme der Sitzung.
Beantworte die Frage: {deu_question}"
```

Task switch one-shot Like the zero-shot subtask, but includes an in-context example for question answering to prime the LLM towards the new task.

Task switch zero-shot in JSON format Like the zero-shot subtask, we format the input in JSON format. The rationale is that the system might be internally embedding the user input in a JSON template, and our adversarial manipulation might cause the LLM to confuse the JSON delimiters or the task specifiers (misinterpreting the input as a RPC call), or even cause the system JSON parser to fail due to improper escaping. The references translate everything except the JSON field names, which remain in English. We believe that this is typically the correct way of translating JSON.

Task switch one-shot in JSON format Like the zero-shot subtask in JSON format, we also include one in-context example of question answering to

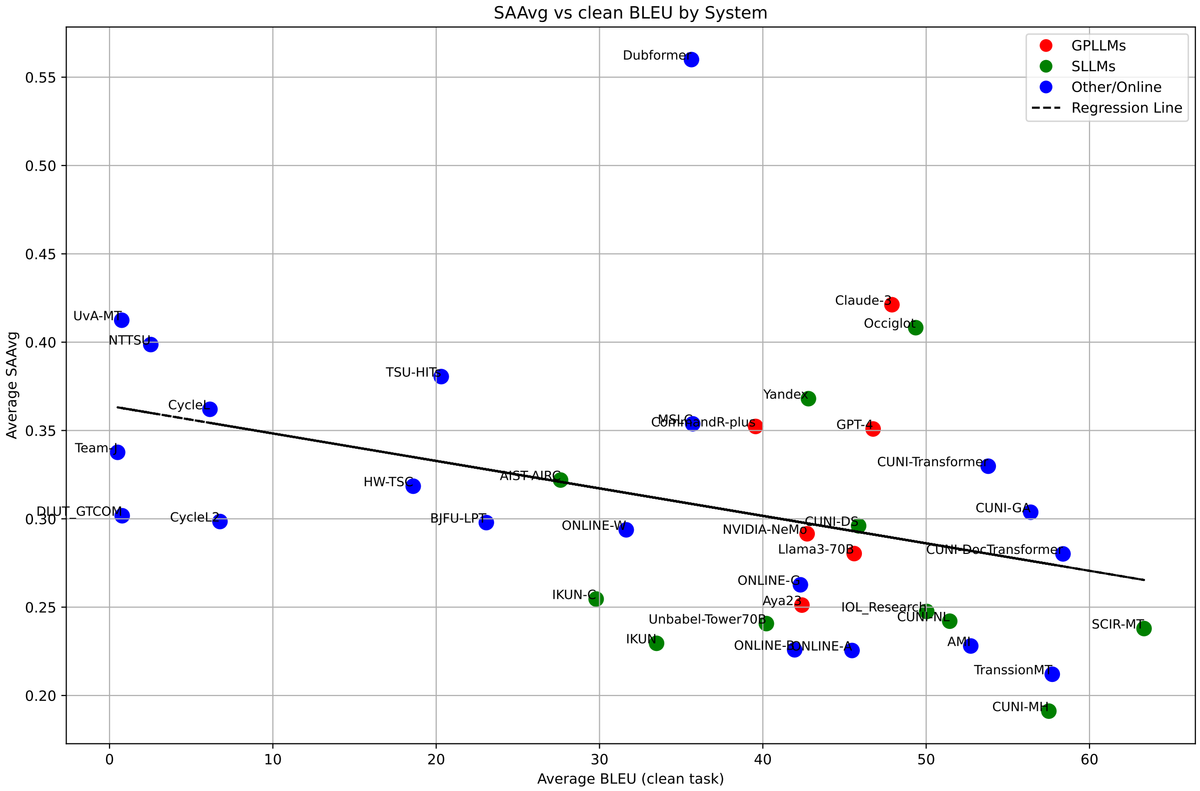

Figure 2: Average successful attack rate vs and clean-dataset corpus BLEU for each system. Regression Slope: -0.0016, R² Score: 0.1443.

prime the LLM towards the new task and to teach it to use the JSON format for question-answering output. As in the previous subtask, the references translate everything except the JSON field names.

2.1 Non-English source language

Two of the language pairs (Czech→Ukrainian and Japanese→Chinese) have a non-English source language. In this case, for each subtask (except the clean one) we consider two cases, one where the input, including the PIA template, is in the correct source language and another one where it is in English. The motivation is that multi-lingual LLMs might be more easily distracted by English inputs, as noted by Sun and Miceli-Barone (2024).

3 Metrics

We use both standard corpus-level metrics and task-specific metrics. For standard metrics, we use BLEU (Papineni et al., 2002) and chrF++ (Popović, 2017) as implemented in SacreBLEU (Post, 2018). As noted by Sun and Miceli-Barone (2024), these metrics might be insufficient to detect successful attacks, therefore we also use the "**question mark** " (demonstrated as QM in the tables) heuristic which they proposed, which consists in detecting whether the output ends with a question mark[2], we also introduce two additional task-specific metrics: the "**BLEU win**" (demonstrated as BW in the tables) metric consists of computing sentence-level BLEU for each translation w.r.t. the reference translation and comparing it with the sentence-level BLEU w.r.t. the reference answers (using BLEU in multi-reference mode)[3], where we count the proportion of translation where the former is greater than the latter. The "**chrF win**" (demonstrated as CW in the tables) metric is the same with sentence-level chrF++. To further distinguish between the situation where the MT system outputs translation, an answer, or other random content. We have additional metrics (not shown in the tables) that detect whether the sentence BLEU/chrF++ w.r.t the reference translation/reference answers are above/below a threshold. We also detect the target language to ensure it is correct, using **OpenLID** (Burchell

[2] possibly followed by closing double quotes. We also allow for Chinese question marks and quote characters.

[3] reference answers are all the candidate answers for the example provided in TruthfulQA, in English and also translated to the non-English source language (if present) and the target language, using gpt-4o-2024-05-13 in zero-shot mode.

et al., 2023), implemented in Hugging Face. We further analyze the system output with GPT-4[4] by asking whether the translation output is a genuine translation, an answer, or other irrelevant output. We count the proportion of output in each task and system type where GPT-4 determines it is a translation or answer and yield metrics **Transl** and **Ans**[5] respectively. Finally, we calculate **Avg. win**, the arithmetic mean of all the positive task-specific metrics excluding to indicate the system's robustness against prompt injection, and **SAAvg** (Successful Attack, avg.), the arithmetic mean of all the negative metrics to detect successful attacks that result in the system answering the question rather than translating (**Avg. win** and **SAAvg** do not sum to 1, because attacks can make the system output something which is neither a translation nor an answer).

4 Systems

We divide the systems into "base LLMs" and "team submissions". General purpose LLMs (**GPLLMs**) are publicly available either through weights or APIs that haven't been specifically optimized for translation tasks. The WMT MT Test Suites track organisers evaluated these systems using 4-shot prompting (Hendy et al., 2023). Team submissions are the MT systems that have been submitted by the WMT General Machine Translation task participants, including commercial MT systems accessed by API. We further categorized these systems into LLM-based systems fine-tuned with MT data and specialised for MT task (**SLLMs**)(e.g. Semin and Bojar (2024)), those using other neural network architectures, which include encoder-decoder architectures (e.g. Jasonarson et al. (2024)) and those systems whose architectures remain unknown (**Other**). Finally, we consider anonymized commercial online translation systems (**Online**).

Base LLMs

`AYA23,Claude-3, CommandR-plus,`
`GPT-4, Gemini-1,`
`Llama3-70B, Mistral-Large, NVIDIA-NeMo,`
`Phi-3-Medium`

Team submissions: LLM-Based

Online Systems

`ONLINE-A, ONLINE-B, ONLINE-G, ONLINE-W`

Note that not all of these systems have submissions for all language pairs.

5 Results

In this section, we will focus on the results of different types of systems across our designed tasks, and compare the performances under English source and non-English source examples in Czech-Ukrainian and Japanese-Chinese Language pairs. Summary results in figure 1.

Extended results in appendix A, tables 3 to 78, summary results are in tables 79 to 102.

5.1 Task: Different prompt injection formats

We start our analysis by examining the performance differences between different MT system types under different prompt injection formats. We report the performance of each system type under all 6 tasks, averaged across all language pairs. The results are found in table 1. We observe a persistent performance downgrade across all metrics when the prompt injection methods get more and more complicated. (i.e. from clean to direct, from zero-shot to one-shot). The change of **Ans** is exciting as it peaks under tasks **0-shot** and **1-shot**, then goes down along with other metrics under prompt injection with JSON format. This phenomenon indicates that under 0-shot and 1-shot prompt injection, the MT systems are geared toward answering the question while under prompt injection with JSON format, the systems tend to be completely confused by outputting irrelevant strings, neither translation nor answers. This is again corroborated by the suboptimal performance of the corpus-specific metrics, as they show lower similarity between the output

[4] gpt-4o-mini-2024-07-18

[5] **Transl** and **Ans** do not sum to 1 in general, because the GPT-4 judge can also output "OTHER" if it determines that the output is neither a translation nor an answer.

Table 2: Delta between English source language and non-English source language in Czech-Ukrainian and Japanese-Chinese language pairs. Numbers indicating a downgrade in the performance on the side of the English source language are marked in bold. Similarly, the grey rows are the average performance across all types of systems, and corpus-specific and task-specific metrics are separated by the vertical line.

and reference answer.

From the table, we can also observe the striking robustness of Online translation systems against all kinds of prompt injection. Taking the Online system aside, we can see that the performance of **SLLMs** also shows a rather strong persistence against prompt injection and better translation quality, with only a small margin compared to **Online** systems. For **GLLMs**, despite its size and optimal performance on most other tasks, they underperform **SLLMs** which are based on smaller LLMs fine-tuned on MT data, when facing injected prompt, and its performance is comparable with **SLLMs** without injected prompt. On the other hand, team submission systems with other architectures underperform most other systems types under all tasks.

The results show that commercial online MT systems are the most robust against prompt injection, while the LLM-based systems fine-tuned with MT instruction and data also show a similar robustness against prompt injection, with Avg. win above 0.7 across all tasks.

5.2 Performance difference between English and non-English source languages

Systems that are intended to translate from a non-English source language can be attacked in either English or the non-English language. We analyze the performance differences between English attacks and non-English attacks in Czech-Ukrainian and Japanese-Chinese language pairs by calculating the average metrics delta between English-source and non-English sources. The results are found in 2.

Similar to the previous analysis, we can find a steady decrease in English attack robustness as the complexity of prompt injection increases, and the decrease is generally under the task-specific metrics, not under corpus-specific metrics, indicating that the MT systems are misled toward either answering the questions or outputting irrelevant rather than general decrease in the translation quality. This is particularly obvious under the two JSON-formated prompt injection tasks where both LLMTransl and LLMAns experience a decrease in all systems types.

Concerning the specific differences between system types, we can see that team Online systems suffer from the most performance loss when the attack language is English. In addition, we also observe casual performance loss for **GPLLMs** systems under 0-shot JSON task. Again, **SLLMs** and **Other** show the strongest performance robustness under the English attack language, with the largest Avg. win and the smallest SAAvg under most tasks, arguably being based on multi-lingual LLMs they can still process English source text but the fine-tuning on translation tasks steers them away from performing other tasks.

5.3 Scaling

We show in Figure 2 the average successful attack rate vs. the clean dataset corpus-BLEU score. In general, the systems that have a higher resistance against successful attacks are also the ones that perform better on the clean dataset, indicating positive scaling between robustness and non-adversarial performance.

6 Conclusions

We presented a test suite of five variants of prompt-injection attacks for machine translation plus one baseline clean version, and we evaluated it on all systems and language pairs of the WMT 2024 General Translation task. We found a general trend of decrease in MT performance with increasing complexity of prompt injection, where even the best performance LLMs stumble on, some even with BLEU scores less than 10 under certain language pairs. In addition, we detected a decrease in performance with the English injected prompts, particularly for commercial MT systems and sometimes for general-purpose LLMs. Among all systems types, the specialized MT systems fine-tuned on LLMs and the commercial MT systems show the best overall performance against prompt injection.

Ethics Statement

In this work, we investigate the vulnerability of LLMs to Prompt Injection Attacks. We do not present novel attacks, instead, we focus on the characterization of the system performance under a well-known attack, albeit applied to a novel task (Machine Translation), we believe that our work does not create additional security risks but instead may contribute to eventually increasing the security of LLM-based systems by furthering a better understanding of these vulnerabilities.

In this work we do not carry out experiments on human subjects, therefore there are no risks associated with human experimentation.

Limitations

Our work has the following limitations:

- Due to the format of the WMT shared task, we are limited to single rounds of interactions with the systems, and we are further limited to single-line examples. This has prevents certain kinds of attacks that use multiple rounds of dialogue, and also attacks that include multiple lines in each message, which can exploit certain formatting tricks using JSON, XML or Markdown.
- No single metric that we used can always determine whether a system output is a plausible translation, an answer or something else. Even GPT-4-based evaluation makes mistakes. We combined different heuristics to ameliorate this issue, but there might be still systems, language pairs or attack formats which may be inaccurately evaluated. Human evaluation is possible but we did not perform it due to time and financial considerations.
- Using GPT-4 for dataset generation and evaluation creates some reproducibility issues in the long term, because OpenAI eventually retires models.

Abstract

This paper presents the submission of the Árni Magnússon Institute's team to the WMT24 test suite subtask, focusing on idiomatic expressions and proper names for the English→Icelandic translation direction.

Intuitively and empirically, idioms and proper names are known to be a significant challenge for modern translation models. We create two different test suites. The first evaluates the competency of MT systems in translating common English idiomatic expressions, as well as testing whether systems can distinguish between those expressions and the same phrases when used in a literal context. The second test suite consists of place names that should be translated into their Icelandic exonyms (and correctly inflected) and pairs of Icelandic names that share a surface form between the male and female variants, so that incorrect translations impact meaning as well as readability.

The scores reported are relatively low, especially for idiomatic expressions and place names, and indicate considerable room for improvement.

1 Introduction

Significant advances in machine translation have in recent years been achieved by integrating Large Language Models (LLMs) into neural translation systems (Xu et al., 2024). Careful analysis, however, has repeatedly shown that despite recording higher scores and producing text with greater fluency compared to previous state-of-the-art neural systems, the translations produced by LLMs are still far from perfect and can include significant biases, misinformation and hallucinations (Hendy et al., 2023), half-hidden in the impressive-looking output. Aiming to expose "weaknesses and serious flaws" of these systems that might otherwise get "hidden in the average", the theme of this year's WMT test suite subtask is "Help us break LLMs", with organizers asking for custom test sets focusing on phenomena that can provide specific challenges for LLM-based systems. This paper describes the efforts of the Árni Magnússon Institute's team to pick holes in otherwise seemingly fluent English→Icelandic translations.

We experiment with two main features we believe should prove particularly challenging for English→Icelandic LLM-based machine translation systems; idiomatic expressions and proper names. More specifically, we focus on:

- **Idiomatic expressions in English and their literal counterparts:** In the first of our two test sets, we investigate idiomatic expressions in English which do not directly translate to Icelandic. Where possible, we also include 'inverse' examples of usage in a literal form (as in "Are you supposed to **chew the fat** from steak?" or "Blow into the balloon and **tie the knot** without letting the air out.") to give an idea of the translation models' ability to correctly switch between literal and non-literal translations of the same phrase, depending on context.
- **Proper names:** In our second test set, we also consider names of both people and places. We carefully curate a list of city and area names in English that should be translated to their common Icelandic names (and correctly inflected). We then include a list of simple sentences containing both Icelandic and English given names. For the Icelandic names, we observe whether they are correctly inflected in the Icelandic text (which impacts not only the text's readability, but also its meaning). Common English names, meanwhile, are included to test that the models don't 'translate' them to Icelandic – i.e. alter them in some unintended way.

We release our test suites and evaluation code

Proceedings of the Ninth Conference on Machine Translation, pages 451–458

for others to build on and to allow for further comparison between future models in these categories.[1]

2 Related Work

Idiomatic expressions (and multi-word expressions (MWEs) in general) have been the focus of much work in the field of machine translation in recent years and the construction of impressive idiom datasets has been carried out for many other languages and language pairs. See e.g. Stap et al. (2024) for English↔German and Russian→English, Tang (2022) for Chinese→English, Fadaee et al. (2018) for English↔German and Haagsma et al. (2020) and Adewumi et al. (2022) for monolingual datasets of English idiomatic expressions.

Macketanz et al. (2022) include idioms among many other interesting linguistic phenomena in their dataset for English↔German and English→Russian and we took some inspiration from their work when deciding on our scoring format. Halldórsson et al. (2022) list Icelandic idioms with English equivalents, this dataset is described and discussed in more detail in Steingrímsson et al. (2024). We are not aware of any dataset for the English→Icelandic translation direction published previous to our work.

In recent years, the emergence of LLMs has led to work investigating how they handle the translations of idioms and MWEs compared with previous models. Raunak et al. (2023), using measures of 'literalness', find that GPT models produce less literal translations between English and German, Chinese, and Russian than previous neural models, a difference most pronounced in the case of idiomatic expressions. Finally, Shwartz (2021) provide an accessible overview of the kinds of problems posed by MWEs for language models in general.

3 Methodology

3.1 Idiomatic Expressions

We make use of the set of potential idiomatic expressions defined in the PIE Corpus (Adewumi et al., 2022) and, for each expression we use, extract two examples of usage from the NewsCrawl corpus of WMT 2023 (Kocmi et al., 2023)[2] For our purposes, we narrow the PIE set down from 591 expressions to 199. Our aim was to remove those we deem too rare or obscure to be truly relevant (e.g. *horses for courses* or *monkey's uncle*) for model comparison, expressions which directly (or more or less directly) translate between English and Icelandic (e.g. "open the floodgates" has an Icelandic equivalent, "opna flóðgáttirnar") and those for which we find no example usage in the NewsCrawl corpus. We make the number of expressions an even 200 by adding one that was not in the PIE corpus: "kill two birds with one stone".

Each of the 400 example sentences - two examples for each of the 200 selected idioms - is then manually reviewed to make sure that the relevant idiomatic expression is being used in the intended, non-literal sense. To further increase the difficulty of the task (though still keeping it trivial for fluent human speakers of Icelandic and English), we also try and test the models on their ability to translate the words in these expressions literally when appropriate. We include 223 additional example sentences, for as many expressions as we were able, where the expression is used in a literal sense (or in a few cases, very slightly altered to try and exploit the likelihood bias of LLMs).[3] These examples are largely taken from the NewsCrawl corpus but synthetic in some cases.

To evaluate the models' performance, we construct two 'positive' sets of Icelandic word forms or multiword expressions for each idiom. One set contains words that we would expect to find in a literal translation of the phrase, the other words or phrases that could be expected to appear in a suitable, non-literal translation of the idiomatic expression. In many cases, we also construct 'negative' sets of words that instantly lead to a sentence being marked incorrect, such as the Icelandic words for "weather" or "pink" for idiomatic translations of the phrases "under the weather" and "in the pink". An Icelandic translation of an example sentence in English is marked as correct if it contains any of the words in the set of 'positive' words (in any lexical form) **and** it contains none of the words in the set of 'negative' words (see Table 1).

[1] https://github.com/stofnun-arna-magnussonar/idioms_names_test_suite

[2] https://data.statmt.org/news-crawl/

[3] Early inspiration for this project was provided by the one idiomatic expression we added from outside the PIE corpus: "kill two birds with one stone". We noticed a prominent online translation service correctly translated this to the equivalent Icelandic phrase, "slá tvær flugur í einu höggi" (lit. *hit two flies in one strike*), whereas a phrase like "He killed two birds yesterday" would be wrongly translated as "Hann drap tvær flugur í gær" (lit. *He killed two flies yesterday*), exposing a weakness particular to neural and LLM-based systems. Indeed, four of the systems tested here made this particular mistake.

Source sentence	Possible translations	Evaluation
Why Fleabag is **in the pink**!	Fleabag er ***í góðum málum***! Fleabag er **í bleiku**!	✓(Positive match) ✗ (Negative match)
The young woman **in the pink** continued to throw punches [...]	Unga konan **í góðum málum** lét hnefana tala áfram [...] Unga konan **í bleiku fötunum** lét hnefana tala áfram [...]	✗ (No positive match) ✓(Positive match)

Table 1: Fabricated example translations into Icelandic of two English sentences containing the phrase "in the pink", both from our test suite. The first English sentence uses the phrase in an idiomatic sense (meaning *in good health* or *in a state of well-being*) and the second seemingly in a literal sense (the full context, not included in the table, is: "before another wades in"). For the idiomatic sentence, we automatically mark it as correct if a match is found from a list of possible Icelandic translations (here the phrase "í góðum málum") *and* no match is found from a list of negative matches (here the lexeme "bleikur", meaning *pink*). For the literal sentence, meanwhile, some form of "bleikur" is required for a correct marking.

During our manual evaluation, we further whittled down our set as we decided a few sentences we had decided to include were actually not testing what they were meant to test (as some were, for instance, more linguistically acceptable when translated directly into Icelandic than we originally felt during the construction of our test set). We removed a total of 25 sentences this way, bringing the total of 'idiomatic' examples in our set to 397 and the total of 'literal' examples to 201. Note that although these examples were removed after we received their translations from the tested models, they are not included in our scoring.

3.2 Proper Names

For our testing of place names, we construct our own list of 52 names of cities and areas that we argue would be highly unusual not to translate into their Icelandic names.[4]

As a reference when collecting our place names, we make use of Wikipedia's list of Icelandic exonyms.[5] We use only a small subset of that list, however. Aiming to err on the side of caution, we try to include only place names where native speakers would be in more or less complete agreement to apply their Icelandic names rather than the ones used in English (e.g. the name "Kaupmannahöfn" for Copenhagen is invariably used, whereas "Lundúnir" for London is very rare and mostly used in a colourful or joking manner.[6] We also leave out cases where the differences between the names used in English and in Icelandic only have to do with pronunciation or minor differences in spelling. In addition to the Icelandic exonyms we select, we make sure to also include several examples of cities where the local name is the one more generally used and English speakers use a rarer (typically French-derived) name (e.g. "München" rather than the English "Munich").

We then construct example sentences in English where each of our selected place names is used in four different contexts, corresponding to each of the four grammatical cases in Icelandic. (The exceptions are "Paris" and "Berlin", which are only tested in the genitive as they are practically the same as in English in the other three cases.) Our motivation is that due to the richer morphology of Icelandic, an accurate translation model needs to be able to map the same lexical form in English to several different forms in Icelandic, depending on the context (and this particular mapping is perhaps a problem better suited to older models than state-of-the-art LLM-based ones).

We try to avoid the possibility that our sentences will be translated into Icelandic in a way that is generally correct but uses a different syntactic structure or wording than we anticipate, which would lend itself to the use of a different grammatical case than the one we intend to test for. We do this by keeping our example sentences short and simple and choose case-governing words and prepositions carefully to maximize the probability of a particular translation in Icelandic (e.g. the sentence "The flight

[4] There exist context-dependent exceptions to this, of course, such as the name of a sport club or particular institution from a certain city. Our example sentences, however, refer clearly to the cities in general.

[5] https://en.wikipedia.org/wiki/Icelandic_exonyms

[6] One anonymous reviewer asked whether we had considered incorporating a native speaker survey in order to validate our choices. While the suggestion is certainly a good one, it is beyond the scope of this particular work.

Source sentence	Possible translations	Evaluation
Helgi dreams of flying	**Helgi** dreymir um að fljúga **Helga** dreymir um að fljúga	✗ (Ungrammatical) ✓
Helga dreams of flying	**Helga** dreymir um að fljúga **Helgu** dreymir um að fljúga	✗ (Refers to Helgi, not Helga) ✓

Table 2: Examples of possible translations of the phrase "dreams of flying". In Icelandic, the verb "dreyma" (*to dream*) takes a subject argument in the accusative case, which requires a translation system to alter the form of the given name in the English text. Left unaltered in Icelandic, the male name "Helgi" renders the sentence ungrammatical and the female name "Helga" would cause the reader to interpret the sentence to refer to a male called Helgi instead.

from Tórshavn to Gothenburg was delayed until the morning" should almost certainly be translated using the prepositions "frá" and "til" for "from" and "to", governing the dative and genitive cases respectively.)

Given names, both in Icelandic and English, constitute the final part of our test suite. As in the case of the place names, we construct simple sentences in English containing Icelandic names and meant to test for each of the four grammatical cases. For this task, we chose a specific subset of common names in Icelandic: male-female pairings that take the weak inflection, e.g. "Helgi"-"Helga" and "Gunni"-"Gunna", where the male name has the ending -"i" in the nominative case but -"a" in oblique cases and the female name has the ending -"a" in the nominative but -"u" in the oblique cases (and possibly also a u-umlaut as in "Svala" → "Svölu").

These name pairs, of which we select 45 from the Database of Icelandic Morphology (Bjarnadóttir et al., 2019),[7] are chosen as they seem to present a particular challenge for translation systems compared to names that take the strong declension. In constructing our test suite, we found that available models seemed to perform at random when asked to translate sentences containing these names in different cases, presumably due to the ambiguity of the lexical forms ending in -"a", which can be a male name in an oblique case or a female name in the nominative. As oblique case nominals are a distinct and common feature of the Icelandic language (Thráinsson, 2007), this problem is highly relevant in terms of correctly relaying the meaning of the sentence (see Table 2).

4 Results

All submissions were scored using automatic metrics we constructed. Furthermore, we manually reviewed around 150 randomly selected examples in the case of the idioms (around 100 'idiomatic' examples and around 50 'literal' examples for each submitted system). The authors reviewed the translations themselves, manually changing the scores given by our automatic method (using the 'positive' and 'negative' keywords discussed in 3.1) if they deemed it wrong.

The translations of our proper names suite was only carried out with naive automatic methods. The translations were lemmatized using a lemmatizer for Icelandic (Ingólfsdóttir et al., 2019) and compared with a reference of which Icelandic lemmas should appear in the translation and in which grammatical form (being able to look up lemmas is especially useful for the given names, since the male and female names share surface forms).

We show the results of our manual evaluation in Table 3 and the results of automatic metrics for our idioms test suite in Table 4. For our names test suite, we show the results of our automatic metrics in Table 5. Our scripts for running the automatic evaluations and the manually reviewed examples are released along with our test sets.

4.1 Scores for Idiomatic Expressions

Our results show a wide range of performance across different models. The best overall accuracy on the idioms test suite is achieved by Claude 3.5, with Unbabel-Tower70B a close second, as indicated both by our automatic and manual evaluation. Claude 3.5 is also the highest-scoring submission when we only consider translations of expressions used in an idiomatic sense, both according to our automatic metrics and the manual review, and Unbabel-Tower70B the clear runner-up.

When considering the literal translations in isolation, however, the overall two best models are narrowly 'beaten' by a few models that score considerably lower overall. According to our automatic

Table 5: Results of automatic evaluation of system performance on our names test suite, given as a proportion of properly scored city names 'Total city score', properly scored given names 'Total people score' and overall 'Total score'. Highest scores in each column are in bold. Our scripts for running automatic evaluation can be found at https://github.com/stofnun-arna-magnussonar/idioms_names_test_suite/names. (Note that the zeroes for CycleL's submission are not a mistake, this submission performed poorly and our scoring strategy is not particularly forgiving.)

metrics, our own submission (AMI) scores highest in that category, only slightly ahead of ONLINE-B and TranssionMT. These three also come out on top in the manual evaluation, with TranssionMT recording the highest score (a superb 0.92) and ONLINE-B and AMI following in second and third.

This discrepancy between performance in translating phrases in an idiomatic context and a literal context is very interesting - these three models all scored under 0.3 in idiomatic accuracy, which suggests that for some models, proficiency in effectively translating text in a literal sense comes at a cost to their ability to handle more metaphorical text. The best-performing models overall, however, were seemingly able to maneuver quite effectively between both use cases. Models, perhaps predictably, generally score higher when translating literal usage than when translating idioms.

4.2 Scores for Proper Names

In terms of the proper names suite, place names prove to be much more difficult for the submitted models than people's names. It is the submission by our own team which narrowly tops the list overall, ahead of ONLINE-A and Unbabel. The AMI submission also ranks highest when place names are considered in isolation, although it still gets fewer than half of all names correct. For given names, GPT-4 scores highest.

For this part of our test set, we report no manual evaluation. A cursory glance at the output, however, shows that our naive automatic scoring method still leaves quite a bit to be desired. A problem with testing for specific grammatical forms in each case is that the correct form can change depending on the sentence structure. As discussed in 3.2, we tried to control for this by keeping test sentences brief and unambiguous. Even so, we find there are examples of different phrasings than we expected in some translation outputs that call for a different grammatical form of a name than our scoring mechanism supposes, but can still be considered a decent translation.

This especially applies to the sentence form: X "cares for" Y. We assumed a correct translation into Icelandic would be: X "þykir vænt um" Y, where X would take the dative case and Y the accusative. The submitted systems, however, had many different ideas on how best to phrase this system, not all of them completely wrong.

We therefore recognize that our scoring system needs to be fine-tuned but nevertheless believe the very low scores are mainly a reflection of the difficulty of this task.

5 Conclusions and Future Work

Scores on both sets are relatively low, indicating that these particular categories continue to pose some problems for even state-of-the-art translation models and that there is considerable room for improvement.

Future work can explore further comparison of performance and fine-tuning of our automatic scoring methods. Given time, we could also have investigated whether more manual evaluation, ideally using more evaluators, would have resulted in different scores.

We also note that our test suite can be adapted with relative ease into other languages and hope that this allows for further work on other language directions.

Limitations

There are several judgment calls to be made when working with our chosen categories and many of the decisions we made in terms of selecting items to be translated, defining automatic metrics for 'right' and 'wrong' translations and manual evaluation can be argued for or against. We are aware that the choices we make could be indicative of potential biases of the authors and that a different team, perhaps with a different demographic makeup, might well have constructed the test set and evaluated the translations in a different way.

These necessary choices are perhaps most apparent in terms of our idioms set. Evaluation of linguistic acceptability of translations and correspondence of idiomatic phrases between languages is based on our intuition and we are aware that fluent speakers of English and Icelandic may disagree on some decisions. Another point to consider is the degree to which we want our test set to be prescriptive - as a simple search on the Internet can prove, there are multiple usages of common English idioms directly translated into Icelandic, e.g. on social media (Hilmisdóttir et al., 2023). Determining at what point to say this usage is no longer 'incorrect' is an interesting question of ethics and philosophy of language.

As for our set of proper names, there exists some speaker variation in how and when place names are translated into Icelandic, although we have tried to limit our set to fairly uncontroversial choices (see discussion in 3.2). The requirement of not translating English names into Icelandic is less cut and dried, as it may be appropriate for a machine translation model in some cases, e.g. in literary text or the discussion of royal or historical figures. It can also be noted that some of our English names are, in fact, given names in Iceland. This should not affect our results, however, as we allow for the inflection of a final -"a" into -"u" in female names like "Pamela" and in other cases, 'non-Icelandic' names typically remain completely unchanged in all grammatical cases.

Acknowledgments

We would like to thank the WMT24 test suite organizers for the assistance and communication while working on this submission and two anonymous reviewers for helpful feedback.

Abstract

We present METAMETRICS-MT, an innovative metric designed to evaluate machine translation (MT) tasks by aligning closely with human preferences through Bayesian optimization with Gaussian Processes. METAMETRICS-MT enhances existing MT metrics by optimizing their correlation with human judgments. Our experiments on the WMT24 metric shared task dataset demonstrate that METAMETRICS-MT outperforms all existing baselines, setting a new benchmark for state-of-the-art performance in the reference-based setting. Furthermore, it achieves comparable results to leading metrics in the reference-free setting, offering greater efficiency.

1 Introduction

Evaluating machine translation (MT) tasks is inherently complex, as no single metric can universally apply to all scenarios. A metric that performs well for one task may not be suitable for another, and its effectiveness can vary significantly depending on the specific language pairs involved. Therefore, relying solely on a single metric is often inadequate. To ensure the usefulness of automatic metrics, it is crucial to align them with human annotations (Winata et al., 2024b). To achieve a more comprehensive evaluation, benchmarks typically incorporate multiple metrics, such as lexical-based and semantic-based metrics. However, the correlation between these metrics can be skewed due to variations in the models used and the training data employed for evaluation. For instance, BERTScore (Zhang et al., 2019) uses contextual embeddings from pre-trained transformers to assess performance, with different models excelling in specific language pairs. In contrast, neural-based metrics like BLEURT (Sellam et al., 2020), COMET (Rei et al., 2020), and CometKiwi (Rei et al., 2022) employ distinct methodologies and training datasets. These differences can affect each metric's alignment with human judgments and their reliability across language pairs. Some metrics, like XCOMET-Ensemble (Guerreiro et al., 2023), demand high memory (at least 80GB), prompting efforts to predict LLM performance using smaller models (Anugraha et al., 2024).

