Introduction

The 2025 edition of the International Workshop on Semantic Evaluation (SemEval) is the nineteenth workshop in the series. SemEval focuses on the evaluation and comparison of systems that analyze diverse semantic phenomena creating high quality annotated datasets in a range of increasingly challenging problems in natural language semantics.

The workshop began in 1998 and was originally known as SensEval and focused on word sense disambiguation. In 2007, the workshop was renamed SemEval, and evolved to include semantic tasks beyond word sense disambiguation. Starting in 2012, SemEval has been organized every year.

SemEval-2025 is co-located with the 2025 Annual Meeting of the Association for Computational Linguistics (ACL-2025) in Vienna, Austria (and with hybrid sessions). SemEval-2025 includes the following 11 tasks grouped by area:

- Semantic Relations
  - Task 1: ADMIRE: Advancing Multimodal Idiomaticity Representation
  - Task 2: EA-MT: Entity-Aware Machine Translation
- LLM Capabilities
  - Task 3: Mu-SHROOM, the Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes
  - Task 4: Unlearning sensitive content from Large Language Models
  - Task 5: LLMs4Subjects: LLM-based Automated Subject Tagging for a National Technical Library's Open-Access Catalog
- Fact Checking and Knowledge Verification
  - Task 6: PromiseEval: Multinational, Multilingual, Multi-Industry Promise Verification
  - Task 7: Multilingual and Crosslingual Fact-Checked Claim Retrieval
  - Task 8: Question-Answering over Tabular Data
  - Task 9: The Food Hazard Detection Challenge
- Knowledge Representation and Reasoning
  - Task 10: Multilingual Characterization and Extraction of Narratives from Online News
  - Task 11: Bridging the Gap in Text-Based Emotion Detection

This volume contains a total of 332 papers. It features 11 task description papers that describe each of the above tasks. It also features 11 system description papers that present the systems that participated in the tasks.

We are grateful to the task organizers for their dedication in carrying out ten very successful tasks and to the large number of participants whose enthusiastic participation has made SemEval-2025 a successful event. We also appreciate the efforts of the task organizers and participants who reviewed the paper submissions. These proceedings have greatly benefited from their detailed and thoughtful feedback. Finally, we also thank the members of the program committee who reviewed the submitted task proposals and helped us to select this exciting set of tasks, the ACL-2025 conference organizers for their support, and the ACL Special Interest Group on the Lexicon (SIGLEX) for sponsoring and supporting this event.

Keynote Talk

Lessons in generics: how language models grapple with human generalisation

Emily Allaway
Chancellor's Fellow at the School of Informatics, University of Edinburgh, Edinburgh, Scotland, UK

Abstract: The ability to generalise is a crucial aspect of human cognition, allowing us to derive broader understandings from specific instances. In language, generalised knowledge over particular instantiations and exceptions can be flexibly expressed through generics — generalisations without quantifiers. However, the flexibility of generics also comes with puzzling properties that have been extensively studied in areas such as linguistics and philosophy of language. This talk will explore the specific challenges that this language of generalisation poses for language models (LMs). I will begin by examining whether language models recognise the quantificational variation inherent in generics. Specifically, I will discuss how accurately LMs process and recognise the quantification in generic expressions, with a particular focus on the phenomenon of overgeneralisation — unwarranted universal quantification. One critical area of overgeneralisation is with stereotypes and I will touch on the implications for LMs of stereotypes that are expressed as generics. Next, I will present evaluations on the capacity of LMs to reason about generics and related examples, probing LMs' ability to both maintain and override their generalisations. In the final part of the talk, I will expand the discussion to visual-language models (VLMs) to determine whether their struggles with generics mirror those of traditional LMs and what the broader implications of these findings might be.

Bio: Emily Allaway is a Chancellor's Fellow at the University of Edinburgh in the School of Informatics, where she is affiliated with both Edinburgh NLP and the Institute for Language, Cognition and Computation (ILCC). Her research is on reasoning about and understanding implicit meaning in language, with a recent focus on generics and their role in reasoning. Emily received her PhD from Columbia University under the supervision of Kathleen McKeown. Her doctoral work there was supported by an NSF Graduate Research Fellowship. Her previous work includes research positions at the University of Washington, the Allen Institute for Artificial Intelligence, and Amazon Science. She is currently a chair for the WiNLP workshop.

amenco@utb.edu.co, epuerta@utb.edu.co, jcmartinezs@utb.edu.co

Abstract

Ensuring food safety requires effective detection of potential hazards in food products. This paper presents the participation of VerbaNexAI in the SemEval-2025 Task 9 challenge, which focuses on the automatic identification and classification of food hazards from descriptive texts. Our approach employs a machine learning-based strategy, leveraging a Random Forest classifier combined with TF-IDF vectorization and character n-grams (n=2-5) to enhance linguistic pattern recognition. The system a notable performance in hazard and product classification tasks, obtaining notable macro and micro F1 scores. However, we identified challenges such as handling underrepresented categories and improving generalization in different contexts. Our findings highlight the need to refine preprocessing techniques and model architectures to enhance food hazard detection. We made the source code publicly available to encourage reproducibility and collaboration in future research.

1 Introduction

Detecting food hazards is an essential challenge to ensure the safety and quality of food products globally (FAO and WHO, 2007; Nogales et al., 2020). Following this line, the task proposed in SemEval-2025 Task 9: The Food Hazard Detection Challenge focuses on identifying and classifying different types of hazards associated with food products through the analysis of descriptive texts. This task is of great relevance due to the growing need to monitor and ensure food safety and the need for automated systems that can process large volumes of data, which facilitates the early detection of potential hazards in food products globally (Randl et al., 2025). The ability to accurately and efficiently detect these hazards contributes directly to preventing public health incidents and improving food safety standards (WHO, n.d.; USDA, U.S. Department of Agriculture, 2024).

Our system employs a strategy based on machine learning and supervised classification using a Random Forest classifier combined with a TF-IDF vectorization to represent textual features. We implemented an n-gram character analysis approach (n=2-5) to capture relevant linguistic patterns to distinguish between different categories of hazards and products, hazard and product. This method facilitated the extraction of contextual information. It improved the model's ability to generalize from training data, thus optimizing prediction accuracy on new unlabeled datasets. By participating in this task, our system a notable performance compared to other teams, obtaining outstanding micro and macro F1 scores in hazard and product categories and hazard and product detection sub-tasks. However, we identified specific challenges, such as the difficulty in handling underrepresented categories and the need to improve the model's generalization in broader contexts. These findings underscore the importance of refining preprocessing techniques and model architecture to address the inherent complexity of food hazard detection effectively.

Participation in this task revealed promising results, positioning our system competitively against other participating teams. Quantitatively, our model obtained outstanding macro and micro F1 scores in the hazard and product category classification sub-tasks, reflecting high accuracy and robustness. However, significant challenges were identified, such as difficulty in handling linguistic ambiguities, difficulty in handling underrepresented categories, and variability in textual descriptions, suggesting areas of improvement for future developments. These findings underscore the importance of refining preprocessing techniques and model architecture to address the complexity inherent in food hazard detection. We published the source code used for developing and training our model to encourage reproducibility and collaboration in future work related to food hazard detection.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1–6

It is available through the following link [1].

2 Background

SemEval 2025 Task 9: The Food Hazard Detection Challenge focuses on automatically identifying and classifying food hazards from textual descriptions of food products. The input type for this task consists of descriptive texts detailing food safety-related incidents, such as reports of contaminants in food products or warnings about unsafe food handling practices see Table1.

The datasets used in this task include mainly training and validation divisions, covering various textual genres related to food incidents. The genre of the data encompasses food safety incident reports from multiple sources, ensuring a varied representation of contexts and scenarios. In terms of size, the training set contains approximately 5,082 samples. In contrast, the test set includes about 5,984 examples, allowing for robust training and accurate model performance evaluation. The competition has two sub-tasks focused on detecting different levels of granularity in the hazard and product categories. We participated in sub-task ST1, which focused on text classification for food hazard prediction, predicting the type of hazard and product, and sub-task ST2, which focused on food hazard and product vector detection, predicting the exact hazard and product. These approaches contribute to strengthening safety in the food supply chain, reducing the incidence of hazards, and protecting consumer health. In addition, it is possible to design and implement more targeted and effective prevention strategies by having a precise classification and accurate identification of affected products. Also, by clearly identifying the risks and products involved, companies and regulators can allocate resources more efficiently to address the most significant risk areas.

In developing our system, we have employed supervised classification methods that have demonstrated efficacy in similar natural language processing tasks. This approach aligns with previous studies showing the effectiveness of Random Forest-based methods for text classification tasks (He et al., 2024; Onyeaka et al., 2024; Qiu et al., 2025) providing a solid foundation for our methodology. Furthermore, using TF-IDF vectorization techniques combined with Random Forest classifiers is not novel. Research such as (Sabri et al., 2022; Sathishkumar et al., 2023) highlighted the effectiveness of these methods in text classification. However, in our contribution, we have implemented a vectorization strategy based on n-grams of characters in the TF-IDF vectorizer, which improves the capture of complex and contextual linguistic patterns present in food incident descriptions. Furthermore, integrating preprocessing techniques and hyperparameter optimization for the Random Forest classifier represents innovations that enhance the accuracy and robustness of the model in different environments.

[1] https://github.com/VerbaNexAI/SemEval2025

3 System Overview

This section details how we integrated advanced natural language processing techniques and robust machine learning models to transform and analyze the information, allowing the accurate identification of incidents and addressing inherent challenges such as semantic ambiguity. It explains, step by step, the key components from vectorization and the application of the RandomForestClassifier to the modular organization of the pipeline, providing a clear and complete overview of the process see figure1.

3.1 Algorithms

The proposed system combines advanced natural language processing (NLP) techniques with robust machine learning models to address the task of food hazard detection and classification from textual data. The main components of the system are detailed below:

Text Vectorization: TfidfVectorizer with Character N-grams. The representation of textual data is a fundamental step in any PLN system. In this work, the TfidfVectorizer from the scikit-learn library transforms food incident titles into numerical feature vectors. The specific configuration employs n-character frames ranging from 2 to 5, which allows for capturing local and contextual patterns in the texts. In addition, the following parameters strip_accents='unicode' are applied to remove accents from characters to reduce linguistic variability, max_df=0.5 to ignore terms that appear in more than 50% of the documents, which helps to eliminate overly frequent and uninformative words, and min_df=5 which considers only terms that occur in at least five documents, ensuring that features are relevant and representative. This configuration allows a rich and discriminative representation of

Table 1: Expected inputs and outputs.

Input	Output			
Title	**hazard-category**	**product-category**	**hazard**	**product**
Imported frozen duck tongue sample tested positive for COVID-19 virus in Macao	biological	meat, egg and dairy products	virus	duck
P&B (Foods) recalls Ahmed Foods Garlic Pickle in Oil and Mango Pickle in Oil because of undeclared mustard	allergens	herbs and spices	mustard and products thereof	garlic pickle

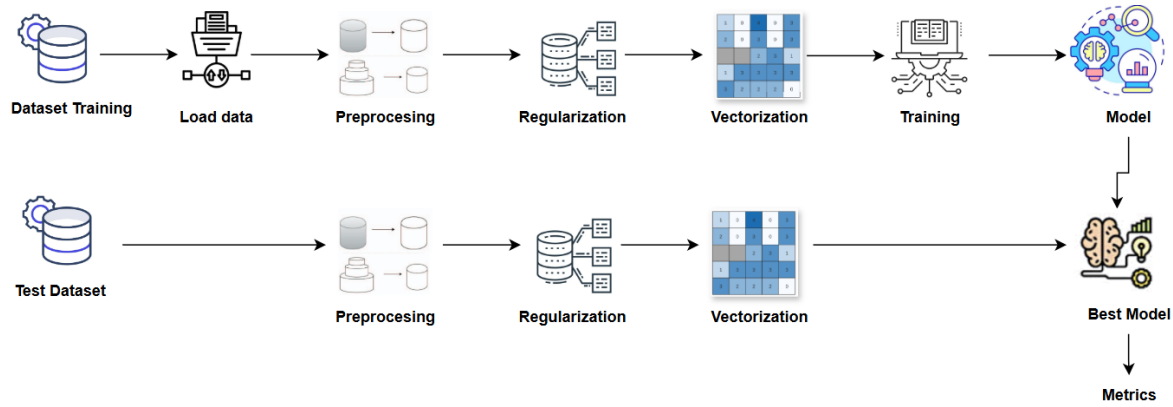

Figure 1: Outline of the proposed model.

the texts, facilitating the subsequent classification task.

Classifier: RandomForestClassifier. For the classification stage, we used RandomForestClassifier from the scikit-learn library. We selected this ensemble model for several reasons. Firstly, it can handle high-dimensional data and provide accurate results without exhaustive hyperparameter tuning. The reduction of overfitting follows this because by training multiple decision trees and averaging their predictions, we decreased the probability of overfitting, improving the model's generalization. Finally, due to the ease of interpretation, it offers some interpretability through feature importance, which can be helpful in understanding which text patterns are most relevant for classification (Nair et al., 2024; Spangenberg et al., 2024). The classifier is set up with 100 estimators and a fixed seed (random_state=42) to ensure the reproducibility of the results.

Machine Learning Pipeline. The system integrates text vectorization and classification into a pipeline that simplifies the training and prediction process. The pipeline is composed of two main stages: **1.** vectorization: application of the TfidfVectorizer to transform texts into feature vectors. **2.** Classification: Training and prediction using the RandomForestClassifier. This modular approach facilitates experimentation and tuning of each system component independently. It ensures that the system takes full advantage of the information available in the data provided without relying on external sources that may introduce biases or inconsistencies.

3.2 Challenges and Solutions

The detection and classification of food hazards from textual descriptions present several inherent challenges. Below are described these issues and the strategies implemented to address them.

3.2.1 Semantic Ambiguity

Challenge: Incident descriptions may be ambiguous or contain terms that have multiple meanings depending on the context.

Solution: Using character n-grams in vectorization allows capturing specific patterns that help dis-

ambiguate terms based on their local context within the text. In addition, the RandomForestClassifier can identify combinations of features that represent specific contexts, improving the model's ability to handle ambiguity.

