#### **Abstract**

Safety-aligned LLMs respond to prompts with either compliance or refusal, each corresponding to distinct directions in the model's activation space. Recent studies have shown that initializing attacks via self-transfer from other prompts significantly enhances their performance. However, the underlying mechanisms of these initializations remain unclear, and attacks utilize arbitrary or hand-picked initializations. This work presents that each gradient-based jailbreak attack and subsequent initialization gradually converge to a single compliance direction that suppresses refusal, thereby enabling an efficient transition from refusal to compliance. Based on this insight, we propose CRI, an initialization framework that aims to project unseen prompts further along compliance directions. We demonstrate our approach on multiple attacks, models, and datasets, achieving an increased attack success rate (ASR) and reduced computational overhead, highlighting the fragility of safetyaligned LLMs. A reference implementation is available at **?**.

# 1 Introduction

LLMs have recently emerged with extraordinary capabilities (Waswani et al., 2017; Lewis et al., 2020; Ahn et al., 2022; Hadi et al., 2023) and have rapidly become integral to numerous fields, transforming everyday tasks such as text generation (Touvron et al., 2023a; Chiang et al., 2023a; Jiang et al., 2023a; Achiam et al., 2023), image generation (Saharia et al., 2022; Nichol et al., 2021), and complex decision-making tasks (Topsakal and Akinci, 2023; Wu et al., 2023). Despite their advantages, the widespread deployment of LLMs has unveiled critical security vulnerabilities (Perez and Ribeiro, 2022; Wan et al., 2023), making them susceptible to involuntary utilization in cyber-attacks and

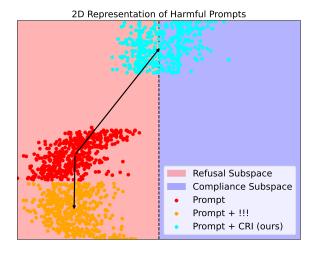

Figure 1: Visualization of CRI compared to standard initialization on the HarmBench dataset over the Llama-2 model.

other malicious activities (Fang et al., 2024; Yao et al., 2024; Xu et al., 2024a; Heiding et al., 2024; Bethany et al., 2025; Guo and Cai, 2025).

A common strategy to enhance the safety of LLMs is safety-alignment, which involves training models to generate outputs that adhere to desired safety and ethical standards (Shen et al., 2023; Wu et al., 2024b; Wang et al., 2023; Lee et al., 2023). This method distinguishes between harmless and harmful prompts to determine whether they should be complied with or refused (Glaese et al., 2022; Wang and Isola, 2020). Thereby, effectively segmenting the input space into Compliance and Refusal subspaces (Yu et al., 2024a), where previous works have shown that each subspace correlates to distinct directions within the LLM's internal activation space (Arditi et al., 2024; Wollschläger et al., 2025). Inadvertently, this fuels jailbreak attacks that manipulate harmful prompts to elicit models into compliance, contrary to their safety guidelines (Marshall et al., 2024; Yu et al., 2024c; Chao et al., 2023; Deng et al., 2023).

Gradient-based jailbreak attacks are a well-

<sup>\*</sup>Equal contribution.

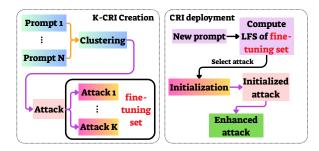

Figure 2: Illustration of the K-CRI framework. First, N harmful prompts are clustered into K groups, and a candidate attack is trained for each cluster (left). When a new prompt arrives, CRI evaluates the LFS of the K attacks and selects the one with the lowest value as initialization for a refined attack (right).

known category that utilizes gradient descent optimization schemes via models' backpropagation (Zou et al., 2023; Liu et al., 2023; Zheng et al., 2024; Schwinn et al., 2024). Such attacks follow a white-box setting, where attackers can access models' gradients, and have been shown to transfer across different models (Wu et al., 2025a; Zou et al., 2023; Liu et al., 2023; Lin et al., 2025). This transferability property reflects the shared vulnerabilities of LLMs (Zhao et al., 2025b), and extends the attacks' relevance to black-box settings, where surrogate models are used in the optimization (Li et al., 2024c; Zhang et al., 2025).

Early jailbreak attacks utilized uninformative initializations in their optimization, such as repeated or random tokens (Zou et al., 2023; Zhu et al., 2023; Hayase et al., 2024; Gao et al., 2024). In contrast, recent attacks aim to provide more informative initializations and often explicitly utilize pre-computed jailbreak prompts as initializations via self-transfer to other prompts (Andriushchenko et al., 2024; IGCG et al., 2024; Liu et al., 2023). Moreover, some jailbreak approaches implicitly leverage the vulnerabilities discovered by previous attacks via utilizing sets of handcrafted jailbreak prompts (Zhu et al., 2023; Schwinn et al., 2024), templates (Jiang et al., 2024; Liu et al., 2024b), or patterns (Wei et al., 2023). While self-transfer initializations significantly enhance attack performance in various scenarios, their underlying dynamics remain unclear. Currently, only abstract categories of efficient initializations have been identified (IGCG et al., 2024), and attacks utilize arbitrary or hand-picked initializations.

This work introduces Compliance Refusal

Initialization (CRI), a novel initialization framework for gradient-based jailbreak attacks. Our approach considers the activation-space refusal direction defined by Arditi et al. (2024) as the average difference between refusal and compliance prompts-induced LLM activations. Previous works showed that while refusal is governed by a single direction, there are multiple opposing compliance directions utilized by jailbreak attacks (Arditi et al., 2024; Ball et al., 2024; He et al., 2024; Zhou et al., 2024b). Nonetheless, the optimization of given jailbreak attacks often exhibits similar compliance directions over different prompts (Ball et al., 2024). CRI then leverages pre-trained jailbreak attacks to project unseen prompts along these compliance directions, and towards the compliance subspace. In Figure 1, we illustrate the initializations' effect using a compliance-refusal SVM classifier, where CRI projects prompts toward the decision boundary. We provide the detailed configurations and additional analysis in Section A.1. Below, we outline our main contributions.

- We present the gradual convergence of given attacks and subsequent self-transfer initializations toward similar compliance directions.
- We propose the CRI framework, which precomputes self-transfer initializations and utilizes the compliance directions' similarity to identify and utilize effective initializations over given prompts. An illustration is presented in Figure 2.
- We evaluate CRI across multiple jailbreak attacks, LLMs, and safety benchmarks, demonstrating higher ASR and reduced computational overhead when compared with baseline initializations, emphasizing its ability to exploit compliance directions in safety-aligned LLMs.

The rest of the paper is organized as follows: Section 2 discusses the attack setting and related works, Section 3 describes our proposed method, Section 4 provides our experimental results, Section 5 concludes the paper, and Section 6 discusses the limitations of our work.

## 2 Background and Related Work

# 2.1 Background

We now present the gradient-based jailbreak attack and initialization settings for both textual and

embedding-based attacks. We then detail the performance evaluation of attacks and indications of their success. Finally, we discuss the theoretical aspects of refusal and compliance. Our notations are based on those suggested by Zou et al. (2023); Schwinn et al. (2024); Andriushchenko et al. (2024); Arditi et al. (2024).

Jailbreak Attack Setting Let V be some token vocabulary that contains the empty token  $\phi$ , let  $V^* \equiv \bigcup_{i=1}^{\infty} V^i$  be the set of all sequences over V, let  $M:V^* \to \mathbb{R}^{D_{out}}$  be an LLM, mapping a token sequence to an output representation with dimension size  $D_{out}$ , let  $E_M:V\to\mathbb{R}^{D_{in}}$  be the token embedder utilized by M, with dimension size  $D_{in}$ , and let  $N_M$  be the number of layers in M. Each layer  $i\in[1,N_M]$  in M is denoted as  $M^{(i)}$  and produces a vector representation along the mapping process, with  $M^{(1)}$  being a tokenwise application of  $E_M$  on an input sequence, and  $M^{(N_M)}$  producing the model's output. Formally, denoting function concatenation as  $\circ$  and sequence concatenation as  $\oplus$ :

$$M \equiv M^{(N_M)} \circ \dots \circ M^{(1)} \tag{1}$$

$$\forall x_{1:n} \in V^n, M^{(1)}(x_{1:n}) \equiv E_M(x_{1:n}) \quad (2)$$
  
 
$$\equiv E_M(x_1) \oplus ... \oplus E_M(x_n)$$

Given an input  $x_{1:n} \in V^n$ , M's output then induces a distribution over the next token to be generated. For each  $t_1 \in V$  the generation probability is then denoted as  $p_M(t_1|x_{1:n})$ . Denoting  $t_0 = \phi$ , we generalize this notation for the generation of output sequences  $t_{1:H} \in V^H$ :