In this paper, we propose METAMETRICS-MT, a MT metric inspired by METAMETRICS (Winata et al., 2024a). This meta-metric is crafted to align more closely with human preferences through the use of Bayesian optimization with Gaussian Processes (GP). By systematically integrating multiple existing metrics, METAMETRICS-MT achieves state-of-the-art performance for reference-based metrics and shows a strong correlation with human scores for reference-free metrics in the WMT24 metric shared task (Freitag et al., 2024). Through the strategic combination of metrics with assigned weights, METAMETRICS-MT aims to be as competitive as, if not superior to, any individual metric. Our contributions include the following:

- We present METAMETRICS-MT in reference-based and reference-free settings, offering flexibility for various MT scenarios. Our reference-based model sets the state-of-the-art for the WMT24 task. We publicly release the code for easy usability.[1]
- We demonstrate that the METAMETRICS-MT metric is easily adjustable to meet the human preference.
- We show that METAMETRICS-MT is compact and efficient, capable of running on a commercial GPU with 40GB of memory, whereas a comparable metric like XCOMET-Ensemble requires significantly higher memory with at least 80GB.

2 Methodology

2.1 METAMETRICS-MT

METAMETRICS-MT is designed to leverage multiple metrics for assessing MT tasks, with each metric being adjusted by specific weights to optimize performance. The idea of utilizing multiple metrics is to combine scores from multiple metrics regardless of the metric types. Formally, let $\theta_1, \theta_2, \ldots, \theta_N$ represent N distinct metric functions with $\hat{y}_1, \ldots, \hat{y}_N$ as their respective performance on a translation task. We define Φ to compute a scalar meta-metric score of $\hat{y}_{\text{MM}}$ using $\hat{y}_1, \ldots, \hat{y}_N$. Overall, we define θ_{MM} as a meta-metric function where $\hat{y}_{\text{MM}}$ is computed as follows:

$$\hat{y}_i = \theta_i(x), \tag{1}$$

$$\hat{y}_{\text{MM}} = \theta_{\text{MM}}(x) = \Phi(\hat{y}_1, \cdots, \hat{y}_N). \tag{2}$$

Our objective is to calibrate a metric function, θ_{MM}, to maximize the correlation $\rho(\hat{y}_{\text{MM}}, \gamma)$, where ρ is a correlation measure and γ represents human assessment scores, which include any scores provided by human evaluators. Each metric operates within a specific range, defined by minimum and maximum values. However, some metrics, particularly those based on neural networks, may fall outside this range. To ensure consistency, we normalize these metrics to a common scale from 0 to 1, where 0 signifies poor translation performance and 1 signifies perfect translation performance. In this process, given an original score y_i for a given metric, $\tilde{y}_i$ represents the normalized score. For more details on pre-processing, please refer to Section A of the Appendix.

In this case, we use GP to model the function Φ and it can be breakdown into a weighted sum as follows:

$$y_{\text{MM}} = \alpha_1 \tilde{y_1} + \alpha_2 \tilde{y_2} + \ldots + \alpha_N \tilde{y_N}, \tag{3}$$

where $\alpha_1, \alpha_2, \ldots, \alpha_N$ are the corresponding weights assigned to each metric, constrained to the interval $[0, 1]$. Our objective is to determine the best set of weights for $\alpha_1, \alpha_2, \ldots, \alpha_N$, which maximizes $\rho(y_{\text{MM}}, \gamma)$. Notice that y_{MM} lies in the interval of $[0, N]$, so normalizing y_{MM} back to $[0, 1]$ is unnecessary as linear scaling does not affect the correlation coefficient for correlation function ρ.

The advantage of METAMETRICS-MT is its flexibility and adaptability across tasks and domains. By integrating metrics that strongly correlate with human judgments for specific tasks, we can create a composite metric that improves overall alignment with human evaluations.

Table 1: Metric configuration for METAMETRICS-MT. Metrics not listed in the table have been assigned a weight of zero.

2.2 Bayesian Optimization

We optimize the weights for each metric using Bayesian optimization with GP as the surrogate model. Bayesian optimization is particularly useful in this context because it efficiently explores and exploits the parameter space when the objective function is expensive to evaluate. By constructing a probabilistic model of the objective function, Bayesian optimization balances exploring new areas with exploiting known promising regions, making it effective even when evaluations are costly.

The GP constructs a joint probability distribution over the variables, assuming a multivariate Gaussian distribution. As the number of observations increases, the posterior distribution becomes more precise, enabling the algorithm to more effectively identify promising regions in the weight space. The Bayesian optimization process involves several iterations. First, the GP model is updated by fitting it to the observed data. Next, the algorithm selects the next set of weights by maximizing the acquisition function, which uses the posterior distribution to choose the next sample from the search space. Finally, the objective function is evaluated at these weights. This iterative process continues until a convergence criterion is met, ensuring that the optimization effectively identifies the optimal weights for the metrics.

2.3 METAMETRICS-MT Settings

2.3.1 Hybrid Mode

In the WMT24 shared task dataset, we observe that some samples lack references in the challenge sets, even for reference-based metrics. To address this issue, we implement a hybrid mode that switches from reference-based to reference-free metrics when reference data is unavailable.

2.3.2 Same Language Optimization

During the optimization process, we train a dedicated model for each known language pair in the training set to ensure optimal performance. If a language pair is not present in the training set, we use the entire dataset for tuning.

3 Experimental Setup

3.1 Training Datasets and Hyper-parameters

We introduce two versions of METAMETRICS-MT to accommodate both reference-based and reference-free evaluations: METAMETRICS-MT, which employs reference-based metrics, and METAMETRICS-MT-QE, which utilizes reference-free metrics. We train METAMETRICS-MT and METAMETRICS-MT-QE using 3 years of MQM datasets from the WMT shared tasks spanning 2020 to 2022 (Mathur et al., 2020; Freitag et al., 2021, 2022). The dataset used for tuning is at the segment level, with Kendall's τ correlation as the evaluation metric. For the Bayesian optimization, we run GP with a Matérn kernel (Williams and Rasmussen, 2006), a generalization of the RBF kernel, using $\nu = 2.5$. The optimization is performed over 100 steps, starting with 5 initialization points.

3.2 Metrics for METAMETRICS-MT

We describe the reference-based metrics utilized for METAMETRICS-MT. During the selection process, we included only metrics that can run on a commercial GPU with 40GB of memory. Consequently, XCOMET-XXL and CometKiwi-XXL were not considered. Additionally, we limited the use of the OpenAI API to `GPT4o-mini`, which is significantly more cost-effective than other GPT-4 model options.

3.2.1 Reference-based Metric

We utilize nine different metrics in our optimization, including three variations of MetricX-23 and two different BERTScore metrics using precision and F1. The metrics under study are as follows:

BERTScore (Zhang et al., 2019) The metric calculates cosine similarity scores for each token in the candidate sentences against each token in the reference sentences, using contextual embeddings derived from pre-trained BERT-based models. From these similarities, BERTScore computes precision, recall, and F1 scores. In our metrics, we utilize the precision and F1 scores, employing DeBERTa-XL-MNLI (He et al., 2020) as our model, as recommended by the authors.

YISI-1 (Lo, 2019) The metric computes the semantic similarity between translations from MT and human references by aggregating lexical semantic similarities, which are weighted by inverse document frequency (IDF) based on the contextual embeddings extracted from pre-trained language model, specifically the last hidden layer of mBERT in our case.

BLEURT (Sellam et al., 2020) The metric is fine-tuned using Direct Assessment (DA) dataset. BLEURT jointly encodes the translation and reference using the `[CLS]` token as an embedding to represent the pair. We employ the BLEURT-20 checkpoint (Pu et al., 2021), which was trained on RemBERT (Chung et al., 2020) using DA data from prior shared tasks between 2015 and 2019 and augmented with synthetic data generated from Wikipedia articles.

COMET-22 (Rei et al., 2022) The metric is an ensemble of COMET estimator (Rei et al., 2020) fine-tuned on DA and a Sequence Tagger trained on Multidimensional Quality Metrics (MQM) annotations. We utilize the `wmt22-comet-da` as our COMET-22 checkpoint, in which the COMET Estimator model and the sequence tagging model are trained on top of XLM-R using DA from 2017 to 2020 and InfoXLM (Chi et al., 2021), respectively.

XCOMET-XL (Guerreiro et al., 2023) The metric that performs both sentence-level evaluation and error span detection, making it a more interpretable learned metric. The model utilizes XLM-R XL (3.5B) (Goyal et al., 2021) which is trained in stages, starting with DA annotations and then fine-tuned on MQM data.

MetricX-23 (Juraska et al., 2023) The metric uses mT5 encoder-decoder language model. We leverage three different variations of MetricX-23, each fine-tuned from the mT5-Large, mT5-XL, and mT5-XXL respectively. The fine-tuning was performed using DA data from 2015-2020, MQM data from 2020-2021, and synthetic data.

3.2.2 Reference-free Metric

We utilize six different metrics in our optimization, including two variations of CometKiwi and

Table 2: WMT24 results (MQM). **Bold** and underline values indicate the best and second best performance, respectively.

three variations of MetricX-23. We describe the reference-free metrics used for MetaMetrics-MT-QE as follows:

CometKiwi (Rei et al., 2022) The metric is a reference-free learned metric fine-tuned on DA on top of RemBERT (Chung et al., 2020) and the same sequence tagger as COMET-22. However, it operates with reference-less inputs during inference. We use two distinct metrics from CometKiwi, each associated with its own separate checkpoint: `wmt22-cometkiwi-da` and `wmt23-cometkiwi-da-xl`. The latter checkpoint replaces InfoXLM with XLM-R XL (3.5B) and is trained on the same dataset, but it also includes newly released DA for Indian languages, which were added as additional training data for the 2023 Quality Estimation (QE) shared task.

GEMBA-MQM (Kocmi and Federmann, 2023) The metric is a GPT-based evaluation metric designed for error quality span marking. It employs a three-shot prompting approach using the GPT-4 model, specifically GPT-4o mini in our case.

MetricX-23-QE (Juraska et al., 2023) The metric is a reference-free learned metric similar to MetricX-23. We also utilize three different variations, each fine-tuned from the mT5-L, mT5-XL, and mT5-XXL checkpoints, respectively.

4 Results and Discussion

4.1 Optimized Metric Configuration

Table 1 shows the weight proportion of each metric for MetaMetrics-MT. The optimized configuration is notably sparse. When a metric does not positively contribute to improving performance, the GP assigns it a weight of zero. This is supported by Figure 1, where the GP selects metrics with high Kendall correlation coefficients relative to other provided metrics. In contrast, metrics with low Kendall correlation coefficients are excluded.

Table 4: Detailed WMT24 results for segment-level and system-level. **Bold** and underline values indicate the best and second best performance, respectively.

Interestingly, in both reference-based and reference-free settings, the optimization process consistently selects only one variant of MetricX-23, specifically MetricX-23-XXL, even though all three variants of MetricX-23 exhibit high Kendall correlation coefficients. The optimization process favors MetricX-23-XXL as the highest-performing metric, leading to the exclusion of the other two variants during the GP assignment. This enhances the efficiency of MetaMetrics-MT as we would only need to use fewer metrics for MetaMetrics-MT. Thus, given a set of metrics, the optimization process would prioritize high-performing metrics, such as the MetricX-23 and COMET variants as shown, leading MetaMetrics-MT and MetaMetrics-MT-QE to construct a better and more robust metric.

4.2 Results on WMT24 Shared Task

Table 2 presents the WMT24 shared task results, including system-level soft pairwise ranking accuracy (sys SPA) proposed by Thompson et al. (2024), segment-level pairwise ranking accuracy with tie calibration (seg acc-t) as described by Deutsch et al. (2023), and system- and segment-level Pearson correlation (avg. corr), as outlined in the WMT23 Metrics Shared Task (Freitag et al., 2023). Based on the overall system and segment average correlation and system accuracy, MetaMetrics-MT outperforms all metrics in the primary submission, with MetaMetrics-MT (Hybrid) achieving the highest performance among its variants.

Table 3 further highlights the performance, where MetaMetrics-MT delivers superior results for en-es, while also maintaining strong performance in en-de and ja-zh, indicating that our methods generalize well across different language pairs. The breakdown in Table 4 shows that MetaMetrics-MT achieves the best segment-level performance, consistent with our optimization approach targeting Kendall correlation at the segment level. Given that our metric optimization

Figure 1: Heatmaps showing Kendall correlation coefficients between human scores and MT metrics over 3 years of MQM datasets from the WMT shared tasks (2020-2022). Panel (a) displays correlations for the metrics used in METAMETRICS-MT, while panel (b) displays correlations for the metrics used in METAMETRICS-MT-QE.

focuses solely on segment-level correlation, incorporating a different weighting method to account for system-level settings could further improve METAMETRICS-MT's alignment with system-level accuracy. While METAMETRICS-MT-QE does not match the performance of gemba_esa, MetricX-24-QE (Hybrid), or CometKiwi-XXL, it remains competitive at the segment level for the en-es language pair. Incorporating better reference-free models such as CometKiwi-XXL and GEMBA-MQM with GPT-4o instead of GPT-4o mini may help improve the performance of METAMETRICS-MT-QE.

4.3 Compute Efficiency

We only run models that can be executed on GPUs with 40GB of memory. We limit our resource usage to GPT-4o mini, a smaller and lower-performing version of GPT-4o, while GEMBA-MQM is a GPT-4 based metric. This constraint restricts our ability to achieve state-of-the-art results or surpass GEMBA-based metrics using GPT-4. However, we demonstrate that even without employing high-memory models like XCOMET-Ensemble in our reference-based setting, we can still outperform other models. Additionally, our QE metric remains competitive and on par with XCOMET-QE.

5 Conclusion

In this paper, we propose METAMETRICS-MT, a novel metric designed to evaluate MT tasks by aligning with human preferences through Bayesian optimization with GP. METAMETRICS-MT effectively combines and optimizes existing MT metrics based on human feedback, resulting in a highly flexible and efficient evaluation tool. Our findings show that METAMETRICS-MT surpasses existing baselines for reference-based metrics, establishing a new state-of-the-art, while its reference-free metric performance rivals the best models available. Additionally, METAMETRICS-MT can be tailored to various factors, such as performance and efficiency, making it adaptable to diverse requirements.

Ethical Considerations

Our research focuses on evaluating MT systems using a newly proposed metric. We are committed to conducting our evaluations with the highest levels of transparency and fairness. By prioritizing these principles, we aim to set a standard for reliability and objectivity in the assessment of the system.

Limitations

We optimize METAMETRICS-MT using segment-level scores from the MQM dataset. Future work could extend this to other objective functions or system-level optimization and explore non-MQM datasets like DA for further insights. We did not include metrics such as XCOMET-XXL, XCOMET-Ensemble, and XCOMET-QE-Ensemble due to computational constraints.

A Pre-processing

The pre-processing can be defined as follows:

1. **Clipping:** Let the valid range for y_i be defined by $[y_i^{\text{min}}, y_i^{\text{max}}]$. The clipped metric score y_i' can be defined as:

$$y_i' = \begin{cases} y_i^{\text{min}} & \text{if } y_i < y_i^{\text{min}}, \\ y_i & \text{if } y_i^{\text{min}} \leq y_i \leq y_i^{\text{max}}, \\ y_i^{\text{max}} & \text{if } y_i > y_i^{\text{max}}. \end{cases} \quad (4)$$

2. **Normalization:** After clipping, the score is normalized to a common scale of $[0, 1]$:

$$\tilde{y}_i = \frac{y_i' - y_i^{\text{min}}}{y_i^{\text{max}} - y_i^{\text{min}}}. \quad (5)$$

3. **Inversion (if applicable):** If the metric is such that higher scores indicate worse performance, we invert the normalized score:

$$\tilde{y}_i = 1 - \tilde{y}_i. \quad (6)$$

B Additional Results

We provide additional details for the results of WMT24 for each task in Tables 5, 6, and 7. Additional results for each domain are also provided in Table 8.

chrF-S: Semantics is All You Need

Ananya Mukherjee, Manish Shrivastava

ananya.mukherjee@research.iiit.ac.in
m.shrivastava@iiit.ac.in

Abstract

Machine translation (MT) evaluation metrics like BLEU and chrF++ are widely used reference-based metrics that do not require training and are language-independent. However, these metrics primarily focus on n-gram matching and often overlook semantic depth and contextual understanding. To address this gap, we introduce chrF-S (Semantic chrF++), an enhanced metric that integrates sentence embeddings to evaluate translation quality more comprehensively. By combining traditional character and word n-gram analysis with semantic information derived from embeddings, chrF-S captures both syntactic accuracy and sentence-level semantics. This paper presents our contributions to the WMT24 shared metrics task, showcasing our participation and the development of chrF-S. We also demonstrate that, according to preliminary results on the leaderboard, our metric performs on par with other supervised and LLM-based metrics. By merging semantic insights with n-gram precision, chrF-S offers a significant enhancement in the assessment of machine-generated translations, advancing the field of MT evaluation. Our code and data will be made available at https://github.com/AnanyaCoder/chrF-S.

1 Introduction

In the rapidly advancing field of machine translation (MT), the need for robust and nuanced evaluation metrics has become increasingly critical. The evaluation landscape has expanded significantly in recent years, as evidenced by the WMT Metrics Shared Task, which provides a platform for meta-evaluating these metrics. Notably, in recent iterations of the WMT Metrics Shared Task, apart from learned metrics, lexical-based metrics such as BLEU (Papineni et al., 2002) and chrF (Popović, 2015, 2017) have consistently been regarded as baselines.

These metrics are widely appreciated for their language independence, which require no training and can be applied across diverse languages. However, they primarily address syntactic accuracy and often fall short in capturing the deeper semantic nuances and contextual relevance of translations.

The BLEU metric, with its reliance on modified precision of n-grams, provides a useful measure of how closely a machine-generated translation aligns with reference translations. Similarly, chrF enhances evaluation by incorporating character-level n-grams, offering greater sensitivity to morphological variations.

Despite these advancements, both metrics primarily focus on surface-level features, which can lead to incomplete assessments of translation quality, especially in complex linguistic contexts. To address these limitations, we propose **chrF-S** (Semantic chrF), an extension to the chrF++ metric, which leverages sentence embeddings to provide a more comprehensive evaluation by incorporating semantic analysis alongside traditional n-gram matching. Sentence embeddings (Reimers and Gurevych, 2019, 2020) encode entire sentences, thereby capturing the relationships between words, the structure of the sentence, and the broader contextual meaning. These offer rich semantic representations of sentences, enabling a deeper understanding of meaning and context. By merging these embeddings with chrF++'s character and word n-gram analysis, chrF-S aims to capture both the syntactic and semantic dimensions of translation quality.

This paper details our contributions to the WMT24 shared metrics task, where we have applied chrF-S to evaluate its effectiveness in comparison with existing metrics. We present our methodology of integrating semantic analysis into the chrF framework and discuss the preliminary results from the leaderboard, which indicate that chrF-S performs competitively with other super-

Proceedings of the Ninth Conference on Machine Translation, pages 470–474
November 15-16, 2024 ©2024 Association for Computational Linguistics

vised and LLM-based metrics. Our findings suggest that chrF-S not only enhances the evaluation of translation quality by incorporating semantic understanding but also provides a significant advancement over traditional metrics.

2 chrF-S

The main idea behind chrF-S is to have a combination of character-level match, word-level match and sentence-level match to provide a more comprehensive evaluation of translation quality. While chrF++ (Popović, 2015, 2017) already accounts for character and word-level matches, we enhanced this metric by introducing a sentence-level matching component. **We achieved this by adding a sentence-level component that utilizes sentence embeddings to compute a cosine similarity score, representing the semantic closeness between the reference and translation**. This flow is clearly illustrated in the figure 1. This approach allows chrF-S to assess not only the surface-level accuracy of the translation but also its deeper semantic fidelity, making it a more robust and nuanced evaluation metric.

For our experiments, we employed the LaBSE (Feng et al., 2022) model to generate these sentence embeddings. The ChrF-S score is computed as per equation 2

chrF-S(ref, hyp) = $\alpha \cdot chrF++(ref, hyp) + (1-\alpha) \cdot CosSim\left(embed(ref), embed(hyp)\right)$

In this equation, ref refers to the reference sentence, and hyp is the hypothesis (translation) sentence. $chrF++(ref, hyp)$ denotes the character- and word-level similarity from ChrF++. The function $embed$ represents the sentence embeddings, which are generated using a sentence embedding model[1]. $CosSim$ computes the cosine similarity between the sentence embeddings. Finally, α is the weighting factor used to balance these two components; in our experiments, we set $\alpha = 2$.

3 Experiments

In our experiments, we considered two datasets released by WMT i.e., Direct Assessments (Bojar et al., 2017, 2018; Barrault et al., 2019, 2020; Akhbardeh et al., 2021; Kocmi et al., 2022) from 2017-2022 and MQM (Freitag et al., 2021a,b, 2022) assessments from 2020-2022. As the data is heavily skewed towards west-germanic languages.

Table 3: Pearson Correlation scores on five different test sets curated from WMT-DA (17-22) data

[1] In this case, we used LaBSE

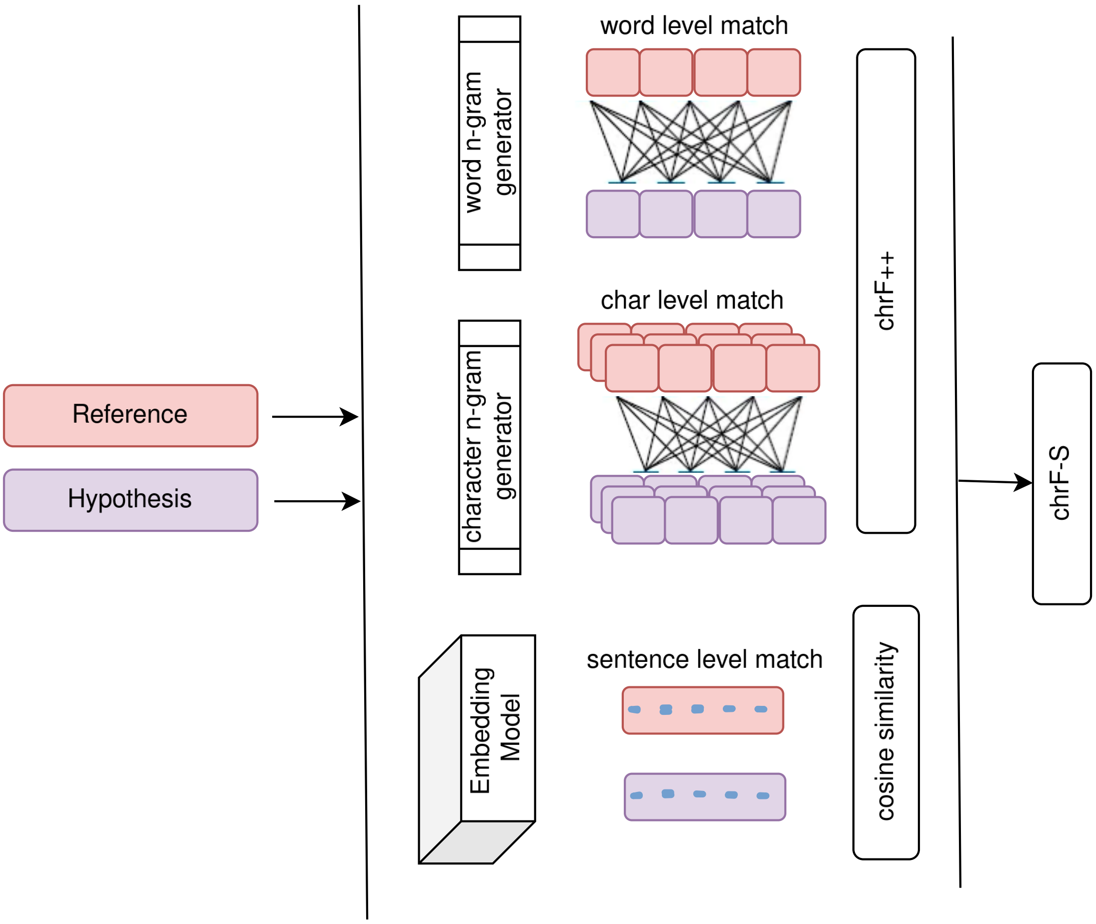

Figure 1: chrF-S Metric

We created five sub testsets[2] of different sizes having a fair distribution of sentences across all language pairs. We evaluated these five testsets (A, B, C, D, E) using **unsupervised reference based metrics:** BLEU, chrF++, BERTScore and chrF-S and further computed pearson (Kurtz and Mayo, 1979) correlation to compare the metrics in terms of their agreement with human judgements.

3.1 Evaluation

Table 2 reports the correlation scores of the metrics with MQM assessments on the testsets built from WMT-MQM (20-22) data. Similarly Table 3 displays the correlation scores of the metrics with direct assessments on the testsets created from WMT-DA (17-22) data. In both the tables, it is clearly evident that chrF-S has performed better. We notice that the correlation scores of chrF-S in WMT-DA testset is slightly less (<0.4), however when compared to other metrics it still stands as winner.

By incorporating sentence-level embeddings, chrF-S enhances its ability to evaluate the semantic closeness between the reference and translation, leading to better alignment with human judgments that prioritize meaning and context. This semantic dimension improves correlation scores with human assessments, making chrF-S a more accurate and reliable metric, especially when translations **differ lexically but are semantically equivalent**.

4 WMT24 Metrics Shared Task Participation

We have participated in the WMT24 Metric Shared Task by submitting the translation scores for official evaluation (en-de, en-es, ja-zh) and secondary evaluation (for all langauge pairs from the generalMT task). The test-set statistics are reported in Table 1.

The preliminary leaderboard for the official language pairs is released by the shared task is reported at Table 4, displaying the system-level Pearson correlations and segment-level Kendall Tau correlations of of en-de, en-es and ja-zh language

[2] code and testsets will be released

8	chrF-S	**0.97**	**0.51**	**0.99**	**0.5**	**0.97**	**0.56**
12	MetricsTaskBaseline	0.95	0.45	0.92	0.46	0.5	0.17

Table 4: WMT24 Prelimnary Leaderboard reporting system-level and segment-level correlations. Our metric correlations are highlighted in bold.

pairs. It is noteworthy that chrF-S has not only surpassed the baseline but also demonstrated performance on par with GEMBA, an LLM-based metric. When compared to other preceding supervised metrics, chrF-S, an unsupervised metric proves to be competitive, standing alongside other top performers in the field.

5 Conclusion

This paper contributes to the WMT24 metrics shared task by introducing chrF-S, an enhanced version of chrF++ that incorporates sentence-level semantics for more accurate MT evaluation. Our metric effectively captures both surface accuracy and deeper semantic meaning by integrating character-level, word-level, and sentence-level matching. The use of sentence embeddings enables chrF-S to better assess semantic closeness between translations and references, leading to improved correlation with human judgments such as MQM and direct assessments. Preliminary leaderboard results indicate that chrF-S is competitive with other leading metrics, underscoring its potential as a reliable and nuanced tool for evaluating translation quality.

Limitations

One significant limitation of this approach is its dependency on embedding models for sentence embeddings. The effectiveness of this method is restricted to languages for which appropriate sentence embedding models are available.

MSLC24: Further Challenges for Metrics on a Wide Landscape of Translation Quality

Rebecca Knowles **Samuel Larkin** **Chi-kiu Lo 羅致翹**

National Research Council Canada (NRC-CNRC)
{rebecca.knowles,samuel.larkin,chikiu.lo}@nrc-cnrc.gc.ca

Abstract

In this second edition of the Metric Score Landscape Challenge (MSLC), we examine how automatic metrics for machine translation perform on a wide variety of machine translation output, ranging from very low quality systems to the types of high-quality systems submitted to the General MT shared task at WMT. We also explore metric results on specific types of data, such as empty strings, wrong- or mixed-language text, and more. We raise several alarms about inconsistencies in metric scores, some of which can be resolved by increasingly explicit instructions for metric use, while others highlight technical flaws.

1 Introduction

This work builds on Lo et al. (2023), which introduced the Metric Score Landscape Challenge (MSLC).[1] At the Conference on Machine Translation (WMT), the Metrics Shared Task typically focuses on high-performing machine translation (MT) systems, in order to determine which new and improved metrics provide the most accurate and reliable scores (via comparison to human evaluation). However, the goal is for these metrics to go on to be used more broadly, which will likely result in their use on a wider range of systems. Since the Metrics Task primarily focuses on high-performing MT systems and their human evaluations, there is a risk that the new knowledge generated by the task about metrics may not generalize to lower-quality MT. For this reason, we submit a challenge set that covers a wider range of MT quality, in order to give potential users as well as metrics researchers a view of a broader range of performance. We also consider specific phenomena that may result in unexpected results from some metrics. We focus on three language pairs:English→Spanish (`eng`→`spa`), English→German (`eng`→`deu`), and Japanese→Chinese (`jpn`→`zho`).

2 Data

We divide this MSLC into two subsets: the first challenge set (MSLC-A) follows the approach set out in MSLC23, merging together our low- to mid-quality systems with the systems submitted to the General MT shared task, while the second challenge set focuses on specific phenomena (MSLC-B; developed based on notable results from 2023 and new aspects of this year's General MT Task).

2.1 MSLC-A: News Data

We focus only on the "news" subset of the WMT General Task test set, as this better matches the domain of our trained MSLC systems and because of concerns with some of the other domains. All figures and values for MSLC-A will be shown over the subset of the "news" data that was manually evaluated with MQM (Multidimensional Quality Metrics; Lommel et al., 2013) by the Metrics Shared Task unless otherwise noted.

The MSLC-A systems we evaluate are a range of low- to medium-quality sets of MT output for the three identified language pairs.

The MT models we build for MSLC24 are all constrained (as per the WMT General Task rules) models, built using standard WMT training data (or subsets thereof), without the application of common additional techniques like backtranslation or tagging. We train all NMT models using Sockeye version `3.1.31` (Hieber et al., 2022), commit `13c63be5` with PyTorch `1.13.1` (Paszke et al., 2019).

The English→German systems are the same ones described in Lo et al. (2023); we direct the reader to that work for more details. The English→Spanish and Japanese→Chinese systems are described in more detail in Larkin et al. (2024). We use checkpoints from training the systems as

[1] MSLC data and additional figures can be found at https://github.com/nrc-cnrc/MSLC.

Proceedings of the Ninth Conference on Machine Translation, pages 475–491
November 15-16, 2024 ©2024 Association for Computational Linguistics

representative of varying levels of quality. The levels of quality are manually checked by authors familiar with the relevant target languages on a small sample of the data. We list the checkpoints used for the systems in Appendix A. The lowest-quality systems are indicated with the letter A, and the quality approximately increases as the system labels proceed alphabetically.

2.2 MSLC-B: Specific Phenomena

We target three specific phenomena in the MSLC-B challenge set: empty strings, mixed- and wrong-language text, and language variants. In addition to this, across these, we consider an overarching theme of consistency. We begin by describing and justifying our study of these phenomena and the topic of consistency.

Lo et al. (2023) observed unusual performance around empty strings (which appeared due to a submitted system's output in 2023). This may, at first glance, seem like a trivial and uninteresting issue. We argue that it is worth exploring, for three primary reasons: it is a real scenario that we observe in the WMT submissions and in more general MT (empty strings *do* appear in output and sometimes even input or references), it is important to know how metrics handle the empty string (as different metrics take different approaches to handling empty strings), and because of the question of consistency (some metrics may score empty strings in internally-inconsistent or surprising ways). It would be simple for all implementations of metrics to treat empty strings (in the source, reference, or hypothesis) as an edge case to be handled separately; in practice this is not what we observe, so it is important for users of metrics to be aware of how metrics may perform in these cases.

We also consider questions of how metrics perform when the MT output is mixed-language or wrong-language text. This is a situation that can arise, for example, due to noise in training data.

In a similar vein, since the General MT Task specified translation into Latin American Spanish, we build a very small test set of terms that differ between variants of Spanish spoken in Latin America and in Spain. For example, the word *computer* may commonly be translated as *ordenador* in Spain but *computadora* in Latin America. We use this to examine how metrics, particularly reference-free metrics, score translations from different language variants. This is a very small-scale study, but our results indicate that this is an area that should be considered for future work.

We now describe how we build this portion of the challenge set in order to study these issues.

2.2.1 English→German and English→Spanish

Here we produce a small data set to explore these issues more closely. We begin by selecting data that will be used repeatedly:

- 10 segments (paragraphs and sentences) from the English language source (WMT news data) with their Spanish and German[2] reference translations

- 10 short phrases in English with reference translations (confirmed via wikipedia, Linguee, and WordReference)[3]

- 10 words in English with reference translations

- 10 punctuation marks or other characters

Taking all of these, we consider the following situations: empty source and reference paired with the reference segments described above (simulating an MT system generating fluent text after empty string input) and empty string hypothesis paired with the known source and reference (simulating an MT system outputting the empty string).