3.2.2 Linguistic Variability

Challenge: Diversity in linguistic expression, including synonyms, grammatical variations, and typographical errors, can make the classification task difficult.

Solution: Preprocessing includes accent removal and text normalization to reduce variability. In addition, character n-grams allow capturing patterns even in the presence of typographical errors, as they consider more minor character sequences that can be robust to such variations.

3.2.3 Handling Multiple Classification Categories

Challenge: The task involves classifying multiple labels simultaneously, such as hazard categories, product categories, hazards, and specific products.

Solution: Implement a multi-label classification approach by training separate models for each target label within the same pipeline. It allows each model to specialize in a specific task, maintaining consistency and improving the system's overall accuracy.

3.2.4 Data Shortage for Some Categories

Challenge: Some categories may have less data available, affecting the model's ability to learn representative patterns.

Solution: Setting min_df=5 in the TfidfVectorizer helps to focus on terms that appear frequently enough, preventing the model from being affected by extremely rare categories. In addition, using RandomForestClassifier with multiple estimators contributes to better generalization even in unbalanced classes.

4 Experimental Setup

4.1 Division of the Data

We divided the data set provided into three main subsets: training, development, and testing. Initially, we loaded training data from incidents_train.csv and test data from incidents_labelled.csv. Then, we used an additional validation set called incidents.csv to evaluate the final performance of the model. For the division of the training set into training and development, the train_test_split function of scikit-learn is employed with a ratio of 80% for training and 20% for development, using a fixed seed (random_state=2024) to ensure reproducibility of the results.

4.2 Evaluation Measures

We evaluated system performance using two primary metrics: F1macro and F1micro. These metrics are suitable for multi-class and multi-label classification tasks, as they consider both accuracy and recall of predictions. In this sense, F1macro calculates the average F1score for each class, treating all classes equally, regardless of frequency. It is beneficial for evaluating performance in scenarios with unbalanced classes, and F1micro calculates the overall F1score considering the total of true positives, false negatives, and false positives. This metric is more sensitive to frequent classes and provides a global view of model performance. Overall, these metrics allow for a comprehensive evaluation of the system, ensuring that the model is broadly accurate and balanced in its performance across all target classes.

5 Results

The official results of our submission for the ST1 and ST2 sub-tasks are shown in Table 2. We report the macro average F1 score and overall ranking of our system, as well as those of the best-performing team for comparison.

Table 2: Results of tasks ST1 and ST2.

System	F1	Rank
ST1		
Task Best System	0.8223	1/27
VerbaNexAI	0.5165	24/27
ST2		
Task Best System	0.5473	1/26
VerbaNexAI	0.3223	16/26

Our system obtained a macro average F1 score of 0.5165 in Sub-task ST1, ranking 24 out of 27 participating teams. In Sub-task ST2, we achieved a macro F1 score of 0.3223, ranking 16 out of 26 teams. These results compare with the reference system, which led the competition with average macro F1 scores of 0.8223 in ST1 and 0.5473 in ST2, respectively.

We conducted several ablation tests and comparisons of different design decisions to optimize system performance. The ablation tests included varying the vectorizer parameters and using different classifiers. We observed that using longer n-grams improved the capture of specific patterns in the incident titles, albeit at the cost of an increase in the dimensionality of the feature space. Also, the random forest classifier proved robust regarding data variability, providing an appropriate balance between accuracy and recall.

Error analysis revealed that our system presented difficulties in classifying hazard categories and products with semantic similarities or specific technical terms not sufficiently represented in the training set. For example, incidents related to food allergies were frequently confused with bacterial contaminations due to the similarity in terminology used. In addition, we observed that product category predictions showed higher variability, possibly attributed to the diversity and specificity of food products mentioned in the data. To address these errors, we propose future incorporation of more advanced natural language processing techniques, such as contextualized embeddings, which could better capture the semantic subtleties of the terms used in the incidents. Although our system did not achieve a top ranking in the competition, the results provide a solid foundation for future improvements. Quantitative and error analysis has identified key areas where significant improvements can be implemented, such as optimizing text representation and exploring more sophisticated classifiers. These strategies and further enrichment of the training data could boost system performance in future iterations of the SemEval 2025 Task 9 challenge.

6 Limitations of the Approach

The proposed approach is subject to several limitations that could be addressed in future versions to enhance its performance. A primary challenge is the management of under-represented categories, which is prevalent in unbalanced classification problems. Despite adjustments made to parameters such as min_df=5 in the TF-IDF vectoriser to mitigate this issue, under-represented classes still exert an influence on the model's accuracy. Furthermore, the presence of semantic ambiguity in texts, where terms may possess multiple meanings depending on the context, poses an additional challenge. While the utilization of character n-grams assists in capturing contextual patterns, the disambiguation of terms in complex texts remains an area for enhancement. Linguistic variability, arising from synonyms, typos and grammatical variations, also exerts a negative influence on model performance, despite pre-processing endeavors.

7 Conclusion

Our system implemented a strategy based on TF-IDF vectorization and Random Forest classifier to address the food hazard detection and product classification tasks in SemEval-2025 Task 9. The performed tests and error analysis underline the importance of optimizing the text representation and exploring more advanced approaches, such as contextualized embeddings, to improve the classification accuracy of poorly represented categories. In future work, we plan to expand the training dataset, integrate architectures based on deep neural networks, and evaluate new natural language processing methods that effectively address the complexity of textual data. These efforts will lay the foundation for more robust and generalizable systems in the food safety domain.

8 Acknowledgments

The authors express their gratitude to the Call 933 "Training in National Doctorates with a Territorial, Ethnic and Gender Focus in the Framework of the Mission Policy — 2023" of the Ministry of Science, Technology and Innovation (Minciencia). In addition, we thank the team of the Artificial Intelligence Laboratory VerbaNex [2] affiliated with the UTB, for their contributions to this project.

Pohang, Republic of Korea
{donggeonlee, hwanjoyu}@postech.ac.kr

Abstract

Hallucinations in large language model (LLM) outputs severely limit their reliability in knowledge-intensive tasks such as question answering. To address this challenge, we introduce REFIND (Retrieval-augmented Factuality hallucINation Detection), a novel framework that detects hallucinated spans within LLM outputs by directly leveraging retrieved documents. As part of the REFIND, we propose the *Context Sensitivity Ratio (CSR)*, a novel metric that quantifies the sensitivity of LLM outputs to retrieved evidence. This innovative approach enables REFIND to efficiently and accurately detect hallucinations, setting it apart from existing methods. In the evaluation, REFIND demonstrated robustness across nine languages, including low-resource settings, and significantly outperformed baseline models, achieving superior IoU scores in identifying hallucinated spans. This work highlights the effectiveness of quantifying context sensitivity for hallucination detection, thereby paving the way for more reliable and trustworthy LLM applications across diverse languages. Our code is available at https://github.com/oneonlee/REFIND.

1 Introduction

Detecting hallucinated information in responses generated by large language models (LLMs) has emerged as a critical challenge in the field of natural language generation (Ji et al., 2023; Zhang et al., 2023). Hallucination, in this context, refers to the generation of content that is factually incorrect or lacks grounding in verifiable sources (Li et al., 2024). This issue is particularly pronounced in knowledge-intensive tasks that demand high factual accuracy, such as question answering (Lee et al., 2022; Sun et al., 2024). The consequences of unmitigated hallucination are significant, ranging from the propagation of misinformation to a decline in trust in AI systems, underscoring the need for effective hallucination detection for the development of safe and trustworthy AI.

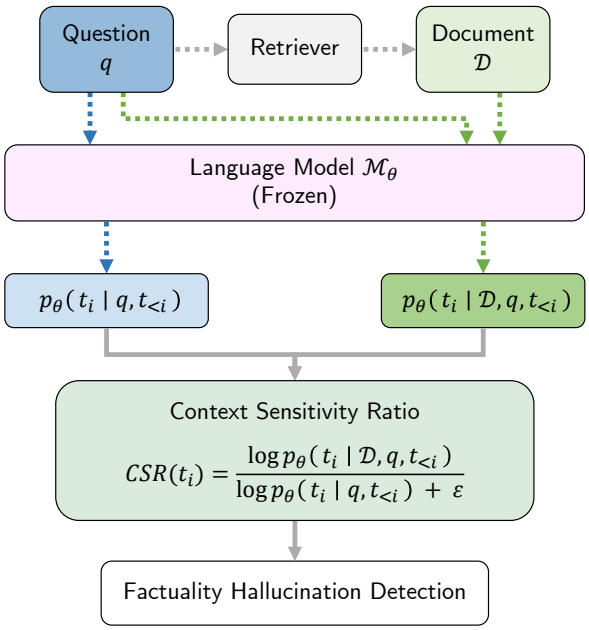

Figure 1: An overview of the proposed **REFIND** method. (1) Given a question q, a set of relevant documents $\mathcal{D}$ is retrieved using a retriever $\mathcal{R}$. (2) A frozen language model $\mathcal{M}_\theta$ computes token probabilities $p_\theta(t_i \mid \cdot)$ for each token t_i, with and without the retrieved context $\mathcal{D}$. (3) The Context Sensitivity Ratio (CSR) is calculated for each token t_i. Tokens with the CSR exceeding a predefined threshold δ are classified as hallucinations.

Prior research has explored various approaches for hallucination detection. Token-level classifiers, for example, leveraging pre-trained language models like RoBERTa (Liu et al., 2019), have been employed for binary classification, labeling individual tokens as either factual or hallucinated (Liu et al., 2022). However, these models often exhibit limitations when applied to low-resource languages and tend to rely heavily on internal knowledge without effectively utilizing external evidence, which can hinder their performance. Extrinsic methods,

*Corresponding author

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 7–15

such as retrieval-augmented models, aim to mitigate hallucinations by integrating external knowledge. Nevertheless, existing retrieval-augmented approaches, such as FAVA (Mishra et al., 2024), can potentially lead to inaccuracies in aligning the modified responses with the original LLM output, due to their multi-step processes involving retrieval, comparison, and editing.

To address these limitations, we introduce **REFIND** (**RE**trieval-augmented **F**actuality hallucI**N**ation **D**etection), a novel framework specifically designed to identify hallucinated spans within LLM-generated text. REFIND achieves this by quantifying the context sensitivity of each token at the token level. By leveraging retrieved documents, REFIND calculates a Context Sensitivity Ratio (CSR) for each token in the LLM's response, measuring the token's dependence on external contextual information. Tokens exhibiting high CSR values are identified as likely hallucinations, offering a more direct and efficient approach to factuality verification.

Our contributions can be summarized as follows:

- We present REFIND, a novel framework for detecting hallucinated spans in LLM responses by leveraging an external retriever and calculating the CSR at the token level.
- We conduct a comprehensive evaluation of REFIND using the SemEval 2025 Task 3: Mu-SHROOM dataset (Vázquez et al., 2025), a multilingual benchmark for detecting hallucinated spans. REFIND is rigorously tested across nine diverse languages – Arabic, Czech, German, Spanish, Basque, Finnish, French, Italian, and English – demonstrating its robustness in both high- and low-resource settings.
- Experimental results demonstrate that REFIND significantly outperforms baseline models such as token-level classifiers and FAVA, achieving superior Intersection-over-Union (IoU) scores. This highlights the efficacy of the CSR in accurately identifying hallucinated content.

2 Related Work

Detection of Hallucinated Responses Several studies have proposed methods to detect whether a response contains hallucinated information. Farquhar et al. (2024); Han et al. (2024); Arteaga et al. (2025) leveraged semantic entropy (Kuhn et al., 2023) to estimate uncertainty and identify hallucinations. These approaches utilize entropy-based metrics to assess the reliability of generated responses. SelfCheckGPT (Manakul et al., 2023) introduces a method that employs the language model itself to sample multiple responses and detect inconsistencies among them, thus identifying hallucinated outputs. However, this method relies solely on the internal knowledge of the language model, making it less effective when the model's knowledge is limited or incomplete.

Detection of Hallucinated Spans Beyond identifying whether a response is hallucinated, other works aim to detect specific spans of hallucinated content within a response of LLMs. Token-level classification approaches (Liu et al., 2022) utilized pre-trained language models to classify individual tokens as factual or hallucinated. These methods focus on analyzing attention patterns, demonstrating that query input tokens (defined as constraint tokens) exhibit strong correlations with factual answer tokens (Yuksekgonul et al., 2024).

FAVA (Mishra et al., 2024) proposes a retrieval-augmented pipeline that integrates retrieval, comparison, and editing steps to identify and correct hallucinated spans. While effective, the multi-step process introduces complexity and alignment challenges, particularly in ensuring that the corrected responses remain consistent with the semantics of the original output.

3 Method

3.1 Task Description

The SemEval 2025 Task 3: Mu-SHROOM (Vázquez et al., 2025) focuses on detecting hallucinated spans in responses generated by LLMs. Given an input question q and its corresponding LLM-generated response (along with the model's identifier), the goal is to identify spans in the response that are hallucinated. Details of the Mu-SHROOM dataset are provided in Section 4.1.

3.2 Retrieval-Augmented Factuality Hallucination Detection

To address the challenge of factual hallucination detection in LLM outputs, we introduce **REFIND** (**RE**trieval-augmented **F**actuality hallucI**N**ation **D**etection). The overall workflow of the REFIND method is illustrated in Figure 1. REFIND leverages external knowledge retrieved from a relevant document set to assess the context sensitivity of each generated token.

The core principle behind REFIND is to quantify the influence of external context on the token generation process. We do this by measuring the change in the conditional probability of generating a token as information from retrieved documents is incorporated. This change is captured by the Context Sensitivity Ratio (CSR). It quantifies the degree to which the conditional probability of generating a token is altered by the inclusion of external contextual information from retrieved documents.