$$p_{M}(t_{1:H} \mid x_{1:n}) \equiv p_{M}(t_{1:H} \mid E_{M}(x_{1:n})) \quad (3)$$

$$= \prod_{i=1}^{H} p_{M}(t_{i} \mid E_{M}(x_{1:n}) \oplus E_{M}(t_{0:i-1}))$$

The jailbreak adversarial criterion  $\ell_M(x,t)$  is then the negative log probability of generating a target  $t \in V^*$ , given an input  $x \in V^*$ . Hereby, given a predefined set of prompts' jailbreak transformations  $JT \subseteq V^* \to (\mathbb{R}^{D_{in}})^*$ , a jailbreak attack A optimizes a transformation  $T \in JT$  to minimize the criterion over the transformed input  $\ell_M(T(x),t)$ . Similarly, given a set of input and target sequences  $\{x_i,t_i\}_i \subset V^* \times V^*$ , a universal jailbreak attack  $A^U$  targets the same minimization in expectation over the set while applying a single

transformation. Formally:

$$\ell_M(x,t) = -\log p_M(t \mid x) \tag{4}$$

$$A(x,t) = \arg\min_{T \in JT} \ell_M(T(x),t)$$
 (5)

$$A^{U}(\lbrace x_{i}, t_{i} \rbrace_{i}) = \arg \min_{T \in JT} \mathbb{E}_{i} \left[ \ell_{M} \left( T(x_{i}), t_{i} \right) \right]$$
(6)

As such, while A considers a single input and target pair,  $A^U$  aims to apply to a distribution of inputs and targets and considers generalization to unknown samples. Therefore, universal attacks often utilize a corresponding evaluation set to optimize the generalization properties of the transformations (Zou et al., 2023; Yi et al., 2024; Xu and Wang, 2024). An attack initialization is then an initial transformation  $T_0 \in JT$ , utilized to initiate the corresponding optimization.

The predefined set of jailbreak transformations JT can be considered to limit the attack to transformations that preserve the intention in the input prompt x. A common practice in text-based adversarial attacks is to consider transformations that add a textual suffix and or a prefix to the input with up to a given length L (Zou et al., 2023; Liu et al., 2023; Yu et al., 2024a; IGCG et al., 2024; Guo et al., 2024). Embedding-based attacks utilize similar suffix transformations but extend the scope of possible suffixes to any embedding vectors rather than those that align with textual tokens (Schwinn et al., 2024). Accordingly, such attacks refer to the token embeddings of LLMs as the input representations<sup>1</sup>. Depending on the transformation type, the attack then optimizes and transforms the discrete text or continuous embeddings. Formally:

$$JT_{text-s}(x_{1:n}) \equiv \{E_M(x_{1:n} \oplus s)\}_{s \in V^L}$$

$$JT_{text-ps}(x_{1:n}) \equiv \{E_M(p \oplus x_{1:n} \oplus s)\}_{p,s \in V^L}$$
(8)

$$JT_{embed-s}(x_{1:n}) \equiv \{E_M(x_{1:n}) \oplus s\}_{s \in \mathbf{R}^{D_{in} \times L}} \tag{9}$$

Attacks Success Evaluation Jailbreak attacks aim to generate a target t via the model M given the transformed input T(x). The intention is then to utilize targets that indicate the compliance over the prompt x. This approach was first suggested by Zou et al. (2023), which utilized targets such as "Sure, here is", where triggering the generation of such tokens strongly correlates with the

<sup>&</sup>lt;sup>1</sup>This can be extended to include attacks on multilayer representations, as in Schwinn et al. (2024).

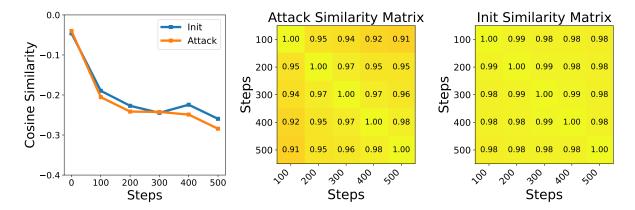

Figure 3: Comparison of directions' cosine-similarity during GCG's optimization process on the HarmBench dataset over the Llama-2 model. We compare the refusal with attacks and self-transfer initializations (left), and present the similarity matrices of attacks (center) and initializations (right).

model continuing to generate the desired jailbroken output. However, this indication is uncertain, and additional evaluations are conducted over the prompt and output to ascertain successful jailbreaks. A common practice is to evaluate the attack's success during the optimization by utilizing "refusal lists", which contain words that indicate the model's refusal. Attacks then define their corresponding ASR based on these two factors, i.e., the exact generation of the intended target, and the non-generation of words in their respective "refusal lists".

During inference, the exact jailbreak input and stochastically generated output of the model are available, and the successful jailbreak attacks can be thoroughly reevaluated via a judge model. The generated output is then produced via M, and we define the mapping between its input and output  $M_{gen}: (\mathbb{R}^{D_{in}})^* \to V^*$ . The judge model then maps the target-output pair to an assessment of its success JUDGE:  $V^* \times V^* \to \{\text{YES}, \text{NO}\}$ . In this evaluation, a jailbreak attack T is considered successful for a given input prompt x and target t, if JUDGE $(t, M_{gen}(T(x))) = \text{YES}$ .

Compliance and Refusal We define the compliance subspace C as the set of inputs and targets, for which a language model M produces complying, non-refusal outputs. The refusal subspace R is then defined as its complement. As each judge defines a distinct notion of compliance, the exact segmentation of C, R varies for each evaluation. In the current work, we define these subspaces independently for each discussed attack via their corresponding notion of adversarial success. In addition, we define the attack direction  $\Delta a$  as the

mean over the layers' corresponding directions. A layer  $l \in [1, N_M]$  attack direction is denoted as  $\Delta a^l$  and defined as the average activation difference at the last token position of the instruction, between prompts with  $(A^l_{jail})$  and without the jailbreak  $(A^l_{base})$  (Ball et al., 2024). Formally:

$$\Delta a^{l} = \frac{1}{|A_{jail}^{l}|} \sum_{\substack{a_{jail}^{l} \in A_{jail}^{l} \\ -\frac{1}{|A_{base}^{l}|}} \sum_{\substack{a_{base}^{l} \in A_{base}^{l} \\ a_{base}^{l} \in A_{base}^{l}}} a_{base}^{l}$$

$$\Delta a = \mathbb{E}_{l}[\Delta a^{l}]$$

$$(10)$$

The *refusal direction* is then similarly defined by taking harmful and harmless prompts instead of jailbreaks and non-jailbreaks (Arditi et al., 2024).

# 2.2 Related Work

Self-transfer-based initialization was first introduced by Andriushchenko et al. (2024) as a strategy for enhancing random-search jailbreak attacks, demonstrating improvements in ASR and reducing computational overhead. This initialization used an arbitrary previously successful jailbreak attack as the starting point for further attack optimization. Building on this idea, IGCG et al. (2024) identified a category of malicious prompts that provided more effective initializations when using self-transfer. An arbitrary initialization is then selected from this category. Other studies, such as Schwinn et al. (2024) and Liu et al. (2023), employed hand-crafted jailbreaks as initializations and demonstrated further enhanced effects. Our work extends these approaches by building on theoretical insights that enable the automatic selection of effective initializations over given prompts. We supplement these previous initialization methods, which were not designed to select self-transfer over individual prompts.

#### 3 Method

## 3.1 Motivation

In this section, we discuss the motivation of the CRI framework. We first consider that attacks project prompts in opposing directions of refusal and toward similar compliance directions (Ball et al., 2024). We expand on this phenomenon by considering the gradual optimization of given gradient-based attacks over different prompts. In Figure 3, we present that such attacks, and subsequent self-transfer initializations, show highly similar directions during their optimization process, while shifting further away from refusal. This entails that gradient-based attacks gradually transfer from refusal to compliance by following a single direction, suggesting that effective initializations project prompts further along this direction. We denote this direction as the *compliance direction*, which is defined independently for each attack and prompts' distribution. As the attack optimization aims to minimize the attack criterion, it indicates the progression along the *compliance direction* and thereby, the proximity to the compliance subspace. Therefore, we consider the metric of loss-in-thefirst-step (LFS), which measures the attack criterion values when utilizing a given initialization over a given prompt. A lower LFS then indicates that the initialization projects said prompt further along the compliance direction, which aids in guiding subsequent optimization and reduces the distance to a successful attack. CRI then utilizes LFS to select an effective initialization from a pre-computed set.