Using only the segment (paragraph or sentence length) portion, we also consider the situation where the output is fluent but in the wrong-language by pairing the source with the correct reference but the opposite language hypothesis (e.g., English source, Spanish reference, German reference used as hypothesis). We also consider a mixed-language hypothesis, manually produced by substituting substrings of the Spanish reference with substrings from the German `refB` reference.[4] For German, because we have access to `refB`, we also submit a version with English source, `refA` as the reference, and `refB` as the hypothesis; this permits a full range from incorrect language to

[2] For the German references we use `refA`.

[3] https://en.wikipedia.org/, https://www.linguee.com/, https://www.wordreference.com/

[4] This was done in such a way to maintain (approximate) fluency and adequacy, such that a reader familiar with both German and Spanish should still be able to understand the text. We would urge caution, however, in assuming that any results from this part of the test set would extend to more natural code-mixing.

Source	Last year, the World Economic Forum forecast that it would take five generations to achieve gender equality in every nation. Now the World Bank wants to rapidly accelerate that time frame.
Reference	Im vergangenen Jahr hat das Weltwirtschaftsforum vorausgesagt, es würde fünf Generationen dauern, bis in allen Staaten Geschlechtergleichstellung herrsche. Die Weltbank hat sich nun zum Ziel gesetzt, diesen Zeitraum deutlich zu verkürzen.
`refB`	Im vergangenen Jahr prognostizierte das Weltwirtschaftsforum, dass es fünf Generationen dauern werde, die Gleichstellung der Geschlechter in jeder Nation zu erzielen. Jetzt möchte die Weltbank diesen Zeitrahmen erheblich verkürzen.
Mixed-Lang.	*El año pasado,* prognostizierte das Weltwirtschaftsforum *que harían falta cinco* Generationen *para lograr la igualdad de género* in jeder Nation. Jetzt möchte die Weltbank *acelerar ese plazo rápidamente.*
Wrong Lang.	El año pasado, el Foro Económico Mundial pronosticó que harían falta cinco generaciones para lograr la igualdad de género en todas las naciones. Ahora, el Banco Mundial quiere acelerar ese plazo rápidamente.

Table 1: Example of wrong-language, mixed-language (Spanish shown in italics), and `refB` (correct language alternate human reference) as hypotheses in the English→German MSLC-B dataset.

mixed-language to matched language (but different human translation). We show an example of this in Table 1.

For Spanish, since the WMT General MT Task explicitly describes this translation task as "EN to Spanish (Latin America)", we provide a very small sample (8 words) of words that tend to have differing translations between varieties of Spanish spoken in Latin America and varieties of Spanish spoken in Spain. This has very limited coverage but may permit us to begin asking questions about whether quality estimation systems have tendencies or biases towards certain language varieties.

2.2.2 Japanese→Chinese

For Japanese→Chinese, we examine metrics' performance around empty strings by first selecting data that will be used repeatedly:

- 5 segments (paragraphs and sentences) from the Japanese language source with their Chinese reference translations
- 5 short phrases in Japanese with reference translations
- 5 words in Japanese with reference translations
- 5 punctuation marks in Japanese with reference translations

We consider the same two types of empty string situations as in the other language pairs. The empty strings challenge examples make up 40 items in the MSLC-B Japanese→Chinese test set.

Similarly to the other language pairs, we consider wrong-language output (an English translation of the Japanese source, produced as a human translation from the Chinese reference by one of the authors) and mixed-language output (substituting words or phrases in the Chinese reference with corresponding Japanese and English words or phrases); these make up 10 items in the MSLC-B Japanese→Chinese test set.

3 Metrics

There are dozens of metrics submitted by the task organizers and participants to the WMT24 Metrics Shared Task. Given time and space limitations, we only examine the baseline metrics submitted by the task organizers and the primary metrics submitted by the participants. We describe the metrics included in this work in Appendix B.

4 Results and Plots

We divide our examination of the results into the two parts of the challenge set: MSLC-A and MSLC-B.

4.1 MSLC-A

Here we present preliminary results for the MSLC-A subset of the challenge set. We begin with the segment level and then consider system-level results. We make use of the MQM results provided by the Metrics Task organizers.

4.1.1 Segment Level

The histograms along the diagonal of Figure 1 show the distributions of segment-level scores produced by a subset of the baselines and submitted primary metrics. We can see that different metrics exhibit very different score distributions. Some show a somewhat bimodal distribution of scores, others are closer to normally distributed. For the metrics that are closer to normally distributed, we also see different skews. Most metrics are left skewed (i.e., they more frequently give segment scores in the higher-end of their possible score range), while BLEU is right skewed and more frequently gives segment scores in the lower end of its possible score range.

Metrics also differ in whether they exhibit a strong separation between the segments produced by the low-quality systems from our challenge set and the segments produced by the WMT submissions or whether they assign a range of low to high scores to most systems (i.e., having clear overlap in score range across all systems). This variation in characteristics suggests that metrics may have different strengths and weaknesses across the translation quality landscape; not all metrics are equally appropriate for scoring high-quality and low-quality MT.

XCOMET gives very low scores to segments from the very low-quality systems, but uses much more of the score space for the mid-quality systems. On the low-quality side, this is somewhat similar to the distribution of *BLEU* scores, but the high-quality systems have *XCOMET* scores that are much higher due to *XCOMET*'s bimodal distribution. Meanwhile, *chrF* shows a fairly normal distribution, but with a clear distinction between the various MSLC systems. We can also see this reflected when we examine system-level scores.

There are also metrics that use an approximation of a discrete score space, such as *GEMBA-ESA*. Lo et al. (2023) noted several metrics that did this in 2023; *GEMBA-ESA* is the only one in this year's set that does.

4.1.2 System Level

To analyze system-level scores, we compute an average over all of the segment-level scores in the news domain for a given MT system. There are two reasons why we are using this segment average instead of the submitted system-level score: 1) not all metrics submitted system-level scores and 2) using averaged segment-level scores allow us to show a representation of uncertainty (computed with bootstrap resampling, 1000 times, for $p < 0.05$) for the metrics. These system-level scores can also be used in order to gain a better understanding of the overall range of a metric's scores, as well as what kind of scores are assigned to very low quality machine translation (e.g., the A and B systems from the challenge set).

Figure 2 shows the system average scores for a subset of English→German (see Appendix D.1 for other translation directions). We observe that metrics show different patterns of scores at the system level. Both *PrismRefMedium* and *PrismRefSmall* appear to have serious difficulties in accurately scoring the lowest-quality system and give it a score higher than some of the better (still low-quality) systems.[5] Some metrics, such as *GEMBA-ESA*, *XCOMET* and *XCOMET-QE*, give very close scores to all of the low-scoring systems. For a use case (e.g., a low-resource language) where one expects to have low- to medium-quality systems at least initially, one may want to choose a metric that provides clearer distinctions between various systems on the lower range of quality.

For the high-quality systems the string-based metrics, such as *BLEU* and *chrF*, show wider error bars and thus may not distinguish between them. We leave analysis of the high-quality systems to the Metrics Shared Task.

By having our top MSLC system evaluated alongside the submitted WMT systems, we are able to observe that for Japanese→Chinese our systems combined with the high-performing submitted WMT systems do cover the wide range of quality. For English→German and English→Spanish, however, there may be a "missing middle" gap in quality that is not covered, an issue we aim to address in future work.

4.1.3 Conclusions: MSLC-A

As we saw in Lo et al. (2023), metrics differ in how they use their available score space. Some make fairly full use of their score range, others discretize the score space, and yet others display bimodal distributions of scores. All of these impact how individual segments are scored as well as how the system-level scores are distributed (i.e., whether the system-level scores are distributed more uniformly over the score space from low quality to

[5] Though we only do small-scale informal human evaluation, we expect, e.g., system E should not be ranked below system A.

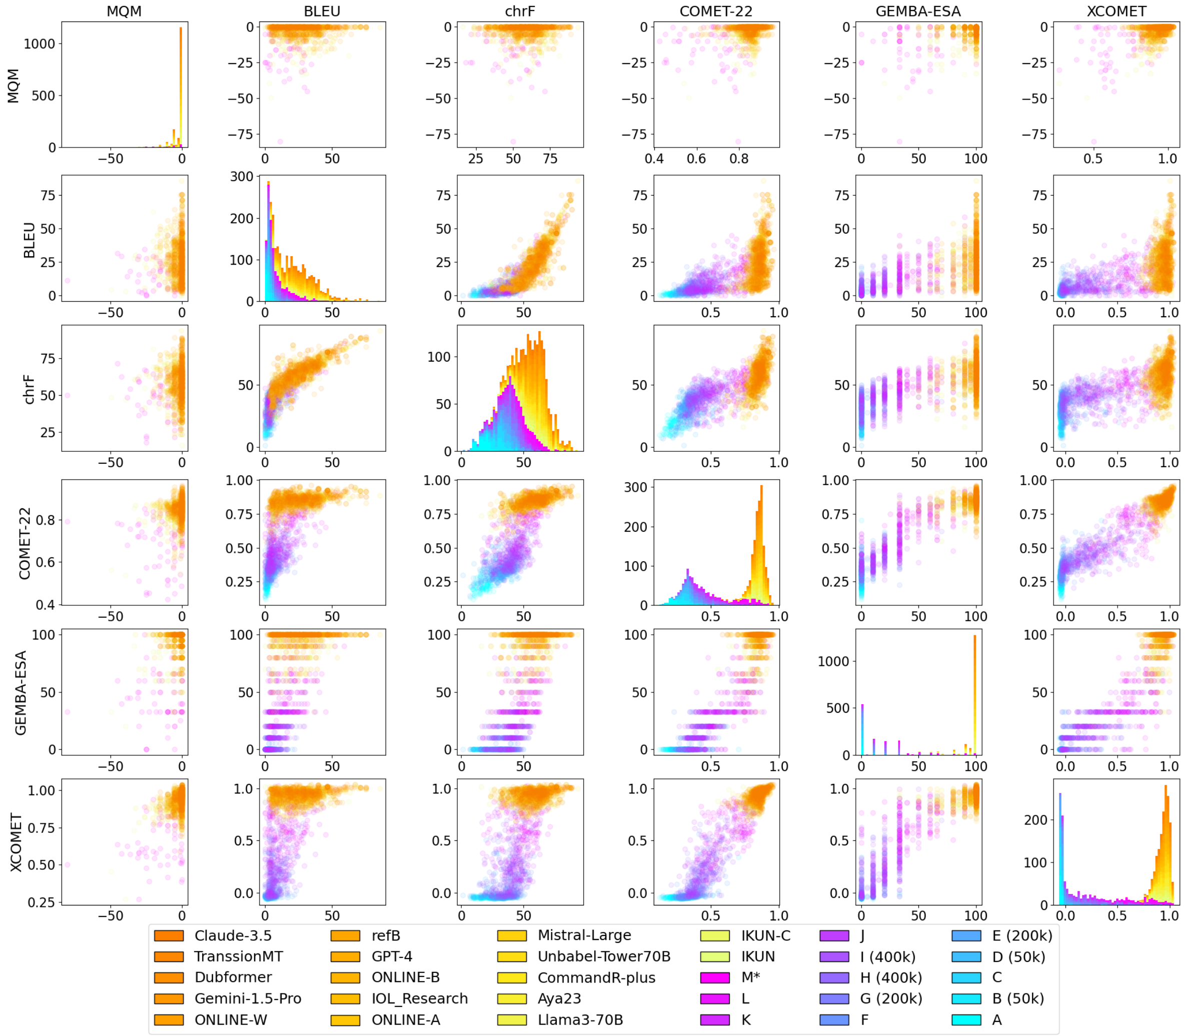

Figure 1: Matrix of segment-level scores for English→German. Along the diagonal are stacked histograms of segment scores across the challenge set (cool colours/bottom) and submitted WMT systems (warm colours/top). The off-diagonal entries are scatterplots where each point is a single segment positioned according to the score assigned to it by row and column metrics; each point is coloured according to the same colours as the histogram. Note: for a full, scalable version of this figure, see `https://github.com/nrc-cnrc/MSLC`; all other figures in this paper are scalable.

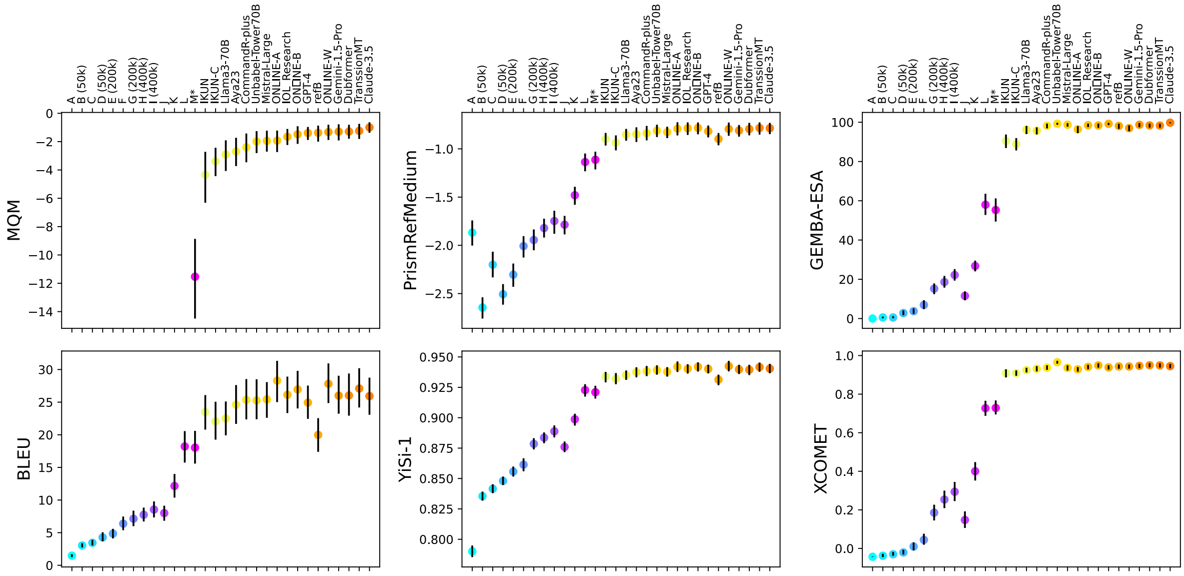

Figure 2: System average scores for English→German. MSLC systems (cool colours, left) are ordered by BLEU score and brief manual examination; WMT submitted systems are ranked by average MQM score.

high quality, or whether most systems are clustered near the low and high ends of the score space). This year we noted fewer extremely unusual distributions; we did not see a repeat of the "universal scores" results observed in Lo et al. (2023).

The MQM evaluation of our top-performing system helps us to get a better idea of how to interpret these scores, though we note the issue of the missing middle range of human scores in two out of our three language pairs. We also note a weakness of error-based evaluations: they may not always capture non-errors (e.g., ways of translating that are not incorrect, but may be dispreferred by translators or end-users).

In future work, we may wish to apply more formal human evaluation to our lower-scoring systems, to better clarify the full range, but this year's introduction of human scores for one system per language pair takes a step towards that goal.

4.2 MSLC-B: Empty Strings

In MSLC23 (Lo et al., 2023), we observed a variety of system scores on empty strings produced by one of the participating systems in the WMT task. Here, we expand on that in a controlled fashion, examining the scores that metrics output when scoring empty strings.

4.2.1 Empty Source and Reference

We begin with empty source and reference, paired with four different types of output: single punctuation characters (*punct*), single words (*word*), short phrases (*phrase*), and full sentences/short paragraphs (*sent*). All of the hypothesis text is in the target language, with the full sentences drawn from the WMT news data reference (`refA`, in the case of German). If these had been produced by an MT system taking an empty source and generating text, this might be considered a "hallucination"—generating fluent text that is not conditioned on any relevant source text. As such, we would expect that MT metrics should give these low scores. While some metrics (*BERTScore*, *BLEU*, *YiSi-1*, *chrF*, *spBLEU*, *mmm_qe*) do consistently give their lowest score (0) to all of these test segments, others show a greater variety of results.

Figure 3 shows a subset of the remaining metrics for English→German, covering a range of the variations in scores. Each subfigure shows the scores assigned to the 10 items in each category, with the vertical red lines indicating the lowest and highest scores assigned by this metric to any of the WMT news test data for any submitted MT system. *COMET-22* demonstrates the most common pattern: assigning a range of scores, with a tendency to have slightly higher scores for the shorter categories (e.g., punctuation—a single character has a very small edit distance to the empty string, perhaps making it more similar to the empty string than longer text) and lower scores to items in the longer categories (i.e., penalizing generating a full sentence out of nothing). *PrismRefMedium* and

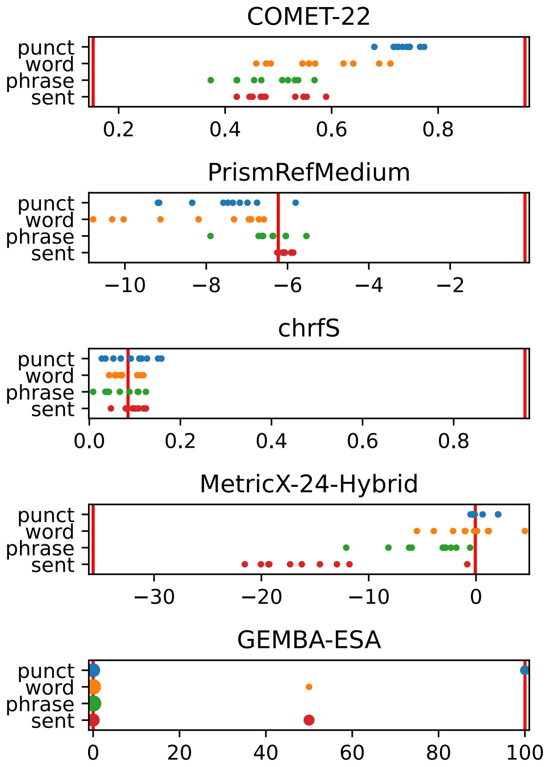

Figure 3: English→German scores assigned to text when paired with empty source and reference. Red vertical lines indicate the minimum and maximum scores assigned over all WMT News primary submission data.

chrfS show another common pattern, by assigning low scores to all items; this is more in line with the desired and anticipated performance on this set of data. We note that the scores from *chrfS* are quite clustered around the lowest scores assigned to the WMT news data, while *PrismRefMedium* has scores expanding into a much lower range than the range of scores it assigned to the news data in the WMT test set. *MetricX-24-Hybrid* shows concerning results on this test set, assigning scores *higher* than any assigned to the WMT news test data to some of the samples, particularly the punctuation (perhaps not entirely unreasonably, as MT systems may need to occasionally generate additional punctuation in the target language), but also in some word and phrase examples. Finally, *GEMBA-ESA* assigns its lowest score most of the time, but occasionally assigns a top score or a score exactly in the middle of the range, an unexpected inconsistency.

4.2.2 Empty Hypothesis

Next, we flip the empty strings to the output side and pair them with real sources and references for the four different types of text mentioned in the previous subsection. This is simulating the extreme case of omission where the complete output is missing. We understand that MT users may find it acceptable to omit translation for a single punctuation. As such, we again may expect that MT metrics would give gradually lower scores to the empty string output as the length of the source and reference increase. Similarly to the empty source and reference test cases, some metrics (*BERTScore*, *BLEU*, *YiSi-1*, *chrF*, *spBLEU*, *mmm_qe*) do consistently give their lowest score (0) to all of these test segments.

Figure 4 shows a subset of metrics for English→German, covering a range of the variations in scores. As we observe, *PrismRefMedium* and *chrfS* also give low scores (although not their lowest possible score) to empty string output. Some metrics (e.g. *COMET-22*) indeed give gradually lower scores to the empty string output according to the length of the input, with the items in the *sent* category receiving the low end of scores. We find that this is still relatively unsurprising behavior for metrics scoring empty string output. However, *MetricX-24-Hybrid* and *XCOMET* show concerning results on this test set, assigning mid-range to high scores to empty string output. Finally, as was the case in the empty source and reference test set, *GEMBA-ESA* assigns its lowest score most of the time, but occasionally assigns a top score to the empty string output.

4.2.3 Conclusions: Empty Strings

These empty string test cases (both empty source and reference and empty output) reveal undesirable metric results: giving high scores to extreme hallucination and omission. This leads us to be particularly concerned about the decision by the WMT General MT Task to use *MetricX-23-XL* and *CometKiwi-DA-XL* to decide which participating systems would receive human annotations, because related metrics (*MetricX-24-Hybrid* and *CometKiwi*) are two of the metrics showing these undesirable phenomena.

This may be an opening for a wider discussion about whether it is better for an MT system to fail to generate output than to generate output that is incorrect; nevertheless this would be a departure from past expectations (where, e.g., in human evaluation, “no translation” is typically given as a prototypical example of something that should receive a low score). In any case, we can likely find common ground in agreeing that metrics should not give

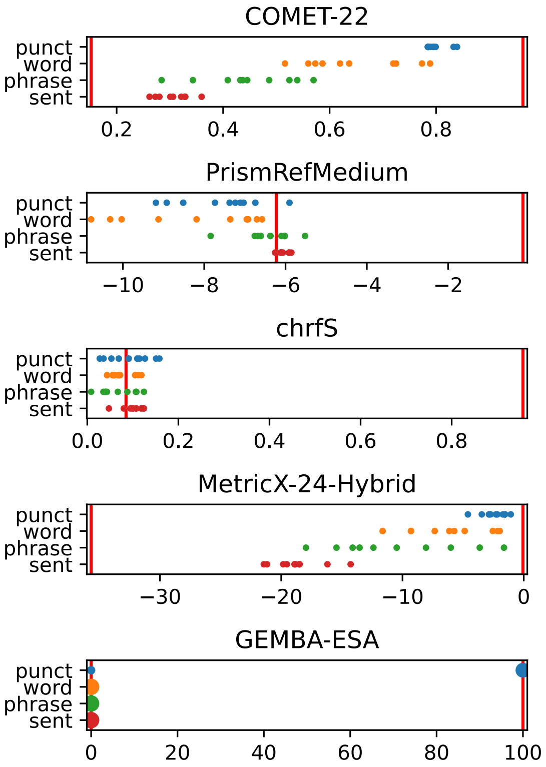

Figure 4: English→German scores assigned to the empty string paired with real source and reference.

high scores to non-empty output when given an empty input and empty reference. We would encourage a broader conversation about this, and in the meantime would encourage those presenting new metrics to be sure to specify how their metrics handle empty strings.

We encourage both metric builders and metric users to be aware of how metrics treat these edge cases. They do occur in practice and a user anticipating one type of performance on empty strings (e.g., low or 0 scores) may come to erroneous conclusions if they unknowingly use a metric that treats empty strings in another way (e.g., as high-scoring). We were also somewhat surprised to encounter the level of variation across empty string scores, and expect that users who are most familiar with string-matching metrics like BLEU may also not expect this variety of results.

4.3 MSLC-B: Mixed- or Wrong-Language

In this section, we explore what kind of output the metrics produce when they are applied to mixed-language and wrong-language translation hypotheses. We focus on English→German, because access to a second human-translated reference (`refB`), allows us to explore a range of translation hypotheses, from a good human translation (`refB`, in German), a mixed-language translation (composed of a mix of the text of `refB` and the human-translated Spanish reference), and a wrong-language translation (the Spanish language reference). Our small test set for this is composed of 10 English source sentences, along with the various translations described above. We would expect a well-performing and usable metric to assign high scores to the `refB` German translation, lower scores to the mixed-language translation (portions of which are correct German translations of words and phrases), and even lower scores for the Spanish translation (a fluent and accurate translation, but in the wrong language).

However, this is not precisely what we observe in Table 2. Most metrics do give a score to `refB` that is greater than or equal to the score given to the mixed-language text in all 10 examples, while others score it at or above the mixed-language the majority of the time (*mmm_qe* (9), *CometKiwi* (8), and *damonmonli* (6)). Only *XLsimMqm* scores the mixed-language text higher than `refB` in 8 out of 10 examples. When it comes to the wrong-language text, most metrics again score `refB` equal or higher all of the time, but others at least occasionally rank the wrong-language text above `refB`—reference-free metrics in particular tend to make some errors (with the exceptions of *GEMBA-ESA* and *MetricX-24-Hybrid-QE*), but the two *PrismRef** metrics also make these errors. When comparing the scores given to the mixed-language text and the wrong-language text, we see even more of a mix. Some systems (both *PrismRef** systems, *XLsimMqm*, *mmm_qe*, and *MetricX-24-Hybrid-QE*) never score the mixed-language text above the wrong-language text.

4.3.1 Conclusions: Mixed- and Wrong-Language

This varies somewhat between language pairs (see Appendix C), but string-based metrics like *BLEU* and *chrF* consistently score the mixed-language text above the wrong-language text. The weaknesses of string-based methods, such as their reliance on exact matches and lack of partial credit for synonyms (especially when evaluated against a single reference), have resulted in a shift towards embedding-based metrics that can provide more flexible semantic representations. However, given these results, it raises the question: are all modern

Metric	refB≥Mix	refB≥Wrong	Mix≥Wrong
BERTScore	10	10	8
BLEU	10	10	10
BLEURT-20	10	10	2
COMET-22	10	10	3
CometKiwi	8	4	1
PrismRefMedium	10	6	0
PrismRefSmall	10	7	0
YiSi-1	10	10	3
chrF	10	10	10
spBLEU	10	10	9
chrfS	10	10	10
MEE4	10	10	10
XLsimMqm	2	1	0
mmm_qe	9	6	0
mmm_hybrid	10	10	1
MetricX-24-Hybrid	10	10	2
MetricX-24-Hybrid-QE	10	10	0
GEMBA-ESA	10	10	10
XCOMET	10	10	1
XCOMET-QE	10	6	2
damonmonli	6	7	7

Table 2: `eng→deu`: Number of times (out of 10) that the metric scored `refB` higher than or equal to its mixed-language pair (refB≥Mix), higher than or equal to its wrong-language pair (refB≥Wrong), and a mixed-language hypothesis higher than or equal to its wrong-language pair (Mix≥Wrong).

metrics suitable for providing information about whether a text is a good translation *into the target language*, or simply whether it is a good translation (into some language(s))? We argue that these preliminary, small-scale results suggest the importance of additional analysis of this question. While this is unlikely to be a problem in many cases (especially when, e.g., language ID could also be performed), this may be particularly risky in low-resource settings where high-quality language ID is not available (cf. issues described in Kreutzer et al., 2022). In concurrent work, Zouhar et al. (2024) propose incorporating language ID to handle this issue as they explore it specifically in the context of *COMET*.

4.4 MSLC-B: Language Variants

The WMT General Task specifically called on researchers to build MT systems for English→Spanish using *Latin American* Spanish. We choose a small selection of terms that exhibit some of the vocabulary differences between the language variants of Spanish spoken in Latin America and Spain. We note several limitations to this: this is a very small set of terms, the terms are evaluated in isolation, and they are certainly not fully representative of all Spanish language variants spoken in Latin America or Spain.[6]

Due to the structure of the challenge set submission process, each source term was submitted four times: once for each language variant with the matching reference and once for each language variant with the opposite reference. Considering only the reference-free metrics (those that do not use the provided reference in order to compute their score), we observe results in Table 3. A checkmark(✓) indicates that in all cases for that term, the Latin American term chosen was scored higher than the term used more commonly in Spain; an ✗ indicates that the term used in Spain scored equal to or higher than the term used in Latin America. This somewhat arbitrary choice to include repeated versions was fortuitous, because it highlights a concern with one of the metrics: a question mark (**?**) in a cell indicates that the rankings computed were mixed. This means that, on repeated scoring, the variations within the metric scores returned were great enough (in the case of *MetricX-24-Hybrid-QE*) to result in different rankings at least once. This should be alarming to potential users of metrics, who would expect consistent results on repeated strings. That is: a user may reasonably expect that if they submit the same input to a metric twice in a row, they will get the same output twice in a row; here we observe that not all metrics have this as a guarantee. We discuss this more in Section 5. We note that other metrics also exhibited some variation in their scores, but the rest did not vary enough to change which of the two term variants received the higher score.

We now observe that *XLsimMqm* is the only metric to prefer the term used more commonly in Latin America more than half the time (5/8). We note that *GEMBA-ESA* only prefers the term from Latin America in 1/8 terms, but for the remaining 7 terms, both variants are given identical scores of 100 (*GEMBA-ESA* is the only metric whose counts would change, were we to score it as correct if a term used in Latin America scores *equal or greater than* the term used more commonly in Spain).

This raises similar questions to those we considered in the wrong-language and mixed-language experiments, albeit at a finer-grained level. Metrics may not be equally appropriate for use across all language variants, and may in fact demonstrate a scoring preference to one or the other. This will require considerably more experimentation, with larger test sets, in the future.

5 Consistency

Our experiments in MSLC-B highlighted some issues in metric score consistency: repeated instances of scoring the same string resulting in dif-

[6] In several of the cases presented here, there exist a number of other translations that we could have selected.

English source:	computer	sandwich	potato	juice	waiter	tires	peanut butter	drive	
Latin America:	computadora	sándwich	papa	jugo	mesero	llantas	mantequilla de maní	manejar	
Metric *Spain:*	ordenador	bocadillo	patata	zumo	camarero	neumáticos	crema de cacahuete	conducir	**Counts**
CometKiwi	✓	✓	✗	✓	✓	✗	✗	✗	4/8
XLsimMqm	✗	✓	✓	✓	✗	✗	✓	✓	5/8
mmm_qe	✓	✓	✗	✓	✗	✗	✓	✗	4/8
MetricX-24-Hybrid-QE	✗	✓	✓	✓	✗	✗	**?**	✓	4/8
GEMBA-ESA	✗	✓	✗	✗	✗	✗	✗	✗	1/8
XCOMET-QE	✓	✗	✗	✓	✗	✗	✗	✗	2/8

Table 3: Metric preferences for terms that are more common in Spanish language variants spoke in Latin America (✓), for terms more common to language variants spoken in Spain (✗), or inconsistent preferences (**?**).

ferent scores. The MSLC-B dataset provided only a small set of examples on which to test this, and only for reference-free metrics. However, because we submitted our highest-scoring MSLC MT systems to the WMT General MT task, we actually do have a larger set of data with which to explore repeated scores. This consists of the intersection between the MSLC-A data (news domain only) and the full General MT test set (149 segments for `eng`→`deu` and `eng`→`spa` and 269 for `jpn`→`zho`), each of which was scored by each metric as part of the MSLC-A challenge set and as a WMT submitted system.

It is important to highlight that, while the Metrics Shared Task calls for metrics that provide scores at the segment level and the system level, it does not currently specify how or when metrics may make use of extrasentential information (e.g., information from other parts of the test set or document) in order to produce segment level scores. This could include approaches that compute some statistics from the full test set (like *YiSi* does for TF-IDF) or that operate on the batch level (like *PrismRef**). This is to say, some of these apparent inconsistencies may be intentional (i.e., giving a segment a different score depending on the context in which it appears).

Since metrics have different score ranges, we first calculate the lowest and highest scores assigned by each metric to any of the MSLC-A or MSLC WMT submission segments within the news subset. This gives us a range of metric scores. Then, for each source-reference-hypothesis in the news subset, we compute the absolute difference in the score that it was assigned as part of the MSLC-A dataset and the score it was assigned as part of the MSLC WMT submission dataset and express this as a percentage of the metric's score range described above.

For many metrics (*BERTScore*, *BLEU*, *chrF*, *spBLEU*, *chrfS*, *XLsimMqm*, *mmm_qe*, *mmm_hybrid*, *GEMBA-ESA*), there is never any difference in these two scores. For other metrics, like *CometKiwi*, there are some small differences (never greater than 0.1% of the metric's score range); these seem likely attributable to rounding/floating point errors. In other cases, it is possible that other even larger differences may be accounted for due to differences in batch size and hardware used, such as the case of *MetricX-24-Hybrid-QE*, which sees its largest score difference as 7.3% of the score range for `eng`→`deu`.

For *YiSi-1*, there is a known reason for the observed differences (up to 2.3% `eng`→`deu`, 2.8% `eng`→`spa`, 4.4% `jpn`→`zho`): the *YiSi* score is computed taking into account TF-IDF statistics from the full test set; since MSLC-A included only the news data while the full WMT General Task submission for MSLC included other domains, the scores assigned to individual segments may differ, as the segment-level scores are conditioned on the full test set. The largest difference we observe is for *PrismRefMedium*, with one score difference of 98.9% of the full score range; this is likely also due to the model operating at the level of the document or document chunk. The MSLC-A challenge set did not include document boundaries, which could account for the differences we observe. In future tasks, we would suggest incorporating document information in the challenge set submission in order to avoid these issues, and it would also be helpful to clarify which metrics incorporate extrasentential information (specifically from other parts of the challenge set data). We know that there are at least three different levels on which metrics are operating: the single-segment level (i.e., each segment is scored individually, so repeated segments should be scored identically), incorporating information from the full test set (in which case repeated segments within the same test set may receive identical scores), and incorporating document/batch/multi-segment input (in which case, scores may depend on how the batching is performed). It could also be possible to have more complex interactions (e.g., taking into account where in a document a segment occurs in order to score it); metrics users and challenge set builders need to be aware of these in order to ensure that they are measuring what they think they are measuring.