Let $\mathcal{M}_\theta$ denote an LLM parameterized by θ, q represent the input question, and t_i denote the i-th token in the LLM's response to q. We use $p_\theta(t_i \mid \cdot)$ to represent the probability of generating token t_i given the input. Furthermore, let $\mathcal{R}$ be a retriever that provides relevant documents based on q, and let $\mathcal{D} = \mathcal{R}(q)$ be the set of retrieved documents. The CSR for each token t_i is defined as:

$$CSR(t_i) = \frac{\log p_\theta(t_i \mid \mathcal{D}, q, t_{<i})}{\log p_\theta(t_i \mid q, t_{<i}) + \varepsilon} \quad (1)$$

where $t_{<i}$ represents the sequence of preceding tokens. The numerator computes the log-probability of generating t_i conditioned on the question q, the preceding tokens $t_{<i}$, and the retrieved document set $\mathcal{D}$. The denominator computes the log-probability of generating t_i conditioned solely on the question q and preceding tokens $t_{<i}$, excluding the retrieved documents.[1]

By comparing these two probabilities, the CSR effectively quantifies the sensitivity of t_i to the external context provided by the $\mathcal{D}$. A higher CSR indicates a stronger influence of the retrieved context on the generation of the token.

Finally, to determine whether a token is a hallucination, we compare its CSR value to a predefined threshold, denoted as δ. If the CSR value for the given token t_i is greater than or equal to the threshold δ, we classify that the token as a hallucination. Conversely, if the CSR value is less than δ, the token is not considered a hallucination. This threshold δ serves as a hyperparameter that can be tuned to optimize the balance between precision and recall in hallucination detection.

4 Experimental Setup

4.1 Dataset

We conduct our experiments on the Mu-SHROOM dataset (Vázquez et al., 2025), which consists of outputs generated by various LLMs in response to specific input questions. Each output is annotated by human annotators to identify spans that correspond to hallucinations.

The dataset includes multiple languages, and for our study, we focus on the following nine languages: Arabic (AR), Czech (CS), German (DE), English (EN), Spanish (ES), Basque (EU), Finnish (FI), French (FR), and Italian (IT). This multilingual diversity enables a comprehensive evaluation of our method across diverse linguistic contexts.

Each data point in the dataset contains the language identifier, the input question posed to the LLM, the model name, the generated output text, and its token-level probabilities. Additionally, binary annotations specify the start and end indices of hallucinated spans, marking each such span as a hallucination.

4.2 Evaluation Metric

To evaluate the performance of our hallucination detection method, we adopt the IoU metric, a standard measure for span-based evaluation.

Given the set of character indices predicted as hallucinations, $\mathcal{H}_{pred}$, and the set of character indices labeled as hallucinations in the gold reference, $\mathcal{H}_{gold}$, the IoU is calculated as:

$$\text{IoU} = \frac{|\mathcal{H}_{pred} \cap \mathcal{H}_{gold}|}{|\mathcal{H}_{pred} \cup \mathcal{H}_{gold}|} \quad (2)$$

This metric quantifies the overlap between the predicted and ground truth hallucinated spans. To handle cases where both $\mathcal{H}_{pred}$ and $\mathcal{H}_{gold}$ are empty (i.e., no hallucinations are present in either prediction or reference), we define $\text{IoU} = 1.0$ to signify perfect agreement.

4.3 Baseline Models

Token-level Hallucination Classifier (XLM-R) We employ a token-level hallucination classifier (Liu et al., 2022) based on XLM-RoBERTa (XLM-R) (Conneau et al., 2020), a multilingual transformer model. The model is fine-tuned to perform binary classification at the token level, where each token is labeled as either hallucinated or non-hallucinated.

FAVA We also include FAVA (Mishra et al., 2024) as a baseline model. FAVA is a retrieval-augmented language model designed to detect and correct hallucinations in outputs generated by LLMs. The model is built upon Llama2-Chat 7B (Touvron

[1] To prevent division by zero, we use a small constant ε, which is set to 10^{-8}.

Method	AR	CS	DE	EN	ES	EU	FI	FR	IT	Average
XLM-R	0.0418	0.0957	0.0318	0.0310	0.0724	0.0208	0.0042	0.0022	0.0104	0.0345
FAVA	0.2168	0.2353	**0.3862**	0.2812	**0.2348**	0.3869	0.2300	0.2120	**0.3255**	0.2787
REFIND	**0.3743**	**0.2761**	0.3518	**0.3525**	0.2152	**0.4074**	**0.5061**	**0.4734**	0.3127	**0.3633**

Table 1: Evaluation results on the Mu-SHROOM dataset (Vázquez et al., 2025) using the IoU metric across eight languages: Arabic (AR), Czech (CS), German (DE), English (EN), Spanish (ES), Basque (EU), Finnish (FI), French (FR), and Italian (IT). The proposed method, REFIND, achieves the highest average IoU score, outperforming the baselines XLM-R and FAVA in most languages, demonstrating its effectiveness for multilingual hallucination detection.

et al., 2023) and employs a two-step process: retrieval and editing. To detect hallucinations in text, we compare the edited text produced by FAVA with the original text and get the span of $\mathcal{H}_{pred}$.

4.4 Implementation Details

The retriever $\mathcal{R}$ used to retrieve context for REFIND and FAVA employs a hybrid approach, combining sparse and dense retrieval methods. Initially, a Wikipedia corpus is preprocessed for each language, including chunking, to serve as the retrieval corpus. The retriever first retrieves the top 10 relevant documents using BM25 (Robertson and Zaragoza, 2009). Subsequently, a document reranking step is performed using a pre-trained language model to select the final 5 documents to $\mathcal{D}$. To maintain consistency across the multilingual setting, we utilize `multilingual-e5-large`[2] (Wang et al., 2024) for the reranking process.

When calculating $p_\theta(t_i \mid q, t_{<i})$ in REFIND, we utilize the token probabilities of the LLM's output response provided in the Mu-SHROOM dataset. The computation of $p_\theta(t_i \mid \mathcal{D}, q, t_{<i})$ is performed using PyTorch 2 (Ansel et al., 2024). The specific prompt template employed for REFIND is illustrated in Figure 4 (Appendix A.1). More details for baselines will be discussed in Appendix A.

5 Result and Analysis

5.1 Performance Comparison

Table 1 presents the evaluation results of our proposed method, alongside the baseline models, XLM-R and FAVA, on the Mu-SHROOM dataset. The results are reported across nine languages (AR, CS, DE, EN, ES, EU, FI, FR, IT) and averaged to provide an overall assessment of performance.

REFIND outperforms the baseline models in terms of average IoU scores. The improvements are particularly notable in low-resource languages such as Arabic, Finnish, and French, where REFIND achieves IoU scores of 0.3743, 0.5061, and 0.4734, respectively, compared to significantly lower scores from the baselines. This indicates that REFIND effectively leverages retrieval-augmented information to enhance hallucination detection in diverse linguistic settings.

5.2 Baseline Comparison

The XLM-R-based token classifier performs poorly on average, with an IoU of 0.0345. Its reliance solely on intrinsic model knowledge without leveraging external context limits its ability to identify hallucinated spans accurately, particularly in low-resource languages.

FAVA exhibits better performance than XLM-R, with an average IoU of 0.2787. This improvement can be attributed to its use of retrieval-augmented information for detecting and editing hallucinated text. However, FAVA's two-step process introduces complexity and potential inaccuracies in aligning the edited text with the original output.

REFIND outperforms both baselines with an average IoU of 0.3633, highlighting its superior ability to integrate retrieved context directly into the token generation process for hallucination detection. This streamlined approach ensures accurate and efficient identification of hallucinated spans.

5.3 Analysis of Multilingual Performance

REFIND demonstrates robust performance across both high-resource and low-resource languages. This indicates the generalizability of its retrieval-augmented approach to varying linguistic contexts. Notably, performance varies considerably across languages for all methods; for instance, XLM-R and FAVA struggle significantly with low-resource languages like Arabic, Finnish, and French. In contrast, REFIND's integration of external retrieval

The gold reference $\mathcal{H}_{gold}$ highlights the correct hallucinated span, while REFIND successfully identifies the hallucinated span in the output, demonstrating its alignment with the gold annotations. The complete text of the retrieved documents is available in Appendix B.

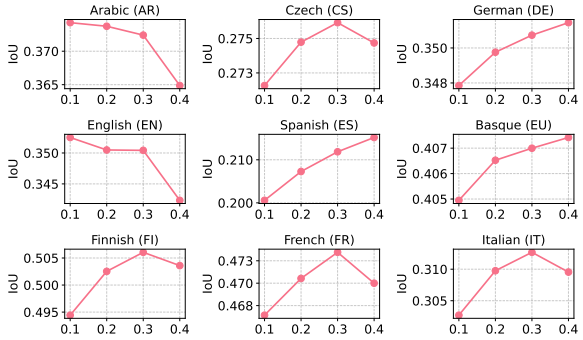

Figure 3: Analysis of IoU scores across different threshold values ($\delta \in 0.1, 0.2, 0.3, 0.4$). Each subplot represents a different language, showing the relationship between threshold values and IoU scores.

with the LLM's internal knowledge helps mitigate performance drops in these settings.

5.4 Analysis of Threshold Sensitivity

Figure 3 illustrates the performance of REFIND across varying threshold values (0.1-0.4) for nine languages. Most languages exhibit consistent IoU scores, indicating robustness to threshold changes. High-resource languages like English and German maintain stable scores around 0.35, while low-resource languages such as Arabic and Finnish show slightly larger variations, especially at lower thresholds. This suggests that the choice of threshold may have a more significant impact on low-resource languages, potentially due to their inherent linguistic challenges and data scarcity. Overall, these findings emphasize REFIND's ability to maintain reliable performance across a range of threshold values while highlighting potential areas for optimization in low-resource scenarios.

5.5 Case Study

Figure 2 illustrates REFIND's ability to detect hallucinations by utilizing retrieved evidence. The question asks about Chance the Rapper's debut year. The LLM's output contains a hallucinated span ("2011"), which is inconsistent with the retrieved documents. By comparing the generated output with external knowledge, REFIND effectively identifies spans that deviate from factual information.

6 Conclusion

In this study, we introduced REFIND, a novel framework for detecting hallucinated spans in LLM-generated outputs by leveraging retrieved documents to compute the Context Sensitivity Ratio (CSR) at the token level. REFIND was rigorously evaluated on the multilingual SemEval 2025 Task 3: Mu-SHROOM dataset, demonstrating superior performance across nine languages, including low-resource settings, compared to baseline approaches. By directly integrating retrieved context into the token probability calculation, REFIND effectively identifies hallucinated spans with greater precision and efficiency.

Our experimental results highlight the robustness and scalability of REFIND in multilingual environments, offering a promising solution for enhancing the factuality of LLM outputs. Moreover, the streamlined detection process avoids the complexities associated with multi-step frameworks, enabling practical deployment in real-world applications.

For future work, we aim to extend REFIND by exploring adaptive thresholding mechanisms to further optimize the balance between precision and recall in hallucination detection.

Limitations

While REFIND achieves notable improvements in hallucination detection, there are limitations to consider. First, the reliance on retrieved documents means that the quality of the retriever directly impacts performance. Errors in retrieval or limited availability of relevant documents may lead to suboptimal CSR calculations and misclassification of hallucinated spans. Second, the approach involves computational overhead associated with calculating token probabilities with and without retrieved context, which could pose challenges in low-latency applications. Lastly, REFIND focuses on detecting factual hallucinations, and its performance in non-factoid question answering (Bolotova et al., 2022; Lee et al., 2025) remains unexplored. Further studies are needed to assess its ability to detect hallucinations in non-factoid QA tasks.

A Implementation Details

All experiments are conducted using NVIDIA A100 80GB GPUs.

For training the XLM-R-based (Conneau et al., 2020) system, we leverage the Trainer from the Hugging Face Transformers library (Wolf et al., 2020). We train the model using token-aligned hallucination annotations from our dataset, with the model parameters optimized using cross-entropy loss and AdamW optimizer with a learning rate of 2e-5 for 5 epochs.

Inference for FAVA (Mishra et al., 2024) is conducted using vLLM (Kwon et al., 2023), adhering to the original settings with *temperature*=0, *top_p*=1.0, and *max_tokens*=1024. The prompt template used for FAVA inference is detailed in Figure 5 (Appendix A.1).

B Full Text of Retrieved Documents $\mathcal{D}$ for Case Study (§5.5)

Document 1. Chance the Rapper discography he discography of American rapper Chance the Rapper consists of one studio album, five mixtapes and 27 singles (including 14 singles as a featured artist). Chance the Rapper released his debut mixtape, "10 Day" on April 3, 2012. The mixtape was followed up with the release of "Acid Rap" the following year, which saw universal acclaim from music critics. Chance the Rapper then released his third mixtape, "Coloring Book" on May 13, 2016. The mixtape peaked at number eight on the "Billboard" 200 chart to continued acclaim and was supported by the singles "Angels"

Document 2. Juice (Chance the Rapper song) "Juice" is a song by American rapper Chance the Rapper, released on January 31, 2013 as the lead single from his second mixtape "Acid Rap" (2013). It was written by Chance and Nate Fox, who also produced the song. "Juice" is a midtempo song, built around a loop of Donny Hathaway's live performance of "Jealous Guy" by John Lennon. Chance the Rapper sings and raps in a comedic manner; his verses in the song have been described as having a "freewheeling, bluesy sway" that "gives way to raucous call-and-response choruses". He references the 1992 film "Juice" (of

Document 3. signs of advertisements and department stores appear in the background, some of which provide imagery and visual references of the lyrics. For example, when Chance lyrically alludes to the film "Juice", a portrait of rapper Tupac Shakur (who starred in the film) flashes across a billboard. When "Acid Rap" was first re-released on streaming services on June 28, 2019, "Juice" was replaced with a 30-second spoken message, in which Chance the Rapper explains the song is excluded from the mixtape because of an uncleared sample. Chance then adds that all streaming proceeds for the alternate

Document 4. Cocoa Butter Kisses "Cocoa Butter Kisses" is a song by American rapper Chance the Rapper from his second mixtape "Acid Rap" (2013). The song features American rappers Vic Mensa and Twista, and was produced by Cam O'bi and Peter Cottontale. It is one of Chance the Rapper's most popular songs to date. At the time when the song was written, Vic Mensa was staying at an apartment in Humboldt Park, Chicago with his manager Cody Kazarian. Chance the Rapper visited one day and showed Mensa a verse and hook he had written earlier. Soon, Mensa began composing his part for the song. In an interview

Abstract

This paper presents our solution for SemEval-2025 Task 1: Learning to Rank Idiomatic Expressions, which addresses the challenge of ranking visual representations for figurative language understanding. We propose a multimodal approach that combines textual context with image caption analysis through systematic data augmentation and model fine-tuning. Our method includes three main components: (1) an option-shuffling strategy to eliminate positional bias in ranking tasks, (2) lexical perturbation through synonym replacement and back-translation to enhance linguistic diversity, and (3) parameter-efficient fine-tuning of large language models optimized for cross-modal ranking. The system achieved first place in Portuguese (Top-1 Acc: 0.92, DCG: 3.43) and second place in English (Top-1 Acc: 0.87, DCG: 3.51) on the CodaBench leaderboard. Through extensive experimentation with models ranging from 7B to 72B parameters, we demonstrate that mid-sized 32B models achieve optimal performance by balancing capacity and trainability. Our analysis reveals that while larger models (72B) suffer from overfitting and optimization challenges, traditional knowledge distillation approaches using GPT-4 prove ineffective for this task. The results highlight the importance of controlled data augmentation and parameter scaling for idiomatic representation learning, providing valuable insights for future work in multimodal figurative language processing.