#### 3.2 CRI Framework

**Objective** Our target is to construct an effective set of initializations, where we aim to reduce the required optimization steps to a successful jailbreak. Per our motivation, we utilize the attack criterion to indicate progression along the *compliance direction*, and as a differentiable alternative to the initialization target. CRI's objective is then to optimize an initial set of attacks  $\mathcal{T}_0 \subseteq JT$  of size K over a fine-tuning set  $S_{FT}$  of size N, while aiming to enhance subsequent attacks over unknown prompts,

which are sampled from the same distribution. As such, the optimization target for fine-tuning the CRI set is the LFS. We then deploy CRI over a given prompt by evaluating the LFS over each pretrained attack, and selecting the best-performing one as the initialization. This evaluation is applied over a limited set of attacks and only requires corresponding inference passes, the computational overhead of which is negligible compared to backpropagation. We denote CRI's initialization set as  $\mathcal{T}_{K-CRI}$ , formally:

$$\mathcal{T}_{K\text{-}CRI} = \arg \min_{\mathcal{T}_0 \subseteq JT, |\mathcal{T}_0| = K}$$

$$\mathbb{E}_{(x,t) \in S_{FT}} \left[ \min_{T \in \mathcal{T}_0} \ell_M(T(x), t) \right]$$
(12)

**Optimization** We now approximate the inner minimization via some individual or universal attacks  $A, A^U$ , and correspondingly denote the resulting sets as  $\mathcal{T}_{N-CRI}, \mathcal{T}_{1-CRI}$ :

$$\mathcal{T}_{N-CRI} = \{A(x,t)\}_{(x,t) \in S_{FT}}$$
 (13)

$$\mathcal{T}_{1-CRI} = \{ A^U(S_{FT}) \} \tag{14}$$

 $\mathcal{T}_{N\text{-}CRI}$  then corresponds to optimizing each attack independently over each  $(x,t) \in S_{FT}$ , and  $\mathcal{T}_{1\text{-}CRI}$  corresponds to optimizing a single attack that optimizes the expectation over the entire fine-tuning set. We limit this work to considering the same attack in fine-tuning and deploying CRI. Nonetheless, we consider both individual and universal attack variants when available.

The single attack in  $\mathcal{T}_{1-CRI}$  considers multiple prompts and is optimized for generalization to unknown prompts. However, it does not consider the LFS metric and the corresponding attunement to the initialized prompt. In contrast,  $\mathcal{T}_{N-CRI}$  optimizes each attack to achieve the minimum over a different prompt in Equation (12), achieving lower loss over the fine-tuning set and providing various initial attacks, which may be relevant to different prompts in deployment. However, these two approaches present corresponding disadvantages.  $\mathcal{T}_{1-CRI}$  only contains a single attack and cannot address different behaviors in deployment. Contrarily,  $\mathcal{T}_{N\text{-}CRI}$  separately optimizes each attack on a single prompt and does not consider its generalization to unknown prompts. Therefore, we extend  $\mathcal{T}_{K-CRI}$  to consider a combination of the approaches via prompt clustering. We then use a universal attack on each cluster and produce multiple attacks with enhanced generalization properties.

**Prompt Clustering** We now consider a combination of the approaches presented in  $\mathcal{T}_{N-CRI}$ ,  $\mathcal{T}_{1-CRI}$ by grouping prompts towards applying  $A^U$ . Firstly, we note that the optimization in Equation (12) only considers the LFS metric. However, CRI benefits the entire attack optimization, especially if the initial starting point does not significantly change during the optimization. Hereby, initial attacks that generalize better to unseen prompts may remain partly unchanged and present a better initialization. Therefore, we utilize a fixed number of prompts to produce each attack in a given CRI set, considering attacks with comparable generalization properties in deployment. In addition, we do not utilize a prompt for optimizing multiple attacks, as it may result in over-fitting to similar prompts. Each attack in  $\mathcal{T}_{K-CRI}$  is then trained over |N/K| distinct prompts, and we correspondingly select K prompt clusters. We aim to cluster similar prompts to initialize other similar prompts effectively. Hereby, we utilize a sentence encoder EN (Warner et al., 2024) and cluster prompt embeddings with minimal Euclidean distance. For clustering, we utilize the constrained k-means algorithm suggested by Bradley et al. (2000), where a single attack is then optimized over each cluster. The full algorithm is presented in Algorithm 1, and a visualization of the prompt clusters in Figure 9.

# 4 Experiments

This section presents a comprehensive empirical evaluation of CRI compared to baseline initializations. We first present the experimental setting in Section 4.1, and continue to discuss the results over the HarmBench dataset in Section 4.2. Additionally, we present ablation studies of our method in Section C.5, and extend the evaluations with additional attacks, models, and datasets in Section C.4. Our evaluation seeks to addresss three key research questions:

- **(RQ1)** Does the *LFS* metric present a reliable indication of the required steps-to-success, thereby enabling the selection of effective initializations?
- (**RQ2**) Does the *CRI* framework present an effective approach to initializing attacks in the proximity of the compliance subspace, enhancing attacks' *ASR* and reducing computational overhead?

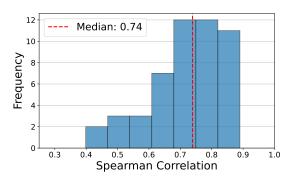

Figure 4: Distribution of per-prompt Spearman correlation of LFS and number of steps-to-success, on Llama-2. (Median r=0.74,  $p=4.61\times 10^{-4}$ ).

• (**RQ3**) How does the tradeoff between the number of initializations and their generalization properties, as represented in the *K* hyperparameter of *CRI*, affect the performance of the resulting initializations?

# 4.1 Experimental Setting

**Datasets** We present our experiments on the "standard behaviors" category of the HarmBench dataset (Mazeika et al., 2024), which is comprised of prompt-target pairs (x,t). We define three disjoint subsets and utilize them in all the presented settings. CRI utilizes 2 subsets of 25 samples each: a fine-tuning set for optimizing CRI, and a validation set for evaluating the universal attacks. The final subset is the 50-sample test set over which we report the results. Additionally, we present results over the AdvBench dataset (Zou et al., 2023) in Sections C.4.1 and C.4.3.

**Models** We evaluate our results over the open-source *Vicuna-7B-v1.3* (Chiang et al., 2023b), and *Llama-2-7B-Chat-HF* (Touvron et al., 2023b) LLMs, which we accordingly denote as *Vicuna*, and *Llama-2*. We present these models to compare with the default setting presented by GCG, and provide results over additional models in Section C.1.

**Attacks** We present the GCG (Zou et al., 2023) and the Embedding attacks (Schwinn et al., 2024), where we utilized the same parameter configuration in all the presented settings, including the initializations' training. The parameter configuration is then the default parameters suggested by the authors, except for the batch-size B parameters of GCG. Thereby, GCG utilizes 500 optimization steps and the JT set in Equation (7) with L=20 tokens.

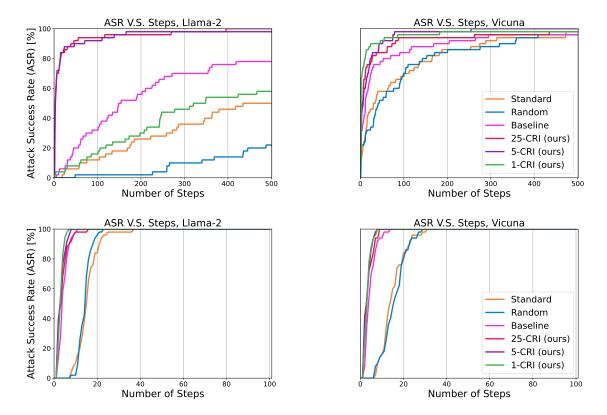

Figure 5: Comparison of ASR and number of steps on the HarmBench dataset for the GCG (top) and Embedding attacks (bottom) over the Llama-2 (left) and Vicuna (right) models.