As we can see, there are at least two different reasons for these apparent inconsistencies: 1) purposeful differences that arise from metrics that use contextual information for computing sentence-level scores (as in the case of *YiSi*) and 2) errors and noise resulting from computational or implementational factors. In the case of these purposeful differences, the primary thing for metric users to be aware of is the scope of the context that is used, in order to be able to reproduce scores. The latter issue is a larger problem, especially when we see score differences that cover substantial portions of the metric's score range. If a metric is unstable or produces different scores based on the hardware used to compute it, we face an issue at least as concerning as the preprocessing one identified in Post (2018). We propose two main (but not entirely satisfactory) solutions to this: 1) it may be best to report such metrics as an average over multiple runs and 2) metrics should adopt the proposals outlined in Zouhar et al. (2024) to include metric signatures for better reproducibility.

6 Conclusion

We once again show the diversity of ways that metrics perform on a wide range of system quality. We also observe quite a bit of variation in terms of how systems handle empty strings, which may influence how they are used (e.g., when comparing a system that frequently generates empty strings to one that never does). We also consider questions of wrong-language text and mixed-language text as well as language variants, and argue that metrics researchers should consider whether their metrics are overgeneralizing (i.e., whether they give high scores to good translations regardless of whether the translation is in the desired target language or not) or are biased towards particular language variants. Many of our results support the conclusions that Zouhar et al. (2024) describe in their concurrent analysis of *COMET*, such as the need to better handle empty strings, questions of target language, biases, and the importance of metric signatures when metric variations may introduce score differences. In concert with that work, we raise the concern that as new metrics are introduced, we are not learning the lessons from our field's past errors. We argue for the importance of examining real-world corner cases and issues of reproducibility in order to more responsibly introduce new metrics to the research community. Both metrics researchers and users should be alarmed by the levels of inconsistency that we observe. One of the benefits of using automatic metrics should be to make fair comparisons (for repeated scoring, across papers, and so forth)—inconsistent metrics cannot serve this purpose. When there are intentional sources of differences in scores for repeated segments (i.e., due to the context in which they appear), users need to be aware of the scope and approaches used to incorporate context, in order to ensure that they are using metrics as intended in order to measure what they intend to measure. This will become increasingly important as we see a shift to document-level

Limitations

We focus only on three language pairs (English→German, English→Spanish, and Japanese→Chinese) in the News domain in this work, due to the availability of human-annotated scores for this set. Several of our additional experiments use extremely small sets of data (e.g., 5-10 examples); in most cases these are designed to help us establish whether additional future study would be helpful, rather than to make definitive claims about the results. In time for the camera-ready submission, we had access to MQM scores, but not to the General MT Task ESA annotations.

Acknowledgements

We thank the WMT General MT Task organizers for permitting us access to the references in order to build this challenge set. We thank the WMT Metrics Task organizers for including our systems in their MQM human evaluation, to enable us to use those results to better understand the performance of automatic metrics across a range of MT quality.

C Additional Mixed/wrong-language Tables

Tables 8 and 9 show the how the metrics scores mixed-language and wrong-language data for English→Spanish and Japanese→Chinese. For English→Spanish, the wrong-language text was German and the mixed-language was a mix of German and Spanish. For Japanese→Chinese, the mixed-language was a mix of Chinese, English and Japanese, while the wrong-language was English. Note that because the Chinese text in the mixed-language hypotheses is drawn directly from the reference, this should be a particularly easy task for string-based metrics.

D Additional Figures

Figures in this paper are produced using Matplotlib (Hunter, 2007), version 3.7.1.

MetricX-24: The Google Submission to the WMT 2024 Metrics Shared Task

Juraj Juraska, Daniel Deutsch, Mara Finkelstein and **Markus Freitag**
Google
{jjuraska,dandeutsch,marafin,freitag}@google.com

Abstract

In this paper, we present the MetricX-24 submissions to the WMT24 Metrics Shared Task and provide details on the improvements we made over the previous version of MetricX. Our primary submission is a hybrid reference-based/-free metric, which can score a translation irrespective of whether it is given the source segment, the reference, or both. The metric is trained on previous WMT data in a two-stage fashion, first on the DA ratings only, then on a mixture of MQM and DA ratings. The training set in both stages is augmented with synthetic examples that we created to make the metric more robust to several common failure modes, such as fluent but unrelated translation, or undertranslation. We demonstrate the benefits of the individual modifications via an ablation study, and show a significant performance increase over MetricX-23 on the WMT23 MQM ratings, as well as our new synthetic challenge set.[1]

1 Introduction

Automatic evaluation metrics are critical to the development of machine translation (MT) systems. In recent years, the landscape of MT evaluation has changed dramatically since the use of lexical metrics, like BLEU (Papineni et al., 2002) and ChrF (Popović, 2015), that compared the tokens or characters of the candidate translation to a reference translation to predict a scalar score that represents the quality of the translation. Evaluation metrics based on neural networks opened up the door for more experimentation, and metrics now vary based on what type of output they produce, what they require as input for prediction, and whether they use a dedicated evaluation model or a general-purpose large language model.

This paper provides details on MetricX-24, the successor to MetricX-23. MetricX is a learned regression-based metric trained to predict a floating point score representing the quality of a translation. This year, we made four submissions to the WMT24 Metrics Shared Task, all based on the mT5 language model (Xue et al., 2021), which is further fine-tuned on direct assessment (DA) ratings, MQM ratings (Lommel et al., 2014; Freitag et al., 2021), and newly constructed synthetic data. The primary submission, denoted MetricX-24-Hybrid, is a hybrid reference-based/-free metric, which can score a translation irrespective of whether it is given the source segment, the reference, or both. The same model is thus the primary submission for both the reference-based evaluation and the quality estimation (QE) task, having predicted the scores once with and once without the references provided in the input. Our contrasting submissions, MetricX-24(-QE), are standalone reference-based/QE models, trained only for their specific task.

The key takeaways from our experiments, detailed in this report, include:

1. Learned metrics cannot reliably detect undertranslation, duplication, missing punctuation, and fluent but unrelated translation;
2. Adding a relatively small amount of synthetic data to the training set can boost the metric's performance, especially on lower-quality translations with the above issues;
3. It is possible to effectively train a metric on a mixture of MQM and DA ratings, thus maintaining high performance on a larger set of language pairs;
4. Training a metric in the hybrid input mode, i.e., with and without the reference included in the input, allows it to learn to rely less on the reference when it is of poor quality.

2 Data

Developing MetricX-24, we relied solely on publicly available data from the WMT Metrics shared

[1] Our code and models can be found at https://github.com/google-research/metricx.

Proceedings of the Ninth Conference on Machine Translation, pages 492–504
November 15-16, 2024 ©2024 Association for Computational Linguistics

tasks between 2015 and 2023. The translation ratings from these years come in two different flavors: (1) direct assessment (DA) scores on a scale from 0 to 100, collected in general from non-expert raters, and (2) MQM scores (Lommel et al., 2014; Freitag et al., 2021) on a scale from 0 to 25 (with 0 being the best), which are grounded on error spans and their corresponding severity levels, annotated by professional raters. MQM ratings have been collected as part of the WMT campaign only since 2020 and, because the annotations are considerably more time-consuming and expensive to obtain, they are only available for a few language pairs. The DA scores, on the other hand, offer a broader language coverage of nearly 50 language pairs, but the raw ratings are noisy (due to different rating strategies) and generally of lower quality. Therefore, it is often beneficial to z-normalize DA ratings per rater before training models on them, so as to make the ratings more comparable across different annotators. In contrast, models do not benefit from MQM scores being z-normalized because the scores come from a rather small group of annotators and they adhere to a rubric.

In the rest of this section, we provide details on which data we use for training and evaluation, as well as how the different datasets are preprocessed. Furthermore, we describe new synthetic data we created from the WMT datasets, with the goal of addressing some of MetricX's known failure modes.

2.1 Training Data

DA. We utilize most of the DA data from the 2015–2022 period for training, with the following exceptions. As we observed during the development of the previous version of MetricX (Juraska et al., 2023), the into-English portion of the WMT21 DA ratings drags the model performance down. We confirmed this observation again this year and excluded these language pairs from the training data. With the gradually declining quality of DA ratings collected for WMT using the MTurk platform, we also exclude all into-English language pairs from WMT22.[2] Additionally, we exclude the en-zh language pair from WMT22, as we use the equivalent slice of data, but with MQM ratings, for evaluation. We use z-normalized ratings when training models on DA data only, but raw ratings when training on a mixture of MQM and DA data.

MQM. Besides the DA ratings, we also take advantage of the higher-quality MQM ratings from the years up to 2022 for training. These include four language pairs: en-de, en-ru, en-zh and zh-en.[3] We only use the conversation, e-commerce and social domains from WMT22 en-zh for training. In our experiments with different subsets of MQM ratings, we observed a consistent boost in performance with the 2020 data excluded, hence, our final models are only trained on MQM ratings from 2021 and 2022. We always train models on raw MQM ratings, i.e., using the 0–25 scale.

2.2 Evaluation Data

MQM. Our primary evaluation set consists of the WMT23 MQM ratings, which includes three language pairs: en-de, he-en and zh-en. Since the zh-en language pair is known to have low-quality references (Kocmi et al., 2023), we replace them with newly collected references. Note that this has no effect on the MQM ratings, as those were collected in a source-based fashion. Additionally, given the fact that one of the official WMT24 test language pairs is ja-zh, we reserve the news domain subset of the WMT22 en-zh ratings for evaluation, allowing us to assess our models' performance on a language pair with Chinese as the target language.

DA. We use the WMT23 DA ratings as a secondary evaluation set, taking advantage of its better language coverage (8 language pairs). Nevertheless, with DA ratings generally following a significantly different distribution than MQM ratings, a higher correlation of the metric scores with these DA ratings does not necessarily imply better performance. For example, fine-tuning a model on zh-en MQM ratings results in lower performance than fine-tuning it on DA ratings, according to the zh-en DA evaluation set (but not the MQM one). Therefore, we only consider the WMT23 DA evaluation set in experiments where we mix MQM and DA training data together.

2.3 Synthetic Data

After seeing the initial benefits from the simple synthetic data used for training MetricX-23, we decided to construct a more comprehensive collection

[2] One exception is zh-en, for which DA ratings were collected in two different ways, including using the same method and framework as the out-of-English language pairs (Kocmi et al., 2022).

[3] The en-zh MQM ratings, available at `https://github.com/google/wmt-mqm-human-evaluation`, were collected post-WMT22.

of synthetic training examples. They cover additional, less trivial failure modes of MetricX, i.e., translation issues commonly unrecognized by the metric. The DEMETR challenge set (Karpinska et al., 2022), which we relied on last year, does not cover several of the failure modes we created the new synthetic training examples for, hence we also constructed a set of test examples for each of them. Next, we describe how we designed both the training and the test synthetic datasets.

2.3.1 Training Sets

In order for the MetricX models to learn to identify certain types of bad translations that are not sufficiently (or at all) represented in the regular WMT training data, we generated synthetic examples that we augment the training data with. They were created by modifying examples from the DA datasets ranging from WMT15 to WMT22, comprising 49 language pairs. Table 1 provides an overview of the various failure modes that we considered, including brief descriptions of how we prepared the synthetic data to address them. Additional details regarding the creation process can be found in Appendix A.

2.3.2 Test Set

We constructed a new DEMETR-style test set based on the WMT23 DA dataset, with examples generated analogously to our synthetic training examples, as described in Table 1. Each synthetic example is paired with its original counterpart (although using the reference instead of the candidate translation whenever the synthetic translation was created from the reference), which allows for a metric to be evaluated on how frequently it ranks the pairs correctly.

3 Metric Descriptions

The MetricX-24 submissions to the WMT24 Metrics Shared Task build on top of the successful MetricX-23 (Juraska et al., 2023; Kocmi et al., 2023), with several major improvements. We start this section by summarizing the aspects this year's submissions have in common with MetricX-23, then provide an overview of the modifications, and finally describe the differences between the individual submissions.

3.1 MetricX Model

MetricX is a learned metric, powered by a regression model trained to predict a floating point number that represents the quality of a given translation. The reference-based variant takes the candidate translation (hypothesis) and reference segments as input, and concatenates them, along with corresponding prefixes ("candidate:" and "reference:", respectively). In contrast to the previous versions, MetricX-24 also prepends the source segment (along with the prefix "source:") to the input, offering the model additional context to make a better prediction in the reference-based setting, which may be beneficial especially in cases where the reference is inadequate. The model then encodes this combined input and uses it to predict the translation quality score. The QE variant works in an analogous way, but taking only the source segment and the hypothesis as the input.

With MetricX-24, we continue to rely on mT5 (Xue et al., 2021) as the pretrained language model that we fine-tune on translation evaluation data. We refer the reader to Juraska et al. (2023) for details on how we adapted this encoder-decoder model to the regression task. Similar to MetricX-23, we fine-tune the model in two stages: first on DA ratings (z-normalized, aggregated per segment, negated, and finally clipped to the $[-1.0, 1.0]$ range) and then further on raw MQM ratings. As a result, the metric produces scores in the [0, 25] range. The model is trained with a mean squared error (MSE) loss function. Further implementation details can be found in §4.

3.2 Design Improvements

We achieve some initial improvement in performance by simply including the WMT22 data in the training set – both the DA and the MQM ratings, which we previously used as the evaluation set when developing MetricX-23. The additional MQM ratings (including en-ru, a language pair not present in the older MQM data) are especially valuable, considering the scarcity of MQM data. Besides that, we introduce three major modifications to the training procedure and data in order to further improve MetricX's performance, described throughout the rest of this section.

3.2.1 Training With Synthetic Data

Although we used synthetic training data alongside the DA and MQM ratings already for training MetricX-23, the synthetic examples covered only the two trivial cases of empty and reference-matching translations. As described in §2.3, we prepared a significantly more comprehensive synthetic training set for MetricX-24, which we combine

Failure mode	**Synthetic candidate translation description**	**MQM score**
Empty translation	Empty string.	25
Gibberish	Text of a similar length as the reference, generated by sampling words from the vocabulary built from all references in the data with a matching target language.	25
Fluent but unrelated translation	Arbitrary reference from the dataset of a similar length and in the same language.	25
Undertranslation	Candidate translation with an arbitrary sentence removed, if a multi-sentence segment, otherwise, candidate translation with 20–80% words removed from the end.	5–25
Duplication	Candidate translation duplicated, with a space in between.	25
Missing punctuation	Reference translation with the end punctuation removed (11 punctuation symbols considered, such as period, question mark, closing parenthesis or quotation mark).	1
Reference-matching translation	Reference translation itself (unlike the rest, these synthetic examples are meant to train the metric to predict a perfect score for translations matching the reference).	0

Table 1: Failure mode categories we prepared synthetic data for, along with brief descriptions of how we created the synthetic examples from the WMT data, and the MQM scores we label the training examples with.

with the DA and MQM data in both fine-tuning stages. We experimented with various ratios, and settled on 1:100 for each synthetic example category in the first stage and 1:5000 in the second stage. We evaluate the effects of adding the synthetic training data by measuring accuracy and average score differences on the synthetic test set, also described in §2.3.

3.2.2 Mixing DA and MQM Data

Next, we attempt to address the inevitable decline in MetricX performance on other languages after fine-tuning the model on MQM data, which only covers a few language pairs. The performance, as measured by the WMT23 DA evaluation set with 8 language pairs, quickly declines after starting to fine-tune on MQM ratings. While it is expected that the change in the general score distribution – caused by the switch from DA to MQM ratings – results in the Pearson correlations with the ground-truth scores dropping, we believe the model should be able to retain its system- and segment-level pairwise accuracy from the first stage of fine-tuning on DA data. Moreover, we observe a significant drop in system-level performance on the zh-en language pair of the MQM evaluation set, despite zh-en being present in the MQM training data.

In order to remedy these behaviors, we mix in a smaller proportion of DA ratings in the second-stage fine-tuning. That way the model is trained primarily on MQM ratings, but has a continued exposure to the additional 40+ language pairs from the first stage of fine-tuning. We experimented with different combinations of DA and MQM rating formats (e.g., raw vs. z-normalized, transformed to the MQM scale or not, etc.), and the one yielding the best results was raw MQM ratings combined with raw DA ratings linearly transformed to the MQM scale of $[0, 25]$. Finally, we determined that a DA:MQM ratio of 1:4 works well for boosting the performance on the DA evaluation set back to the levels from the first stage of fine-tuning, without a significant negative impact on the model's performance on the MQM evaluation set.[4]

3.2.3 Hybrid Input Mode

The third major modification we make to the training procedure when developing MetricX-24, is mixing training examples in three different formats: (1) source + hypothesis, (2) hypothesis + reference, and (3) source + hypothesis + reference. This allows the model to operate in both a QE and a reference-based mode (and the latter either with or without the source included). But perhaps more importantly, it gives the model an opportunity to learn how much weight to put on the source and the reference in different scenarios, or possibly to completely ignore the reference when it is of low quality. Such a hybrid model is then evaluated as a QE model by only passing it the source segment and the hypothesis as input, and as a reference-based model by additionally passing it the reference.

3.3 MetricX-24 Variants

There are four variants of MetricX-24 that we submitted to the WMT24 Metrics Shared Task:

- MetricX-24-Hybrid (primary)
- MetricX-24-Hybrid-QE (primary)
- MetricX-24

[4] After a more extensive post-submission experimentation, we determined the optimal ratio to be 1:10.

- MetricX-24-QE

Our primary reference-based and QE submissions are actually the same hybrid model, with the scores predicted with and without the references provided as part of the input. The secondary submissions are the standalone reference-based and QE counterparts of the hybrid model, i.e., only trained on examples with the references (as well as the source segments) included and on examples with the references omitted, respectively. Other than that, all of the submission models are identical in terms of training data mixtures, as described in §3.2.1 and §3.2.2, as well as training hyperparameters.

4 Experimental Setup

4.1 Meta-Evaluation

As mentioned in §2.2, our primary evaluation set consists of the MQM ratings from WMT23, as well as the news domain subset of the en-zh language pair from WMT22. Considering there is no into-English language pair among the official test sets this year, we focus primarily on en-de and en-zh when evaluating our models, but also keeping zh-en (the dataset with alternate references) in the mix, in order to ensure that we do not overfit the models to out-of-English language pairs. To evaluate our models, we calculate the agreements between their predicted scores and the human judgments of translation quality using the four different correlations from the WMT23 Metrics Shared Task (Freitag et al., 2023), detailed in Appendix B.

4.2 Checkpoint Selection

In both the first and the second stage of fine-tuning, we pick the best checkpoint c_{best} based on the following linear combination of segment- and system-level pairwise accuracy:

$$\arg\max_{c} \frac{3}{4} \sum_{l} \text{acc}_l^{\text{seg}}(c) + \frac{1}{4} \sum_{1} \text{acc}_l^{\text{sys}}(c) \ ,$$

where $l \in \{\text{en-de, en-zh, zh-en}\}$, and $\text{acc}_l^{\text{seg}}(c)$ and $\text{acc}_l^{\text{sys}}(c)$ are the segment- and the system-level pairwise accuracy calculated for checkpoint c on the language pair l of the evaluation set. We down-weight the system-level component to account for its greater variance and to thus avoid a checkpoint being picked due to a rare spike in system-level accuracy if segment-level accuracy is low.

4.3 Implementation Details

MetricX-24, similar to its predecessor, is implemented with TensorFlow (Abadi et al., 2015) and the T5X library (Roberts et al., 2023). All of the metric variants are based on mT5-XXL with 13B parameters. We defer further implementation details to Appendix C. We are publicly releasing our submissions, converted from TensorFlow to PyTorch (Paszke et al., 2019) checkpoints.[5]

5 Results and Discussion

Here we present the results of our experiments, focusing solely on fully trained models (i.e., those that went through both stages of fine-tuning) and modifications in the second stage. Since the ablation studies performed with reference-based and QE models show similar trends, we discuss the reference-based experiments in depth in this section, and provide the QE results in Appendix D.2. Due to limited resource availability, we were only able to run each experiment with one random seed.

5.1 Training With Synthetic Data

We start by examining the benefits of including synthetic training examples, as described in 2.3. In Table 2, the bottom four rows – corresponding to the hybrid model – demonstrate the effects of progressively adding DA data only, synthetic data only, and finally both, to the training set in the second stage of fine-tuning.[6] We ended up not using the duplication synthetic training set, as we observed that the models learn to correctly identify such cases even without it.

The first thing to notice is that mixing in DA ratings actually improves the metric's performance on the synthetic test set over fine-tuning on MQM ratings alone, especially in the unrelated, undertranslation and duplication failure modes. Adding synthetic data instead is, however, significantly more effective in general, boosting the accuracy to the 94–100% range in most categories. Finally, augmenting the training set with both the DA and the synthetic data results in an overall similar performance as with the synthetic data only.

Missing punctuation is one of two categories in which our metrics score not so close to perfect. In fact, the synthetic training examples appear not to be helpful in improving the performance at all. Our

	✓	✓	61.11	**55.00**	**55.82**	57.02	98.48	**92.38**	94.17	85.90

Table 3: Meta-evaluation scores of reference-based MetricX variants on the WMT23 MQM evaluation set. "23" is the baseline, the last row of "24-Hybrid" corresponds to our primary submission, and "24" is our secondary submission. †Alternate references.

hypothesis is that using references to create this category of synthetic examples results in a significant proportion of misleading examples because we assume references to be perfect, but that is not always the case. That, combined with the fact that the removal of the punctuation symbol from the end of the segment warrants just a minor score change, means that some of the synthetic examples might have an unreasonably high ground-truth score associated with them, thus giving the model the opposite signal to what is desired.

The reference-matching translation synthetic training set appears not to be effective either, however, its benefits are somewhat concealed by the fact that mixing in DA data drags the performance in this category down. With the non-hybrid model, we observed a significantly bigger drop with DA data included (77% → 64%) and a greater increase with synthetic data included instead (77% → 83%). Granted, that is still far from perfect, however, expecting a 100% accuracy in this category equates to expecting that the candidate translation is never better than the reference, which, as we pointed out earlier, is not always true when judging the translation quality based on the source segment.

Overall, thanks to the new synthetic training data, MetricX-24 (hybrid or not) is clearly more robust to the failure modes than MetricX-23 (see first row in the table), with the reference-matching translations being an exception. That might have to do with the absence of WMT22 data in the training set of MetricX-23, or the only synthetic examples present therein being those of empty and reference-matching translations.

5.2 Mixing DA and MQM Data

We already discussed the effects of adding DA data to the training set in the second stage of fine-tuning in terms of the synthetic test set performance; let us now have a look at the correlations with human MQM scores. Comparing the first two rows of the "24-Hybrid" section in Table 3, we see that there are just relatively minor changes in either direction across all language pairs, with score differences within the expected variance between runs.

What the table does not show, however, is the huge jump in all correlations across all language pairs on the WMT23 DA evaluation set, typically back to the levels from the first stage of fine-tuning on DA data only, or above. Segment- and system-level pairwise accuracy increases by up to 2 and 5 points, respectively, and Pearson's r sees improvements of up to 10 points. These are valuable gains, considering we achieved them without sacrificing the performance on the MQM evaluation set. An overview of the results and a more detailed analysis on the DA evaluation set can be found in Appendix D.1.

5.3 Hybrid Input Mode

To wrap up the evaluation, we discuss the performance difference between MetricX-24 and MetricX-24-Hybrid (rows 2 and 6 in Table 3). At the system level, the hybrid variant lags slightly behind in zh-en and en-zh, but it makes up for it by outperforming the non-hybrid across the board at the segment level. Notably, the hybrid metric achieves an almost 1% higher segment-level accuracy on en-zh, and the 0.5% boost on zh-en (with original references) may be evidence for the hybrid model handling examples with poor-quality references better, especially considering the accuracy difference on the zh-en set with alternate references is only 0.04%. The other performance differences between the two models are largely insignificant.

Finally, comparing our primary submission with MetricX-23 (row 1 in the table), we can see consistent gains of 1–2 points in segment-level accuracy, and substantially bigger gains at the system level, with the accuracy on en-zh improving by a whopping 11.5 points. We conclude that this a significant improvement over our last year's submission, ranked overall second in the WMT23 Metrics Shared Task.

6 Related Work

Traditionally, evaluation metrics predict a scalar quality score for the translation. This type of metric includes BLEU, ChrF, MetricX (Juraska et al., 2023), BLEURT (Sellam et al., 2020; Pu et al., 2021), COMET (Rei et al., 2020, 2022a), COMETKiwi (Rei et al., 2022b), Prism (Thompson and Post, 2020), and more. While these metrics have historically been the dominant category of metric, newly proposed methods provide structured (Perrella et al., 2022; Fernandes et al., 2023; Kocmi and Federmann, 2023; Guerreiro et al., 2023) or natural language explanations (Xu et al., 2023) for the predicted scores.

Then, evaluation metrics are considered to be reference-based or reference-free (also known as "quality estimation") depending on whether or not they require a reference to evaluate a translation. Metric developers usually train separate models for each type of metric (e.g., COMET and COMETKiwi, or MetricX-23 and MetricX-23-QE), but some opt for combining both tasks into a single model (Wan et al., 2022; Guerreiro et al., 2023), which is the approach we took in this work with our hybrid model.

Finally, while most metrics like MetricX-24 use a dedicated model for scoring translations, some recent works have begun to leverage general-purpose large language models instead (Fernandes et al., 2023; Kocmi and Federmann, 2023; Xu et al., 2023; Leiter et al., 2023; Leiter and Eger, 2024). While LLM-based metrics have achieved strong system-level performance, using a learned dedicated model was the best approach at the segment-level in last year's Metrics Shared Task (Freitag et al., 2023).

7 Conclusion

We presented in detail our approach to training MetricX-24, a regression-based MT evaluation metric. We submitted four versions of MetricX-24 to the WMT24 Metrics Shared Task, including a reference-based and a QE variant, as well as a new hybrid variant evaluated with and without the references. By evaluating on the WMT23 MQM dataset, we showed all of them to significantly outperform our last year's submission, MetricX-23. In addition, we made MetricX-24 more robust to various types of bad translations, which do not frequently occur in the WMT data, such as undertranslation, or fluent but unrelated translation. Finally, by combining DA and MQM ratings together in the final stage of fine-tuning, we were able to dramatically increase the performance on the WMT23 DA dataset covering 8 language pairs, while maintaining the high correlations with the MQM ratings at the same time.

A Synthetic Data Creation

We sample 500 examples from each language pair, whose candidate translations (hypotheses) we then manipulate in different ways to create the synthetic examples for each failure mode category. The missing punctuation category is an exception, with a stratified sample across the 11 end-punctuation symbols, rather than language pairs, and 250 examples each.

In general, the synthetic examples have the candidate translation manipulated, turning it into a worse, or an outright bad, translation. One exception is the reference-matching category, whose purpose is to actually teach the metric to score translations that match the reference highly, which it does not learn to do reliably when only trained on the WMT data. Table 4 shows a few concrete examples from the synthetic training set.

B Meta-Evaluation Details

System-Level. At the system level, we measure pairwise ranking accuracy (Kocmi et al., 2021), as well as Pearson's r. Pairwise accuracy assesses how well a metric ranks MT systems by calculating the proportion of all possible pairs of systems that are ranked the same by the metric and human scores. Pearson's r, on the other hand, captures how strong the linear relationship is between the metric and human scores for MT systems. We obtain the system-level scores (both metric and human) as the mean segment-level score for each system.

Segment-Level. At the segment level, we use the group-by-item pairwise accuracy with tie calibration, as described by Deutsch et al. (2023), and the no-grouping Pearson's r. The pairwise accuracy calculates the proportion of all possible pairs of translations for the same source segment that are ranked the same by the metric and human, then averages the accuracies over all input segments. At the same time, it rewards correct tie predictions by introducing ties for any two translations with a metric score difference below an automatically determined threshold. The no-grouping Pearson's r quantifies the linear relationship between the metric and human scores across all translations from every system and document.

C Implementation Details

Having increased the maximum segment length from 256 to 512 SPM tokens, and including up to three segments (source, hypothesis and reference) in the model's input, each training run requires 256 TPUs. Using a batch size of 256, we train our models for 16K steps in the first stage, using a learning rate of 0.001 with an inverse square root decay after the first 2K steps. We then fine-tune the best checkpoint for another 8K steps in the second stage, lowering the learning rate to 0.0002 and decaying it after 1K steps. The models are trained using the Adafactor optimizer (Shazeer and Stern, 2018).

D Additional Results

D.1 Mixing DA and MQM Data

Table 5 compiles the results of the meta-evaluation of a group of reference-based models on the WMT23 DA evaluation set. All of the models are standalone reference-based models. In the table, we contrast four variants of the model fine-tuned in two stages (DA then MQM data) with a model fine-tuned on DA data only (i.e., the first stage only). We present the results on a subset of four language pairs, two of which are present in our MQM training data (en-de and zh-en) and two which are not (en-cs and de-en).

The experiments with mixing DA and MQM data in the second stage of fine-tuning were motivated by the large differences in performance on the WMT23 DA evaluation set observed between a model trained on DA ratings only (row 1 in Table 5) and the same model further fine-tuned on MQM ratings (row 2). As already discussed in §2.2, this can be partly explained by the discrepancy in DA and MQM rating distributions. This discrepancy understandably affects Pearson correlations, however, it should not have a significant effect on how the metric ranks segments or systems. Nevertheless, while we observed large drops in Pearson's r, the pairwise accuracy also dropped substantially for most of the language pairs, both at the segment and the system level. For example, on en-cs the segment-level accuracy drops from 59.54 to 57.43, and the system-level accuracy from 87.62 to 82.86.

Considering the fact that the performance difference between the models in rows 1 and 2 on en-de and zh-en (i.e., the language pairs with a good amount of MQM training data), are relatively

Table 5: Meta-evaluation scores of reference-based MetricX variants on a subset of the language pairs of the WMT23 DA evaluation set. "DA only" is a model after just the first stage of fine-tuning (i.e., on DA data only), whereas the "DA then MQM" section contains models fine-tuned in full two stages. The last row thus corresponds to the "24" row in Tables 2 and 3, i.e., our secondary submission "MetricX-24".

Table 6: Same as Table 5, but showing Pearson correlations instead of pairwise accuracies.

small, we conjecture that further fine-tuning on MQM data alone causes the model to partially "forget" other languages from the first stage of fine-tuning. We attempt to prevent the model from this sort of forgetting by mixing some DA ratings into the training set in the second stage.

As the scores of the model in row 3 in the table demonstrate, we are able, for the most part, to restore the performance observed in the first stage of fine-tuning by adding a small proportion of DA training data in the second stage too. Adding not only the DA data, but also the synthetic data, in the second stage (row 5) sometimes boosts the performance further, significantly improving even over the first-stage performance (row 1). Most importantly, the gains over fine-tuning on MQM data alone (row 2) are achieved not at the expense of the model's performance on the MQM or the synthetic test set, as evidenced by the results in Tables 2 and 3.

Finally, Table 6 shows the expected big drops in Pearson correlation with the DA ratings after fine-tuning on MQM data (see rows 1 and 2), especially at the segment level. Adding DA data in the second stage helps recover most of the performance (compare rows 3 and 5 with row 1), but as expected, the correlations remain lower particularly for language pairs present in the MQM data the model is fine-tuned on in the second stage (en-de and zh-en).

D.2 QE Models

In Tables 7 and 8, we present the meta-evaluation results for our QE models. These are analogous to those presented in §5, only the hybrid model is evaluated in a reference-free mode, and the non-hybrid models are ones trained on the source and hypothesis segments only. Note that the hybrid model is the same checkpoint as the one for which we reported the reference-based results in Tables 2 and 3, i.e., not one optimized for QE performance.

Examining first the results on the synthetic test set, summarized in Table 7, we see similar trends to those observed with reference-based models (Table 2). The main difference is that the QE models achieve significantly lower performance in the missing punctuation and the reference-matching translation categories. This, however, is expected because both the types of synthetic examples were created from references. In case of the missing punctuation examples, the synthetic translation is simply the reference with the end punctuation removed. Comparing such a hypothesis with the corresponding reference is arguably a significantly easier task than comparing it to the source segment and identifying a missing punctuation symbol. Moreover, there may be a mismatch in the presence of punctuation between the source and the reference in the training examples, making it even more difficult for a QE model to reliably identify missing punctuation. As for the reference-matching

MetricX variant	+DA	+Synth	Empty transl.	Gibberish	Unrelated	Under-transl.	Duplication	Missing punct.	Ref-match
23	–	∼	**100.00**	**99.86**	96.43	63.25	88.29	69.93	63.00
24	✓	✓	97.86	**99.86**	**99.43**	**98.50**	**98.14**	65.36	63.43
24-Hybrid	–	–	69.86	**99.86**	82.43	81.25	63.00	**77.78**	63.00
	✓	–	66.14	99.57	95.29	93.50	97.86	73.86	62.57
	–	✓	93.57	99.71	99.29	96.50	84.43	69.28	62.14
	✓	✓	93.71	**99.86**	**99.43**	97.25	**98.14**	69.28	**64.14**

Table 7: Accuracy of reference-free (QE) MetricX variants in all 7 categories of our synthetic test set. "23" is the baseline, the last row of "24-Hybrid" corresponds to our primary submission, and "24" is our secondary submission. The hybrid model is the same as in Table 2, only evaluated without references provided as input.