1 Introduction

Idiomatic expressions are a fundamental component of natural language and often pose challenges to human interpreters and computational models. Unlike literal expressions, idioms convey meanings that are not directly inferred from the individual words, but are instead shaped by cultural and contextual usage. These expressions are essential for natural language understanding, influencing tasks such as sentiment analysis, machine translation, and automated summarization. However, despite significant advances in large-scale language models (LLMs), understanding and accurately interpreting idioms remains a key challenge in NLP.

The AdMIRe (Aesthetic Multi-modal Idiomatic Representation) task(Pickard et al., 2025) was introduced to address these challenges by combining textual and visual information to better represent idiomatic expressions. This multimodal approach aims to move beyond traditional text-only models, which often struggle with the figurative meanings of idioms. Through the use of images alongside context sentences, AdMIRe seeks to improve model comprehension by providing a richer, more nuanced understanding of idiomatic expressions.

In this paper, we present our approach to Subtask A - Static Images, where we were tasked with ranking a set of images based on their ability to represent the meaning of a given idiomatic expression in a specific context. We participated in the competition in both English and Portuguese, achieving notable results: first place in Portuguese with a score of 0.93 and second place in English with a score of 0.86. Our approach leverages state-of-the-art language models that integrate textual cues, offering an improved representation of idiomatic expressions.

This paper outlines our methodology for tackling the task, discusses the challenges we encountered, and provides insight into how the integration of visual information can significantly enhance the performance of language models in understanding figurative language.

2 Related Work

Idiomatic expressions are a key component of natural language, posing significant challenges for both human interpreters and computational mod-

els. Early research highlighted the cognitive difficulty of processing idioms, with Lakoff and Johnson(Lakoff and Johnson, 1980) emphasizing that idioms often carry meanings beyond their literal interpretations.

Although previous tasks have explored how language models represent idioms, Boisson (Boisson et al., 2023) argue that artifacts in these datasets may enable models to perform well on idiomaticity detection without producing high-quality semantic representations.

Traditional NLP models struggled with idiomaticity due to their reliance on literal word meanings, but recent advancements in deep learning have improved idiom detection. Models like BERT(Devlin et al., 2019) and GPT-3 have shown progress in leveraging large-scale contextual embeddings. Currently, generative models in the realm of NLP, exemplified by the GPT series(Brown et al., 2020; Bai et al., 2023; Yang et al., 2023; Wang et al., 2023; Y et al., 2024c,b,a), have shown remarkable abilities in interpreting and producing natural language.

More recently, multimodal approaches have gained attention, integrating visual information to enhance understanding of idioms. AdMIRe demonstrated that combining text and images can significantly improve idiomatic representation, suggesting that multimodal models may offer a promising direction for future research.

3 Method

3.1 Preprocessing

During the data pre-processing stage, we first processed each input record by extracting the idiomatic expressions, contextual sentences, and descriptions and names of five images, constructing input-output pairs from the image description data. For each record, we extractedmpound words, sentences, image captions, and image names formulated an English prompt. The prompt asks: *Which caption best represents the meaning of the phrase compound in the sentence? Provide the ranking of the options using only numbers 1, 2, 3, 4, 5 without additional content. Option1:... Option5*, as shown in fig. 1. Using this data, we trained a large language model (LLM) to perform the ranking task.

In the testing phase, we applied the trained model to the test set for inference, prompting the LLM to generate a context-based ranking of the five image captions. The resulting ranking, represented by numbers from 1 to 5, was then mapped to the corresponding image names and saved as the final ordered output.

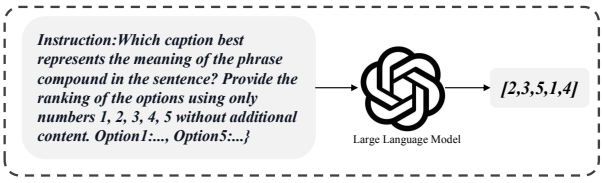

Figure 1: Prompt Construction.

However, relying solely on the original data may lead to model overfitting to specific linguistic expressions, limiting its generalization capability. To mitigate this issue, we introduced a series of data augmentation strategies to enhance model robustness and adaptability.

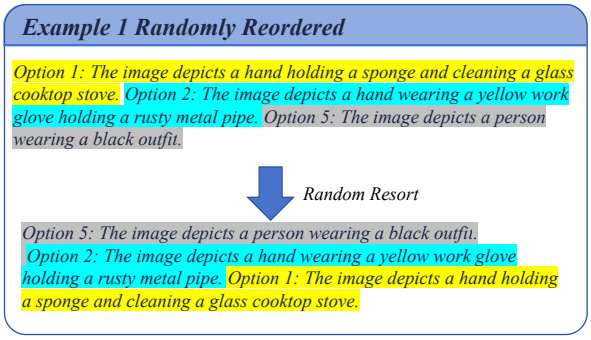

Figure 2: Randomly reordered method.

3.2 Enhancing Ranking Diversity

To prevent the model from developing a dependency on fixed option positions and improve its generalization in ranking, we applied an option-shuffling strategy to augment the dataset. Specifically, we randomly reordered Options 1-5 while simultaneously adjusting the expected_order field to reflect the new arrangement, as shown in Fig. 2. This process reduces the model's reliance on positional biases and encourages it to focus on the actual content of the options rather than learning patterns from their fixed order.

3.3 Data Self-Augment

Furthermore, to enhance model robustness and enrich data diversity, we perform lexical perturbations in the option texts. We randomly selected words from each input-output pair and replaced them with synonyms, introducing minor variations in the image captions while preserving their core semantics. Additionally, we employed back-translation,

where captions were translated into other languages (e.g., Chinese) and then translated back into English. This approach introduces linguistic variations, allowing the model to better adapt to different paraphrases and reducing the risk of overfitting to specific expressions.

4 Experiment Results

We conducted an evaluation of Portuguese and English text only data on the CodaBench platform, as presented in Table 1. The primary evaluation metrics were Top-1 accuracy and DCG score, with additional extended criteria also considered. For the Portuguese dataset, the CTYUN-AI system achieved the highest performance, achieving a Top-1 accuracy of 0.92 and a DCG score of 3.43 in the base test set. In the English setting, CTYUN-AI ranked second, with a Top-1 accuracy of 0.87 and a DCG score of 3.51, showcasing its strong competitive edge. Moreover, under the extended evaluation criteria, CTYUN-AI scored 0.56/2.97 for Portuguese and 0.64/3.10 for English, further reinforcing its robustness and stability. These results underscore the significant advantages of our approach in text-processing tasks. Furthermore, we performed a ranking using GPT-4 on the task data, with scores of 0.6 and 0.7 for English and Portuguese, respectively, which were lower than those achieved by our proposed method.

We employed the Qwen2.5(Bai et al., 2023) model series as the backbone and trained our models using the dataset constructed in the Method section. Specifically, we conducted training and inference using four Ascend-910B nodes, each equipped with eight GPUs. The learning rate was set to 5e-6, the gradient accumulation steps were configured as 8, and the models were trained for a total of five epochs. We experimented with models of different parameter scales, as summarized in Table 2.

Model Size	Top-1 Acc. (PT)	DCG Score (PT)
7B	0.70	3.06
14B	0.67	3.14
32B	**0.92**	**3.61**
72B	0.87	3.42

Table 2: Performance of Different Model Sizes on Portuguese Data

4.1 Unsuccessful Attempts

Larger Models and Parameter Scaling: We experimented with models of different parameter sizes, including the Qwen2.5(Bai et al., 2023) model series, ranging from 7B to 72B parameters. While the 72B model had a significantly larger capacity, it did not outperform the 32B model. We hypothesize that this is due to an optimal balance between parameter size and dataset scale, allowing the model to learn complex patterns effectively while avoiding

excessive optimization challenges. In contrast, the 7B and 14B models likely lacked sufficient parameters to fully capture the intricate relationships in the input data, thereby limiting their performance. Meanwhile, although the 72B model featured a larger parameter size, it did not outperform the 32B model. We attribute this to two potential factors: first, larger models tend to overfit when trained on a limited dataset, resulting in reduced generalization ability. Second, the computational overhead of training and inference with the 72B model was significantly higher, which may have constrained the batch size and negatively impacted the stability of the gradient.

Leveraging GPT-4 for Data Augmentation and Knowledge Distillation: We initially intended to leverage GPT-4 to augment our dataset and distill its capabilities for improved performance. However, GPT-4's performance in this context was suboptimal, likely due to its inherent limitations when applied to this specific task. This was particularly disappointing given the recent surge in interest around knowledge distillation techniques (e.g., DS-R1(DeepSeek-AI and et al., 2025)) for transferring model knowledge. Despite these efforts, GPT-4 did not provide the anticipated improvements, and we decided to focus on optimizing the core model instead.

These explorations underscore the challenges of scaling up the model parameters and using external models such as GPT-4 for distillation, which, although promising in some contexts, did not yield the expected benefits for this particular task.

5 Conclusion

In this paper, we present our approach to SemEval-2025 Task 1, focusing on ranking idiomatic expressions using a multimodal framework. By integrating textual and visual information, along with data augmentation and fine-tuning, we achieved strong results, securing first place in Portuguese and second place in English on the CodaBench platform. Our approach demonstrated improved understanding of idiomatic expressions and better generalization. Although experiments with larger models and GPT-4 for knowledge distillation were less effective, they provided valuable information. This work highlights the potential of multimodal models in enhancing figurative language processing, and we plan to refine these methods further in future work.

Abstract

With the rapid advancement of global digitalization, users from different countries increasingly rely on social media for information exchange. In this context, multilingual multi-label emotion detection has emerged as a critical research area. This study addresses SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection. Our paper focuses on two sub-tracks of this task: (1) Track A: Multi-label emotion detection, and (2) Track B: Emotion intensity. To tackle multilingual challenges, we leverage pre-trained multilingual models and focus on two architectures: (1) a fine-tuned BERT-based classification model and (2) an instruction-tuned generative LLM. Additionally, we propose two methods for handling multi-label classification: the *base* method, which maps an input directly to all its corresponding emotion labels, and the *pairwise* method, which models the relationship between the input text and each emotion category individually. Experimental results demonstrate the strong generalization ability of our approach in multilingual emotion recognition. In Track A, our method achieved Top 4 performance across 10 languages, ranking 1st in Hindi. In Track B, our approach also secured Top 5 performance in 7 languages, highlighting its simplicity and effectiveness[1].

1 Introduction

With the rapid proliferation of social media, particularly in the context of global digital communication, online platforms have emerged as the primary medium for information dissemination (Nandwani and Verma, 2021). Users from diverse linguistic backgrounds frequently express their opinions through comments, highlighting the growing need for cross-lingual sentiment detection (Nandwani and Verma, 2021). Consequently, multilingual sentence-level sentiment analysis has become a critical task for tracking public sentiment (Wankhade et al., 2022). Sentiment analysis is one of the most extensively studied applications in natural language processing (NLP). In text emotion recognition, it is common for a single sentence to express multiple emotions with varying intensities (Deng and Ren, 2020). However, developing reliable multi-label emotion analysis systems remains particularly challenging due to the scarcity of training data, especially for low-resource languages. Additionally, pre-trained language models often have limited knowledge of these languages, further complicating the task. To address these challenges, this paper presents our approach for SemEval-2025 Task 11, "Bridging the Gap in Multilingual Multi-Label Emotion Detection from Text Using Large Language Models" (Muhammad et al., 2025b). We participated in two tracks: Track 1 (Multi-Label Emotion Detection) using the BRIGHTER dataset, which includes 28 languages (Muhammad et al., 2025a; Belay et al., 2025), and Track 2 (Emotion Intensity Prediction), which covers 11 languages.

In this study, to address the challenges of multilingual sentiment analysis, we leveraged pre-trained models (such as RoBERTa) and large language models (LLMs) to perform multi-label sentiment analysis on both high-resource languages like English and Chinese, as well as low-resource languages such as African languages. We formulated multi-label emotion recognition as a text generation task. To overcome the challenge of limited training data, we utilize the capabilities of multilingual pre-trained language models to enhance both semantic understanding and the recognition of emotional tone, especially in low-resource languages. Furthermore, to tackle the multi-label classification challenge, we propose two methods: the *pairwise* method and the *base* method. Our findings also indicate that training the model on a combined multilingual dataset improves performance compared

[1]Our code is available at https://github.com/yingjie7/mlingual_multilabel_emo_detection

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 20–27

to training on individual language datasets. We present experiments comparing the applicability of these methods and conduct ablation studies to validate their effectiveness. Our approach demonstrates strong performance in both multi-label emotion recognition and emotion intensity detection. In Track A, it achieved top-four rankings in 10 languages, including first place in Hindi. In Track B, our method ranked within the top five for 7 languages, further highlighting its simplicity and effectiveness. Moreover, our approach exhibits strong generalization across both competition sub-tasks, making it particularly beneficial for low-resource languages.