Similarly, the Embedding attack utilizes 100 optimization steps and the JT set in Equation (9) with L=20 tokens. To present a more robust setting, we limit the computational resources of the GCG attack and take the batch-size parameter of GCG to be B=16 instead of the default 512 value. This entails that only B=16 tokens are sampled as possible replacements in each iteration of GCG, emphasizing the effect of the compared initializations. Additionally, we present results with increased batch size in Section C.5.1.

Initializations We compare the K-CRI initializations over K=1,5,25 to existing approaches, i.e., "Standard" which utilizes repeated '!' tokens, "Random" which utilizes uniform random tokens, and "Baseline" which utilizes randomly selected self-transfer initializations similarly to Andriushchenko et al. (2024); Jia et al. (2024). We then refer to "Standard" and "Random" initializations as uninformative and to others as informative. For each attack, CRI pre-trains the transformations on the designated data subsets and utilizes LFS to select an initialization for a given prompt. The "Baseline" approach then utilizes the same initializations set as 25-CRI, but selects each ini-

tialization uniformly.

Metrics In each attack's evaluation, we follow the default evaluation framework suggested by the authors to compute the ASR. Thereby, GCG evaluates success as not generating refusal-list keywords, where we provide the list in Section C.1.4. In contrast, the Embedding attack requires generating the exact target. We additionally present an evaluation of the resulting attacks via a GPT-4 judge in Section C.1.4. In addition to the ASR and LFS, we define two metrics for estimating the computational overhead of attacks: MSS—Median Steps to Success, ASS—Average Steps to Success. Hereby, a lower MSS/ASS of initializations indicates their corresponding decrease in computational overhead.

**Computation** In all the presented settings, the computation was executed on Intel(R) Xeon(R) CPU and NVIDIA L40S GPU. An evaluation of runtime on this hardware can be found in Section C.5.2.

# 4.2 Experimental Results

In Figure 4, we present the distribution of perprompt Spearman correlations between the LFS

Attacks	Initialization		Llan	na-2			Vic	ına	
		$\overline{ASR}\uparrow$	$MSS\downarrow$	$ASS\downarrow$	$\overline{LFS\downarrow}$	$ASR\uparrow$	$MSS\downarrow$	$ASS\downarrow$	$LFS \downarrow$

Table 1: Comparison of attacks' metrics on the HarmBench dataset.

metric and the number of steps to a successful attack, on *Llama-2*. For each prompt, we utilize 18 different initializations to calculate both measures, including the standard, random, baseline, and the initializations used in a separate ablation study over the number of training steps as in Figures 21 to 23. The distribution seems to be heavily skewed to the right, with most per-prompt Spearman correlations clustered at relatively high values (median 0.74), and accompanied by low p-values (median  $4.61 \times 10^{-4}$ ). These results confirm a statistically significant, positive monotonic relationship between LFS and steps to success when selecting an initialization for a given prompt, supporting our approach for selecting initializations via the LFS metric. In Figure 16, the Vicuna distribution also leans to the right, but the median correlation and p-values are somewhat decreased. This may be due to *Vicuna* being considerably less robust than Llama-2, which aligns with our main results.

In Figure 5, we present the ASR of the GCGand Embedding attacks depending on the number of steps, over the Llama-2 and Vicuna models. In the Embedding attack, all initializations quickly achieve 100% ASR, with the uninformed initializations requiring somewhat more computational resources. This may indicate that these settings are less robust, which aligns with the Embedding attack being considered better performing. In addition, these results emphasize the computational benefit of utilizing informed initializations. Comparable results are presented on newer models in Figures 11 and 15. Similarly, for GCG on the Vi- $\it cuna$  model, all initializations achieve nearly 100%ASR, yet with more distinct computational requirements. CRI now requires the fewest optimization steps, with comparable performance for K = 1, 5, 25, the baseline approach requires somewhat more, and substantially so for the uninformed approaches. The high ASR again indicates this setting as non-robust, where the computational comparison implies the benefit of utilizing the LFSmetric for selecting initializations. In contrast, for GCG on Llama-2, only 25-CRI, 5-CRI achieve near 100% ASR, with all other approaches achieving substantially less. This may indicate that this setting is more robust, where the effective initializations of 25-CRI, 5-CRI aid in circumventing this robustness, and is supported by those two approaches exclusively achieving substantial ASR in the first few steps. The baseline initialization then achieves a higher ASR than 1-CRI, which suggests that 1-CRI is inefficient in robust scenarios. This is supported by the corresponding training results of 1-CRI, presented in Section C.3, where it achieves negligible ASR over the validation set.

In Table 1, we compare the resulting ASR of the GCG and Embedding attacks over the Llama-2 and Vicuna models. CRI then achieves the best ASR, MSS, ASS, LFS in all the presented settings, substantially outperforming other initialization strategies. This is further supported by more models, data, and attacks in Table 4. Similarly to previous indications, 5-CRI, 25-CRI consistently achieves the best or comparable results, and 1-CRI is only effective in non-robust settings. This supports our previous indications that LFS-based initialization selection is an effective initialization strategy.

# 5 Discussion

This work suggests CRI, an initialization framework for gradient-based jailbreak attacks. Our findings suggest that given attacks optimize prompts' distributions by gradually shifting them along single compliance directions. We then define the LFSmetric to indicate progress along this direction and corresponding proximity to the compliance subspace. This metric both guides the optimization of the CRI set and provides our initialization selection criterion. Our results indicate that this approach produces and utilizes effective initializations, which enhance attacks' ASR and reduce their computational overhead. For example, with the GCG attack on Llama-2, 25-CRI achieves 100% ASR with an MSS of 2, while randomly selected initializations from the same initialization set only achieve 78% ASR with an 122 MSS, emphasizing the strength of CRI's selection criterion. The uninformative initializations then achieve 50% ASR with an MSS of 185.

Previous approaches that utilized self-transferbased initializations presented significant attack enhancements; however, they rely on arbitrary initializations. Conversely, CRI extends this approach to an automated process by considering multiple initializations, thereby addressing a range of diverse scenarios. Our selection metric then matches a corresponding initialization to each scenario.

The success of our methods supports the assumption that given attacks gradually follow singular directions. This implies that the safeguards of LLMs can be circumvented with relative ease, as only the identification of such directions is required. Moreover, these directions are defined over the input space and could potentially be transferred to other LLMs. Therefore, eliminating these compliance directions is vital to producing robust LLMs. Jailbreak attacks may still persist in models that achieve such. However, they will require distinct optimization for each malicious prompt, significantly increasing their computational overhead. Future studies could leverage CRI as a framework to gauge LLM robustness, specifically by testing how well a model resists attacks with highly effective initializations. This can be measured by evaluating the minimal required computational resources for computing an effective CRI set, i.e., the minimal number of prompts and their optimization overhead required to increase the success of initialized prompts and reduce per-attack computational overhead.

#### 6 Limitations

Despite the advantages of initialization-based attack strategies, these initializations may restrict the diversity of the produced attacks. Initializations that converge in several optimization steps can lead to narrow attack trajectories that rely on one compliance direction that may not be relevant to enhancing models' robustness to other jail-break attacks. When utilized for alignment training (Mazeika et al., 2024), such initializations can inadvertently harm the model's effectiveness against the variety of real-world jailbreak threats.

## 7 Ethical Considerations

While this work can potentially facilitate the generation of harmful data on open-source LLMs or reveal vulnerabilities that expedite attacks, we believe it is vital to highlight these threats to promote AI security research. By identifying and studying these weaknesses, we can build stronger defenses and reduce risks in an environment where LLMs are rapidly developing. Recognizing the risks and limitations is essential for creating adequate safeguards, allowing researchers and developers to address emerging threats proactively.

#### **A** Introduction

# A.1 Fig-1: Generation of 2D Visualization

The visualization in Figure 6, is a refined variant of Figure 1, is presented under identical experimental conditions. In this figure, each point represents a distinct harmful prompt. The color scheme differentiates prompt types: red denotes clean harmful prompts, orange indicates prompts initialized using GCG's standard method, and cyan corresponds to prompts initialized with our proposed method (1-CRI). To analyze these prompts, we first obtained their embeddings using Llama-2 and determined whether Llama-2 complied with each prompt. Using these embeddings and compliance labels, we trained an SVM classifier. This process yielded a weight vector w and bias b, which define the SVM decision function:  $\langle w, x \rangle + b$ . A negative SVM score indicates a refusal, while a positive score signifies compliance. This score is plotted on the x-axis. The y-axis represents a one-dimensional t-SNE projection. The orange and cyan paths illustrate the optimization trajectories of the attack: the orange path follows GCG's standard initialization, while the cyan path traces the attack starting from our initialization. The x-axis values are computed using the previously trained SVM classifier.