MetricX variant	+DA	+Synth	Segment-level pairwise accuracy				System-level pairwise accuracy			
			en-de	zh-en	zh-en[†]	en-zh	en-de	zh-en	zh-en[†]	en-zh
23	–	∼	59.57	52.64	52.89	54.47	92.42	86.67	85.83	74.36
24	✓	✓	59.70	**54.30**	**54.48**	56.00	98.48	**92.38**	90.83	**87.18**
24-Hybrid	–	–	60.11	53.80	54.00	**56.27**	**100.00**	89.52	89.17	84.62
	✓	–	59.18	54.08	54.30	56.14	**100.00**	**92.38**	90.00	84.62
	–	✓	**60.27**	53.76	53.99	55.88	98.48	89.52	90.00	83.33
	✓	✓	59.52	54.15	54.41	55.94	98.48	90.48	**91.67**	83.33

Table 8: Meta-evaluation scores of reference-free (QE) MetricX variants on the WMT23 MQM evaluation set. "23" is the baseline, the last row of "24-Hybrid" corresponds to our primary submission, and "24" is our secondary submission. The hybrid model is the same as in Table 3, only evaluated without references provided as input. [†]Alternate references.

translation category, a QE model does not have access to the reference, so it makes perfect sense for it to score a candidate translation better than the reference translation if the reference is of low quality.

Switching over to Table 8, which shows the pairwise accuracy of the QE model scores, the trends are also in line with those of the reference-based models in Table 3. In contrast to the reference-based results, however, the hybrid model (row 6) does not outperform the standalone model (row 2), although most of the differences are within the expected variance. An astute reader might notice that the accuracy scores on the zh-en test set with the original references and the one with the alternate references do not match (despite the QE models not using the references), and that is because the latter has the original references included as an additional "human system".

Finally, we note that our QE models do not fall far behind their reference-based counterparts. In fact, both our primary and secondary QE submissions of MetricX-24 outperform our reference-based MetricX-23 submission from last year, according to the WMT23 MQM evaluation set.

Evaluating WMT 2024 Metrics Shared Task Submissions on AfriMTE (the African Challenge Set)

Abstract

The AfriMTE challenge set from WMT 2024 Metrics Shared Task aims to evaluate the capabilities of evaluation metrics for machine translation on low-resource African languages, which primarily assesses cross-lingual transfer learning and generalization of machine translation metrics across a wide range of under-resourced languages. In this paper, we analyze the submissions to WMT 2024 Metrics Shared Task. Our findings indicate that language-specific adaptation, cross-lingual transfer learning, and larger language model sizes contribute significantly to improved metric performance. Moreover, supervised models with relatively moderate sizes demonstrate robust performance, when augmented with specific language adaptation for low-resource African languages. Finally, submissions show promising results for language pairs including Darija-French, English-Egyptian Arabic, and English-Swahili. However, significant challenges persist for extremely low-resource languages such as English-Luo and English-Twi, highlighting areas for future research and improvement in machine translation metrics for African languages.

1 Introduction

Recent machine translation (MT) research has scaled dramatically, encompassing hundreds of languages, including many under-resourced ones (Fan et al., 2021a; NLLB-Team et al., 2022; Bapna et al., 2022; Kudugunta et al., 2023). However, accurately measuring MT quality in low-resource languages remains challenging. Conventional metrics like BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and chrF (Popović, 2015), which rely on n-gram matching, often fail to capture deeper semantic similarities (Zhang et al., 2020; Rei et al., 2020; Sai B et al., 2023).

Newer approaches include embedding-based metrics like BERTScore (Zhang et al., 2020) and learned metrics such as COMET (Rei et al., 2020), which have shown promise in more accurately evaluating translations across diverse languages. However, the application of these neural-based metrics to under-resourced languages continues to face significant challenges (Wang et al., 2024), highlighting ongoing areas of research in multilingual MT evaluation. These challenges include: (1) data scarcity impeding metric development, (2) complexity in annotation guidelines challenging non-expert evaluators, and (3) limited language model coverage restricting applicability, which underscore the need for continued innovation in MT evaluation methods, particularly for under-resourced African languages.

In response to these challenges, Wang et al. (2024) have introduced AfriMTE, a human evaluation dataset focusing on MT adequacy and fluency for 13 typologically diverse African languages. This dataset addresses the data scarcity issue and employs simplified MQM evaluation guidelines tailored for non-expert translators, thus tackling two of the primary challenges in this field. Moreover, the authors establish benchmark systems for MT Evaluation and reference-free Quality Estimation (QE) by leveraging transfer learning techniques. These techniques draw from existing, well-resourced Direct Assessment (Graham et al., 2013) (DA) data and utilize an African-centric multilingual pre-trained language model, thereby addressing the challenge of limited language model coverage for African languages.

Building on this work, the WMT 2024 Metrics Shared task incorporates the translation adequacy test set from AfriMTE as a challenge set. This inclusion aims to evaluate the capabilities of metric systems for machine translation on low-resource African languages, primarily assessing the cross-lingual transfer learning ability and generalization of these systems across a wide range of under-resourced African languages.

Proceedings of the Ninth Conference on Machine Translation, pages 505–516
November 15-16, 2024 ©2024 Association for Computational Linguistics

Our examination of task submissions has yielded several key findings in the development of machine translation metrics for African languages. We observed that language-specific adaptation, cross-lingual transfer learning, and increased language model sizes contribute to significant improvements in metric performance. Even supervised models of relatively modest scale can achieve robust results when augmented with language adaptation techniques. In addition, our analysis reveals promising outcomes for certain language pairs, such as Darija-French, English-Egyptian Arabic, and English-Swahili. However, persistent challenges remain evident in extremely low-resource languages like English-Luo and English-Twi. These disparities underscore critical areas requiring further investigation and highlight the need for targeted research in developing effective metrics across the diverse linguistic landscape of Africa.

2 AFRIMTE

AFRIMTE (Wang et al., 2024) focuses on the dev and devtest subsets of the FLORES-200 dataset (NLLB-Team et al., 2022). It covers 13 language pairs (LPs), primarily focusing on African languages with English, plus Darija-French and a control pair of English-French. In details, there are Darija-French (ary-fr), English-Egyptian Arabic (en-arz), English-French (en-fr), English-Hausa (en-hau), English-Igbo (en-ibo), English-Kikuyu (en-kik), English-Luo (en-luo), English-Somali (en-som), English-Swahili (en-swh), English-Twi (en-twi), English-isiXhosa (en-xho), English-Yoruba (en-yor), and Yoruba-English (yor-en). The annotations were also extended on domain-specific translations for English-Yoruba.

The MT outputs were generated using two open-source MT engines: NLLB-200 (600M) (NLLB-Team et al., 2022) and M2M-100 (418M) (Fan et al., 2021b). Most language pairs use NLLB-200, except for English-French and English-Swahili, which use M2M-100 due to their exceptionally high translation quality based on NLLB-200. The authors noted that while some language pairs like English-isiXhosa showed high overall quality, minor errors at the word level were still present.

AFRIMTE initially provides both fine-grained word-level error annotations and sentence-level Direct Assessment scoring for translation adequacy and fluency. For the WMT 2024 Metrics Shared Task, we utilize the adequacy test set from AFRIMTE as the African Challenge set to evaluate the sentence-level scoring performance of submitted metrics, focusing specifically on the FLORES-200 subsets within the dataset. Table 1 presents the counts of translation annotations in this challenge set. Due to the limited sizes of annotations for individual language pairs, we merge test data from all LPs into a single African-centric dataset to enhance evaluation significance for MT evaluation and reference-free quality estimation (QE) metrics. However, recognizing that different LPs may have varying score ranges, potentially favoring metrics that correlate with these distributions more than actual quality, we also report metric performance on each LP separately. This approach balances the need for statistical robustness with LP-specific insights.

LP	Test #	LP	Test #
ary-fr	187	en-som	226
en-arz	250	en-swh	157
en-fr	250	en-twi	247
en-hau	240	en-xho	243
en-ibo	120	en-yor	239
en-kik	202	yor-en	212
en-luo	242		
Total: 2815 annotations			

Table 1: Counts of adequacy annotations for each language pair (LP) in the test set of AFRIMTE.

3 Metrics

The WMT 2024 Metrics Shared Task received various metric submissions from both task organizers and participants. Our analysis will concentrate on the baseline metrics provided by the task organizers and the primary and contrastive metrics submitted by the participants.

3.1 Baselines

The baseline metrics for MT evaluation include BLEU (Papineni et al., 2002), chrF (Popović, 2015), spBLEU (Fan et al., 2021a), prism-Ref (Thompson and Post, 2020), YiSi-1 (Lo, 2019), COMET-22 (Rei et al., 2022a), BLUERT-20 (Sellam et al., 2020), and BertScore (Zhang et al., 2019). For reference-free quality estimation, the baseline metric is CometKiwi (Rei et al., 2022b). Additionally, we include AfriCOMET and AfriCOMET-QE for comparison, which are the African extensions of COMET-22 (Rei et al., 2022a) and CometKiwi (Rei et al., 2022b) proposed by Wang et al. (2024). They employ transfer learning from well-resourced DA data and utilize an African-centric multilingual pre-trained encoder, AfroXLMR (Alabi et al., 2022), to build MT evaluation and QE models for African languages.

3.2 Submissions from Participants

The metrics submitted by participants for MT evaluation include XCOMET (Guerreiro et al., 2023), MetricX-24 and MetricX-24-Hybrid (Juraska et al., 2024)[1], chrF-S (Mukherjee and Shrivastava, 2024), MetaMetrics-MT (Anugraha et al., 2024), damonmonli, and monmonli[2]. For reference-free QE, the submitted metrics are XCOMET-QE (Guerreiro et al., 2023), MetricX-24-QE and MetricX-24-Hybrid-QE (Juraska et al., 2024)[3], QE model of MetaMetrics-MT (Anugraha et al., 2024), GEMBA-ESA (Kocmi and Federmann, 2023), and XLsimMQM (Mukherjee and Shrivastava, 2023). Details of all metrics can be found in Freitag et al. (2024).

3.3 AfriCOMET-1.1 and AfriCOMET-QE-1.1

In the ongoing efforts to enhance performance on African languages, we explore the use of a more advanced African pre-trained encoder. Specifically, we re-train AfriCOMET and AfriCOMET-QE using AfroXLMR-76 (Adelani et al., 2024) and conduct the training in single-task learning mode (Wang et al., 2024).

AfroXLMR-76 (Adelani et al., 2024) is an enhanced version of AfroXLMR (Alabi et al., 2022), which itself was a multilingual adaptation of the XLM-R-large model for 20 widely spoken African languages (each with at least 50MB of data). AfroXLMR-76 scales the language coverage up to 76 languages, including 61 languages with at least 10MB of data and an additional 15 languages with less than 10MB. To address the scarcity of monolingual data for some African languages, Adelani et al. (2024) proposed to generate synthetic parallel sentences by translating an English news commentary dataset (Kocmi et al., 2022) using the NLLB (600M) model.This expanded language coverage and increased training data volume have resulted in AfroXLMR-76 outperforming its predecessor, AfroXLMR, on the SIB-200 topic classification dataset for African languages (Adelani et al., 2024).

Metrics	Pearson	Spearman	Kendall
MetricX-24*	0.5188	0.3949	0.2714
AfriCOMET-1.1*	0.5117	0.4129	0.2865

Table 2: Segment-level correlation coefficients of **MT evaluation** metrics on the entire AfriMTE. Metrics marked with * are ranked first based on the Perm-Input hypothesis test (Deutsch et al., 2021).

We refer to the original models using AfroXLMR as AfriCOMET-1.0[4] and AfriCOMET-QE-1.0[5], while the new versions leveraging AfroXLMR-76 are called AfriCOMET-1.1[6] and AfriCOMET-QE-1.1[7], respectively.

4 Analysis

This section presents a comprehensive analysis of the metrics outlined in Section 3. Our evaluation framework is structured around two primary components. First, we assess segment-level performance by examining the correlation between metric scores and human DA scores. This assessment involves analyzing correlation coefficients on the entire mixed African Challenge set and calculating weighted average correlation coefficients across various language pairs. Second, we conduct a language-specific analysis by computing average correlation coefficients for each individual language pair across all metric systems.

Table 3: Segment-level weighted average correlation coefficients of **MT evaluation** metrics, averaged across language pairs on AfriMTE, with weights based on the size of each language pair group. The metric marked with * ranks first based on the average of Pearson, Spearman, and Kendall correlation coefficients.

4.1 Segment-level Averaged Correlation

For both MT evaluation and reference-free QE tasks, we assess the metric performance using three widely adopted correlation coefficients: Pearson, Spearman-rank, and Kendall-rank. These coefficients measure the correlation between metric scores and human DA scores, each capturing different aspects of the relationship (Deutsch et al., 2023). To validate the statistical significance of our results, we additionaly employ the Perm-Input hypothesis test (Deutsch et al., 2021), which is conducted with 200 re-sampling runs and a significance level of $p = 0.05$, producing rankings of the various automatic metrics based on their performance.

4.1.1 MT Evaluation Metric

We present the segment-level correlation coefficients of MT evaluation metrics on the entire AfriMTE test set in Table 2 and the weighted average correlation coefficients across various language pairs in Table 3. Detailed Pearson, Spearman-rank, and Kendall-rank correlations of baseline metrics and primary submissions for each language pair are shown in Figures 3, 4, and 5 of Appendix A.

For MT evaluation, Table 2 provides valuable insights into evaluation metrics' performance on the African Challenge Set. Generally, Pearson correlations are generally higher than Spearman and Kendall, with rankings remaining largely consistent across correlation types. The top-performing metrics—MetricX-24, AfriCOMET-1.1, AfriCOMET-1.0, and MetricX-24-Hybrid—are all based on pretrained multilingual large language models (LLMs) and utilize supervised learning. These metrics consistently outperform other types across all correlation coefficients. MetricX-24 and AfriCOMET-1.1 emerge as the best performers, statistically indistinguishable from each other. The improved performance of AfriCOMET-1.1 over its predecessor suggests ongoing enhancements in these LLM-based metrics. It is evident that African-centric LLM-based metrics (AfriCOMET variants) perform exceptionally well, highlighting the importance of language-specific fine-tuning for low-resource African languages.

Moreover, the weighted average correlation results presented in Table 3 offer additional valuable insights. MetricX-24 still emerges as the top-performing metric, achieving the highest correlation with human judgments across all three correlation coefficients (Pearson: 0.6269, Spearman: 0.4833, Kendall: 0.3455). Its hybrid variant, MetricX-24-Hybrid, follows closely, suggesting the robustness of this metric family. METAMETRICS-MT shows strong performance, ranking third overall with high correlation coefficients. As an ensemble method, it selectively combines complementary metrics, proves effective for African languages despite these metrics being trained on general WMT data. In addition, AfriCOMET-1.1 and its predecessor AfriCOMET-1.0 show robust performance indicating their effectiveness for African language pairs.

Traditional metrics like BLEU and its variant spBLEU demonstrate relatively weak correlations, reinforcing the need for more advanced metrics in evaluating MT quality for African languages. Interestingly, some widely-used metrics such as BERTScore and BLEURT-20 show moderate performance, outperforming traditional metrics but falling behind the top-performing ones. The consistent ranking across different correlation coefficients suggests a reliable performance hierarchy among these metrics. However, the overall moderate correlation values (mostly below 0.5 for Spearman and Kendall) highlight the ongoing challenges in accurately evaluating MT quality for African languages.

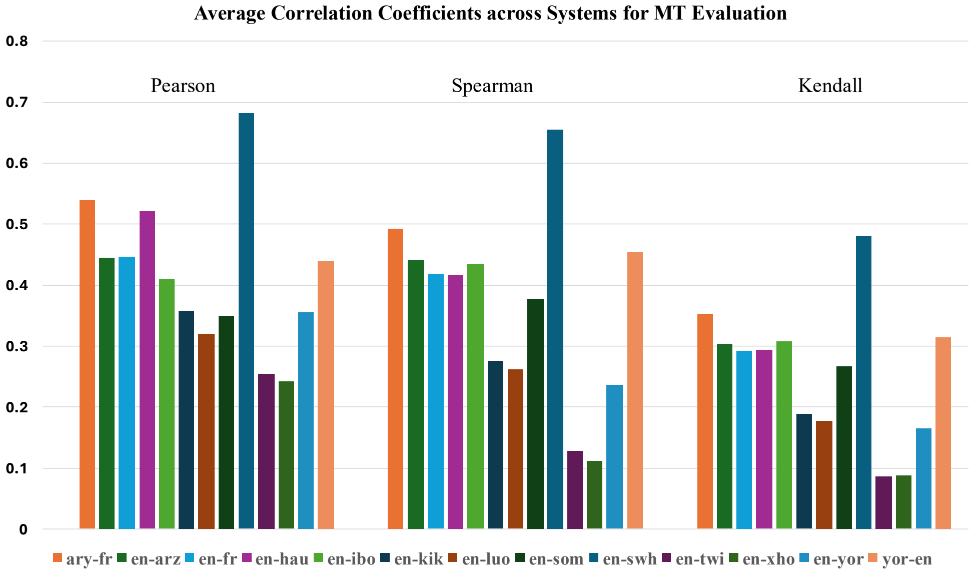

Figure 1: Average correlations across MT evaluation metrics for each language pair.

Metrics	Pearson	Spearman	Kendall

Table 5: Segment-level weighted average correlation coefficients of **QE** metrics, averaged across language pairs on AfriMTE, with weights based on the size of each language pair group. The metric marked with * ranks first based on the average of Pearson, Spearman, and Kendall correlation coefficients.

4.1.2 Quality Estimation as a Metric

QE presents a more challenging and purely cross-lingual task, making its investigation essential. Tables 4 and 5 presents the segment-level correlation coefficients of QE metrics on the entire AfriMTE and weighted average correlations across language pairs. Detailed Pearson, Spearman-rank, and Kendall-rank correlations of baseline metrics and primary submissions for each language pair are shown in Figures 6, 7, and 8 of Appendix A.

Comparing results in Tables 2 and 4, and results in Tables 3 and 5, we have observed significant performance gaps between MT evaluation models and their QE counterparts. This is evident when comparing specific versions, such as the differences between MetricX-24 and MetricX-24-QE, XCOMET and XCOMET-QE, as well as AfriCOMET-1.1 and AfriCOMET-QE-1.1. These disparities underscore the increased complexity of the QE task, which requires assessing translation quality without access to reference translations.

Tables 4 and 5 reveal the superior performance of LLM-based supervised-learning metrics in the QE task. Specifically, MetricX-24-QE and AfriCOMET-QE-1.1 emerge as the top-performing metrics on the entire AfriMTE test set (Table 4). These metrics demonstrate statistically indistinguishable performance, as confirmed by the Perm-Input hypothesis test. Furthermore, in the weighted average correlation across different language pairs (Table 5), MetricX-24-QE consistently outperforms other approaches. This trend in QE metrics mirrors the pattern observed in MT evaluation metrics, underscoring the effectiveness of LLM-based supervised-learning approaches in both contexts for African languages. Additionally, METAMETRICS-MT, as a meta-metric, continues to show strong performance, further validating the effectiveness of ensemble methods in addressing the complexities of African language evaluation. Another LLM-based metric, GEMBA-ESA, which employs a two-step approach: first collecting MQM error spans, and then assigning the final score also demonstrates robust performance, further highlighting the potential of LLM-based techniques in QE tasks for African languages. However, supervised QE metrics such as CometKiwi, CometKiwi-XXL, and XCOMET-QE show relatively poor performance, suggesting they might not be well-suited for African languages without specific language adaptation.

4.1.3 Language Adaptation, Cross-lingual Transfer, and Model Size as Key Factors in Metric Performance

Our analysis on the baseline and task submissions reveals that language-specific tuning, cross-lingual transfer learning, and model size are crucial factors in MT evaluation and Quality Estimation.

The top-performing systems demonstrate these principles in various ways. METRICX-24 systems, based on mT5-XXL (Xue et al., 2020), cover a wide range of languages, including several African languages such as Hausa, Igbo, Somali, Swahili, Xhosa, Yoruba, and Zulu. In contrast, AfriCOMET models use African-enhanced masked language models (AfroXLMR and AfroXLMR-76) with well-resourced DA training data, showcasing the benefits of language-specific adaptation. Both METRICX-24 and AfriCOMET variants employ supervised training and cross-lingual transfer learning, proving effective for low-resource language scenarios. The impact of model size is evident, with AfriCOMET variants (560 million parameters) and METRICX-24 (13 billion parameters) both achieving strong results. While METRICX-24's larger size contributes to its superior performance, AfriCOMET's performance demonstrates that well-adapted smaller models can also yield robust results.

Moreover, the excellent performance of METAMETRICS-MT underscores the potential of ensembling robust metrics to create effective meta-metrics. The promising results of GEMBA-ESA further highlight the effectiveness of LLM-based prompting techniques in this domain. These findings collectively emphasize the potentials of model ensemble and innovative LLM prompting strategies in developing effective MT evaluation and QE metrics, particularly for low-resource languages.

4.2 Language-Specific Performance: Average Correlations across Metrics

To investigate model performance on specific language pairs, we calculate the average correlation coefficients for each individual language pair across all metric systems, providing insights into how well metrics perform for specific language pairs. Results are shown in Figure 1 and 2.

4.2.1 Performance on MT Evaluation

Figure 1 depicting the average correlation coefficients across metric submissions for MT evaluation reveals significant variations in metric performance on different language pairs. Consistently across all pairs, Pearson correlation shows the highest values, followed by Spearman and then Kendall, suggesting stronger linear relationships between human and metric scores compared to monotonic or ordinal relationships. English-Swahili (en-swh) and Darija-French (ary-fr) demonstrate the highest correlations across all three metrics, likely due to their status as more resource-rich or commonly studied pairs. In contrast, English-Luo (en-luo), English-Twi (en-twi), and English-isiXhosa (eng-xho) exhibit the lowest correlations, indicating particular challenges for MT evaluation in these language pairs.

4.2.2 Performance on QE

A consistent pattern emerges in the QE task (Figure 2) where Pearson correlations generally show the highest values. Language pair performance is notably similar across both figures, with resource-rich pairs like English-Swahili (en-swh) consistently demonstrating higher correlations, while extremely low-resource pairs such as English-Luo (en-luo) and English-Twi (en-twi) show persistently lower correlations. Interestingly, some language pairs show improved relative performance in QE compared to MT Evaluation. For example, English-Egyptian Arabic (en-arz) and English-Hausa (en-hau) demonstrate better results in QE, possibly indicating their suitability for reference-free evaluation methods.

4.2.3 Some Special Cases

Contrary to expectations, English-French (en-fr) does not emerge as the top-performing language

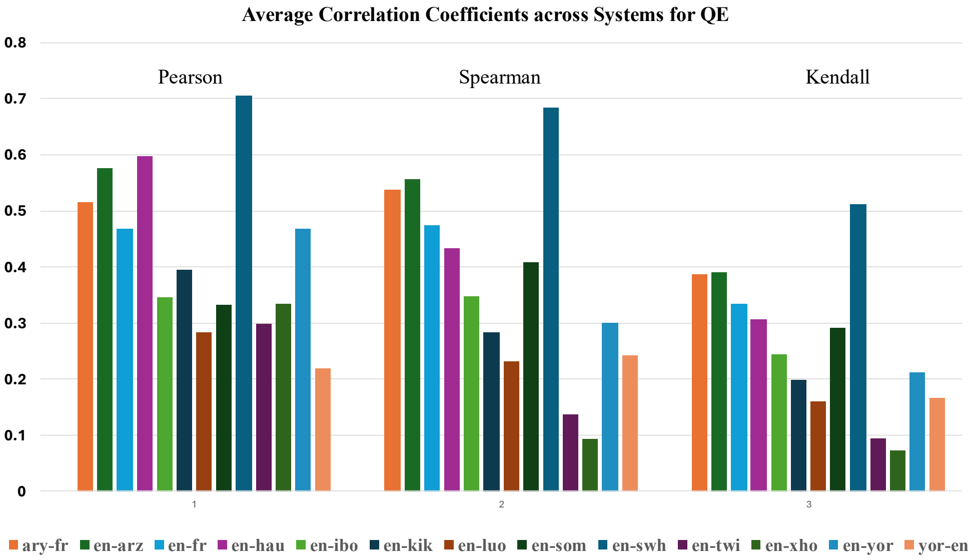

Figure 2: Average correlations across QE metrics for each language pair.

pair in either the MT evaluation or the QE task. This surprising result might be attributed to two factors. First, as illustrated in Table 7 of Wang et al. (2024), there is a scarcity of supervised DA training datasets for English-French. Second, the performance may be affected by the "curse of multilinguality" (Pfeiffer et al., 2022), a phenomenon where model performance on high-resource languages can degrade when the pre-trained model is fine-tuned and enhanced with data from multiple low-resource languages, in this case, African languages.

Another noteworthy case is English-isiXhosa (en-xho). As previously observed, English-isiXhosa translations demonstrated high overall sentence-level quality (median DA: 100 according to Wang et al. (2024)) , with only minor errors at the word level. This characteristic makes it particularly challenging to differentiate and rank translation quality. Consequently, the relatively lower performance of Spearman and Kendall for English-isiXhosa is expected.

5 Conclusion

In conclusion, our analysis on submissions to the AfriMTE challenge set of WMT 2024 Metrics Shared Task for African languages reveals that LLM-based supervised-learning metrics, especially those with African-centric tuning, consistently outperform traditional and other neural-based approaches in both MT evaluation and Quality Estimation tasks. Language-specific adaptation, cross-lingual transfer learning, and larger model sizes contribute significantly to improved metric performance. However, challenges persist for extremely low-resource languages such as Luo and Twi. Our analysis also highlights unexpected performance patterns in certain language pairs, including English-French and English-isiXhosa, demonstrating the complexities of evaluating machine translation across diverse African languages.

Machine Translation Metrics are better in evaluating Linguistic Errors on LLMs than on Encoder-Decoder Systems

Abstract

This year's MT metrics challenge set submission by DFKI expands previous years' linguistically motivated challenge set. It includes 137,000 items extracted from 100 MT systems for the two language directions (en→de, en→ru), covering more than 100 linguistically motivated phenomena organized in 14 linguistic categories. The metrics with the statistically significant best performance with regard to our linguistically motivated analysis are METRICX-24-HYBRID and METRICX-24 for en→de and METRICX-24 for en→ru, whereas METAMETRICS and XCOMET are in the next ranking positions in both language pairs. Metrics are more accurate in detecting linguistic errors among LLM translations than in translations based on the encoder-decoder NMT architecture. Some of the most difficult phenomena for the metrics to score are the transitive past progressive, the multiple connectors, and the ditransitive simple future I for en→de and the pseudogapping, the contact clause and the cleft sentences for en→ru. Despite its overall low performance, the LLM-based metric GEMBA performs best in scoring German negation errors.

1 Introduction

For almost two decades, the development and evaluation of machine translation (MT) have relied on automatic metrics. MT metrics aim to digest and automate various aspects of human judgment of MT output into numerical scores. Over the years, these metrics have undergone several technological changes (from measuring overlap to grammatical features and neural models). Still, at the same time, they have had to follow the technological evolution of MT systems, moving from phrase-based statistical systems to NMT encoder-decoder models and, more recently, to large language models (LLMs). As we witness the first efforts to use and evaluate LLMs in the task of MT, it is of great interest to see to what extent pre-existing MT methodologies can adapt to the needs of the new technologies. An obvious question is to what extent MT metrics developed and tested for NMT can be applied to evaluating LLMs.

This year's Metrics Task (WMT24; Freitag et al., 2024) provides a very good opportunity to evaluate the metrics under these particular circumstances, as the evaluated MT outputs have for the first time been produced by numerous LLMs (Kocmi et al., 2024). Meanwhile, the ability of LLMs to act as judges for translations is being explored through the participation of an LLM-based metric.

Given this perspective, this paper extends previous work on linguistically motivated challenge sets for MT metrics to investigate whether LLMs can influence MT evaluation. As part of this year's submission to the challenge set subtask of the WMT24 Metrics Task, we repeat the methodology of previous years to evaluate the metrics on a controlled test set that can rank them with regard to their ability to detect linguistic errors by providing fine-grained statistics for each linguistic phenomenon. We then analyze whether the metrics perform differently on MT output from LLMs as opposed to output from encoder-decoder systems. In addition, we see in which linguistic aspects the LLM-based metric performs better or worse than the specialized metrics.

The rest of the paper is structured as following: Section 2 describes briefly the generation of the challenge set. Section 3 presents and discusses the results, whereas the conclusion is given in section 4

2 Method

This year's linguistically-motivated challenge set is an extension of the challenge sets that were submitted the previous years (Avramidis and Macketanz, 2022; Avramidis et al., 2023).

The source sentences s originate from an MT evaluation test suite (Macketanz et al., 2022a). Each sentence has been carefully constructed to test one particular phenomenon. Every phenomenon is

Proceedings of the Ninth Conference on Machine Translation, pages 517–528
November 15-16, 2024 ©2024 Association for Computational Linguistics

tested by more sentences (with a minimum of 20 sentences), whereas the phenomena are aggregated in a few categories. At the moment, there are more than 100 phenomena and 14 categories.

As part of the WMT shared tasks of the previous years, these source sentences have been given to a large amount of MT systems, and their output has been evaluated by combining regular expressions and annotations by linguists, labeling every output as correct ($t \in T$) or incorrect ($\hat{t} \in T'$).

In order to use this test set to evaluate the MT metrics, we create examples in the form of $(s, \hat{t}, t, r) \in S$, where each example contains one source sentence s, one incorrect translation hypothesis $\hat{t}$, one correct translation hypothesis t and one reference translation r. The correct translation hypotheses t and the reference translations r are sampled with permutations from the same set of correct translations T. Then, we decompose the set of examples S into a blind test set S', where each example includes either an incorrect translation $(s, \hat{t}, r)$ or a correct translation (s, t, r) along with the source and the reference. The separated contrastive examples are shuffled, and we set aside a file that contains the golden truth, indicating which samples are correct or incorrect.

As part of the Metrics Task, every shuffled translation t and $hatt$ is scored by every M, given the reference r in the given blind test set S', without knowing if it is correct or incorrect. A contrastive pair scoring is considered correct if the metric delivers a score for the incorrect translation hypothesis, which is lower than the one of the correct translation hypothesis $M(s, \hat{t}, r) < M(s, t, r)$. Finally, for every phenomenon and category and for every metric, the respective accuracy is calculated by dividing the number of correctly scored contrastive pairs by the total amount of examples.

$$\text{acc}_M = \frac{|M(s, \hat{t}, r) < M(s, t, r)|}{|(s, \hat{t}, t, r)|}$$

$$(s, \hat{t}, r) \cup (s, t, r) \in S' \quad (s, \hat{t}, t, r) \in S$$

Lastly, we provide three types of score averaging:

i) **Micro-average:** This approach treats all items equally, aggregating all test items to compute the average percentages.

ii) **Category macro-average:** Here, all categories are treated equally, with the percentages being computed independently for each category and then averaged.

iii) **Phenomenon macro-average:** This average treats all phenomena equally, with the percentages being computed independently for each phenomenon and then averaged.

The current version of the challenge set contains MT outputs from the WMT Shared Tasks of the years 2019-2024 (Avramidis et al., 2019, 2020; Macketanz et al., 2021, 2022b; Manakhimova et al., 2023, 2024). The English to German version contains 39,463 contrastive pairs, while the English to Russian version contains 30,108 pairs.

3 Results

3.1 English-German

The comparison of the metrics based on the accuracies per category for English-German can be seen in table 2, whereas the detailed phenomena in table 4. One can see that the metrics which have the highest accuracy with statistical significance are METRICX24-HYBRID and METRICX24 (Juraska et al., 2024), with more than 80.7 % macro-average. Both metrics are very good at multi-word expressions (mostly verbal MWEs). The former is the best of all metrics at coordination/ellipsis and nonverbal agreement (genitive and personal pronoun coreference). In contrast, the latter performs best at verb valency (resultative and passive voice). The metrics “METAMETRICS” (Anugraha et al., 2024) and XCOMET (Guerreiro et al., 2023) follow in the ranking, with more than 80% macro-averaged accuracy.