2 Background

Sentence-level sentiment analysis (SLSA) has advanced significantly with the rise of deep learning and multilingual sentiment detection. Early research primarily focused on extracting handcrafted sentiment features such as n-grams (Tripathy et al., 2016), lexicons, rule-based heuristics (Chikersal et al., 2015) to enhance SVM-based classifiers (Kumari et al., 2017) and deep neural networks, such as CNNs and RNNs (Chikersal et al., 2015; Minaee et al., 2019). Nonetheless, their reliance on static word embeddings limited their ability to handle complex linguistic phenomena such as long-range dependencies and cross-lingual variations. To address these limitations, researchers turned to Transformer-based pretrained language models (PLMs) such as BERT (Devlin et al., 2019) and T5 (Raffel et al., 2020), which more effectively capture fine-grained emotional representations (Zhou et al., 2016; Li et al., 2018) by modeling richer linguistic semantics. In multilingual sentiment analysis, models like mT5 (Xue et al., 2021) and XLM-RoBERTa (XLM-R) (Conneau et al., 2020) further advanced the field by learning cross-lingual representations, making them the standard for multilingual applications (Hu et al., 2020). More recently, the widespread adoption of large language models (LLMs) such as LLaMA 2 (Touvron et al., 2023) has driven major breakthroughs in various NLP tasks (Upadhye, 2024; Sharma et al., 2023). These models exhibit remarkable zero-shot and few-shot learning capabilities, making them highly adaptable to new sentiment analysis tasks (Maceda et al., 2024). Furthermore, in the domain of Emotion Recognition in Conversations, LLMs have been leveraged with prompt-based techniques to extract latent supplementary knowledge from text, injecting this information to facilitate emotion recognition (Xue et al., 2024). In the broader NLP landscape, various methodologies including fine-tuning, prompting, transfer learning, and domain adaptation have been pivotal in adapting pre-trained LLMs for sentiment analysis across specific domains and languages.

However, as most PLMs are predominantly pretrained on English text, their effectiveness in multilingual sentiment analysis is often limited without additional fine-tuning is performed to optimize performance across diverse linguistic contexts (Zhang et al., 2023). Numerous studies have explored leveraging embeddings from LLMs for sentiment classification, using various low-resource datasets to assess their adaptability across languages (Dadure et al., 2025; Mujahid et al., 2023). In our work, we leverage BERT-based multilingual models to extend multi-label classification tasks, enabling knowledge transfer across languages. By integrating LLMs, we also present a *pairwise emotional recognition* method, which efficiently captures both emotional intensity and sentiment polarity within each sentence. This approach ensures that the model concentrates on one label at a time. Additionally, we reformulate the multi-label classification task as a text generation problem, enhancing the model's adaptability and generalization across NLP tasks.

3 System Description

In this work, the target task involves the perception of emotions in various languages, which aims to identify the emotion that most people would attribute to the speaker based on a given sentence or short text snippet. Given a text input (x), a machine learning system needs to retrieve all the multi-label emotions (y_e) expressed in the given text (Track A) and the intensity (y_i) of each class (Track B).

3.1 System Overview

In general, we leverage the capabilities of pretrained multilingual models to tackle cross-lingual challenges. Our system primarily focuses on two architectures: fine-tuning BERT-based classification models (Devlin et al., 2019) and instruction fine-tuning generative LLMs, building upon recent SOTA methods in the field of emotion recognition (Xue et al., 2024). To handle multi-label classification, we design two strategies: (1) the *base* method,

which maps a given input to all its corresponding labels, and (2) the *pairwise* method, which models the relationship between the input text and each label class individually.

$$\textit{base}: \quad \mathbb{P}_A(\{y_e\} \mid x) \qquad \mathbb{P}_B(\{\langle y_e, y_i \rangle\} \mid x) \quad (1)$$

$$\textit{pairwise}: \quad \mathbb{P}_A(\{0,1\} \mid x, y_e) \quad \mathbb{P}_B(y_i \mid x, y_e) \quad (2)$$

where x is the given input text; $\mathbb{P}_A, \mathbb{P}_B$ are probability models for track A and B; y_e, y_i are the emotional label and its corresponding emotional intensity from a pre-defined label set, respectively.

3.2 Methods

BERT-based method. For the baseline, we design a BERT-based multi-label classification model. In detail, fully connected layers with nonlinear activation functions (sigmoid (σ) and tanh) are added to the top layer of the BERT architecture to transform the `[CLS]` feature vector (Devlin et al., 2019) from the hidden representation to the output dimension (number of labels).

$$h^{CLS}, h^{words} = \text{BERT}(x) \quad (3)$$

$$h^{out} = \sigma(\tanh(h^{CLS} \cdot W^h) \cdot W^o) \quad (4)$$

Finally, during the fine-tuning process, the learnable weights (W^*) are optimized using cross-entropy loss on annotated data to maximize the log-likelihood of the model.

LLM-based method. Leveraging the robust natural language understanding capabilities of large language models (LLMs) (Touvron et al., 2023), we employ instruction prompting (highlighted in blue in Table 1) to guide the model in comprehending the task requirements. Our methodology follows instruction fine-tuning as outlined by Chung et al. (2022), using a *causal language modeling* objective to train the LLM to generate emotional label text, which is highlighted in red in Table 1.

$$s = \text{instruction-prompting}(x, y) \quad (5)$$

$$\mathbb{P}(s) = \Pi_{z=1}^{|s|} \mathbb{P}(s_z | s_0, s_1, ..., s_{z-1}) \quad (6)$$

where s, x represent a sequence of tokens, and z denotes the token index within the prompting input (Table 1). To optimize efficiency, we employ LoRA (Hu et al., 2022), a lightweight training methodology that reduces the number of trainable parameters. The fine-tuned LLM is designed to learn the distribution of emotional labels (or emotional intensity) based on the given prompt (s). During inference, the emotional label (y), which is omitted from the input prompt, is generated by the fine-tuned model.

system
You are an expert in analyzing the emotions expressed in a natural sentence. The emotional label set includes {anger, fear, joy, sadness, surprise}. Each sentence may have one or more emotional labels, or none at all.
user
Given the sentence: "`{input text: x}`", which emotions are expressed in it?
assistant
`{emotional label in text:` y_e `or` $\langle y_e, y_i \rangle$`}`

Table 1: Instruction prompting with the *base* template (track A).

Task	Strategy	Input	Output	Output example
Track A	base	x	$\{y_e\}$	*"disgust, sadness"*
Track B	base	x	$\{\langle y_e, y_i \rangle\}$	*"moderate degree of anger, low degree of sadness"*
Track A	pairwise	x, y_e	$\{0, 1\}$	*"yes"*
Track B	pairwise	x, y_e	y_i	*"moderate"*

Table 2: Examples of output format for text generation.

As outlined in the overview section, we have devised two approaches, *base* and *pairwise*, to tackle this task. Both approaches employ the same training techniques across tracks A and B and between the two approaches themselves. We provide example outputs designed for both tracks in Table 2. Detailed examples for each track are provided in Appendix A.

4 Experimental Setup

Dataset. To evaluate our methods, we use the original emotional data provided by the SemEval Task 11 organization. This dataset consists of three subsets: training, development, and test sets, spanning two competition phases: development and test. However, to ensure greater generalization, we consistently set aside 10% of the training data from each language as an internal development set. This held-out portion is used for hyper-parameter tuning, ensuring that the optimized checkpoints are selected based on this internal dev set. Additionally, to handle multilingual data, we design two settings: (1) *separated langs*, where a separate model is trained for each language, and (2) *mixed langs*, where a single model is trained to learn all languages simultaneously.

Evaluation Metric. According to the competition guidelines, the evaluation metric for Track A is the macro-averaged F1-score, while for Track B, it is the Pearson correlation coefficient between the predicted and gold-standard labels.

Table 4: Results of Sub-task B. The meanings of the denotations and colors are the same as in Table 3.

Experimental Environments. We implement all our experiments using widely adopted libraries such as PyTorch and HuggingFace. For pre-trained LLMs, we primarily experiment with XLM-RoBERTa-Large, Llama2 (7B-13B), and Qwen2.5 (14B–32B). For hyper-parameters, we train the model with a learning rate of $3e^{-4}$, using the AdamW optimization algorithm, 5–6 epochs.

5 Results

Overall, we evaluate our methods and their variants on the development set to select the best model and setting for each language (indicated in red in Tables 3, 4) for the final test submission.

5.1 Track A: Multi-label Emotion Detection.

Development Result. As shown in Table 3, we conducted experiments using both the *base* and *pairwise* methods on Qwen-32B, Qwen-14B, and RoBERTa models. The results indicate that the Qwen models with the *pairwise* method achieved the best overall performance. However, in datasets where the majority of samples contain zero or only one emotion label, the *base* method outperformed the *pairwise* approach. We attribute this to the fact that the *pairwise* method is inherently more suited for multi-label emotion recognition tasks. Additionally, in low-resource languages, LLMs performed poorly, whereas the RoBERTa-based approach yielded better results.

Test Result. Overall, our approach achieved 4th place in Track A for CHN, ESP, PCM, and PT-BR, secured 3rd place in ARQ, ARY, RON, and RUS, and ranked 2nd and 1st for SWE and HIN, respectively. These results demonstrate the strong generalization ability of our method, highlighting its simplicity and efficiency.

5.2 Track B: Emotion Intensity.

The results of Track A demonstrated the strength of LLMs compared to the XLM-RoBERTa model, leading us to primarily experiment with LLMs rather than XLM-RoBERTa in this track.

Development Result. As shown in Table 4, we conducted experiments using both the *base* and *pairwise* strategies on LLaMA 2 and Qwen-32B models. The results indicate that Qwen-32B outperforms LLaMA 2, and the *pairwise* strategy consistently achieves better overall performance compared to the *base* method.

Test Result. In Track B across 11 languages, our model achieved 3rd place in Ukrainian (ukr) and Algerian Arabic (arq), 4th place in Romanian (ron), and 5th place in Russian (rus), Brazilian Portuguese (ptbr), English (eng), and German (deu). With top-five rankings in seven languages, these results demonstrate the effectiveness and generalizability of our approach.

5.3 Result Analyses

Strategies Comparison. To gain a comprehensive understanding of the base and pairwise strate-

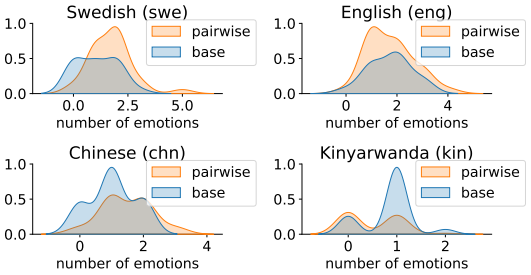

Figure 1: Distribution of improved samples between strategies *base* and *pairwise* with respect to the number of emotions (track A).

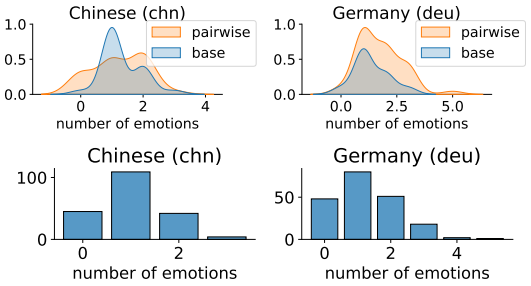

Figure 2: Distribution of improved samples between strategies *base* and *pairwise* with respect to the number of emotions (track B).

gies, we conducted experiments to analyze the distribution of improved examples, measured by the F1 score for each sample, across four languages: English, Swedish, Chinese, and Kinyarwanda (Figure 1 for Track A and Figure 2 for Track B). Our findings indicate that the pairwise strategy predominantly improves samples in languages that convey various emotions within a sentence, particularly in English and Swedish. Conversely, in languages or datasets with a limited variety of emotional labels, such as Chinese and Kinyarwanda (where each sample typically contains 0 to 2 emotions), the base strategy demonstrates a distinct advantage. We argue that this is because the pairwise strategy evaluates only one emotion at a time, making it more sensitive to label imbalance, which in turn leads to lower performance in languages with a limited variety of emotion labels compared to the base strategy. In contrast, the base strategy generates all emotions present in a sample simultaneously, highlighting its advantage in languages with fewer distinct emotion categories.

Emotional Type. To evaluate the model's effectiveness concerning emotional intensity across various emotions, we plotted the distribution of emotional labels alongside their corresponding intensities (Fig 3). We conducted experiments by aggregating all the languages and examined the correlation between performance and emotions, as well as their respective intensities. Our analysis revealed that classes with limited data, such as high-surprise or high-joy, typically exhibited poorer performance in our system. Conversely, the major emotional class, *"disgust"*, achieved the highest performance compared to other emotional classes, such as surprise, particularly high-surprise.

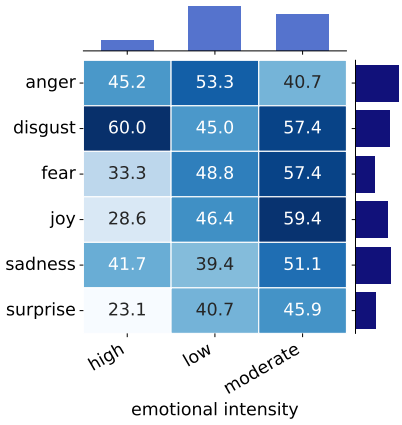

Figure 3: Overall performance of the pairwise strategy across all emotional labels in all languages (Track B).

Mixed languages. In both Sub-tasks A and B, mixed-language training, where a single model is fine-tuned for all languages, demonstrates superior performance compared to training separate models (Tables 3, 4). This improvement can be attributed to a more balanced distribution of emotion types across languages and the model's enhanced ability to generalize across linguistic variations.

6 Conclusion

In this work, we present a multilingual emotion recognition system for SemEval-2025 Task 11, which demonstrates strong performance and remains competitive with the top-performing teams. To address multilingual challenges, we design two architectures, BERT-based and LLM-based, and introduce two strategies, *pairwise* and *base*, for handling the multi-label classification task. We conduct extensive experiments to analyze the effectiveness and limitations of each approach, aiming to provide valuable insights for multilingual emotion recognition research. The results validate the simplicity and effectiveness of our methods, highlighting their strong generalization ability and applicability to other tasks.