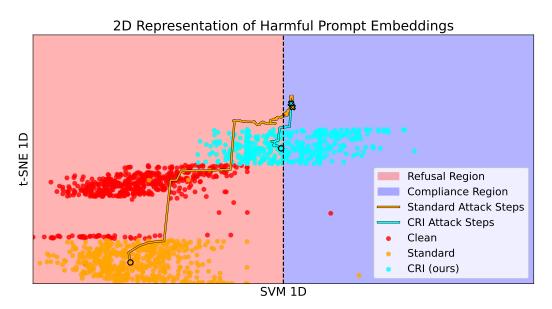

Figure 6: Visualizations of harmful prompts' initializations and corresponding GCG's attack steps. Disclaimer, CRI is not an attack and "CRI Attack Steps" are for the attack steps when using CRI as an initialization.

## **B** Method

#### **B.1** Motivation

# **B.1.1** Train and Test Refusal Similarity vs. Train Steps

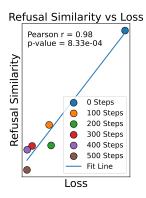

Figure 7: Correlation between refusal similarity and attack loss over optimization steps of attack.

# **B.1.2** Correlation between Loss and Refusal Similarity

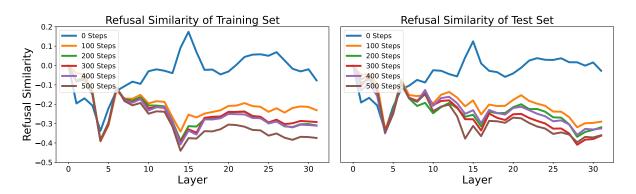

Figure 8: Refusal similarity comparison: (left) Normal GCG optimization steps; (right) Initialization trained on different optimization steps.

# **B.2** K-CRI algorithm

# Algorithm 1 Compliance–Refusal Initialization (CRI)

- 1: Input: Fine-tuning set  $S_{\rm FT}$ , number of clusters K, encoder EN, universal attack  $A^U$
- 2: **Output:** Initialization set  $\mathcal{T}_{K\text{-CRI}}$
- 3: Initialize  $\mathcal{T}_{K\text{-}\mathrm{CRI}} \leftarrow \emptyset$
- 4: Compute embeddings  $\{EN(x) \mid (x,t) \in S_{\mathrm{FT}}\}$
- 5: Cluster the embeddings into K groups  $\{C_1, \ldots, C_K\}$  using constrained k-means
- 6: **for** each cluster  $C_k$  **do**
- 7: Learn universal transformation  $T_k \leftarrow A^U(C_k)$
- 8: Update  $\mathcal{T}_{K\text{-CRI}} \leftarrow \mathcal{T}_{K\text{-CRI}} \cup \{T_k\}$
- 9: end for

10:

11: **return**  $\mathcal{T}_{K\text{-}\mathrm{CRI}}$

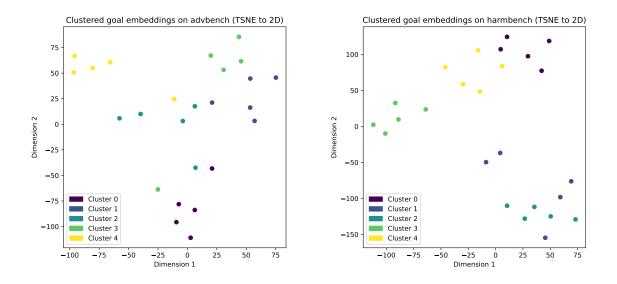

Figure 9: AdvBench (left) and HarmBench (right) prompt clustering for 5-CRI, projected to 2D using t-SNE.

# **B.4** CRI Integration Guidelines

To support the broad applicability of the CRI framework, we outline generic integration strategies adaptable to various optimization-based paradigms. These strategies utilize K-CRI templates to initialize prompts near the compliance subspace, enhancing efficiency while remaining agnostic to specific attack mechanisms. Integration approaches align and adaptable across gradient-based jailbreak attacks such sampling-based, and reinforcement-driven optimization settings. Concrete integration examples are provided in our experiments, in Section 4.

Classic Gradient Attacks This paradigm employs gradient-based optimization to iteratively refine input prompts, minimizing the negative log probability of eliciting a target response. The CRI framework integrates by initializing prompts utilizing K pre-computed attacks, which serve as starting points for gradient descent, thereby reducing the number of iterations required for convergence. By leveraging the semantic clustering inherent in CRI, this approach ensures that initial prompts are optimally positioned within the compliance subspace, enhancing optimization efficiency (Zou et al., 2023; Wallace et al., 2019; Shin et al., 2020; Guo et al., 2021; Ebrahimi et al., 2018). Similarly, CRI can also be integrated for extended attack variants of this category, which utilize a scalar energy function (Guo et al., 2024) to guide prompt modifications toward model outputs that align with desired behaviors, often without specifying a precise target response. CRI integrates by selecting K attacks that minimize the initial energy score, providing robust initial prompts for untargeted optimization. This strategy capitalizes on CRI's ability to group prompts by semantic similarity, thereby improving generalizability across diverse prompt distributions (Liu et al., 2023; Chao et al., 2023; Zhang et al., 2022; Wei et al., 2024; Li et al., 2023a). Results for (Zou et al., 2023) can be found in Table 1,

Embedding Attacks Embedding attacks manipulate prompt representations within the latent space to circumvent refusal mechanisms, using training-time attacks as a baseline to identify vulnerable directions that trigger compliance. CRI integrates by selecting K attacks within the LLMs' embedding space, followed by selecting the one that minimizes the attack criterion for a given prompt (Leo et al., 2024; Qi et al., 2023; Li et al., 2024a; Zhao et al., 2023; Huang et al., 2023), results for (Schwinn et al., 2024) appear in Table 1.

Universal Attacks These attacks optimize a single transformation applicable across multiple prompts, prioritizing broad generalizability. CRI integrates by training K attacks on clustered subsets of the fine-tuning set, then selecting the optimal template for a given prompt during inference. This approach balances universal applicability with prompt-specific efficacy, leveraging CRI's clustered structure to enhance transformation robustness (Zou et al., 2023; Mozes et al., 2021; Liu et al., 2022; Brown et al., 2023; Yang et al., 2024b), results for (Zou et al., 2023) can be found in Section C.4.1 for Llama-2 and Table 3 for Vicuna.

**Model-Based Black-Box Attacks** These attacks rely on querying the model without gradient access, using output feedback to iteratively refine prompts. CRI integrates by employing K attacks as an initial set, minimizing the number of model interactions required to achieve compliance. The diversity of CRI clusters enhances query efficiency, particularly in resource-constrained black-box settings (Zou et al., 2023; Chen et al., 2021; Garg et al., 2022; Li et al., 2023b; Zhang et al., 2024), for results on the GCG-M model transferability (Zou et al., 2023) presented in Section C.4.1 for Llama-2-based jailbreak attack and Table 3 for Vicuna-based jailbreak attack.

Other Attacks and Attacks Improvements Beyond standard optimization-based attacks, CRI extends to additional paradigms such as prefix optimization, refusal unlearning, and alignment modulation (Jones et al., 2024; Smith et al., 2024; Xu et al., 2023; Lin et al., 2023; Wu et al., 2024a). Its flexible K initialization set framework enables adaptation to diverse objectives while remaining model- and method-agnostic. Moreover, CRI integrates seamlessly with recent optimization improvements, including techniques like BOOST and I-GCG (Boost et al., 2024; IGCG et al., 2024), enhancing convergence and success rates by leveraging robust initializations. An example integration of CRI with BOOST, can be found in Figure 27.

Alignment Backdoor and Refusal Direction. Safety-Alignment divides input prompts into *compliance* and *refusal* regions—boundaries that adversaries can exploit (Marshall et al., 2024; Baumann, 2024; Huang et al., 2024; Yu et al., 2024c; Chao et al., 2023; Deng et al., 2023; Li et al., 2025; Yan et al., 2024; Xu et al., 2024b; Xiao et al., 2024a). Recent studies suggest **refusal direction**—a single vector in the residual stream that governs refusal behavior (Arditi et al., 2024). Modifying this direction can toggle the model's safety responses, prompting offensive uses like CAST's real-time content control (Lee et al., 2025) or defensive uses like GradSafe's gradient-based detection (Xie et al., 2024). However, new work represents *refusal cones*—suggesting multiple interacting refusal directions (Wollschläger et al., 2025).