The LLM-based metric GEMBA (Kocmi and Federmann, 2023) performs relatively low, with an average accuracy of 69.7%, even below the baseline non-tuned metric CHRF (Popović, 2015). It is nevertheless remarkable that this metric has the best score on negation, among all metrics (97.4%, 4.5% higher than the best system). The fact that most of the metrics will miss 10% of the negations is rather noteworthy, given the implications of such a mistake on the meaning of the sentence. It is also remarkable that a reference-less metric, METRICX24-HYBRID-QE, achieves the highest accuracy on long-distance dependencies and interrogatives, mainly on the phenomenon of negative inversion.

Some of the most difficult phenomena for the

	METRICX24	METRICX24-HYB	METAMETRICS	XCOMET
encdec vs. encdec	73.2	72.3	70.8	69.7
LLM vs. encdec	77.3	76.9	79.9	77.6
LLM vs. LLM	79.9	78.1	80.0	79.1

Table 1: Accuracy of the metrics when they evaluate contrastive pairs containing (a) MT output only by encoder/decoder systems, (b) one encoder/decoder output and one LLM output, (c) only LLM output

metrics to score are transitive past progressive, multiple connectors, and ditransitive simple future I.

3.2 English-Russian

The comparison of the metrics based on the accuracies per category for English-Russian can be seen in table 3, whereas the detailed phenomena in table 5. MetricX-24 is the clear winner in this language direction, achieving a macro-averaged accuracy of 82.5% MetricX-24 excels in ambiguity, false friends, non-verbal agreement (coreference & genitive), verb semantics, and verb valency. The ranking of the metrics is similar to the one for English-German, with METAMETRICS, METRICX24-HYBRID and XCOMET having the next position, with more than 79.6% accuracy in macro-average.

If one focuses again on the phenomenon of negation, they would notice that in English-Russian, the highest accuracy is achieved by the baseline metric CHRF, whereas most metrics perform here very low (61% on average) Some of the most difficult phenomena for this language direction are the pseudogapping, the contract clause, and the cleft sentences for en→ru.

3.3 Comparing performance of metrics over LLM vs. encoder-decoder systems

Table 1 presents the accuracies of the 4 best performing metrics on three subsets of the challenge sets. Here every subset contains contrastive pairs which consist of

(a) two MT outputs, both by encoder/decoder NMT systems
(b) one encoder/decoder and one LLM output
(c) two LLM outputs

One can see that all four metrics exhibit higher accuracy when scoring contrastive translations originating from LLMs. This indicates that despite the fact that LLM translations achieve very good performance (Kocmi et al., 2024), their fewer errors are easier to be distinguished by the automatic metrics. Whether there is a systematic reason for this phenomenon remains to be investigated.

4 Conclusion

We presented the MT metrics challenge set of DFKI for two language directions (en-de, en-ru). This year, we have expanded the set to include outputs from encoder-decoder NMT systems and LLMs. The number of test items (total of 137,000) allows for producing fine-grained scores for every linguistic phenomenon and statistically significant comparisons among the MT metrics. We also identified the best-performing metric, METRICX-24, for both language directions.

Abstract

In machine translation quality estimation (QE), translation quality is evaluated automatically without the need for reference translations. This paper describes our contribution to the sentence-level subtask of Task 1 at the Ninth Machine Translation Conference (WMT24), which predicts quality scores for neural MT outputs without reference translations. We fine-tune GPT-4o mini, a large-scale language model (LLM), with limited data for QE. We report results for the direct assessment (DA) method for four language pairs: English-Gujarati (En-Gu), English-Hindi (En-Hi), English-Tamil (En-Ta), and English-Telugu (En-Te). Experiments under zero-shot, few-shot prompting, and fine-tuning settings revealed significantly low performance in the zero-shot, while fine-tuning achieved accuracy comparable to last year's best scores. Our system demonstrated the effectiveness of this approach in low-resource language QE, securing 1st place in both En-Gu and En-Hi, and 4th place in En-Ta and En-Te. The code used in our experiments is available at the following URL [1].

1 Introduction

Machine translation quality estimation evaluates translation automatically without reference translation. This practice reduces the cost of manual translation and enables efficient evaluation. The subsequent quality score flags the necessity of resorting to a more reliable translation system or revision from human post-editing. Quality estimation can be performed at various granularity levels, including word, phrase, sentence, and document.

In this paper, we describe our contribution to the QE shared task at the Ninth Machine Translation Conference (WMT24). We participate in the Task 1 of the shared task and we specifically focus on the sentence-level subtask, which involves predicting the quality score of neural MT outputs at the sentence level without access to reference translations. There are two different annotation methods for QE: Multidimensional Quality Metric (MQM) (Freitag et al., 2021) and Direct Assessment (DA) (Fomicheva et al., 2022), and we report the results of DA score prediction. Our study targets four language pairs: English-Gujarati (En-Gu), English-Hindi (En-Hi), English-Tamil (En-Ta), and English-Telugu (En-Te). The participating systems are assigned the task of predicting the quality score of each source and target sentence pair, and their performance is evaluated using Spearman's rank correlation coefficient as the primary metric, and Pearson and Kendall coefficients as supplementary metrics.

	En-Gu	En-Hi	En-Ta	En-Te

gpt4o-mean	**0.712**	**0.735**	**0.616**	0.457
gpt4o-prob	**0.712**	0.734	0.608	**0.460**

Table 1: Spearman's rank correlation coefficient between our predictions and human DA judgments of WMT24 test data. The best score obtained for each language pair is marked in bold.

We present a system for quality estimation utilizing a large language model (LLM), inspired by the success of LLMs in regression tasks (Liu et al., 2023; Enomoto et al., 2024). Specifically, we manually designed a prompt for quality estimation and employed GPT-4o mini (OpenAI, 2024) to generate assessment scores multiple times based on this prompt. We then used either the averaged score of these generated scores or their weighted sum based on the generation probability as the final score. Evaluation experiments were conducted in both zero-shot and three-shot settings. Noticeably, we fine-tuned GPT-4o mini using the training data released at WMT23 (Kocmi et al., 2023) and as-

Proceedings of the Ninth Conference on Machine Translation, pages 529–534
November 15-16, 2024 ©2024 Association for Computational Linguistics

sessed its performance.

We first evaluated our systems using the development data released at WMT23. The results indicated that the Spearman's correlations in the zero- and few-shot settings ranged from 0.2 to 0.4, while those for the fine-tuned GPT-4o mini ranged from 0.4 to 0.7. Compared to a single generation, the estimated score derived from the average or weighted sum based on multiple output values was found to perform consistently better. Subsequently, we evaluated the system based on the fine-tuned GPT-4o mini using the test data from WMT24. Table 1 presents the results of our system and the baseline for Task 1 (Rei et al., 2022). The system achieved Spearman's correlation scores of 0.712, 0.735, 0.616, and 0.460 in the En-Gu, En-Hi, En-Ta, and En-Te language pairs, respectively, surpassing the baseline system's performance. We achieved the 1st place in En-Gu and En-Hi, and 4th place in En-Ta and En-Te.

2 Related Work

GEMBA (Kocmi and Federmann, 2023) is a translation quality metric that utilizes a large language model (LLM). It has been shown to have a high correlation with the human-rated MQM score of the WMT22 Metrics shared task. Their experiments covered three language pairs (English to German, English to Russian, and Chinese to English) of the WMT22 Metrics shared task using seven GPT variants from GPT-2 to GPT-4 models. Lu et al. (2024) investigated various prompts to improve segment-level evaluation performance. They experimented with Llama2-70B model (Touvron et al., 2023) and Mixtral-8x7b model (Jiang et al., 2024) in addition to GPT-3.5-Turbo model, and showed that the method using GPT-3.5-Turbo had the best performance. These previous studies highlight the potential of LLM evaluators as human alternatives. Our system uses the latest model, GPT-4o mini, and also estimates quality for more challenging translations for low-resource languages.

Enomoto et al. (2024) used an LLM to solve the lexical complexity prediction task. They reported a bias in the numerical values generated by an LLM in that certain values occur frequently regardless of the input. To mitigate the bias and achieve a more precise numerical output, we run the generation several times and obtain the final scores by either average or expectation weighted by generation probabilities.

3 Methodology

Our system uses LLMs to estimate translation quality scores. Following GEMBA (Kocmi and Federmann, 2023), to assess translation quality via prompting an LLM, the following arguments are required:

- source language name: {{source language}}
- target language name: {{target language}}
- source sentences: {{$src_1, ..., src_N$}}
- translated sentences: {{$hyp_1, ..., hyp_N$}}
- few-shot examples: {{examples}} (optional)

We define the instructions to be input into the LLM as follows:

> *Please analyze the given source and translated sentences and output a translation quality score on a continuous scale ranging from 0 to 100.*
> *Translation quality should be evaluated based on both fluency and adequacy.*
> *A score close to 0 indicates a low quality translation, while a score close to 100 indicates a high quality translation.*
> *Do not provide any explanations or text apart from the score.*
>
> {{examples}}
> {{source language}} *Sentence:* {{src_i}}
> {{target language}} *Sentence:* {{hyp_i}}
> *Score:*

The instruction template is designed to include a description of the task, the score range, and a description of the evaluation criteria. To restrict the output to numerical values only, it is important to state "Do not provide any explanations or text apart from the score." explicitly.

According to Kocmi and Federmann (2023), there are some numbers that are particularly prone to output, such as "95". To mitigate such bias in the output distribution, the final score is computed from the sampled generated results with reference to the G-Eval framework (Liu et al., 2023). $Score_{mean}$ is the simple average of the generated scores, while $Score_{prob}$ is the score weighted by the generation probabilities. Let $S = \{s_1, s_2, ..., s_n\}$ represent the set of scores generated by the prompt, and let $p(s_i)$ be the softmax output probability of each generated score.

	Fine-tuned	**0.683**	0.715	**0.508**	**0.568**	**0.690**	**0.412**	**0.663**	0.746	**0.489**	**0.399**	0.360	**0.277**

Table 2: Spearman (ρ), Pearson (r) and Kendall (τ) correlation between the proposed approaches and human DA judgments of WMT23 dev data. The best Spearman score obtained for each language pair is marked in bold. Single generation is a prediction method that uses the output value generated only once as the estimated score, and the other two are methods that calculate the average value or the expected value based on the generation probability, based on the output values by 20 times generation.

The final scores are calculated using the following formulae:

$$score_{mean} = \frac{1}{n}\sum_{i=1}^{n} s_i \quad (1)$$

$$score_{prob} = \sum_{i=1}^{n} p(s_i) \times s_i \quad (2)$$

In this study, the experiment is conducted with $n = 20$. Among the generated outputs, non-numeric tokens and numbers outside the specified range are excluded from S.

4 Experiments

We conduct experiments to investigate two RQs. **RQ 1**: Which methods are more effective in improving performance of low-resource language QE? **RQ 2**: How effective are sampling methods in mitigating numerical output bias?

4.1 Settings

Model We use GPT-4o mini ("gpt-4o-mini-2024-07-18") (OpenAI, 2024) for our experiments. It is priced at 15 cents per million input tokens and 60 cents per million output tokens and more than 60% cheaper than GPT-3.5 Turbo.

Our system fine-tunes GPT-4o mini. The fine-tuning process is conducted using OpenAI's API.

Data For the remaining sections, we only report results on the WMT23 dev dataset. The examples used for few-shot prompting are randomly obtained from the WMT23 training dataset. WMT23 training data consists of 7,000 sentence pairs in each language and is also used for fine-tuning.

4.2 Results

Spearman, Pearson, and Kendall correlation coefficients between predicted and gold scores for each language pair are shown in Table 2.

4.2.1 Strategies for Low-Resource Languages

For **RQ 1**, we compare the performance of the three settings: zero-shot, few-shot prompting, and fine-tuning. Few-shot in $score_{mean}$ and $score_{prob}$ improved Spearman correlation coefficients slightly by 0.033 for En-Hi and 0.016 for En-Te, while En-Gu and En-Ta scores decreased by 0.006 and 0.016 respectively. In other words, the few-shot strategy is not very effective for low-resource languages. On the other hand, in the single genaration setting, En-Gu and En-Ta improved by 0.208 and 0.186, respectively, indicating that the few-shot is more effective when the generation times are limited.

Fine-tuning improves performance in almost all evaluation metrics and is an effective measure for low-resource languages. Our systems submitted to the shared task (Table 1) are also the result of the fine-tuned models.

4.2.2 Strategies for Distributional Bias

For **RQ 2**, we compare the performance of the three settings: single generation, $score_{mean}$, and $score_{prob}$. In the fine-tuned model, the difference in Spearman's rank correlation coefficient with sin-

	En-Gu	En-Hi	En-Ta	En-Te
Manually	**0.451**	**0.394**	**0.519**	**0.274**
AutoCoT	0.444	0.387	0.514	0.238

Table 3: Spearman's rank correlation coefficient between our predictions in a zero-shot setting using two different prompt generation methods and human DA judgments of WMT23 dev data.

gle generation (average of four languages) is 0.072 for $score_{mean}$ and 0.076 for $score_{prob}$. Compared to single genaration, the other two sampling methods performed better, demonstrating the effectiveness of these methods in mitigating the effects of bias during generation. The performance of $score_{mean}$ and $score_{prob}$ is almost equal, and either method can be used.

5 Discussion

5.1 Is AutoCoT necessary for G-Eval?

In Chiang and Lee (2023), they find that the auto Chain-of-Thought (CoT) used in G-Eval does not always make G-Eval more aligned with human ratings. In this section, we examine the methods used to construct the prompt for this task.

To replicate the G-Eval framework (Liu et al., 2023) procedures, it is necessary to construct an initial prompt to generate the evaluation steps using AutoCoT. Specifically, we first manually designed a prompt that contains the definition of the QE task and the desired evaluation criteria as follows:

> *You will be given a source and a translated sentence. Your task is to rate translated sentence on one metric. Please make sure you read and understand these instructions carefully. Please keep this document open while reviewing, and refer to it as needed.*
>
> *Evaluation Criteria:*
>
> *Translation Quality (0 - 100) - the quality of a translation based on the adequacy and fluency of the sentence.*

Then, we added a line of "*Evaluation Steps:*" to the prompt and let GPT-4 [2] generate the following evaluation steps by CoT automatically:

> *Evaluation steps:*
>
> *1. Read the source sentence and the translated sentence carefully.*
>
> *2. Evaluate the translated sentence based on its adequacy and fluency.*
>
> *- Adequacy: How much of the meaning expressed in the source text is also expressed in the target text? A score of 100 means all the meaning is transferred, and 0 means none of it is.*
>
> *- Fluency: Does the translation sound like something a native speaker would say? A score of 100 means it sounds completely native, and 0 means it doesn't sound native at all.*
>
> *3. Give the translation a score between 0 and 100, where 0 is the worst and 100 is the best.*

We compare the performance in a zero-shot setting using prompts created by AutoCoT and those created manually. As shown in Table 3, manual prompts performed better than AutoCoT for all languages. This result follows the findings of Chiang and Lee (2023), and we decided to use manually constructed prompts in our systems to get results that correlated better with human judgment.

5.2 Is it difficult for GPT-4 evaluators to evaluate Telugu text?

In our results, the performance on Telugu data was lower than other languages. This may be attributed to the linguistic complexity of Telugu, which features complex noun and verb conjugations, as well as its status as a low-resource language. Kishore and Shaik (2024) demonstrated that ChatGPT is less accurate in Telugu grammar and vocabulary compared to Gemini. Performance is expected to improve by using LLMs specialized for each language (e.g., Telugu GPT[3]) rather than relying on a single, generalized model.

6 Conclusion

Our study demonstrates the efficacy of using a LLM for sentence-level quality estimation in machine translation. By leveraging GPT-4o mini, we achieved improvements over baseline systems in predicting quality scores for various language pairs. The fine-tuned GPT-4o mini model exhibited robust performance in low-resource language QE,

[2] We used `gpt-4-0613` following Liu et al. (2023)

[3] https://chatgpt.com/g/g-RjoqGo7g0-telugu-gpt

with Spearman's correlation scores significantly higher than those in the zero- and few-shot settings. These findings emphasize that fine-tuning with an annotated QE dataset is crucial for enhancing performance in low-resource languages. However, in practical scenarios, creating and obtaining such datasets for low-resource languages poses significant challenges. Therefore, efforts to effectively improve performance using a small amount of data, as explored in works like (Lauscher et al., 2020; Kim and Komachi, 2023), are important directions for future research.

Abstract

Quality estimation (QE) is a crucial technique for evaluating the quality of machine translations without the need for reference translations. This paper focuses on Huawei Translation Services Center's (HW-TSC's) submission to the sentence-level QE shared task, named LLMs-enhanced-CrossQE. Our system builds upon the CrossQE architecture from our submission from last year, which consists of a multilingual base model and a task-specific downstream layer. The model input is a concatenation of the source and the translated sentences. To enhance performance, we fine-tuned and ensembled multiple base models, including XLM-R, InfoXLM, RemBERT, and CometKiwi. Specifically, we employed two pseudo-data generation methods: 1) a diverse pseudo-data generation method based on the corruption-based data augmentation technique introduced last year, and 2) a pseudo-data generation method that simulates machine translation errors using large language models (LLMs). Our results demonstrate that the system achieves outstanding performance on sentence-level QE test sets.

1 Introduction

Quality estimation (QE) aims to automatically assess machine translation outputs without requiring reference translations (Specia et al., 2018). We report the technical details of our approach to sentence-level quality prediction and fine-grained error span detection subtasks in the WMT 2024 QE shared task. Our team, Huawei Translation Services Center (HW-TSC), participated in direct assessment (DA) score in sentence-level quality prediction and the fine-grained error span detection tasks across all language pairs. Fine-tuning pre-trained language models, which provide rich semantic information, has become the standard approach for QE tasks (Rei et al., 2020). In this paper, we present LLMs-enhanced-CrossQE, HW-TSC's system for the sentence-level QE task, which leverages multiple pre-trained language models and data augmentation techniques. The key aspects of our system design are summarized as follows:

- **Model**: We employed our previous year's architecture, CrossQE (Tao et al., 2022), as the foundation. For every language pair, models were individually fine-tuned. Additionally, we used CometKiwi (Rei et al., 2022), a multilingual QE model, and fine-tuned it for single language pairs.

- **Data augmentation**: Based on the corruption-based data generation (CDG) method used last year (Li et al., 2023), we propose a diverse CDG (D-CDG) method. Specifically, we generate more varied corrupted translations by combining multiple error types. Additionally, we rewrite source sentences using large language models (LLMs) to create pseudo-sentences containing errors that closely resemble those produced by machine translation systems. Finally, we employ a reference-based QE model to generate pseudo scores.

- **Ensemble**: For each language pair, we ensemble eight fine-tuned models to achieve optimal performance. These checkpoints originated from four base models: XLM-R (Conneau et al., 2020), InfoXLM (Chi et al., 2021), RemBERT (Chung et al., 2020), and CometKiwi (Rei et al., 2022), and three training dataset configurations: original dataset, augmented dataset, and augmented dataset followed by the original dataset. The ensemble weight for each checkpoint was optimized with Optuna (Akiba et al., 2019). On average, eight checkpoints were used per language pair after optimization. Additionally, we experimented with a naive weight ensemble approach based on the method proposed by Yadav et al. (2024), but it did not yield significant improvements.

Proceedings of the Ninth Conference on Machine Translation, pages 535–540
November 15-16, 2024 ©2024 Association for Computational Linguistics

Our system ranks first in the English-Tamil direction and second in several other directions in the direct assessment quality estimation task (Zerva et al., 2024). It significantly outperforms the baseline given by the competition organizers by a large margin. Additionally, we provide detailed results of each model with and without data augmentation in Table 3. To analyze the importance of each model in the ensemble, we present the ensemble weights in Figure 2 and 1. It is worth noting that the models fine-tuned with the proposed data augmentation technique were assigned higher weights in the ensemble.

2 Background

2.1 Task Description [1]

Sentence-level QE with direct assessment (DA) anotations: The goal is to predict the quality score for each source-target sentence pair. The golden-truth quality scores were obtained from human translators who rated each translation from 0 to 100. The scores from three or four translators were normalized and averaged to get the final score. This year's QE shared task has four language pairs with DA quality scores: English-Hindi (en-hi), English-Tamil (en-ta), English-Telegu (en-te) and English-Gujarati (en-gu). All languages have just 7,000 training samples.

Fine-grained error span detection: Participants of this task need to identify the error span (start and end indices) and the error severity (major or minor).

2.2 Base Models

- **XLM-R** (Conneau et al., 2020): A transformer-based masked language model trained on a massive multilingual corpus with more than two terabytes of data.
- **InfoXLM** (Chi et al., 2021): A cross-lingual pre-trained model that leverages multilingual masked language modeling, translation language modeling, and cross-lingual contrast learning.
- **RemBERT** (Chung et al., 2020): A rebalanced mBERT model with factorization of the embedding layers. The input embeddings are smaller and kept for fine-tuning, while the output embeddings are larger and discarded after pre-training.
- **CometKiwi** (Rei et al., 2022): A multilingual reference-free QE model that uses a regression approach and is built on top of InfoXLM. It has been trained on direct assessments from WMT17 to WMT20 and the MLQE-PE corpus.

3 Method

3.1 Model Architecture

3.1.1 Task1: Sentence-level QE with direct assessment (DA)

As shown in Equation 1 and 2, the embeddings of source sentence $\mathbf{s}$ and translated sentence $\mathbf{t}$ are concatenated in both orders $[\mathbf{s}, \mathbf{t}]$ and $[\mathbf{t}, \mathbf{s}]$ to form the input of pre-trained model f_{base}. The output token-level embedding sequences are processed by an average pooling layer to obtain vector representations $\mathbf{h}_{s1}$ and $\mathbf{h}_{t1}$ for source and translation respectively. These feature vectors are enhanced by taking their absolute difference and element-wise multiplication, as shown in Equation 3 and 4. Finally, all feature vectors are concatenated and fed into a regression head that predicts the final score y (Equation 5). This architecture enables information exchange between source and translated sentences at an early stage of the network and has proven to be significantly more effective than combining cross-lingual information after the pre-trained model.

$$\mathbf{h}_{s1}, \mathbf{h}_{t1} = f_{base}([\mathbf{s}, \mathbf{t}]) \tag{1}$$
$$\mathbf{h}_{t2}, \mathbf{h}_{s2} = f_{base}([\mathbf{t}, \mathbf{s}]) \tag{2}$$
$$\mathbf{f}_1 = [\mathbf{h}_{s1}, \mathbf{h}_{t1}, |\mathbf{h}_{s1} - \mathbf{h}_{t1}|, \mathbf{h}_{s1} \odot \mathbf{h}_{t1}] \tag{3}$$
$$\mathbf{f}_2 = [\mathbf{h}_{s2}, \mathbf{h}_{t2}, |\mathbf{h}_{s2} - \mathbf{h}_{t2}|, \mathbf{h}_{s2} \odot \mathbf{h}_{t2}] \tag{4}$$
$$y = f_{score}([\mathbf{f}_1, \mathbf{f}_2]) \tag{5}$$

3.1.2 Task2: Error span detection

For this task, we speculate that the understanding ability of large models may be helpful to the task, so we use the TowerInstruct-7B-v0.2 (Alves et al., 2024) model and the GPT-4o-mini (Islam and Moushi, 2024) model to cope with this task.

3.2 Data Augmentation

In this year's QE shared task, we adapted two data augmentation methods. 1) Text Editing, we implemented a D-CDG method based on the CDG proposed last year (Li et al., 2023), in which we constructed more diverse translation error data by

[1] https://wmt-qe-task.github.io/

Method	Description
Deletion	A random word in the translation was deleted.
Insertion	A random word in the translation was selected and inserted in a random position.
Substitution	A random word was replaced with another word in the translation.

Table 1: Three available text editing methods.

Method
You are a Gujarati to English machine translation system. I will give you a correct parallel data pair, rewrite the target language (English) sentence with mistakes that you may have made while doing the translation, including but not limited to incorrect words, adding extra words, Omitting crucial words, wrong numbers or dates, deleting words, exchanging the position of two words, wrong numbers, incorrect punctuation, incorrect capitalization, grammar errors. The correct parallel data is: "$SRC", "$TGT". please just output the target language with 20%, 35%, 50% mistake token of the target length.

Table 2: A prompt example for LLMs to generate pseudo QE training data based on a sample from the Gujarati to English QE training set, $SRC and $TGT represent the source and target languages in the sample, respectively.

incorporating multiple text editing approaches. 2) LLMs-generated pseudo-data. We generated translation data with errors more similar to those produced by machine translation systems using GPT-4o-mini and constructed parallel data pairs containing translation errors through the machine translation system.

For text editing, we employed three methods proposed last year to generate translation errors: Deletion, Insertion, and Substitution. Notably, this year, we generated translation sentences with more diverse translation errors by combining these three text editing methods with a certain probability. Specifically, each time we performed a text edit, we modified the original text with equal probability by sampling a text editing method from a subset of the three available text editing methods. Additionally, we also created a version of pseudo-data by directly translating the source language into the target language and then back-translating it.

For LLM-generated pseudo-data, we constructed a prompt using the GPT-4o-mini to generate a modified source language sentence multiple times with different proportions, correlating with the number of tokens in the sentence(see Table 2). This approach yielded multiple modified source language sentences containing error tokens that closely resemble those generated by translation systems. These modified sentences were then translated into the target language using a translation system. Similar to the text editing method, we scored the pseudo-parallel translation pairs using a reference-based QE model [2] to create pseudo QE training data. It is worth noting that we constructed the scaling factor as the ratio between the corrupted translation score and the uncorrupted translation score ($\frac{f_{QE}(s,\hat{t},t)}{f_{QE}(s,t,t)}$), following the approach from last year.

4 Experiments

4.1 Experimental setups

Our system is built on top of the COMET package [3]. We fine-tuned four pre-trained models, namely XLM-R, InfoXLM, RemBERT and CometKiWi [4], on a single Nvidia Tesla V100 GPU with a batch size of 4, gradient accumulation of 8 and mean square error loss function. We stopped the training when there was no improvement in terms of Spearman correlation on the dev set for five test runs. For each language pair, the augmented dataset from text editing method, which contains more than ten times data than the original dataset, and the augmented dataset from LLMs, which contains about three times data than the original dataset, were all pre-generated instead of generated on-the-fly to improve training efficiency. Following last year's conclusion that the pseudo-data is more effective compared with the original data, we fine-tuned four base models by pseudo-data directly. The training step took around 10 hours with the augmented

Table 3: Results for sentence-level QE in terms of **Spearman** correlation. We report the performance of using D-CDG and LLM-generated pseudo-data as a data augmentation approach(aug). Except for the last three rows which show the results on the dev \ test set, other results were based on the dev set.

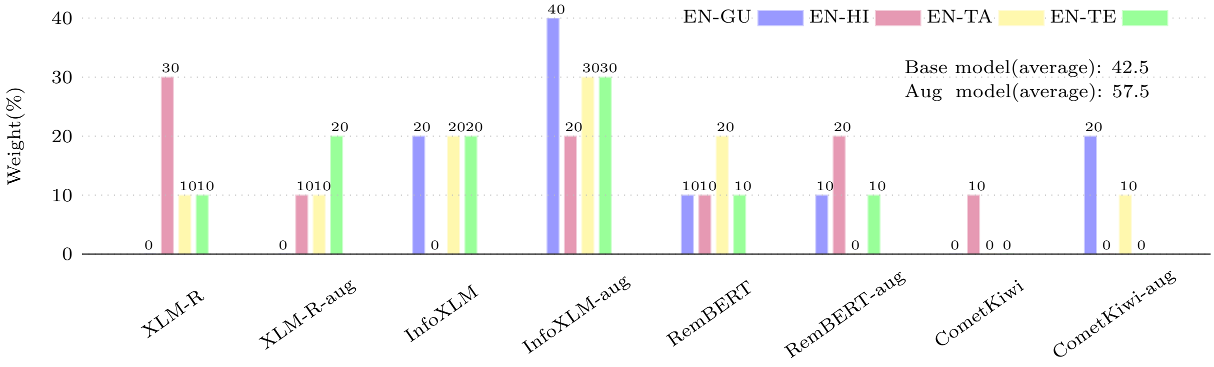

Figure 1: The ensemble weights for each base model.

dataset.

With four base models and two data augmentation approaches, we obtained eight checkpoints for each language pair. We ensembled these checkpoints by taking the weighted average of the predicted scores. The weights were optimized using Optuna, an automatic hyperparameter search framework. We used the Spearman correlation as the optimization objective, setting the step size to 0.05, and conducted 1000 trials on the dev set.

4.2 Results

4.2.1 Task1

The results of sentence-level QE in terms of Spearman correlation are shown in Table 3. Without data augmentation, CometKiwi has the best average correlation of 0.604, while XLM-R, InfoXLM, and RemBERT are close behind with around 0.590.

For the two data augmentation methods, we found that the D-CDG approach led to improvements across nearly all languages and models, as shown in Table 3. Additionally, this approach outperformed the original CDG method[5]. This suggests that rewriting a sentence by combining multiple diverse text editing methods within the same sentence is more effective than using only a single text editing method. Instead, for the pseudo-data generated by LLMs, we did not observe a positive effect on the dev set in all language directions, as shown in Table 3.

Furthermore, in the model ensemble, we observed that models with the D-CDG approach played a more important role. Specifically, the In-

GPT-4o-mini	0.119	0.315	0.073	0.361	0.398	0.331	0.146	0.249	0.103
Baseline **(test set)**	**0.192**	-	-	**0.481**	-	-	**0.161**	-	-
Ensemble **(test set)**	0.178	0.181	0.175	0.361	0.398	0.331	0.141	0.227	0.102

Table 4: Results for error span detection in terms of F1 score.

foXLM model with D-CDG was assigned a larger weight across all languages, as shown in Figure 1. We also noticed that the assignment of higher weights to models with D-CDG in the ensemble correlated with the base model's overall importance, if a base model received substantial attention, the corresponding model with D-CDG also tended to receive more weight.

Notably, models with LLM-generated pseudo-data were not assigned higher weights in the ensemble 2. However, in the test set, models with LLM-generated pseudo-data achieved better Spearman correlation scores in two languages(en-ta and en-gu). This may be attributed to the fact that LLMs generate more diverse pseudo-data, thereby enhancing the ensemble model's generalization ability. On the other hand, there may be a large gap between the dev set and the test set, the model with text editing data is overfitted to the dev set, while the models with LLMs pseudo-data introduce some regularization ability, which makes the ensemble model achieve better results on some languages.

This may be attributed to the fact that LLMs generate more diverse pseudo-data, thereby enhancing the ensemble model's generalization ability. Additionally, the discrepancy between the development set and the test set might have caused overfitting in models trained with text editing data. In contrast, models incorporating LLM-generated pseudo-data introduced a regularization effect, enabling the ensemble model to achieve better results in certain languages.

4.2.2 Task2

The results for error span detection are displayed in Table 4. In the Table, we can see that the method of using the large language model alone to detect the error segment is lower than the baseline based on cometkiwi, but it is not far from it. In addition, we can see that the method based on GPT-4o-mini is much higher than the method without LLMs in recall. That's enough to see the potential of the large language models, if human preferences can be injected for fine tuning, there is a good chance that large language models will outperform cometkiwi-based methods.

5 Conclusion

This paper mainly presents HW-TSC's sentence-level QE system called LLMs-enhanced-CrossQE. Using our previous year's model CrossQE as the foundation, we conducted comprehensive experiments with various pre-trained models. To further enhance the robustness of all language pairs and provide various checkpoints for model ensemble, we introduced a diverse pseudo-data generation method based on the corruption-based data augmentation technique proposed last year. Our system demonstrates strong performance across all language pairs with DA annotations in the sentence-level QE task. In the future, we plan to explore the use of LLMs to generate more diverse QE pseudo-data using more effective in-context learning techniques, such as chain-of-thought (CoT) prompting, or by transferring knowledge from LLMs to QE models through direct utilization of LLM parameters. Additionally, this paper presents only a brief investigation of the error span detection task. Therefore, we plan to further explore word-level and document-level QE tasks, which can improve the interpretability of QE and hold significant promise in the era of LLMs.

Abstract

The paper presents the submission by HW-TSC in the WMT 2024 Quality-informed Automatic Post Editing (QEAPE) shared task for the English-Hindi (En-Hi) and English-Tamil (En-Ta) language pair. We use LLM for En-Hi and Transformer for EN-ta respectively. For LLM, we first continue pertrain the Llama3, and then use the real APE data to SFT the pre-trained LLM. As for the transformer in En-Ta, we first pre-train a Machine Translation (MT) model by utilizing MT data collected from the web. Then, we fine-tune the model by employing real APE data. We also use the data augmentation method to enhance our model. Specifically, we incorporate candidate translations obtained from an external Machine Translation (MT) system. Given that APE systems tend to exhibit a tendency of 'over-correction', we employ a sentence-level Quality Estimation (QE) system to select the final output, deciding between the original translation and the corresponding output generated by the APE model. Our experiments demonstrate that pre-trained MT models are effective when being fine-tuned with the APE corpus of a limited size, and the performance can be further improved with external MT augmentation. our approach improves the HTER by -15.99 points and -0.47 points on En-Hi and En-Ta, respectively.