Limitations and potential improvements. Despite the promising results achieved in our work, several limitations remain. First, the LLM-based approach is heavily dependent on the knowledge and capabilities within the LLMs themselves, which may limit its adaptability to evolving data. Furthermore, compared to BERT-based methods, LLM-based approach incurs higher computational costs, making it less efficient for large-scale or real-time applications.

There are several directions for future improvement. One potential enhancement lies in the utilization of finer-grained information contained in the logits output. Specifically, for the LLM Pairwise strategy, instead of relying solely on the final "yes" or "no" response, it is better to aggregate the logits corresponding to the tokens generating "yes" and compute a probability distribution via softmax. This would enable a more nuanced and probabilistic interpretation of the model's predictions, potentially improving robustness.

Another limitation is the incomplete handling of label imbalance. Our current framework does not fully address the issue, which may cause the model to overfit to dominant emotional categories. Future work could incorporate targeted data augmentation strategies, such as generating additional samples for underrepresented emotions, to mitigate this imbalance and enhance the overall performance and stability of the system.

YNU-HPCC at SemEval-2025 Task3: Leveraging Zero-Shot Learning for Hallucination Detection

chenshen@stu.ynu.edu.cn, {wangjin, xjzhang}@ynu.edu.cn

Abstract

This study reports the YNU-HPCC team's participation in SemEval-2025 shared task 3, which focuses on detecting hallucination spans in multilingual instruction-tuned Large Language Models (LLMs) outputs. This task differs from typical hallucination detection tasks in that it does not require identifying the entire response or pinpointing which sentences contain hallucinations generated by the LLM. Instead, the task focuses on detecting hallucinations at the character level. In addition, this task differs from typical hallucination detection based on binary classification. It requires not only identifying hallucinations but also assigning a likelihood score to indicate how likely each part of the model output is hallucinatory. Our approach combines Retrieval-Augmented Generation (RAG) and zero-shot methods, guiding LLMs to detect and extract hallucination spans using external knowledge. The proposed system achieved first place in Chinese and fifteenth place in English for track 3[1].

1 Introduction

Hallucination in large language models refers generating of information that appears plausible but is factually incorrect or fabricated. This issue is common in open-domain tasks, such as question answering and summarization, where the model may produce answers inconsistents with the provided context or external knowledge.

Hallucinations can be categorized into two main types (Ji et al., 2023): intrinsic, which conflicts with the source content, and extrinsic, which cannot be verified from the source content. These errors are closely related to the nature of knowledge. Some knowledge is static, such as the date of the Civil War, while other knowledge evolves over time, such as the current population of China. The distinction between these two types of knowledge implies that hallucinations cannot be eliminated—especially for the latter—unless the model adopts a Retrieval-Augmented Generation (RAG)-based (Lewis et al., 2020) approach.

As a result, much effort has been dedicated to hallucination detection. These detection methods can be broadly classified into the following categories (Huang et al., 2025): 1) Methods based on model output logits, such as uncertainty and semantic entropy; 2) Fact-based detection methods, which generally calculate the similarity between factual documents and the model's output. The shortcomings of both approaches are evident: the former can only detect hallucinations but cannot correct them, and it requires the detection process to be tightly coupled with model generation. The latter, on the other hand, struggles in domains where factual documents are difficult to retrieve.

This task evaluated whether the model's output addressed the question and whether the answer was accurate. Neither of these approaches effectively addresses the task's minimum interval requirement because both focus on the entire model output rather than specific spans within the answer.

Therefore, our team's approach initially combined fact-based documentation with Machine Reading Comprehension (MRC) (Kenton and Toutanova, 2019), followed by integrating the factual document-based method with zero-shot detection. The final experimental results demonstrated that our solution was both effective and competitive (Vázquez et al., 2025).

2 Related Work

Machine Reading Comprehension. Machine reading comprehension is often applied in tasks that answer questions based on context, and we similarly use it to detect erroneous content. As men-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 28–33

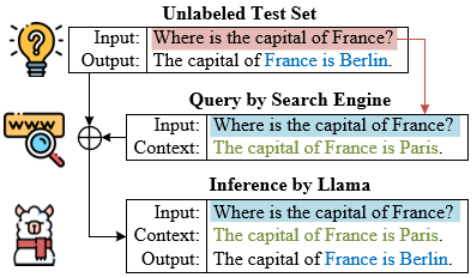

Figure 1: Combining MRC and RAG system architecture approach

tioned in the Introduction, the task requires identifying hallucinations at the character-level interval, rather than evaluating the entire answer, which is more common in hallucination detection.

Zero-shot Learning. (Brown et al., 2020) The Zero-Shot Prompting approach is highly flexible and generalizable, eliminating the need for task-specific training across new tasks or domains. Instead, it relies on pre-trained language models combined with carefully designed examples or prompts to facilitate reasoning and generate outputs. Although the validation set for the task initially contained up to 807 Q&A pairs when categorized by language, filtering for unique questions reduced the dataset to around 50 distinct entries. Given this constraint, we adopted the zero-shot approach as our solution.

3 Approach

3.1 MRC Combined with RAG for Hallucination Detection

Our initial approach combined MRC techniques with an RAG strategy to label hallucination intervals,as shown in the flow in Figure1. The core of this approach focused on the retrieval-augmented component. While interfaces like Google and Bing required extensive data cleansing, our team opted for a more direct method: we manually queried the model input field. We filtered the generated answers to ensure they were concise and directly addressed the question. Additionally, since the interval-based hallucination detection dataset is only available in English, the fine-tuned LLM must possess cross-linguistic capabilities. For this reason, we selected LLaMA3 (Dubey et al., 2024) as the model for our approach.

To meet the task's minimum interval requirement, we used BIO tagging (Ramshaw and Marcus, 1999) for individual tokens. However, a limitation of this approach was that it did not allow us to populate the soft labels field with probability values. To overcome this, we used the softmax value of the hallucination end token as a proxy. This decision was informed by two factors: (1) LlamaForTokenClassification[2], uses Cross-Entropy as the loss function for multi-label training, and (2) marking the end token marginally improved the CoR score in the final evaluation.

3.2 Zero-shot Combined with RAG for Hallucination Detection

Following the previous phase, we created a question-answer pair document based on the test set. In the next step, we applied prompt engineering to guide the LLM in directly categorizing the contents of the model output text field. The model was instructed to output the soft and hard labels fields separately, as shown in the flow in Figure2. Our team selected four models for this solution: OpenAI-o1, Claude-3.5, Gemini and DeepSeek V3 (Liu et al., 2024).

We also explored using the task-provided training set, along with data from the validation set or open-source datasets (e.g., RAGTruth (Niu et al., 2023) and HaluEval (Li et al., 2023)) for a few-shot learning approach. However, based on our previous experience with MRC, we found that some entries in the official dataset contain hallucination spans shorter than a token. Additionally, open-source datasets often lack the probability values required for the soft labels field. While we attempted to annotate these datasets with probability values, we encountered a challenge: assigning error probabilities to clearly incorrect content and assigning probabilities to valid content. Furthermore, when the text is known to be incorrect, it is challenging for the LLM to provide the required probability values for the soft labels field.

The task organizers explicitly stated that 12 reviewers annotated the probability values for both English and Chinese. Therefore, using a prompt, we instructed the model to select a probability value between 0.0833 (1/12) and 1.0 (12/12) for the soft labels field. The organizers' statement aligns with the challenges we described in the previous paragraph. This method of assigning probabilities is

[2] https://huggingface.co/docs/transformers/en/model_doc/llama#transformers.LlamaForTokenClassification

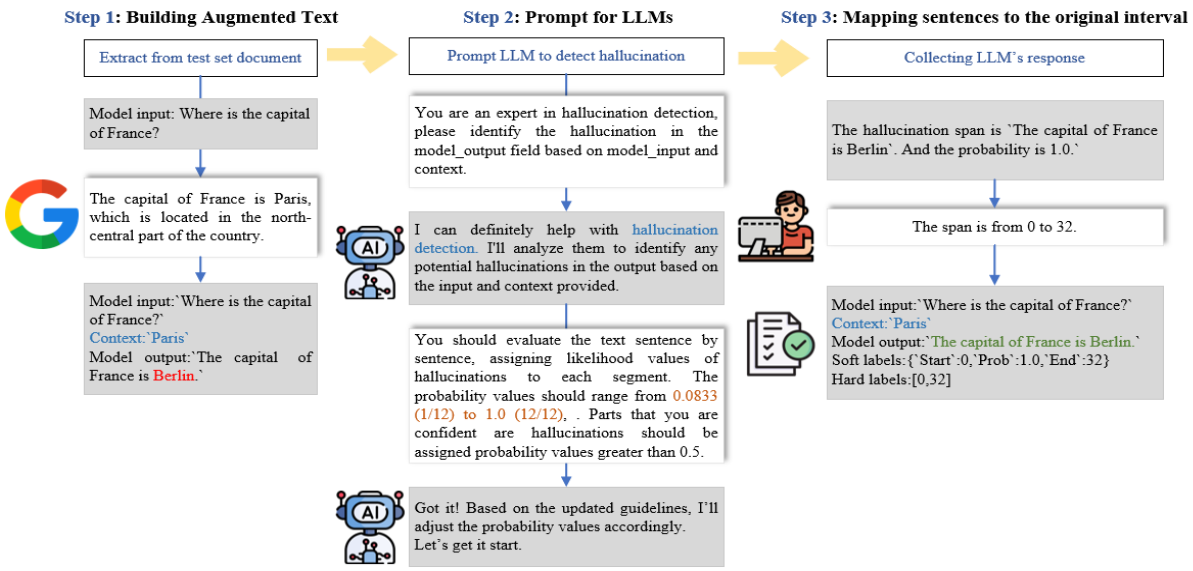

Figure 2: Combining zero-shot and RAG system architecture approach

virtually infeasible, as it relies on aggregating multiple binary labels to approximate probability values.

Both models naturally use sentences as the unit for the minimum hallucination span during the response collection process. Although this approach does not fully meet the "minimum" span requirement set by the organizers, it aligns with our team's intuition about hallucinations. We typically don't distinguish between correct and incorrect information at the word level; instead, we usually make distinctions at least at the sentence or clause level.

As widely known, the strawberry challenge revealed LLMs' weakness in counting. The results are often unreliable when directly asked to generate soft and hard labels in JSON format. Fortunately, both models apply chain-of-thought (CoT) (Wei et al., 2022) reasoning to generate responses, improving accuracy. To mitigate counting errors in the LLM outputs, we required both OpenAI-o1 and DeepSeek V3 to provide the spans and the corresponding textual content for each span. After collecting the LLM responses, we used the KMP algorithm to map the text to its corresponding position in the model output text field.

4 Experiment Detail

Datasets. In our MRC solution, we fine-tuned the LLaMA model using RAGTruth and HaluEVAL datasets. RAGTruth explicitly labels hallucination intervals in numerical form, closely aligning with the task requirements, while HaluEVAL only identifies the text segments containing hallucinations without specifying precise intervals.

Evaluation Metric. This task adopts IoU and Cor as evaluation metrics during the assessment phase. The scoring criteria for IoU are outlined below:

$$IoU = \frac{\text{Intersection}(Gold, Prediction)}{\text{Union}(Gold, Prediction)} \quad (1)$$

where *Gold* refers to the intervals marked by the organizers as hard labels, while *Prediction* refers to the intervals marked by participants as hard labels. Cor's score was calculated using the Spearman Rank Correlation Coefficient, which is calculated as follows:

$$Cor = 1 - \frac{6 \sum d_i^2}{n(n^2 - 1)} \quad (2)$$

where d_i refers to the difference in probability values between the soft labels published by the organizers and the soft labels submitted by the participants, while n represents the character-level length of all soft label intervals marked by the organizers.

5 Result

In the final evaluation phase, the tournament organizers used Intersection-over-Union (IoU) to evaluate the hard_labels, while Spearman correlation was used to assess the soft_labels.Table 2 and 3 presents the results achieved using different models and methods.

As shown in the table 1 and 2, OpenAI-o1 outperforms the other models by a significant margin.

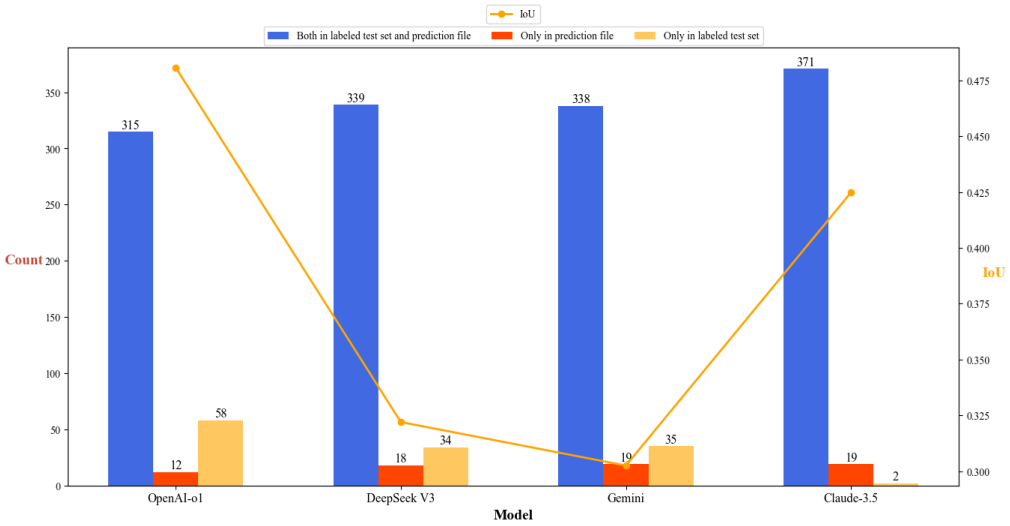

Figure 3: Performance of different LLMs on the EN test set. Blue bars represent sentences correctly labeled by the model, red bars indicate sentences incorrectly labeled, and yellow bars show sentences that the model failed to detect.