Initializations Early Jailbreak attack approaches utilize uninformative seeds, employing repeated characters or random Gaussian token embeddings (Zou et al., 2023; Hu et al., 2024). Subsequent methods introduced techniques such as Langevin dynamics or beam search (Guo et al., 2024; Sadasivan et al., 2024; Mehrotra et al., 2023). Implicit initialization approaches rely on subtle mechanisms—few-shot distractors, puzzle-like games, or dynamic context shifts—that implicitly guide models toward generating harmful outputs (Xiao et al., 2024b; Chang et al., 2024; Ramesh et al., 2025). Transfer-based initializations leveraging previously successful jailbreak prompts as starting points for subsequent optimizations (Jia et al., 2024; Andriushchenko et al., 2024; Wu et al., 2025b). Explicit initialization methods directly embed crafted injection prompts or obfuscated content (Liu et al., 2024a, 2023; Schwinn et al., 2024; Liu et al., 2024b; Sun et al., 2025; Xu et al., 2025; Jiang et al., 2024; Zhao et al., 2025a). Additional possible enhancements to initialization strategies include employing energy-based objectives (Zhao et al., 2024), prefix-tuning methods (Zhu et al., 2024; Zhou et al., 2024a; Zhang and Wei, 2025; Li et al., 2024d), or gradient-based optimization techniques (Li et al., 2024b; Yu et al., 2024b).

# **C** Experiments

# **C.1** Experiments Settings

GCG and the Embedding attacks keep the same settings as before.

#### C.1.1 Datasets

We utilize the AdvBench dataset (Zou et al., 2023), providing prompt-target pairs (x,t). We define five disjoint subsets: **A** 25-sample fine-tuning set for CRI, **B** 25-sample validation set for universal attacks on the fine-tuning set, **C** 25-sample optimization set for universal attacks and **D** 25-sample second validation set for the universal attack, **E** 100-sample test set for evaluation. Subsets C and E follow the splits proposed by Zou et al. (2023).

# C.1.2 Models

We evaluate the following open-source LLMs: *Vicuna-7B-v1.3* (Chiang et al., 2023b), *Llama-2-7B-Chat-HF* (Touvron et al., 2023b) and *Meta-Llama-3-8B-Instruct* (Touvron et al., 2024), Falcon3-7B-Instruct (Almazrouei et al., 2023), Phi-4-Mini-Instruct (Abouelenin et al., 2025), Meta-Llama-3-8B-Instruct and Llama-3.1-8B-Instruct (Touvron et al., 2024), DeepSeek-LLM-7B-Chat (Bi et al., 2024), DeepSeek-R1-Distill-Qwen-7B and DeepSeek-R1-Distill-Llama-8B (Liang et al., 2025), Qwen2.5-7B-Instruct (Yang et al., 2024a), Mistral-7B-v0.1, Mistral-7B-Instruct-v0.2 and v0.3 (Jiang et al., 2023b).

#### C.1.3 Attack Settings

For the AutoDAN attack variants (GA, HGA) (Liu et al., 2023), we utilize the same reference file filled with hand-crafted jailbreaks, and perform 100 optimization steps.

### C.1.4 Attack Evaluation

Refusal lists of different papers, used for our evaluation. Each attack used its refusal list.

GCG Taken from their GitHub <sup>2</sup>:

<sup>&</sup>lt;sup>2</sup>https://github.com/llm-attacks/llm-attacks/blob/main/experiments/evaluate.py lines 33-63

**Attack Evaluation - GPT-4 Judge** In Figure 26, we compare the ASR of our initializations vs. standard and random using a GPT-4 judge for the ASR-Recheck calculation on the output, according to (Liu et al., 2023). This is relevant because the current evaluation of GCG is outdated, results and further details represented in C.5.3.

## **C.2** Experimental Results

In this part, we present ablation studies of our method C.5, extend the evaluations with additional attacks, models, and settings C.4, and provide results over the *AdvBench* dataset and cross-dataset settings C.5.2.

# C.3 CRI Optimization - HarmBench

Below, we discuss the success in the attacks used for initialization on the *HarmBench* dataset.

Initialization	Cluster	Llama-2 ASR (%)	Vicuna ASR (%)
1-CRI	_	4	64
5-CRI	cluster 0	8	12
	cluster 1	0	40
	cluster 2	4	0
	cluster 3	60	56
	cluster 4	64	28
25-CRI	_	44	96

Table 2: Attack-success rate (ASR%) for each model, initialization, and cluster.

## C.4 Additional Attacks, Models And Datasets

#### C.4.1 Full Experiments Tables - HarmBench and AdvBench

We evaluate the open-source LLMs as mentioned in Section C.1.2.

# C.4.2 ASR VS. Steps - HarmBench

In Figure 10, we present evaluations on the GCG attack using two younger models: DeepSeek-LLM-7B-Chat and Falcon3-7B-Instruct. The DeepSeek models seems to be the least robust out of the four examined, demonstrating  $100 \ ASR$  quickly using all initializations, with ours taking the lead. When

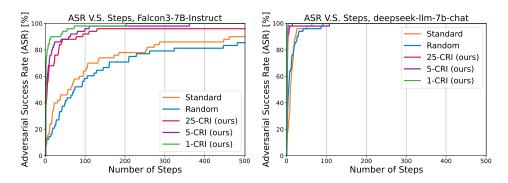

Figure 10: Comparison of K-CRI (K=1,5,25) to standard and random initialization on the GCG attack over the HarmBench dataset. The attacks' ASR are presented on Falcon3-7B-Instruct (left) and deepseek-llm-7b-chat (right).

examining Falcon, we can notice a clear difference between the uninformative initializations and ours, where all of ours achieve higher ASR way more quickly.

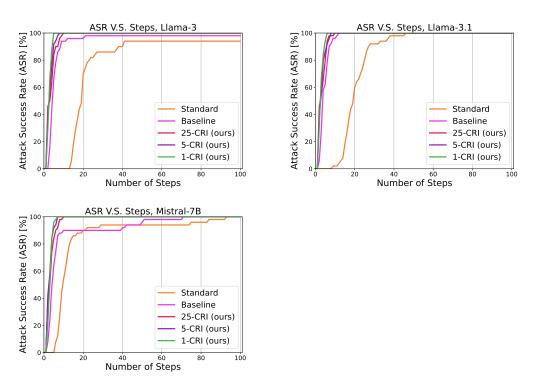

Figure 11: Extra ASR vs. steps results on the embedding attack with three more models on the HarmBench dataset.

# C.4.3 ASR VS. Steps - AdvBench

In Figure 12, we present evaluations on Llama-2, Vicuna and Llama-3. Our initialization prove superior in both Llama models comparative to the uninformative initializations. On Vicuna, which is a less robust model, all initializations converge quickly to 100~ASR. But, our initializations still converge way more quickly, demonstrating its advantage even here, in a less robust setting. In Figures 13 and 14, we present evaluations on the same models on the AutoDAN attack variants (GA, HGA), when using 1-CRI vs. its standard initialization. On Llama-2, we can notice an improvement in the ASR in both variants, converging more quickly to a higher ASR. On Llama-3, which is surprisingly less robust than Llama-2 in the attack, we can notice a slight faster convergence to 100~ASR. On Vicuna, the attacks converge to 100~ASR very quickly, noticing little to no difference between our initialization and the standard one.

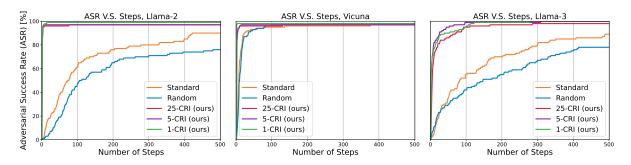

Figure 12: Comparison of K-CRI (K=1,5,25) to standard and random initialization on the GCG attack over the AdvBench dataset. The attacks' ASR are presented on Llama-2 (left), Vicuna (middle), and Llama-3 (right).

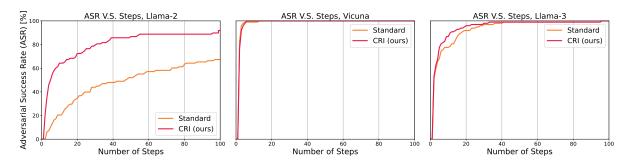

Figure 14: Comparison of 25-CRI to standard initialization on the AutoDAN-HGA attack over the AdvBench dataset. The attacks' ASR are presented on Llama-2 (left), Vicuna (middle), and Llama-3 (right).