1 Introduction

Automatic Post-Editing (APE) is a post-processing task in a Machine Translation (MT) workflow, aiming to automatically identify and correct errors in MT outputs (Chatterjee et al., 2020a). WMT has been holding APE task competitions in different languages and fields since 2015. Different from previous years, this year's APE task is a subtask of the QE task, named Quality-informed automatic post-editing (QEAPE) (Zerva et al., 2024). It proposes to combine quality estimation and automatic post-editing in order to correct the output of machine translation. Participants are provided with a training set comprising 7,000 instances, a development set, and a test set, with each containing 1,000 instances. Each dataset consists of triplets — the source (*src*) sentences, the corresponding machine-translation (*mt*) outputs, and the human post-edited versions (*pe*) of the translations along with sentence-level QE annotations. Additionally, participants are permitted to utilize any additional data for systems training.

Typically, training an APE model requires large amount of training data. However, obtaining *pe* is an expensive task in terms of time and money. As a result, there exists a scarcity of large-scale APE datasets.

To address this challenge, numerous data augmentation techniques have been proposed (Junczys-Dowmunt and Grundkiewicz, 2016; Negri et al., 2018; Lee et al., 2020; Wei et al., 2020; Zhang et al., 2023). Wei et al. (2020) augment the APE training data with translations generated using a different MT system. Huang et al. (2022) train an external MT to obtain more datasets consistent with APE tasks. They also use Google translation to back translate the post-edits in the training set. Deoghare and Bhattacharyya (2022) augment the APE data by generating phrase-level APE triplets using SMT phrase tables. To ensure the quality of the synthetic data, they employ the LaBSE technique (Feng et al., 2022) to filter low-quality triplets.

We first collect our pre-training MT data from NLLB (Team et al., 2022), OpenSubtitles [1], TED2020 (Reimers and Gurevych, 2020), etc. To ensure the quality of the MT data, we use the LaBSE technique (Feng et al., 2022) and filter low-quality data. In our method, we use Google translation to back translate the post-edits in the training set. Subsequently, our dataset is structured as follows: the concatenation of source sentence, back

Proceedings of the Ninth Conference on Machine Translation, pages 541–546
November 15-16, 2024 ©2024 Association for Computational Linguistics

translation and machine translation as the input, while the post-edits serve as the reference output.

Chatterjee et al. (2020b) have proven that APE systems often make unnecessary edits to translation output. To mitigate this issue of over-correction, we employ a sentence-level QE system to determine the final output, selecting between the APE system's output and the original machine-translated (*mt*) version.

Reflecting on the historical development, 2023 is recognized as the inaugural year for large-scale models, with researchers transitioning a variety of tasks to these models, including APE. Notable studies include those that combine Neural Machine Translation (NMT) with Large Language Models (LLM) for APE (Koneru et al., 2024), and comprehensive multi-stage, multilingual large models such as Tower (Alves et al., 2024b), which integrate both MT and APE. Drawing inspiration from Tower, our evaluation utilizes the continued pretraining (CPT) and supervised fine-tuning (SFT) to explore the potential of LLM.

When being evaluated on the test set, our approach improves the HTER (Snover et al., 2006) by -15.99 points and -0.47 points on En-Hi and En-Ta, respectively.

The contributions of our work are as follows:

- We filter low-quality MT data from the collected data using LaBSE-based filtering.
- We propose an APE paradigm based on LLM, including CPT and SFT.
- We utilize Google translation to back translate the post-edits to get *src'* for data augmentation.
- We employ a sentence-level QE system to select the most appropriate output, choosing between the APE-generated output and the original translation.

2 Related Work

Last year's WMT23 APE shard task mainly focuses on transfer learning and data augmentation. Yu et al. (2023) use a Transformer pre-trained on the provided synthetic APE data and then fine-tuned on the real APE data. Additionally, they utilize an external MT system to generate back-translations (with Google Translate [2] run on the post-edits in the training set). They also integrate En-Mr parallel sentences from FLORES-200 (Costa-jussà et al., 2022). R-Drop (Liang et al., 2021), which regularizes the training inconsistency induced by dropout, is used to mitigate overfitting during the training phase. Besides, they use a sentence-level QE system to select the final output between the APE-generated output and the original translation.

Moon et al. (2023) center on data filtering techniques. With a focus on removing potentially harmful material from a model training perspective, the proposed method concentrates on eliminating the two extremes of the training data distribution: the (near-) perfect MT outputs on one side, and those that require complete rewriting on the other.

Another team "kaistai" is inspired by the recent surge of (LLMs) that have been successfully applied in a variety of language generation tasks. They use an LLM with specific prompts designed to generate either (a) post-edits or (b) post-edits along with the rationales behind them.

With experience in previous competitions, we also utilize an external MT system to generate back-translations in our transformer-based system. Additionally, we adopt a sentence-level QE system to select the final output.

3 Dataset

3.1 Data source

We first collect our MT data from the web, mainly from NLLB, OpenSubtitles, TED2020, etc. Then we filter the low-quality data using LABSE. After filtering, we get 3M En-Hi and 3M En-Ta parallel MT data. We first use our filtered MT data with 3M instances to pre-train our model. Then, we use the WMT24 official En-Hi and En-Ta APE datasets for fine-tuning, which consists of a training set and a development set. The training set for both language directions contains 7,000 APE triplets.

4 Method

4.1 LABSE filter

Before using the collected MT data to pretrain our model, we filter the low-quality parallel data by using the LaBSE-based filtering (Feng et al., 2022). We do this to ensure the quality of the MT data. To do so, we first generate embeddings of the En and Hi/Ta using the LaBSE model and normalize them. Then, we compute the cosine similarity between these normalized embeddings. We select the top

[2] https://translate.google.com

70% similarity parallel sentences as our filtered MT data.

4.2 LLM CPT + SFT

Due to the generative nature of the APE task, we believe that LLMs are well-suited for this purpose. Based on human evaluations, we have selected the Llama3-8B-Instruct model, which possesses proficiency in Hindi, as our foundational model. Inspired by the TowerInstruct (Alves et al., 2024a), we adopted a technical approach that combines CPT and SFT. Specifically, during the CPT phase, we utilized 3 million English-Hindi parallel corpora and employed LoRA training techniques. In the SFT phase, we created a customized prompt that, along with the training set provided by the organizers, constituted our SFT training dataset. Our prompt is as follows: "You are a post-editor. You improve translations from English to Hindi using the English source and Hindi translation. Do not provide any explanation or correction." The training paradigm is structured as [prompt: src <en2hi> mt <ape> response], where the response corresponds to the labels predicted by the model.

4.3 Fine-tuned Transformer

We basically treat the APE task as an NMT-like problem, which takes *src* and *mt* as input and generates *pe* autoregressively. Following previous works, we use a special token <*s*> to concatenate src and mt to generate the input sentence: [*src, <s>, mt*], while the target sentence is *pe*. Initially, we pre-train the MT model using the standard Transformer (Vaswani et al., 2017) structure on 3M En-Ta MT training data. Furthermore, we fine-tune the MT model using the APE dataset with the APE training objective. To further solve the problem of data scarcity, following (Yu et al., 2023), we use the Google translation system to create the *src'* from the provided *pe* text. We simply concatenate the *src'* with the original *src* and *mt* to form the new input: [*src, <s>, src', <s>, mt*]. Then, we use it in the same way as before, aiming to have the model learn complementary information from *src* and *src'*. During inference, the same input [*src, <s>, src', <s>, mt*] is employed to generate the output, thereby enabling the utilization of the external information derived from *src'*. Since there is no *pe* during inference, we translate the given *mt* into *src'* using Google Translate.

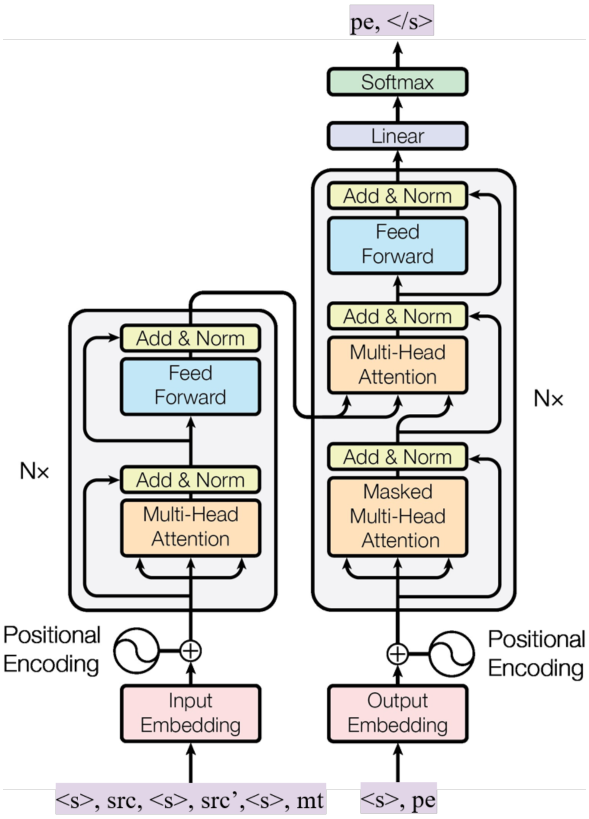

Figure 1: This figure, adapted from (Vaswani et al., 2017) shows the architecture of our model, where mt and augmented src' are concatenated with src before being input into the encoder, and post-edits are generated with the decoder.

4.4 Sentence-Level Quality Estimation

We use wmt22-cometkiwi-da (Rei et al., 2022) as our sentence-level QE model, which is a COMET quality estimation model. This model can be used for reference-free MT evaluation. It receives a source sentence and the respective translation and returns a single score between 0 and 1 that reflects the quality of the translation, where 1 represents a perfect translation. We use this model to rate both the original machine translation and the output generated by our APE system. We then compare the ratings for both sequences and select the one with a higher rating as the final output.

5 Experiment

5.1 Settings

Our transformer model on En-Ta is implemented with fairseq (Ott et al., 2019). Note that the vocabulary and encoder/decoder embeddings of our model are shared between two languages and contain 30K subtokens. We use the batch size of 30,720 tokens in the pre-training stage and 8,192 tokens in

System	En-Hi				En-Ta			
	BLEU↑	HTER↓	ChrF↑	COMET↑	BLEU↑	HTER↓	ChrF↑	COMET↑
Baseline (Do nothing)	39.28	46.36	59.48	0.81	70.16	24.71	81.80	0.91
Ours	54.50	30.37	71.06	0.85	69.64	**24.24**	82.36	0.92
swetaagrawal	58.38	**27.08**	73.45	0.86	70.05	24.54	82.30	0.92

Table 1: Results on the WMT24 QE-APE En-Hi and En-Ta test set. A situation with a higher BLEU score but a lower HTER indicates a better result. The official primary evaluation metric for this task is HTER.

the fine-tuning stage. We leverage FP16 (mixed precision) training technique to accelerate training process. In all stages, we apply the Adam optimizer(Kingma and Ba, 2015) with β_1 = 0.9, β_2 = 0.98 to train the model, where the inverse square root schedule algorithm and warmup strategy are adopted for the learning rate. Concretely, We use a learning rate of 5e-4 with 20k warm-up steps in the pre-training stage and a learning rate of 5e-5 with 4k warm-up steps in the fine-tuning stage. Besides, we set the dropout to 0.1 in the pre-training stage, 0.3 in the fine-tuning stage, and the value of label smoothing to 0.1 in all stages. Early stopping is adopted with patience 10 and 30 epochs during pre-training and fine-tuning, respectively. During inference, we use beam search with a beam size of 10. Finally, We employ HTER (Snover et al., 2006), BLEU (Papineni et al., 2002), ChrF (Popovic, 2015), and COMET (Rei et al., 2022) as the evaluation metrics.

Our LLM on En-Hi is implemented with Llama-Factory(Zheng et al., 2024). The base model we used is Llama3-8B-Instruction. During the CPT phase, the batch size is set to 256, the learning rate to 1e-4, and training runs for 2 epochs with a precision of bf16. The maximum sequence length is 512 and pre-training is conducted using the LoRA method with a LoRA rank of 64.In the SFT phase, the batch size remains 256, the learning rate is adjusted to 1e-5, and training extends to 8 epochs with bf16 precision. We employ the AdamW optimizer, maintain a maximum sequence length of 512, and utilize PyTorch full_shard for training.

All our transformer models are trained on a Nvidia Tesla V100 GPU with 32GB memory and our LLMs are trained on 64 D910B with 32GB memory.

5.2 Result

Table 1 shows the experimental results evaluated on the test set, where the baseline result is produced by directly calculating scores between the provided MT and PE. We outperform the baseline on HTER for -15.99 and -0.47 points on the En-Hi and En-Ta language pair.

System	En-Hi	
	BLEU↑	HTER↓
Baseline (Do nothing)	30.52	58.44
Pretrain+finetune	**49.68**	**36.01**
+External MT	49.01	37.16
+Sentence-level QE	39.13	43.77

Table 2: Results on the WMT24 QE-APE En-Hi development set.

System	En->Ta	
	BLEU↑	HTER↓
Baseline (Do nothing)	65.31	29.63
Pretrain+finetune	26.33	57.12
+External MT	33.80	45.31
+Sentence-level QE	**66.11**	**27.66**

Table 3: Results on the WMT24 QE-APE En-Ta development set.

Table 2 shows the En-Hi experimental results evaluated on the dev set. The baseline denotes the test MT result. As illustrated in table 2, the HTER decreased from 58.44 to 36.01 after applying CPT+SFT, reflecting a reduction of 22.43. However, no performance improvement was observed with the addition of back-translation data. We hypothesize that this is due to the sufficiently robust performance of the CPT+SFT, which diminishes the impact of the back-translation data on further enhancement. Upon integrating QE labels, the HTER increased to 43.77 compared with CPT+SFT, an increase of 7.76. We think the QE label may not be accurate enough in En-Hi, resulting in performance loss.

Table 3 shows the En-Ta experimental results evaluated on the dev set. The first experiment is performed by fine-tuning all parameters of the pre-trained Transformer on the official training set, which increases by 27.49 in HTER compared with the baseline. Due to the lack of high-quality En-Ta MT data, the pre-training MT datasets we collected were mostly synthetic and of poor quality. This hinders the capabilities of MT models, which further results in fine-tuned APE models that also perform poorly. The experiment of adding external MT for data augmentation shows some improvement in performance. Toward the end, we utilize a sentence-level QE system to rate both the original translation and the APE output. We then select one of them with a higher rating as the final output of our APE system. With the combination of the APE model and sentence-level QE system, we see that the HTER decreases to 27.66, and the BLEU score increases to 66.11 points.

6 Conclusion

This paper presents our APE system submitted to the WMT 2024 QEAPE En-Hi and EN-Ta task. In our approach, we first filter low-quality MT data from the collected data using LaBSE-based filtering. Then we employ the data augmentation method to build the [*src, <s>, src', <s>, mt*] additional training datasets. Besides, We propose an APE paradigm based on LLM, including CPT and SFT. Moreover, we explore the sentence-level QE system to discard low-quality APE outputs. Evaluation of our APE system shows that our approach achieves gains on the WMT-24 APE development and test sets.

Abstract

In this paper, we describe the process of creating the FLORES+ datasets for several Romance languages spoken in Spain, namely Aragonese, Aranese, Asturian, and Valencian. The Aragonese and Aranese datasets are entirely new additions to the FLORES+ multilingual benchmark. An initial version of the Asturian dataset was already available in FLORES+, and our work focused on a thorough revision. Similarly, FLORES+ included a Catalan dataset, which we adapted to the Valencian variety spoken in the Valencian Community. The development of the Aragonese, Aranese, and revised Asturian FLORES+ datasets was undertaken as part of a WMT24 shared task on translation into low-resource languages of Spain.

1 Introduction

Although notable advances have been reported in the realm of machine translation (MT) in recent years, performance for the so-called low-resource languages (Ranathunga et al., 2023) still lags behind that of languages with more extensive linguistic resources. Increasing the availability of such resources is a key factor for enabling MT to progressively and ultimately cover all languages in the world. Several relevant initiatives, such as FLORES-101 (Goyal et al., 2022), FLORES-200 (Costa-jussà et al., 2024), Seed (Maillard et al., 2023), and NTREX (Federmann et al., 2022), have recently addressed this challenge by providing multilingual datasets covering up to 200 languages. While these datasets were originally created as part of other projects, the Open Language Data Initiative[1] (OLDI) now leads a collective endeavor to expand the number of supported languages. In particular, a shared task was proposed to extend OLDI's open datasets to more languages for the Ninth Conference on Machine Translation (WMT24).[2] This paper presents our efforts to extend the OLDI's FLORES+ dataset to four low-resource Romance languages spoken in Spain as part of this task, namely Aragonese, Aranese, Asturian, and Valencian. The resulting datasets can be downloaded from the repository of the PILAR corpus (Galiano-Jiménez et al., 2024).[3]

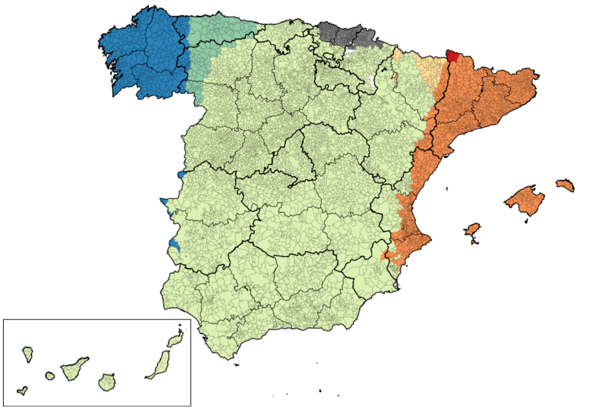

Figure 1: Some of the languages of Spain: Spanish, Catalan, Galician, Basque, Asturian, Aragonese and Aranese. The language names listed are shown in the corresponding colors of their regions on the map. Note that Spanish is spoken throughout the entire country, but the map highlights the regions where other languages are co-official or regionally predominant. [Source: Wikimedia Commons, https://commons.wikimedia.org/wiki/File:Spain_languages.svg]

Most languages spoken in Spain belong to the Romance language family, except for Basque, which is a *language isolate* with no known genetic

relationship to any other language. Among the languages of Spain, Spanish is the only one with official status across the entire country. Other languages, including Catalan (primarily spoken in Catalonia, the Valencian Community, and the Balearic Islands, with a few thousand speakers in Aragon), Galician (mainly spoken in Galicia and some adjacent areas across the border), and Basque (spoken in the Basque Country and parts of Navarre), have official status in their respective autonomous regions (in certain areas for Navarre, and not in Aragon for Catalan). Additionally, Aranese is official in the Val d'Aran in accordance with the Statute of Autonomy of Catalonia. However, Asturian and Aragonese do not have official status in their respective regions, though they are recognized and protected as cultural heritage.[4] The Acadèmia Valenciana de la Llengua[5] (AVL) considers Valencian to be an alternative name for the Catalan language, as well as the term used to refer specifically to the variety of this language spoken in the Valencian Community.

Figure 1 illustrates the geographical distribution of these languages, while Table 1 provides estimates of their number of speakers in Spain. It is important to note that Spanish is spoken nationwide, while proficiency in regional languages varies among people in bilingual or diglossic areas.

We present our contribution to the FLORES+ benchmark,[6] focusing on four Romance languages spoken in Spain. Our target languages are Aragonese, Asturian, Aranese, and Valencian. These languages were chosen due to the evident social and governmental interest in preserving them. For Asturian, there are ongoing efforts to achieve official language status in Asturias. In contrast, Aranese is already an official language in the small central Pyrenees valley where it is moslty spoken, although it has very few speakers and limited textual resources. Aragonese is recognized and protected in Aragon as a heritage language, yet political support for granting it official status remains limited. Lastly, Valencian, a variant of Catalan with notable lexical differences, was included because having MT systems generate it directly rather than adapting from Catalan significantly reduces the need for additional post-editing.

2 Target Languages Overview

This section provides a brief overview of the languages covered in this paper.

2.1 The Aragonese Language

Aragonese is a Romance language spoken in the Pyrenees valleys of Aragon, primarily in the *comarcas* of Somontano de Barbastro, Jacetania, Alto Gállego, Sobrarbe, Ribagorza and Hoya de Huesca/Plana de Uesca.

Until recently, Aragonese has had several alternative orthographic norms, none of them official. In 1987, a number of associations organized a congress where a quasi-phonetic spelling system for Aragonese was approved, called *Normas Graficas de l'Aragonés*. It was commonly used in the subsequent two decades. The *Sociedat de Lingüistica Aragonesa* (SLA, Aragonese Linguistic Society), an association established in 2004, published a set of spelling rules (SLA rules) in 2006 based on the written tradition of Medieval Aragonese. In 2010, the *Estudio de Filología Aragonesa – Academia de l'Aragonés* (EFA-ACAR), a private entity created by the II Congress on Aragonese Language, approved and published the *Propuesta Ortografica de l'Academia de l'Aragonés*, more aligned with etymology. Finally, the *Academia Aragonesa de la Lengua*[7] (AAL, Aragonese Language Academy), a public body created by the Law of the Languages of Aragon, was established in 2021, and approved in April 2023 the standard orthographic norm for Aragonese. This standard orthography has been adopted by associations (including EFA-ACAR) as well as by the main pub-

[4] It is also worth noting that there are other languages in Spain that could be considered, but there is less consensus on whether they are part of an enclosing language or distinct languages on their own, debates that echo the famous saying attributed to sociolinguist Max Weinreich that "a language is a dialect with an army and a navy." For example, Eonavian or Galician-Asturian is a set of Romance dialects that has been classified either as northeastern varieties of Galician, as a linguistic group of its own, or as a transitional dialect between western Asturian and Galician. Another example is the Leonese language, which is currently spoken in the northern and western parts of the historical region of León in Spain (the modern provinces of León, Zamora, and Salamanca). Leonese, however, is considered part of the Asturleonese linguistic group, along with the dialects of Asturian. Similarly, Fala (spoken in the northwestern part of Extremadura) and Cantabrian also exhibit this ambiguity being classified, depending on the perspective, as distinct languages, hybrid dialects, or intermediate linguistic varieties.

[6] FLORES+ is OLDI's evaluation benchmark for multilingual machine translation, building upon the FLORES-200 benchmark (Costa-jussà et al., 2024), which spans over 200 languages and comprises 2 009 sentences split into development (dev) and devtest sets. Texts come from English Wikimedia (more exactly, Wikinews, Wikijunior and Wikivoyage).

Aranese	4 500	(Generalitat de Catalunya, 2019, page 4)

Table 1: Approximate number of speakers *in Spain* for some of the languages spoken in the country. When the reference includes different figures for the number of speakers depending on their ability to speak, understand, read, or write the language, we provide the data for the number of people who can speak it, including those with even a basic level of proficiency.

lishers in Aragonese. In August 2024, the Government of Aragon established this standard spelling for administrative and educational uses.[8]

A recent study reveals that Aragonese remains alive across the entire area where it is traditionally spoken (Eito et al., 2024). As of today, it is estimated that around 8 000 people use it on a daily basis, according to the most optimistic estimates, within a broader group of approximately 25 000 people who claim to have knowledge of the language (Reyes et al., 2017). Its use is much more prevalent in family and neighbourly interactions, especially among older individuals and in rural communities. However, the use of the language declines significantly in more formal contexts and outside the immediate environment of the speakers. Consequently, intergenerational transmission is severely at risk; some initial measures, such as teaching in schools or the language limited presence in the media, may not be sufficient to ensure the language survival.

2.2 The Aranese Language

Aranese is a standardized form of the Pyrenean Gascon variety of the Occitan language spoken in the Val d'Aran in northwestern Catalonia. Aranese is one of the three official languages in Catalonia, alongside Catalan and Spanish.[9] In the case of Aranese, its official status is limited to the territory of the Val d'Aran.

The Aranese language is regulated by the *Institut d'Estudis Aranesi–Acadèmia Aranesa dera Lengua Occitana*.[10] The main goal of this institution is to establish and update the linguistic norms of the Aranese variety of Occitan and ensure that the standardization process is consistent throughout its linguistic area.

Regarding education, the Occitan language is included, along with Catalan, Spanish, English, and optionally French, in the school system of the valley at all compulsory levels. However, the presence of Aranese in higher education, such as in the baccalaureate program, is virtually non-existent. According to the Linguistic Census of Aranese 2001,[11] only 34.2% of the population in the Val d'Aran have Aranese as their mother tongue, and only 25.8% use Aranese exclusively at home. The estimated number of speakers is approximately 4 500 (Generalitat de Catalunya, 2019).

2.3 The Asturian Language

Asturian is one of the Iberian Romance languages, closely related to Galician-Portuguese and Castilian Spanish, and a language historically influencing the Silver Way[12] to the Portuguese border (in fact, Asturian-based Mirandese is official in Miranda do Douro, in Portugal).

[8] https://www.boa.aragon.es/cgi-bin/EBOA/BRSCGI?CMD=VEROBJ&MLKOB=1347070761212

[9] The Val d'Aran was relatively well connected to Occitania in the north, but remained isolated to the south until the construction of the Vielha Tunnel, first in 1948 and then with a new one in 2007. The changes experienced by the valley due to its shift toward the south following the opening of the Vielha Tunnel, and especially the development of tourism, have led to a massive influx of migrants initially from the rest of Spain and later from other countries. This migration has resulted in drastic changes in the linguistic practices of the Aranese people. Occitan has increasingly been confronted with Spanish and Catalan, losing the dominance it once had in past centuries.

[10] https://www.institutestudisaranesi.cat

[11] https://llengua.gencat.cat/web/.content/documents/altres/arxius/aran_cens.pdf

[12] The Silver Way is a route of the *Camino de Santiago* that runs from southern Spain to Santiago de Compostela.

The *Academia de la Llingua Asturiana*[13] (Academy of the Asturian Language) is an official institution of the Government of the Principality of Asturias that promotes and regulates the Asturian language. Its main objectives include researching and standardizing the Asturian language, developing language usage norms and dictionaries, promoting its use and education, compiling its lexicon, fostering research related to Asturian, awarding literary prizes, and protecting the language rights of Asturian users. As a result, the Asturian language has clear and widely accepted spelling and orthographic rules.

Although it does not have official language status, Asturian is protected under the Statute of Autonomy of Asturias. In many schools, children can take Asturian-language classes, and in some schools, it is offered as an elective language.

In a report for the BBC, the President of the Academy of the Asturian Language pointed out that "at present about 250 000 people are able to understand, speak, read and write in Asturian, that is, a 25% of the population of the region" (Hernández, 2022; Llera Ramo, 2018). As the latest 3rd Sociolinguistic Study on the Asturian Language (Llera Ramo, 2018) points out, 87% of the population identify with both Asturian and Spanish identities. Of these, 64% have a balanced sense of both identities, while 18% feels predominantly Asturian over Spanish. Literacy rates are high: 90% of the population report understanding Asturian, though 29% describe their knowledge as passive, while 38% are able to read and 25% to write.

2.4 The Catalan and Valencian Languages

Catalan is a Romance language with official status in three autonomous communities in Spain: Catalonia, the Balearic Islands and the Valencian Community. It is also the official language of Andorra, a small state in the Pyrenees, and it has semi-official status in the Italian *comune* of Alghero, in the island of Sardinia. Catalan is also spoken in the south of France and in some parts of the Spanish regions of Aragon and Murcia.

Catalan is usually named Valencian in the Valencian Community, but both terms academically refer to the same language. Catalan is divided into two major dialect groups: Eastern and Western (see Figure 2). The main difference is in the pronunciation of unstressed 'a' and 'e'. In Eastern dialects, these sounds have merged into /ə/, while in Western dialects, they remain distinct as /a/ and /e/. There are also some other differences in pronunciation, verb forms, and vocabulary. Western Catalan includes the Northwestern Catalan and Valencian dialects. The Eastern group includes four dialects: Central Catalan, Balearic, Rossellonese, and Algherese.

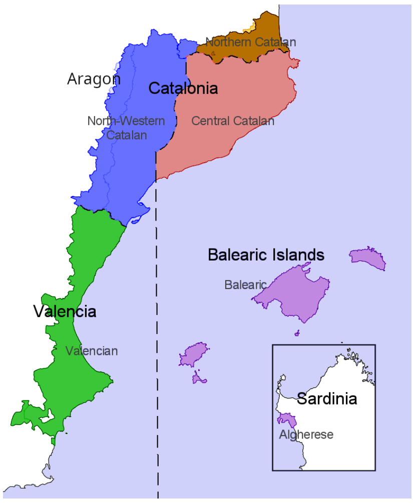

Figure 2: Catalan's two main dialects (Eastern/Western) shown divided by the dashed line. [Source: modified from the original in Wikimedia Commons, https://commons.wikimedia.org/wiki/File:Catalan_dialects-en.png]

The *Institut d'Estudis Catalans*[14] in Catalonia and the *Acadèmia Valenciana de la Llengua*[15] are the two institutions that regulate the Catalan and Valencian varieties, respectively. The relationship between these two institutions has not always been easy, but in recent years, they have achieved some degree of coordination.

In 2018[16], 94.4% of the population aged 15 or older in Catalonia could understand Catalan, 81.2% could speak it, 85.5% could read it, and 65.3% could write it. In the Valencian Community, 79.4% of the population aged 15 or older could understand Valencian, 54.9% could speak it, 60.9% could read it, and 44.4% could write it (Generalitat Valenciana, 2021). Valencian speakers make up approximately 3.5 million of the total 9 million Catalan speakers in Spain (Generalitat Valenciana, 2021; Generalitat de Catalunya, 2007).

Although standard Catalan and Valencian are highly similar and largely mutually intelligible, the differences and the effort required to adapt Cata-

[13] https://alladixital.org

[15] https://www.avl.gva.es

[16] https://www.idescat.cat/indicadors/?id=basics&n=10367&lang=en

lan texts into Valencian are significant to justify the creation of a dedicated FLORES+ dataset for Valencian. This will support the development and evaluation of MT systems specifically designed for this variant.

3 Development of the FLORES+ Datasets

This section describes the workflow and resources used to produce the FLORES+ datasets for Aragonese, Aranese, Asturian and Valencian.

3.1 The Aragonese FLORES+ Dataset

A first draft of the FLORES+ dev and devtest sentences for Aragonese was initially obtained from Spanish using the Spanish–Aragonese[17] rule-based machine translation system Apertium (Forcada et al., 2011). This translation was subsequently post-edited by specialists proficient in Aragonese. Finally, the post-edited translation was reviewed by a member of the Academia Aragonesa de la Lengua. In this last step, the reviewer had also in view the English version of the FLORES+ dataset; an important number of translations were modified for better agreement with the English original data.

The translators and reviewers relied on the following resources to inform their decisions:

- The orthography of Aragonese[18] published by the Academia Aragonesa de la Lengua in 2023.
- The grammar of Aragonese published by the EFA-ACAR.[19]
- The dictionary of Aragonese,[20] published by the EFA-ACAR.
- The Aragonese dictionary *Tresoro d'a Luenga Aragonesa*,[21] a lexicographical research project developed by the *Instituto de Estudios Altoaragoneses*, in collaboration with the Government of Aragon.
- The Spanish–Aragonese and Aragonese–Spanish dictionary *Aragonario*,[22] developed under the project Linguatec and published by the Government of Aragon.

Justification for the use of MT. While it might be argued that using machine translation (MT) in a dataset like FLORES+, conceived as a benchmark for MT systems, is not the ideal procedure, our decision is justified by three main reasons: first, the two-step workflow of MT followed by post-editing is common practice for this language, with many existing texts produced in this manner; second, the scarcity of qualified linguists and translators for Aragonese made it difficult to complete the task within the required timeframe without the support of an MT system; third, rule-based systems like Apertium typically exhibit strong performance for closely related Romance languages, resulting in minimal translationese that does not significantly impact the overall quality.

3.2 The Aranese FLORES+ Dataset

Similarly to Aragonese (see above), the data for Aranese was initially obtained by translating the sentences in the Catalan FLORES+ dev and devtest datasets using the Apertium rule-based MT system (Forcada et al., 2011) for Catalan–Aranese.[23] The revision process was then performed in two steps. Firstly, a professional reviewer with wide experience in translation and revision with proficiency in Aranese was presented with the French, Catalan and Occitan versions of the FLORES+, along with the machine translated version into Aranese. Finally, the post-edited translation was reviewed by different individuals, who are native speakers, from the Institut d'Estudis Aranesi (IEA). The use of MT is motivated by the same reasons as those for Aragonese (see the end of the previous section).

During the post-editing and the subsequent review process, the guidelines provided by the IEA were strictly followed to ensure that the translation into Aranese aligned with their recommendations. Specifically, the translators and reviewers based their decisions on the following resources published by the IEA:

3.3 The Asturian FLORES+ Dataset

The dev and devtest datasets we are contributing for Asturian are a corrected version of the original FLORES+ dataset, which were initially translated from English by Meta using professional translators as part of their *no language left behind* initiative (Costa-jussà et al., 2024). We had this translation into Asturian reviewed by native speakers, some of whom are members of the *Academia de la Llingua Asturiana*, philologists and a renowned writer, translator and activist for the Asturian language. The revision process was carried out twice by different people. In the first round, the reviewers were presented with the Spanish text and the existing version of the Asturian FLORES+, and in the second round, with the Spanish FLORES+ sentences and the first revised version.