LLM	IoU	Cor
OpenAI-o1(Prompt)	**0.5540**	**0.3518**
DeepSeek V3(Prompt)	0.1219	0.0497
Gemini V2(Prompt)	0.3265	0.0664
Claude-3.5(Prompt)	0.4769	0.0795
LLaMA-3(MRC)	0.4565	0.1846
Baseline(mark all)	0.4772	0.0000

Table 1: Results obtained with different LLMs in the ZH test set.

LLM	IoU	Cor
OpenAI-O1(Prompt)	**0.4807**	**0.4075**
DeepSeek V3(Prompt)	0.3220	0.1802
Gemini V2(Prompt)	0.3025	0.1722
Cluade-3.5 (Prompt)	0.4248	0.3391
LLaMA-3(MRC)	0.3800	0.3974
Baseline(mark all)	0.3489	0.0000

Table 2: Results obtained with different LLMs in the EN test set.

The MRC-based approach using LLaMA for hallucination interval detection also performs well.

To better demonstrate the effectiveness of our team's solution, we also performed a more refined data analysis at the end of the evaluation phase. Our analysis is based on the labeled test set released by the organizers at the end of the evaluation phase. As we stated in Section 3.2, the granularity of the labels provided by the organizers is lower than our

Model	Rank	IoU	Cor
Chinese(Mandarin)			
OpenAI-o1	1	0.5540	0.3518
Claude-3.5	5	0.4769	0.0795
LLaMA-3	14	0.4565	0.1846
Gemini V2	21	0.3265	0.0664
DeepSeek V3	26	0.1219	0.0497
English			
OpenAI-o1	15	0.4807	0.4075
Cluade-3.5	24	0.4248	0.3391
LLaMA-3	26	0.3800	0.3974

Gemini V2	35	0.3025	0.1722

Table 3: Ranking of our practices in the official ranking table

team's judgment of the LLMs' hallucination phenomenon, and also Tables 3 have demonstrated the accuracy and relevance at the character level. Therefore, we split the model output text by sentence and analyze it at the sentence level, as shown in Figure 3 and Figure 4. In terms of detection ability at the sentence level, Claude-3.5 performs ahead of all other models. However, OpenAI-o1 scores higher under the IoU metric due to its fewer false positive results. Meanwhile, Figures 3 and 4 show a disproportionate increase in sentences that were not detected by the Gemini and DeepSeek V3 models in the Chinese track. However, the opposite trend is observed under the IoU metric. This dis-

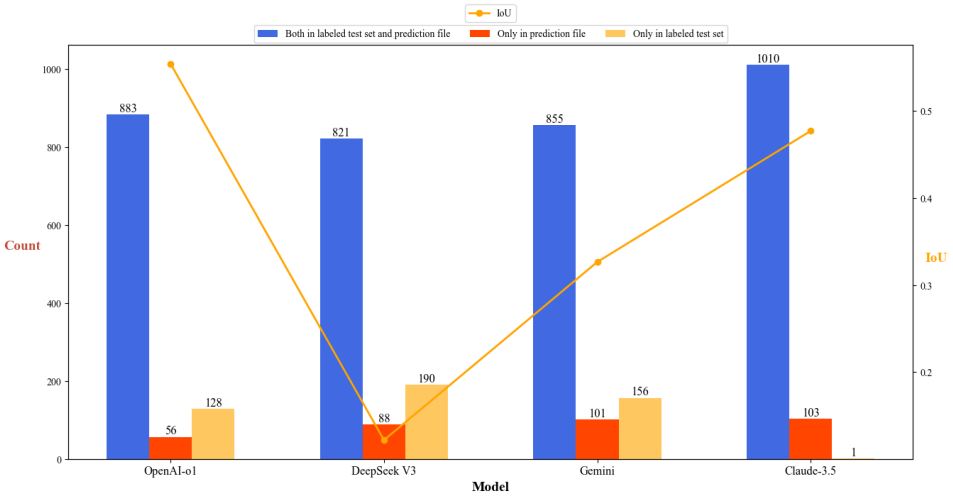

Figure 4: Performance of different LLMs on the ZH test set. Blue bars represent sentences correctly labeled by the model, red bars indicate sentences incorrectly labeled, and yellow bars show sentences that the model failed to detect.

crepancy is primarily due to the fact that the model responses in the Chinese test set often include more Markdown syntax for structured, point-by-point responses to questions. This is also reflected in the overall length of the text, which is 48040 for the Chinese test set and 36745 for the English dataset. As a result, regular expressions struggle to segment the text according to human linguistic conventions.

6 Analysis

The data in the table indicates a low correlation in our solution, which can be attributed to at least the following factors:

- Following the example provided by the task organizers, if the text in the model output text is *The capital of France is Berlin*, the hallucination interval we provide should only include the token "Berlin." This tokenization approach is, of course, correct. We replace *Berlin* with *Paris* to correct the LLM's response.

- Similarly, for hallucination detection, fitting the probability of a binary classification task to the results derived from 12 individuals' votes proves too challenging. We also considered using multiple rounds of sampling (Shanahan et al., 2023), where the discriminative results of 12 judgments made by the same model would be used to fit the final probability; however, this exceeded our team's budget.

- As shown in Tables 1 and 2, our team's results in the English track were not as strong as those in the Chinese track, which seems contradictory considering the training data used by the relevant models. This discrepancy may be related to the quality of the augmented documents we created. Specifically, for the test set, there were 12 instances in the English portion where content could not be retrieved or was overly verbose, while only 4 were present in the Chinese portion. This difference could have a significant impact, given that the test set contains only 150 entries.

7 Conclusion

This study describes the work conducted by the YNU-HPCC team for participation in "MuSHROOM (SemEval 2025)." The methods we employed include Augmented Document-based MRC and Augmented Document-based Prompt Engineering. The final results showed that using OpenAI-o1 with Augmented Document-based Prompt Engineering achieved first place in the Chinese track, with an IoU score of 0.5540 and a Cor score of 0.3518. In the English track, the model achieved 15th place, with an IoU score of 0.4807 and a Cor score of 0.4075.

Future work attempts to adopt a knowledge graph-based approach for self-checking LLM-generated answers in the future. After all, compared to a simplistic model, a more intelligent model that outputs incorrect answers tends to cause more significant harm to society and the economy.

Therefore, integrating online retrieval-augmented generation (RAG) with offline knowledge graphs will be key for mitigating hallucination.

AtlasIA at SemEval-2025 Task 11: FastText-Based Emotion Detection in Moroccan Arabic for Low-Resource Settings

Abdeljalil El Majjodi[1], Imane Momayiz[1], and Nouamane Tazi[1]

[1]AtlasIA

Abstract

This study addresses multi-label emotion classification in Moroccan Arabic. We developed a lightweight computational approach to detect and categorize emotional content in seven distinct categories: anger, fear, joy, disgust, sadness, surprise, and neutral. Our findings reveal that our efficient, subword-aware model achieves 46.44% accuracy on the task, demonstrating the viability of lightweight approaches for emotion recognition in under-resourced language variants. The model's performance, while modest, establishes a baseline for emotion detection in Moroccan Arabic, highlighting both the potential and challenges of applying computationally efficient architectures to dialectal Arabic processing. Our analysis reveals particular strengths in handling morphological variations and out-of-vocabulary words, though challenges persist in managing code-switching and subtle emotional distinctions. These results offer valuable insights into the trade-offs between speed and accuracy in multilingual emotion detection systems, particularly for low-resource languages.

1 Introduction

Emotion detection in natural language processing (NLP) presents significant challenges, particularly for low-resource languages like Moroccan Darija (Moroccan Arabic). As digital communication proliferates, understanding emotional nuances becomes crucial for applications in sentiment analysis, social media monitoring, and psychological research (Gandhi et al., 2023). Despite extensive research in emotion classification for well-resourced languages, Moroccan Darija remains under-explored due to several challenges. Its *linguistic complexity*, marked by high context-dependency and significant deviations from Modern Standard Arabic, complicates NLP tasks. The unique *code-switching patterns*, blending Berber, French, Spanish, and Arabic, further hinder traditional approaches (Zaidan and Callison-Burch, 2014). A major bottleneck is the *scarcity of annotated datasets, linguistic tools, and computational resources*. Unlike well-studied languages, Darija lacks sentiment lexicons and annotated corpora necessary for emotion detection. Additionally, *dialectal variability* introduces regional and social variations, making generalization difficult. Lastly, Darija's *nuanced emotional expression*, deeply tied to prosody, idiomatic speech, and cultural context, remains a challenge for conventional NLP techniques.

For these reasons, traditional machine learning approaches often struggle with Darija's unique dialectal characteristics, requiring specialized computational techniques to navigate its intricate linguistic landscape. Developing robust emotion detection models for Darija is not only a technical challenge but also a crucial step toward preserving and understanding the linguistic and emotional nuances of Moroccan Arabic communication.

This paper presents the following contributions:

- **Multi-label Emotion Classification**: We develop[1] a multi-label emotion classification model for Moroccan Darija using FastText (Joulin et al., 2016), achieving **46.44%** accuracy in a low-resource setting.
- **Linguistic Adaptation**: We introduce a specialized preprocessing and modeling approach that handles the linguistic complexities of Moroccan Arabic, including code-switching, non-standard spellings, and dialectal variations.
- **Low-Resource NLP Insights**: We provide insights into the challenges of multi-label emotion detection in under-resourced languages,

[1]Our implementation is open-sourced at https://github.com/atlasia-ma/semeval-emotion-detection

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 34–37

highlighting the trade-offs between model accuracy and computational constraints.

2 Background

SemEval 2025 Task 11 (Muhammad et al., 2025b) focuses on emotion classification in Moroccan Arabic (Darija), requiring systems to categorize text into seven emotions: *anger, fear, joy, disgust, sadness, surprise*, and *neutral*. For example:

Input: "إليسا: كنعيش قصة حب جديدة ومغاديش نقول لكم معامن"
Label: `joy`

Moroccan Darija presents distinct challenges due to its lack of standardization, extensive dialectal variability, and frequent code-switching with French, Berber, and Spanish. These factors make traditional NLP techniques less effective, requiring specialized preprocessing and modeling strategies. Successfully addressing this task not only advances emotion detection for under-resourced languages but also enhances the accessibility and understanding of sentiment in Moroccan Arabic social media and digital communication.

3 System Overview

Our system leverages FastText (Joulin et al., 2016) for multi-label emotion classification, chosen for its efficiency and ability to handle dialectal variations. A key advantage of FastText is its subword-aware representations, which are particularly beneficial for dialectal Arabic, where words exhibit high morphological variability (Bojanowski et al., 2017). Additionally, its lightweight architecture makes it well-suited for resource-constrained environments, ensuring scalability for real-world applications. Another crucial factor is its robustness to out-of-vocabulary (OOV) words, a common issue in informal Moroccan darija text due to spelling variations, transliterations, and code-switching.

The system follows a structured pipeline, beginning with text preprocessing to clean and normalize input, addressing noise, non-standard spellings, and multilingual elements. The processed text is then used to train the FastText model, leveraging subword embeddings. Finally, during inference, emotion labels are predicted and post-processed to refine outputs, ensuring interpretability and better alignment with the nuances of Moroccan Darija. This approach effectively tackles the linguistic challenges of the task, making emotion detection in Darija more robust and scalable.

4 Data Preparation and Model Training

Our study is based on the SemEval 2025 Task 11 (of SemEval-2025 Task 11, 2025) dataset (Muhammad et al., 2025a), which focuses on emotion detection in Moroccan Arabic (Darija). The dataset is loaded using the Hugging Face `datasets` library, allowing for efficient and reproducible data handling. We specifically work with the Moroccan Arabic ('ary') subset, ensuring that our approach directly addresses the challenges posed by dialectal variation and code-switching in Darija.

4.1 Dataset Statistics

The dataset is relatively small compared to high-resource languages, highlighting the challenges of training robust emotion classification models for underrepresented languages. It consists of:

- **Training set:** 1,608 samples
- **Validation set:** 267 samples
- **Test set:** 812 samples

Each text sample is annotated with one or more emotion labels from seven categories: *anger, fear, joy, disgust, sadness, surprise*, and *neutral*. The multi-label nature of the task reflects the complexity of emotional expression, where a single utterance may convey overlapping sentiments.

4.2 Data Processing Pipeline

To effectively handle noisy and informal text, we employ a structured data processing pipeline using Python. The preprocessing pipeline is designed to normalize noisy user-generated text while preserving relevant linguistic information. The processing in Algorithm 1 was applied.

This approach ensures that irrelevant symbols and formatting inconsistencies are removed, improving the model's ability to generalize across different textual styles.

4.3 Label Processing

Emotion detection in Moroccan Darija is particularly challenging due to the subtle interplay between linguistic and cultural factors. Our multi-label classification framework captures overlapping emotions by assigning one or more labels from the following categories:

Algorithm 1 Tweet Preprocessing

Require: tweet: input string containing raw tweet text
Ensure: cleaned and preprocessed tweet string

```
function PreprocessTweet(tweet)
    // Remove @mentions (user handles)
    tweet ← REGEX_REPLACE(tweet, "@+", "")
    // Remove URLs
    tweet ← REGEX_REPLACE(tweet, "https?:§+|www§+", "")
    // Remove hashtags, including hashtagged words
    tweet ← REGEX_REPLACE(tweet, "+", "")
    // Normalize whitespace
    tweet ← REGEX_REPLACE(tweet, "+", " ")
    tweet ← TRIM(tweet)
    // Normalize punctuation (remove excessive spaces around punctuation)
    tweet ← REGEX_REPLACE(tweet, "*([.,!?;:])*", " ")
return tweet
end function
```

- **Primary emotions:** anger, fear, joy, disgust, sadness, surprise
- **Neutral category:** for texts that do not explicitly express emotion

Given the inherent subjectivity of emotion annotation, the model must learn to distinguish between subtle variations in sentiment while accounting for dialectal expressions, code-switching, and informal speech patterns. By structuring our label processing accordingly, we enhance the model's ability to capture the nuances of Moroccan Arabic emotional expression.

4.4 Model Configuration

The FastText model was trained with the optimized parameters outlined in Table 1.