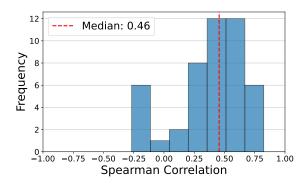

Figure 16: Distribution of per-prompt Spearman correlation of LFS and number of steps-to-success, on *Vicuna*. (Median r = 0.46,  $p = 5.73 \times 10^{-2}$ ).

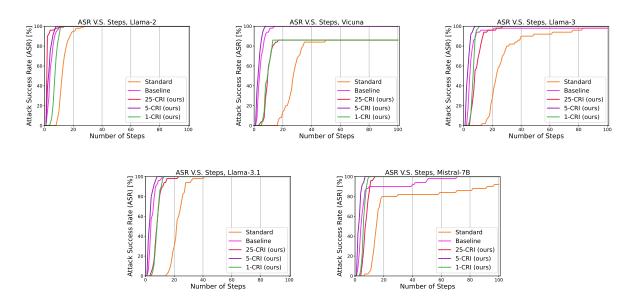

Figure 15: Embedding attack results on AdvBench. We compare K-CRI (K=1, 5, 25) to standard and random initialization across five models.  $Top\ row$  (left to right): Llama-2, Vicuna, Llama-3.  $Bottom\ row$  (left to right): Llama-3.1, Mistral-7B.

# C.4.4 LFS VS. Steps to Success - HarmBench

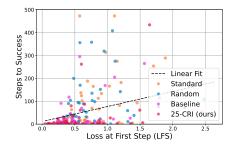

Figure 17: LFS versus steps-to-success for four initialization strategies on *Vicuna* in the GCG attack. The dashed line is the least-squares regression fit across all points (Pearson r = 0.31,  $p = 1 \times 10^{-5}$ ).

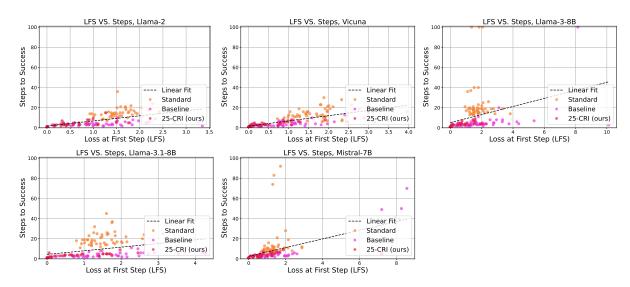

Figure 18: LFS versus the number of optimization steps required for the embedding attack across five LLMs, Pearson correlation. Llama-2 ( $r=0.62,\ p=4\times10^{-17}$ ); Vicuna ( $r=0.70,\ p=2\times10^{-23}$ ); Llama-3-8B ( $r=0.32,\ p=7\times10^{-5}$ ); Llama-3.1-8B ( $r=0.39,\ p=10^{-6}$ ); Mistral-7B ( $r=0.51,\ p=4\times10^{-11}$ ).

# C.5 Ablation Study

#### C.5.1 Batch Size

In this part, we experiment with the batch size hyperparameter of the GCG attack, which governs computational resources per attack iteration. A larger batch size allows considering more potential token replacements at each iteration. In Figure 19, we evaluate on the HarmBench dataset, and in Figure 20, on AdvBench. We observe that for both datasets, using a small batch size of 16, the 1-CRI initialization underperforms compared to other CRIs and the baseline. However, performance significantly improves, becoming comparable or superior to other initializations, when the batch size increases. Additionally, the baseline initialization severely underperforms relative to 25-CRI and 5-CRI at small batch sizes (16 and 32), and only becomes somewhat comparable, yet still inferior, at larger batch sizes (64). This highlights the significance of our framework under varying computational resources.

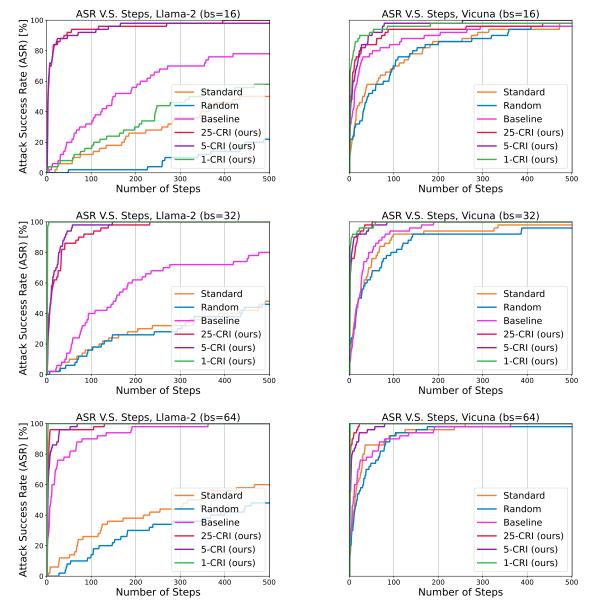

Figure 19: Comparison of K-CRI (K = 1, 5, 25) to standard and random initialization on the GCG attack over the HarmBench dataset. The attacks' ASR are presented on Llama-2 (left) and Vicuna (right). Across different batch sizes: 16 (top), 32 (center), and 64 (bottom).

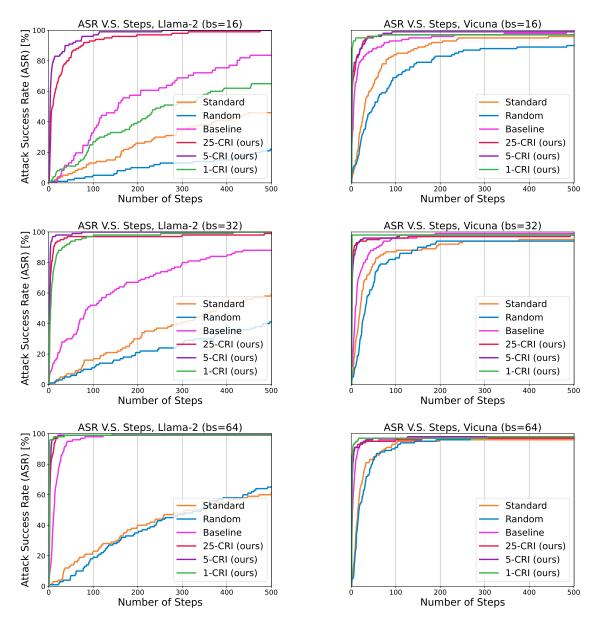

Figure 20: Comparison of K-CRI (K = 1, 5, 25) to standard and random initialization on the GCG attack over the AdvBench dataset. The attacks' ASR are presented on Llama-2 (left) and Vicuna (right). Across different batch sizes: 16 (top), 32 (center), and 64 (bottom).

# C.5.2 CRI Cost

Given a fine-tuning set  $S_{FT}$  of size N, the total CRI training cost is  $C_{CRI} = \sum_{i=1}^{K} T_i$ , where  $T_i$  is the number of optimization steps for the i-th initialization in the set  $\mathcal{T}_{K\text{-}CRI}$ . At deployment, each test input uses this initialization to reduce optimization cost from  $C_{\text{base}}$  (baseline) to  $C_{\text{CRI-deploy}}$ . The total amortized cost over  $N_{test}$  test prompts is:

$$C_{\text{CRI-total}} = C_{CRI} + N_{test} \cdot C_{CRI\text{-deploy}} \ll C_{\text{total}} = N_{test} \cdot C_{\text{base}}$$
 when  $N_{test} \gg K$ .

**Runtime Analysis** On our hardware (Intel(R) Xeon(R) CPU and NVIDIA L40S GPU), we find that the GCG attack steps take different GPU times on different models, as expected. On *Llama-2-7B*, a single iteration of GCG takes approximately  $3 \times 10^{-4}$  GPU hours. As such, our computational analysis is as follows (Table 1):

$$C_{CRI} \approx 500[step] \times 25[prompts] \times 3 \times 10^{-4}[hours/step] = 3.75[hours]$$

where each initialization is trained for 500 iterations, and there are 25 prompts in the initialization set.

$$C_{base} \approx 212.16[step] \times 3 \times 10^{-4}[hours/step] = 0.064[hours]$$
  
 $C_{CRI-deploy} \approx 22.64[step] \times 3 \times 10^{-4}[hours/step] = 0.0068[hours]$ 

where 212.16 and 22.64 are the average steps to success of the standard and 25-CRI initializations. On a test set of 500 prompts:

$$C_{CRI-total} = 3.75[hours] + 500[prompts] \times 0.0068[hours] = 7.15[hours]$$

$$C_{total} = 500[prompts] \times 0.064[hours] = 32[hours]$$

That entails a **savings of approximately 25 GPU hours**, in addition to the attack success rate improvements.