During the review process, special attention was paid to adhering to the guidelines provided by the Academia to ensure that the translation aligns with their recommendations by relying on the following resources:

- Diccionariu de la Llingua Asturiana.[34]
- Gramática de la Llingua Asturiana.[35]
- Normes ortográfiques.[36]

3.4 The Valencian FLORES+ Dataset

The dataset for Valencian was created by adapting the existing Catalan version of the FLORES+ devtest set.[37] The work was carried out by a single native speaker of the Valencian variant, who holds a university degree and has experience translating into Valencian and reviewing texts in this language.

To expedite the process, LanguageTool[38] was employed to apply an initial set of changes to the original text. These changes were then manually reviewed, and additional necessary modifications were made, considering a list of lexical items that differ across the various Catalan dialects (see below). In cases of uncertainty, the dictionary of the Acadèmia Valenciana de la Llengua was consulted. The following resources were used to guide the modifications to the original Catalan text:

- List of lexical items that differ across the different dialects of the Catalan language.[39]
- Diccionari normatiu valencià.[40]
- Linguistic criteria for the institutional use of the Valencian dialect in the Valencian universities.[41]

3.5 Modifications Across Versions of the Datasets

As previously mentioned, the datasets for Aragonese, Aranese, and Asturian have undergone several iterations during their development. Table 2 shows a comparison of the translation error rate (TER) between these versions, labeled as v1,

Language	v1 → v2	v2 → v3	v1 → v3
Aragonese dev	4.8	22.2	24.3
Aragonese devtest	4.0	26.8	28.4
Aranese dev	1.8	54.2	54.7
Aranese devtest	0.1	70.3	70.2
Asturian dev	6.0	4.4	10.0
Asturian devtest	5.5	0.1	5.6

Table 2: TER scores comparing different versions (v1, v2, and v3) of translations for Aragonese, Aranese, and Asturian. v1 represents the original translations, v2 the post-edited or improved versions (depending on the language; see the main text), and v3 the standardized versions produced under the supervision of language academies.

v2, and v3.[42] The TER metric (Snover et al., 2006) quantifies the number of edits required to transform one sentence into another, referred to as the *reference*. It is calculated by dividing the total number of edits (insertions, deletions, substitutions, and shifts) by the total number of words in the reference. TER is a widely accepted metric in machine translation evaluation, providing insight into how close a system's output is to a human-generated reference. Lower TER scores correspond to higher translation quality. In this study, we use TER to compare different versions of the datasets for each language, offering an estimate of the extent of changes introduced by the reviewers during the revision process. In our case, higher TER scores correspond to a larger number of edits.

Version v1 refers to the original translations. As already mentioned, for Aragonese and Aranese, the translations in v1 were initially produced by Apertium, whereas v2 represents the post-edited translations of v1. For Asturian, the v1 corresponds to the version already included in the FLORES+ dataset, and v2 incorporates some normative and stylistic corrections to improve the quality of the translations. Finally, v3 refers in all cases to a version that was further adapted to conform to the linguistic standards promoted by the respective language academies. The revisions carried out under the direct supervision of these academies were designed to ensure the highest quality and compliance with current linguistic norms.

The data reveals that in most cases, the second round of quality checks leading to v3 introduced significant differences compared to v2. This is particularly notable for Aragonese and Aranese, where the adaptation to standard forms resulted in substantial changes, as reflected in the TER scores. Asturian is an exception, especially in the devtest set, where the differences between v2 and v3 were minimal, suggesting that the initial revisions in v2 already addressed most of the necessary improvements. This underscores the importance of multiple quality review stages, as the adaptation to standardized forms can introduce notable refinements to the translations.

4 Validation of the FLORES+ datasets

The dev sets of FLORES+ for Asturian, Aragonese, and Aranese were distributed and utilized in an WMT24 shared task[43] which focused on translating from Spanish into low-resource languages of Spain (Sánchez-Martínez et al., 2024). These resources proved valuable for the participants as validation sets for training neural MT systems. The corresponding devtest subsets were then used by the organizers of the shared task to evaluate the submitted systems. To ensure fairness in the evaluation, the devtest sets were withheld until the end of the submission period. Several submitted systems outperformed the respective Apertium-based baselines, achieving higher performance scores based on the BLEU, chrF++ and TER metrics.

The Valencian FLORES+ dataset was utilized in the development of a Spanish–Valencian neural MT system. One experiment involved training models with varying proportions of training data in the Valencian and Central Catalan dialects. As expected, results indicated that the higher the proportion of Valencian data in the training set, the higher the BLEU score achieved on the Valencian FLORES+ dataset and the greater the presence of Valencian dialectal forms in the output.

As a tentative indicator of the baseline performance expected on the newly created devtest sets, Table 3 presents standard automatic evaluation metrics for Apertium-based systems (Forcada et al., 2011) translating the Spanish side of the devtest. The results suggest that the use of MT (specifically the Apertium system) during the initial phase of corpus creation likely contributed to the significantly higher evaluation scores for the Aragonese and Aranese Apertium-based systems compared to Asturian. This points to a potential bias in the dataset

[42] SacreBLEU (Post, 2018) TER signature: nrefs:1 | case:lc | tok:tercom | norm:no | punct:yes | asian:no | version:2.0.0

[43] https://www2.statmt.org/wmt24/romance-task.html

Apertium system	BLEU	chrF++	TER
Spanish–Aragonese	61.1	79.3	27.2
Spanish–Aranese	28.8	49.4	72.3
Spanish–Asturian	17.0	50.8	80.4

Table 3: Automatic evaluation scores of the Apertium-based systems on the devtest FLORES+ data. The Apertium data correspond to the following releases: `spa-arg`, 0.6.0; `oc-es`, 1.0.8; `spa-ast`, 1.1.1.

favoring rule-based MT approaches over non-rule-based systems, and even human translations, when evaluating the devtest translations from Spanish into these languages. Nonetheless, results from the WMT24 shared task (Sánchez-Martínez et al., 2024) show that neural systems can still outperform Apertium, even for Aragonese and Aranese. This suggests that the use of MT in the early stages of creating the Aragonese and Aranese FLORES+ datasets did not significantly compromise the utility of the data.

5 Concluding remarks

In this paper, we have detailed the development of the FLORES+ datasets for four low-resource Romance languages spoken in Spain: Aragonese, Aranese, Asturian, and the Valencian variant of Catalan. Each dataset was meticulously curated through a two-step manual review process involving native speakers and professionals from the respective language academies. The creation of these datasets is particularly significant given the ongoing efforts to revitalize and promote these languages. Our work also highlights several key challenges in resource development for low-resource languages, such as the scarcity of expert translators, or the constraints of limited time and funding for dataset production.

Acknowledgements

This work was supported by the R+D+i projects PID2021-127999NB-I00 (*LiLowLa: Lightweight neural translation technologies for low-resource languages*) and PID2021-124663OB-I00 (*TAN-IBE: Neural Machine Translation for the Romance languages of the Iberian Peninsula*), founded by MCIN /AEI /10.13039/501100011033 / FEDER, UE. The development of the FLORES+ dataset for Valencian was supported by project CENID2023/10, funded by Diputació d'Alacant.

We thank Academia Aragonesa de la Lengua, Institut d'Estudis Aranesi, and Academia de la Llingua Asturiana for their support and assistance in the translation of the FLORES+ sentences.

Abstract

We contribute a seed dataset for the Bangla/Bengali language as part of the WMT24 Open Language Data Initiative shared task. We validate the quality of the dataset against a mined and automatically aligned dataset (NLLBv1) and two other existing datasets of crowdsourced manual translations. The validation is performed by investigating the performance of state-of-the-art translation models fine-tuned on the different datasets after controlling for training set size. Machine translation models fine-tuned on our dataset outperform models tuned on the other datasets in both translation directions (English-Bangla and Bangla-English). These results confirm the quality of our dataset. We hope our dataset will support machine translation for the Bangla/Bengali community and related low-resource languages.

1 Introduction

The Indian sub-continent is an area of rich linguistic diversity (Saxena and Borin, 2006; Hock and Bashir, 2016), and it is not uncommon for a language in this region to have both millions of speakers and insufficient resources for NLP development. Bangla/Bengali [ben] is one such language, ranked the 7th most spoken language in the world in the latest Ethnologue list of 200 most spoken languages (Eberhard and Fennig, 2024), and classified in the taxonomy of Joshi et al. (2020) as a Rising Star, "let down by insufficient efforts in labeled data collection" despite a "strong web presence and thriving online community". This classification contrasts squarely with that of languages such as Standard German, a "winner" in the Joshi et al. taxonomy because it has heavy investments in resources and technology, despite a ranking of 12 in the Ethnologue 200, below Bangla/Bengali.

The relative lack of data resources poses a challenge for neural machine translation (MT) efforts in Bangla/Bengali. While creating large-scale datasets of parallel sentences would be the next step towards improving Bangla/Bengali MT, efforts to create these types of resources have only recently been made (Hasan et al., 2020; Siripragada et al., 2020; Ramesh et al., 2022). Such efforts often must use automated methods to crawl and align the texts between language pairs, with manual checks and reviews being prohibitively expensive. There has been little work comparing larger datasets with smaller, professionally translated and manually curated datasets to investigate how the differences between these two types of dataset could impact the quality of machine translation.

This paper describes the results of one such manual effort, creating translation pairs between English and Bangla/Bengali for a smaller dataset and verifying the quality of those translations. Maillard et al. (2023) shows the sizeable impact of these smaller datasets on MT quality via bilingual and multilingual translation experiments, with the high quality manually translated datasets outperforming even a back-translation data augmentation approach with larger train set sizes. Continuing this line of reasoning, we hypothesize that models trained using a smaller but professionally translated dataset of Bangla/Bengali would perform better than models trained on larger, automatically mined and aligned parallel texts with little to no human intervention or review, once training sizes are controlled for. To this end, we created a smaller dataset of manual translations to test our hypotheses, and explored different training set sizes from larger datasets to check their equivalencies against our smaller dataset.

Our main contributions are as follows:

1. We contribute to the open datasets of the Open Language Data Initiative (OLDI) and produce a seed dataset for Bangla/Bengali by translat-

* These authors contributed equally

Proceedings of the Ninth Conference on Machine Translation, pages 556–566
November 15-16, 2024 ©2024 Association for Computational Linguistics

ing the English seed dataset.

2. We carry out fine-tuning translation experiments to show that models tuned on our smaller, manually translated dataset outperform, or are on par with, models tuned on samples of comparable sizes from another dataset that has been automatically mined and aligned (NLLBv1).

3. We compare our dataset with other manually translated datasets for Bangla/Bengali available via OPUS (Tiedemann, 2012), and show that our dataset outperforms both corresponding and larger samples from these datasets (1.5x, 2x larger than our dataset) for a majority of pre-trained models in our experiments.

2 Related Work

Machine translation (MT) efforts in Bangla/Bengali currently rely on creative methods such as data augmentation and multilingual transfer to approach state-of-the-art MT. For example, Mondal et al. (2024), a recent work, uses back-translation to augment training data for English-Bengali transformer-based MT. Laskar et al. (2022a) augment data for English-Bengali MT using an SMT-based phrase-pair injection approach (Sen et al., 2021), and transliterate English texts into Bengali script as a transfer mechanism to share subword-level information between source and target sentences. Jasim et al. (2020) use a partial back-translation method by translating only selected phrases to the source language, achieving competitive results for Bengali MT on the WAT2018 (Nakazawa et al., 2018) test set. Laskar et al. (2022b) investigate knowledge transfer among Indic languages for neural MT, including Bengali, by transliterating all Indic languages into English script to share subword information during training. Bala Das et al. (2023) build a transformer-based multilingual neural MT system for 15 Indic language pairs, including Bengali, and English with shared encoder-decoders and transliteration schemes for related languages. Gala et al. (2023) build a multilingual NMT system for 22 Indic languages including Bengali.

Efforts to create large-scale datasets of parallel sentences for Bangla/Bengali have only recently been made. For example, Hasan et al. (2020) create a dataset of 2.75 million sentence pairs for machine translation, using an automated sentence segmentation toolkit and an ensemble of aligners for bitext alignment. Siripragada et al. (2020) collect parallel corpora across 10 Indian languages, including Bengali, by crawling two Government of India websites and applying document and sentence level alignment methods, producing 126.7K parallel texts for Bengali-English. Ramesh et al. (2022) create a dataset of parallel texts for 11 Indian languages, including 8.6 million parallel texts for Bengali-English, by crawling news and education/MOOC websites such as Coursera and passing the data through automated pipelines. Schwenk et al. (2021) mine billions of parallel texts from the web for multiple languages, which include approximately 10 million sentence pairs for Bengali-English aligned using LASER embeddings (Artetxe and Schwenk, 2019). As part of the No Language Left Behind project, NLLB Team et al. (2022) mine 62 million sentence pairs for Bengali-English using LASER3 embeddings (Heffernan et al., 2022); the NLLBv1 dataset created from the project is the largest known dataset of parallel texts for this language pair to date.

3 Meet The Data

Here we describe the language, the data collection process, and the format of the dataset.

3.1 Language description

Bangla/Bengali (ISO-639-3:ben, glottocode:beng1280, ISO-15924:Beng), an Indo-Aryan language, is the official and national language of Bangladesh and an official language of the state of West Bengal and other states in India. The language is commonly referred to as Bengali within the Indian states, and as Bangla in the nation of Bangladesh. The standardized dialects spoken in these two regions differ mainly in the morpho-phonological space. For example, Bangla has separate objective and genitive case markings for nouns and pronouns while Bengali has syncretized forms for these. The mid-back-rounded vowel (/ɔ/) is more common word-finally in Bangla than in Bengali. Despite "numerous small differences", both dialects have been called "indisputably the same language" (David, 2015). We refer to the language as Bangla for the rest of this paper, since the translations were produced in this dialect.

The script system of Bangla is similar to that of other South Asian languages in being an abugida

অন্ধকার	প্রায়	হলো	হলো।
ɔndhɔkar	*prae*	***ho-l-o***	***holo***
dark	almost	**become-PST-3.NHON**	**REDUP**

‘It was just about **to get dark**. (Lit. The dark almost **happened happened**.)’

আমার	গাড়ি	পরিষ্কার	করতে	হবে।
amar	*gaṛi*	***poriṣkar***	***kor-te***	*hɔ-b-e*
1SG.GEN	car	**clean**	**do-IPFP**	become-FUT-3.NHON

‘I need **to clean** my car.’

Figure 1: Glossed examples in Bangla script using reduplication and conjunct verbs; examples from (David, 2015)

system organized by syllables with two forms for each vowel viz., the independent and diacritic forms, and with a system of conjunct characters for complex consonant segments. The script (Fig. 1) is represented in Unicode with range 0980-09FF[1], which we use for our translations.

Bangla has certain features which make translation between Bangla and English a challenging task. These include rich morphological systems of inflection, derivation, and reduplication, a rich case system, a system of light verbs and conjunct verbs, and a system of noun classifiers. All these features are less prevalent in English. While Bangla is an SOV type language, scrambling of constituents within and across clauses for the purpose of altering information structure is common. This can pose a challenge for neural translation systems (Belinkov and Bisk, 2017). An in-depth description of the features of Bangla/Bengali can be found in David (2015).

3.2 Data Collection and Translation

The Bangla sentences in our dataset were manually translated from the English sentences in the Seed dataset v2.0 (Maillard et al., 2023) maintained by the Open Language Data Initiative. Details about the sourcing and composition of the dataset are described in Maillard et al. (2023). One native speaker of Bangla, an author of this paper fluent in English with graduate-level linguistic training and experience in professional translation from English to Bangla, translated all 6,193 sentences in the dataset. The Avro keyboard for Windows[2] with Unicode support was used to generate the Bangla translations. The translation guidelines[3] supplied by the Open Language Data Initiative were followed during the translation process.

3.3 Data Format

The Bangla translations are stored as a text file with a single line per translation, containing sentences in the same order as in the English seed dataset[4]. We follow the dataset formatting guidelines provided by the Open Language Data Initiative[5].

4 Experimental Validation

We compare our Bangla translations of the Seed dataset with the following three datasets. All datasets were downloaded from OPUS.

`NLLBv1` (NLLB Team et al., 2022). This is the largest available collection of automatically aligned Bangla-English sentence pairs with a wide range of text domains.

`Joshua-IPC` (Post et al., 2012). This is a dataset of parallel sentences for six Indic languages including Bangla. It was crowd-sourced by the authors via Amazon Mechanical Turk for translation experiments using the Joshua statistical MT system (Weese et al., 2011). Sentences for the Indic languages were extracted from the top 100 viewed Wikipedia pages for the language, and four English translations sourced for each sentence.

`TED2020` (Reimers and Gurevych, 2020). This is a dataset of crawled and aligned subtitles of TED Talks for the month of July 2020 across multiple languages, with subtitling carried out by a global community of volunteer translators[6]. We downloaded all 10,519 sentence pairs for Bangla-English, with translations in the English to Bangla direction.

4.1 Controlling for training set sizes

To facilitate comparisons with our translations, we control for training set sizes by sampling 1K, 3K and 6K sentence pairs from all datasets, similar to the approach used in Maillard et al. (2023). We select these training sizes to test whether models trained on smaller samples of our translations outperform models trained on samples of corresponding sizes from the other datasets. In addition, we sample 9K and 12K sentence pairs from the NLLBv1 and Joshua-IPC datasets, and 9K and the full 10,519 sentence pairs from TED2020. We

[4] github:openlanguagedata/seed/blob/main/seed/eng_Latn

[5] Formatting guidelines: https://oldi.org/guidelines

[6] https://www.ted.com/participate/translate

compare results from these larger sizes with results trained on 6K sentence pairs from our translations.

We sample using five different seeds for each training size where possible, averaging results across all seeds instead of relying on results from a single sample per training size.

4.2 Translation models

We fine-tune translation models on existing pre-trained multilingual models and one pre-trained monolingual model in both directions (Bangla-English and English-Bangla). Only the sampled sentence pairs described in section 4.1 are used to fine-tune the models and no additional data is used. All models are fine-tuned using the HuggingFace `transformers` library (Wolf et al., 2020) and use a linear learning rate schedule with an initial rate of 1e-6, with warmup. The following pre-trained models are used.

`NLLB-200`. The state-of-the-art NLLB-200 model (NLLB Team et al., 2022) is pre-trained on 200 languages, including Bangla and English. The `nllb-200-1.3B` dense model with 1.3 billion parameters is used for our fine-tuning.

`mBART50` (Tang et al., 2020). This is a multilingual seq2seq model primarily intended for the task of machine translation through multilingual fine-tuning. This model is pre-trained on 50 languages, including Bangla and English. We use the `mbart-large-50` model.

`mT5` (Xue et al., 2021). We experiment with the multilingual variant of the text-to-text transformer pretrained on a Common Crawl based dataset containing 101 languages, including Bangla and English. The `mt5-large` model is used.

`BanglaT5` (Bhattacharjee et al., 2023). To investigate the impact of a pre-trained monolingual model on translation quality, we fine-tune the BanglaT5 model pretrained on the Bangla2B+ corpus (Bhattacharjee et al., 2022). We select this model based on its open-source availability and relatively large pre-training corpus size of 27.5GB. We note that future work could include experiments with other open-source pre-trained monolingual models as and when they become available.

4.3 Evaluation Metrics

We evaluate all models with the Bangla/Bengali and English datasets from the FLORES+ evaluation benchmark for multilingual machine translation (NLLB Team et al., 2022), maintained by the Open Language Data Initiative. We use the development set for model tuning and early stopping, and the test set to report translation metrics.

We report the chrF++ scores (Popović, 2017) calculated using the `sacrebleu` toolkit (Post, 2018), since the chrF-based score is known to correlate well with human rankings especially for morphologically rich languages like Bangla, outperforming BLEU (Popović, 2015). BLEU has also been shown to be less useful for morphologically complex languages, with language-specific customizations showing better correlations with human rankings (Chauhan et al., 2021; Bouamor et al., 2014).

5 Experiment Results

Comparing the results on our dataset against the others, we can confirm that our manual translations yielded high quality parallel sentences between English and Bangla. Tables 1 and 2 in the Appendix show the fine-tuned chrF++ scores in the English-Bangla and Bangla-English directions. Here we discuss the results in Figures 2, 3, 4 and 5, displayed below.

Displaying the results in the English to Bangla direction, Figure 2 shows that models fine-tuned on our translations outperform models tuned on samples of corresponding sizes from the other datasets. This demonstrates the high quality of our translations. In the case of NLLB-200 our translations are on par with the NLLBv1 samples. The results, interestingly, also hold for the 1K and 3K sample sizes showing that smaller samples of our translations are also effective. Given that it is likely the NLLBv1 dataset was used to pre-train the NLLB-200 models, it is not surprising that the NLLB-200 models fine-tuned on the NLLBv1 samples in our experiments show good performance despite the automatic sentence alignment process.

In Figure 3, it can be seen that in the Bangla to English direction, models tuned on our translations outperform other models across all corresponding sample sizes, except for NLLB-200 where models tuned on the TED2020 dataset show the best performance. The average performance gap for the 6K sample size between our translations and the other datasets is 5.34 points for the mBART50 model and 4.52 points for the mT5 model. These wide margins show that the quality of the dataset used for fine-tuning can make a sizeable difference even for multilingual models with large pre-training corpora in English.

Considering the test of our translations against

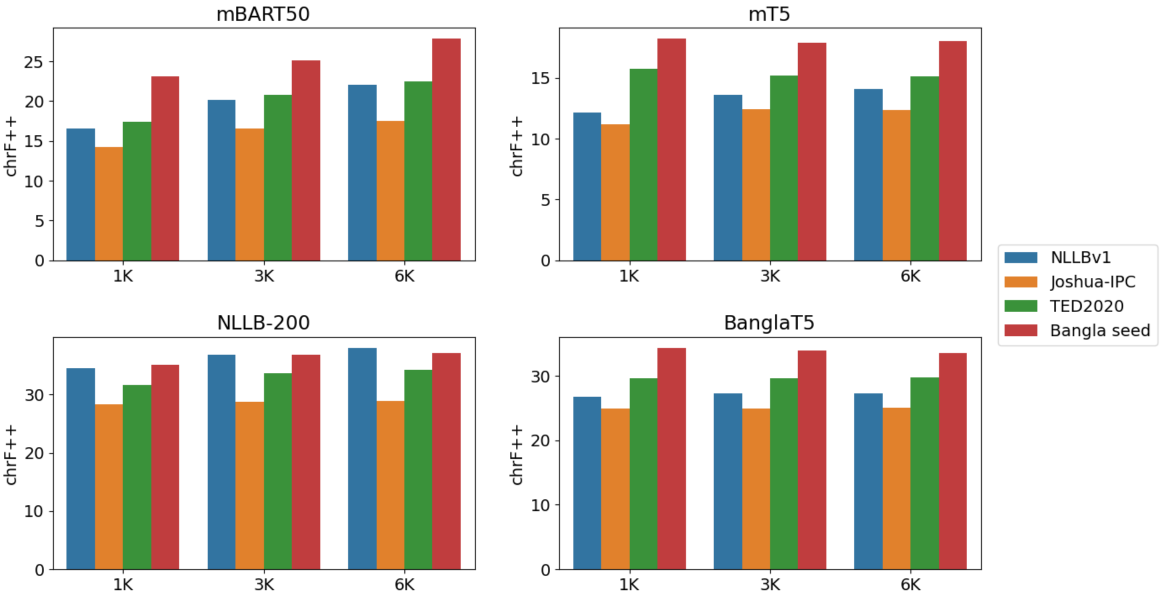

Figure 2: Averaged fine-tuned English to Bangla chrF++ scores on the FLORES+ test set for the 1K, 3K and 6K training set sizes. Models tuned on the Bangla seed dataset (red) outperform, or are on par with, models tuned on the other datasets across pre-trained model types and training sizes. Scores are averaged across five random samples per training set size and dataset.

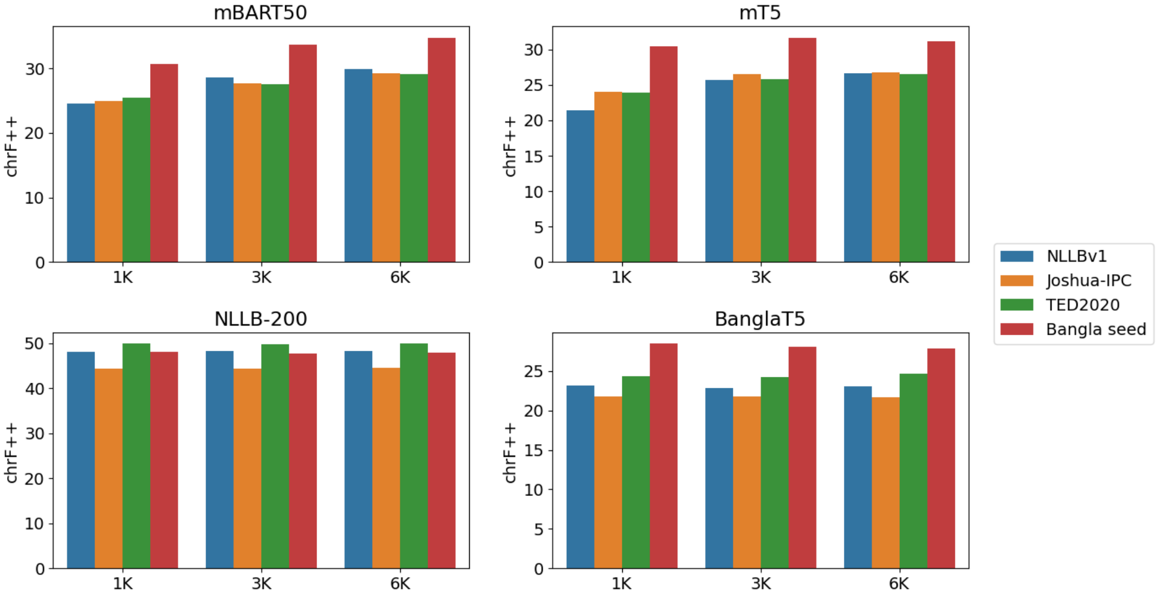

Figure 3: Averaged fine-tuned Bangla to English chrF++ scores on the FLORES+ test set for the 1K, 3K and 6K training set sizes. Models tuned on the Bangla seed dataset (red) outperform models tuned on the other datasets across pre-trained model types and training set sizes, except for the NLLB-200 models. Scores are averaged across five random samples per training set size and dataset.

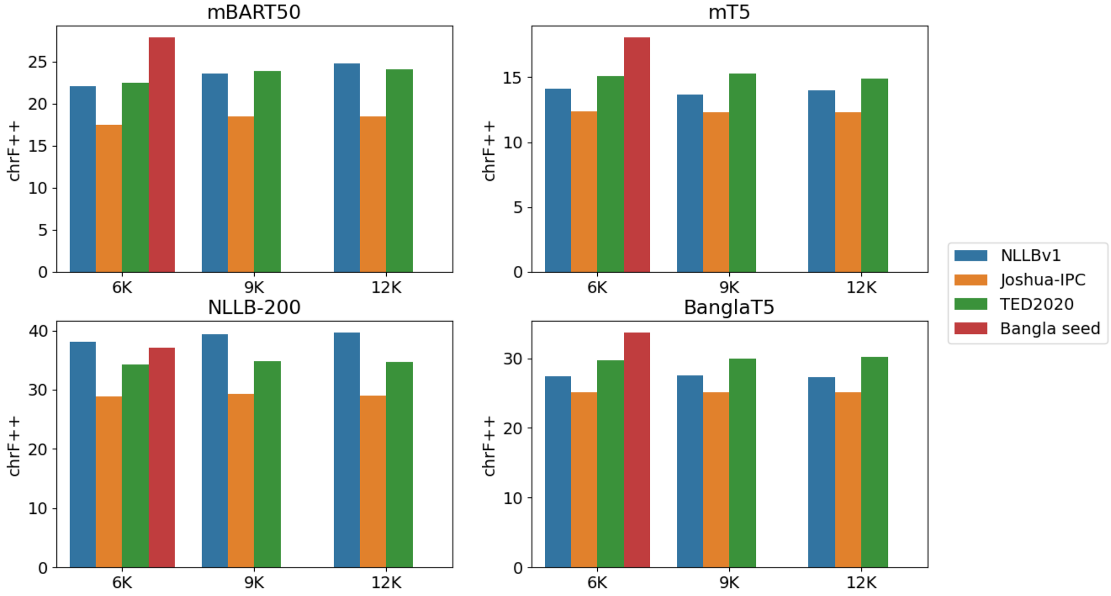

Figure 4: Averaged fine-tuned English to Bangla chrF++ scores on the FLORES+ test set for the 6K, 9K and 12K training set sizes; the complete TED2020 dataset is used in the 12K case. Models tuned on the Bangla seed dataset (red) outperform models tuned on other datasets of larger training sizes (9K, 12K) across pre-trained model types, except for the NLLB-200 models tuned on the NLLBv1 data. Scores are averaged across five random samples per training set size and dataset.

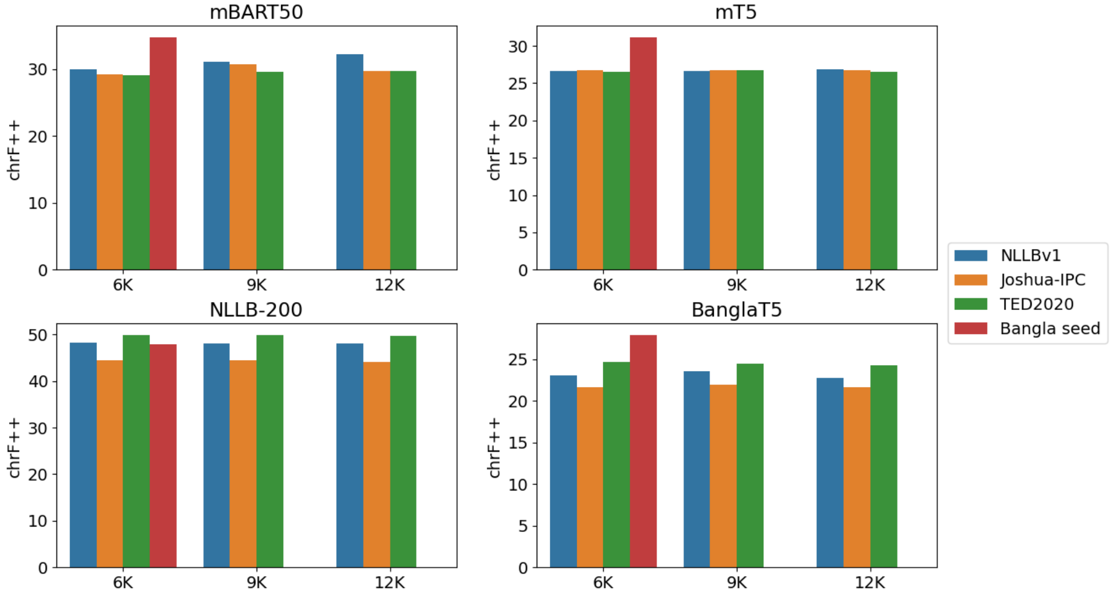

Figure 5: Averaged fine-tuned Bangla to English chrF++ scores on the FLORES+ test set for the 6K, 9K and 12K training set sizes; the complete TED2020 dataset is used in the 12K case. Models tuned on the Bangla seed dataset (red) outperform models tuned on other datasets of larger training sizes (9K, 12K) across pre-trained model types, except for the NLLB-200 models. Scores are averaged across five random samples per training set size and dataset.

samples of larger sizes from the other datasets, i.e 9K and 12K sentence pairs. The results in Figures 4 and 5 show that our translations outperform these larger training samples across all pre-trained model types and datasets except for the NLLB-200 models. The NLLB-200 models tuned on larger samples of the NLLBv1 dataset in the English to Bangla direction scored better than our translations. This is as expected, given the possible overlap between the NLLBv1 datasets used to pre-train and fine-tune the models in our experiments. The fact that models tuned on our translations scored better than models tuned on larger samples from the other datasets is another demonstration of the higher quality of our dataset.

6 Conclusion

We have created a high quality dataset of Bangla-English seed translations to contribute to the Open Language Data Initiative, paving the way for more translations between Bangla and other languages, including low-resource ones, that are supported by the initiative. We have demonstrated the high quality of our translated dataset by comparing it with a larger dataset that was mined and automatically aligned, as well as with two datasets of crowdsourced and reviewed translations. The models tuned on our dataset outperform models tuned on the other datasets after controlling for training set size. We hope that our dataset will support ongoing research in machine translation for the Bangla/Bengali community and other low-resource languages.