**Ablation** Ablation study of the number of steps used to create the initialization on GCG in the HarmBench dataset can be found in Figures 21 to 23. We notice that quite consistently, the more steps used for training the CRI set, the better the results in deployment are, with not a large difference between 400 and 500 initialization steps.

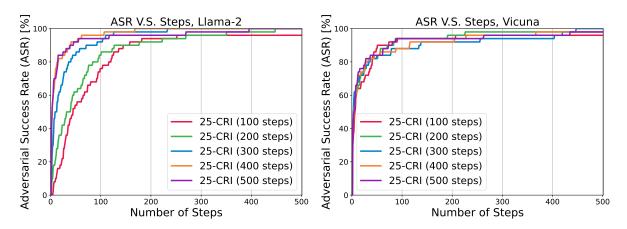

Figure 21: Ablation on the training steps of the 25-CRI initialization, and the attack performance when used in deployment.

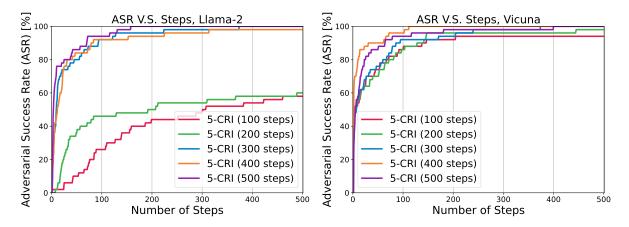

Figure 22: Ablation on the training steps of the 5-CRI initialization, and the attack performance when used in deployment.

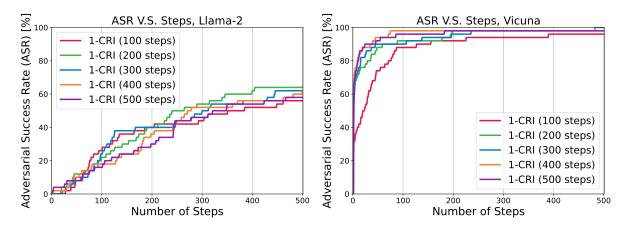

Figure 23: Ablation on the training steps of the 1-CRI initialization, and the attack performance when used in deployment.

Cross-Dataset CRI Transferability To evaluate the generalization capacity of CRI, we train the initialization set  $\mathcal{T}_{K\text{-}CRI}$  on  $S_{FT}^{\text{AdvBench}}$  and directly deploy it on  $S_{FT}^{\text{HarmBench}}$  without retraining. Experiments on both Llama-2 and Vicuna show that CRI maintains high ASR across datasets, suggesting that the compliance-refusal structure captured by CRI is model- and dataset-agnostic. This transferability further reduces the need for repeated initialization training, offering near-zero overhead in cross-dataset settings. In Figure 24, we compare using the same dataset for initialization and testing vs. using separate datasets. Here we test on the HarmBench dataset, and compare using it for initialization vs. using AdvBench for initialization.

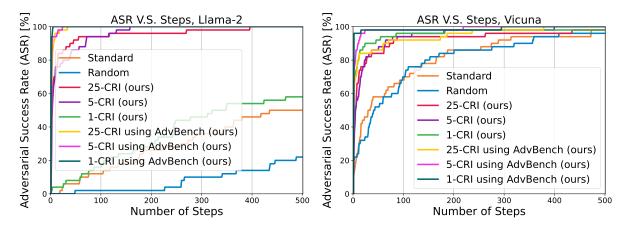

Figure 24: Attack success rates on HarmBench: in-dataset initialization versus cross-dataset initialization from AdvBench. Llama-2 (left) and Vicuna (right).

**ASR Under Equalized Computational Budget** To better evaluate CRI's effectiveness under fair cost conditions, we compare it to baseline attacks executed with a proportionally increased computational budget. Specifically, we benchmark CRI against baselines that are allowed twice the number of optimization iterations (e.g., 500 steps). In Figure 25, we compared 25 - CRI with baselines over a proportionally increased computational budget.

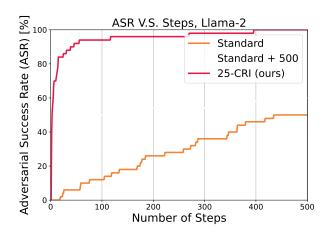

Figure 25: Comparison of 25 - CRI and running the standard attack for an extended amount of steps.

. Results show that even under this relaxed constraint, CRI consistently achieves higher attack success rates (ASR), demonstrating its efficiency in navigating the compliance-refusal space. This highlights CRI's advantage not only in low-cost regimes, but also indeed enhances the ASR performance of the attacks.

# C.5.3 Additional Studies, Attacks Transfer, Defenses, Evaluations And Integration with other improvements

Initialization Transferability Between Attacks We evaluated the transferability of initialization by extracting the 1-CRI initialization set from the GCG individual attack (Liu et al., 2022) and using it to initialize the **Embedding** attack (Schwinn et al., 2024), we choose the model deepseek-llm-7b-chat as we find it new and robust for jailbreak attacks. While partial improvements were observed, the effectiveness was limited, suggesting that the optimization dynamics of these two distinct attack paradigms differ significantly. This highlights that while CRI can generalize across certain frameworks, its performance is sensitive to the underlying optimization mechanisms

Setup	MSS (↓)	ASS (↓)	<b>ASR</b> (%) (†)	LFS (↓)
Baseline	20.0	20.04	100.0	2.2598
1- $CRI$	10.0	10.20	100.0	1.6445
25- $CRI$	13.0	12.96	100.0	1.3027
Transfer	14.5	14.32	100.0	2.2246

Table 7: Performance comparison of initialization strategies for deepseek-llm-7b-chat. Bold indicates best performance per metric.

# Performance consistency: Integrating CRI with Advanced-Attack-Evaluations, integration with other Improvements-Methods and Defenses

**Advanced Evaluation** In our work, we adhere to the evaluation setting used in the original attack baseline to ensure coherent results, however, we acknowledge that more sophisticated metrics could further enhance robustness. We have extended our evaluation as recommended to include a GPT-4-based judgment setting (Liu et al., 2024a). Following the protocol from (Liu et al., 2024a), GPT-4 is used to assess the ASR of generated jailbreak prompts. Our results show that CRI continues to improve ASR in this setup. Furthermore, the best-performing initialization remains consistent across both the keyword-matching and GPT-4-based evaluation frameworks, reinforcing the reliability and transferability of CRI-enhanced prompts, the results are demonstrated in Figure 26.

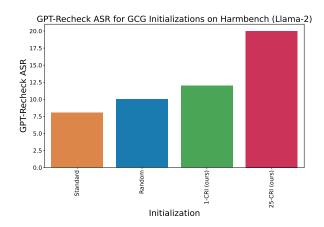

Figure 26: Evaluation using GPT-4 as a judge.

**BOOST** We present additional evaluations of our approach in more challenging settings. Specifically, we integrate BOOST (Yu et al., 2024a) into our attack framework, using a pre-trained initialization set in place of the standard GCG initialization. The resulting variant—combining both CRI and BOOST—achieves the highest ASR, demonstrating that CRI is compatible with BOOST without requiring retraining. To compare against baselines in the setting proposed by the original BOOST authors, we use a keyword-matching evaluation method. In Figure 27, we compare our initializations to using BOOST (Yu et al., 2024a).

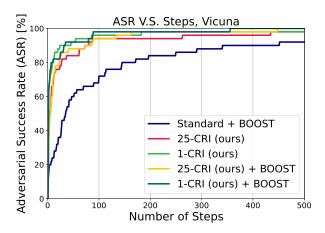

Figure 27: Comparison of using our initialization, vs. using BOOST vs. using both BOOST and our initialization.

**Perplexity Defense** When utilizing the same perplexity defense as in (Liu et al., 2023).

We extended our evaluations to consider adversarial defenses. We present results on the perplexity-based filter suggested by (Liu et al., 2023) on Llama-2, Vicuna and Llama-3. The perplexity-based defense does not affect the previously reported ASR for the AutoDAN attack, with or without CRI.