Parameter	Value
Learning rate	0.40
Dimension	8
Window size	5
Epochs	100
Min word count	1
Character n-grams	3-6
Word n-grams	1
Loss function	One-vs-All (OVA)
Bucket size	2,247,558
Threads	7
Learning rate update rate	100
T value	0.0001

Table 1: FastText model configuration parameters

5 Results

5.1 Model Performance

Our system achieved a validation accuracy of **46.44%**, demonstrating the viability of using FastText for emotion classification in Moroccan Arabic. Despite the challenges of working with a low-resource language, this result serves as a promising baseline for future research and model improvements in the context of under-resourced dialectal languages.

5.2 Analysis of Errors

A thorough qualitative error analysis revealed several factors contributing to model misclassifications:

- **Handling of Code-Switched Text:** The model struggles with tweets containing multiple languages, particularly when sentiment-laden words are in French or Berber rather than Arabic.
- **Ambiguity Between Similar Emotions:** Emotions such as *anger* and *surprise*, or *fear* and *sadness*, share overlapping linguistic markers and contextual cues, making differentiation challenging.
- **Performance on Multi-Label Cases:** The model tends to focus on the most dominant emotion, neglecting secondary emotions when multiple labels are present in a sample.

For example, the following error case illustrates the model's difficulty in distinguishing between closely related emotions:

Input:
"بنكي فكازا ضرب فلوس صحيحة لكايان"
Predicted: anger
True label: surprise
Analysis: The model misclassified *surprise* as *anger*, likely due to the intense tone and overlapping intensity between

the two high-arousal emotions. This example underscores the challenges in capturing subtle emotional distinctions in informal, dialectal speech.

These insights point to opportunities for improving the model's handling of ambiguous emotions and code-switching, suggesting potential avenues for enhancing the model's robustness and accuracy in future iterations.

6 Conclusion and Future Work

Our emotion detection system for Moroccan Arabic faces several limitations, including difficulty handling code-switching between Arabic, French, and Berber, reduced performance on informal text variations, and challenges in capturing context-dependent emotional nuances. The current model architecture also struggles with Darija's complex morphology, and the evaluation is limited to accuracy, which does not fully reflect the model's performance.

Future work should focus on developing emotion lexicons specific to Moroccan Arabic, integrating Darija-specific linguistic features, and exploring hybrid approaches combining FastText with transformer models like AraBERT (Antoun et al., 2020). Cross-lingual transfer learning, larger and more diverse emotion datasets, and the adoption of advanced evaluation metrics will further improve the model's effectiveness and robustness.

Acknowledgments

We thank the SemEval 2025 Task 11 (of SemEval-2025 Task 11, 2025) organizers for providing the dataset and evaluation framework. We also acknowledge the Hugging Face team for their datasets library and the FastText(Joulin et al., 2016) team for their efficient implementation.

Irapuarani at SemEval-2025 Task 10: Evaluating Strategies Combining Small and Large Language Models for Multilingual Narrative Detection

Gabriel Assis, Lívia de Azevedo
João Vitor de Moraes, Laura Alvarenga and **Aline Paes**
Institute of Computing, Universidade Federal Fluminense, Niterói, RJ, Brazil
{*assisgabriel, liviaazevedosilva, joaovitormoraes, l_alvarenga*}*@id.uff.br*, *alinepaes@ic.uff.br*

Abstract

This paper presents the Irapuarani team's participation in SemEval-2025 Task 10, Subtask 2, which focuses on hierarchical multi-label classification of narratives from online news articles. We explored three distinct strategies: (1) a direct classification approach using a multilingual Small Language Model (SLM), disregarding the hierarchical structure; (2) a translation-based strategy where texts from multiple languages were translated into a single language using a Large Language Model (LLM), followed by classification with a monolingual SLM; and (3) a hybrid strategy leveraging an SLM to filter domains and an LLM to assign labels while accounting for the hierarchy. We conducted experiments on datasets in all available languages, namely Bulgarian, English, Hindi, Portuguese and Russian. Our results show that Strategy 2 is the most generalizable across languages, achieving test set rankings of 22st in English, 8th in Bulgarian, 9th in Portuguese, 10th in Russian, and 11th in Hindi.

1 Introduction

Trusting online content has become increasingly difficult due to the rise of misinformation, disinformation, deceptive content, and deliberate attempts at manipulation (Marwick and Lewis, 2017; Anderson, 2019). Not only is it more challenging to distinguish between credible information and fake news, but the sophisticated techniques used to shape perceptions can intensify conflicts and influence political opinions, potentially swaying voter behavior (Stanley, 2015; Rutheford, 2023). The vast amount of online disinformation highlights the urgent need for automated tools to identify such content (Piskorski et al., 2022).

Our research is centered on SemEval-2025 Task 10 (Piskorski et al., 2025), which addresses the Multilingual Characterization and Extraction of Narratives from Online News. Specifically, we focus on Subtask 2, which involves classifying narratives and sub-narratives within a two-level taxonomy. The primary objective of the task is to foster the development of classification methodologies capable of identifying narratives designed to manipulate readers, instantiated this year in the domains of Climate Change and the Ukraine-Russia War. Additionally, the task provides resources and enables participants to work in at least one of five languages: Bulgarian (BG), English (EN), Hindi (HI), Portuguese (PT), and Russian (RU). Our team, however, has chosen to evaluate our approaches across all available languages, aiming to achieve a multilingual analysis.

We evaluated three distinct methodologies leveraging both Small Language Models (SLMs) and Large Language Models (LLMs) to address this task. Moreover, we intend to assess whether the strategies exhibit generalizability across different languages, pursuing a general framework rather than a language-specific strategy. The approaches are as follows: (1) a direct classification method employing a multilingual SLM; (2) a translation-based approach, where texts in multiple languages were translated into a single target language using an LLM, followed by classification with a monolingual SLM; and (3) a hybrid strategy that integrated the strengths of both model types, utilizing an SLM for domain filtering and an LLM for hierarchical label assignment. Our experiments on the development set show that Strategy 2 is the most generalizable across languages among the approaches we evaluated, ranking 8th in Bulgarian, 9th in Portuguese, 10th in Russian, 11th in Hindi and 22st in English on the test set[1].

July 31 - August 1, 2025

creasingly leveraged the advanced capabilities of language models. Encoder-based SLMs have been successfully employed in narrative classification tasks. For instance, Coan et al. (2021) explored combining the RoBERTa model (Liu et al., 2019) with the traditional machine learning algorithm logistic regression, utilizing a taxonomy within the climate change domain. Similarly, Kotseva et al. (2023), working in the context of COVID-19, reported success with a fine-tuned BERT (Devlin et al., 2019) model for classifying narratives.

In addition to encoder-based SLMs, LLMs have also been applied in analyzing narratives and propaganda (Liu et al., 2025). Hasanain et al. (2024) experimented with GPT-4 for annotating spans of propaganda in Arabic news articles, highlighting the model's potential when provided with additional contextual information. Jones (2024) evaluated GPT-3.5-turbo's performance in identifying up to 18 possible persuasion techniques in news articles, reporting promising results while noting that the model's ability to detect these techniques varied across some categories. Furthermore, Sprenkamp et al. (2023) compared the performance of RoBERTa with GPT-3 and GPT-4 for propaganda detection, emphasizing that GPT-4 ranked among the best-performing models, alongside RoBERTa.

Our work aims to evaluate strategies that integrate both SLMs and LLMs for classifying narratives in news articles within a multilingual context. Moreover, we aim to determine whether the strategies exhibit generalizability across different languages, pursuing a general approach over a narrowly specialized one. More details are in the sections below.

3 Background

The data utilized in this work was provided by the SemEval-2025 Task 10, which comprises a multilingual corpus of news articles. The corpus spans articles collected between 2022 and mid-2024, focusing on two primary topics: the Ukraine-Russia War and Climate Change. In the context of the addressed subtask, namely Subtask 2, the data also includes labels associated with Narrative Classification, structured into a two-level hierarchy dataset based on the provided annotations (Stefanovitch et al., 2025) . The Ukraine-Russia War (URW) domain includes 11 narrative labels and 38 sub-narratives. In contrast, the Climate Change (CC) domain has 10 narrative labels and 36 sub-narratives. The label *Other* can be used at the narrative level to indicate that a narrative does not match any available labels. It can also be paired with a narrative label to indicate that the corresponding sub-narrative does not fit the predefined categories. Finally, the task organizers pre-divided the set as outlined in Table 1.

Table 1: Distribution of the dataset across languages and its partitioning into train, dev and test sets.

Set	BG	EN	HI	PT	RU	Total
Train	401	400	366	400	348	1915
Dev	35	41	35	35	32	178
Test	100	101	99	100	60	460

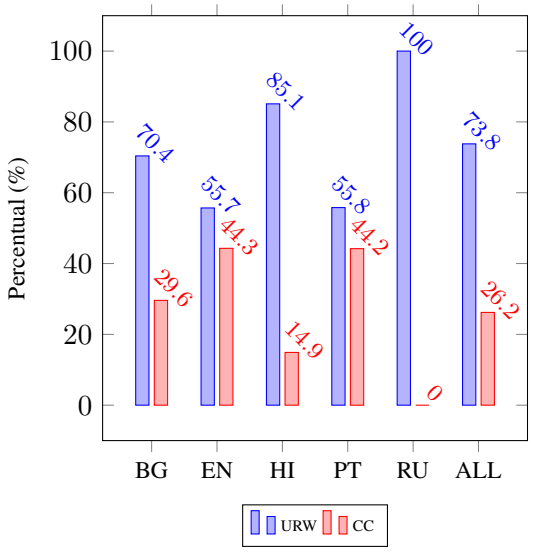

Figure 1: Distribution of the train set across domains.

The dataset exhibits an imbalance across domains, as illustrated in the Figure 1, which highlights the predominance of the URW class over the CC class both overall and across languages. EN and PT are the closest to achieving balance among the analyzed languages. However, even within these relatively balanced languages, a significant observation arises when examining the label taxonomy more closely: not all labels are represented across all languages. For instance, the label associated with the pair {narrative: *Amplifying Climate Fears*, subnarrative: *Whatever we do, it is already too late*} is entirely absent from the training instances in English. Despite this, our data analysis confirms that each label is present in the training set for at least one language. Consequently,

any approach aiming to comprehensively cover all labels across all languages, must address the label underrepresentation. Our approach is detailed in the next section.

4 System Overview

This section outlines the methodology employed for the multilabel classification of narratives within the task's two-level hierarchy. Based on the data characteristics previously described, we evaluated three strategies to ensure comprehensive label and language coverage. The **(a) Single-Model Strategy**, following Vasconcelos et al. (2024), uses a multilingual SLM to classify narratives without considering their hierarchical structure. The **(b) Translation Strategy** involves translating texts into a single target language with an LLM, followed by classification using a monolingual SLM. Lastly, the **(c) Hierarchical Strategy** applies a hybrid approach: an SLM first classifies texts into URW or CC domains, guiding an LLM to assign the final label based on the hierarchy.

4.1 Single-Model Strategy

This approach aims to evaluate the performance of a simplified solution to the problem, deliberately disregarding hierarchical structures (Vasconcelos et al., 2024). To achieve this, a label engineering process is applied, combining each narrative with its respective sub-narratives to create a single, flattened level of possible labels. Formally, let N represent a narrative and $S = \{S_1, S_2, \ldots, S_k\}$ represent its associated sub-narratives. For each pair (N, S_i), a new label is generated in the form N-S_i, where $i \in \{1, 2, \ldots, k\}$. Additionally, for each narrative N, a corresponding "Other" label N-$Other$ is created to represent cases where no specific sub-narrative is identified. Finally, a global label Other-Other is included to handle instances where neither the narrative nor its sub-narratives are recognized.

For the classification process, we employed the multilingual version of the DeBERTa (He et al., 2021a,b) model[2], with linear layers appended to the top of the model's language representation stack. For this approach, we leverage supervised fine-tuning, allowing the weights of both the language model and the newly added linear layers to be jointly optimized. The selection of this model was motivated by its effectiveness as a robust alternative for classification tasks, owing to its advanced ability to encode and represent contextual information (He et al., 2021a).

4.2 Translation Strategy

Given that the previously presented approach assigned the classifier the dual responsibility of handling both multilingual representation and multilabel classification within the hierarchy, the present approach seeks to decouple these two tasks. The goal is to determine whether such a separation leads to any observable improvement in performance.

To achieve this, non-English texts were first translated into English. The decision to translate into English was based on the extensive availability of state-of-the-art models and resources for this language (Joshi et al., 2020; Üstün et al., 2024), also enabling an evaluation of whether a monolingual model could outperform the multilingual approach used in the Strategy 4.1. For a more aligned comparison, a monolingual DeBERTa (He et al., 2021a,b) model[3] was selected, configured similarly to the previous strategy, also with labels presented in a flat structure.

We evaluated two models for the translation stage, namely the Aya Expanse 8B model (Dang et al., 2024) and GPT-4o-mini (Hurst et al., 2024), both with recognized multilingual capabilities. This selection aims to assess the potential impact of translation differences throughout the process by comparing a leading open-source, smaller-scale model with a top-tier proprietary model. Such a comparison enables informed implementation decisions based on the available resources. Lastly, the prompt used can be found in the Appendix A.

4.3 Hierarchical Strategy

In this strategy, we evaluate the performance of a larger, general-purpose LLM by directly assigning multilabel narrative labels. However, similar to Strategy 4.2, we also divide the task into two distinct stages, forming a two-level classification hierarchy (Zangari et al., 2024). In the first stage, we utilize an SLM — specifically, the same multilingual DeBERTa model employed in Strategy 4.1 —— as the basis for a classifier responsible for determining the domain of each article. This classifier predicts a label from the set {URW, CC, Other}, a ternary classification scheme derived through a label engineering process applied to the training

[2]https://huggingface.co/microsoft/mdeberta-v3-base

[3]https://huggingface.co/microsoft/deberta-v3-base

dataset. Importantly, when the classifier assigns the label "Other" to a given text, our framework automatically designates the corresponding sub-narrative label as "Other".

Next, for texts classified as either URW or CC, an LLM is employed with an appropriately designed prompt, guiding the model to provide both the narrative and the sub-narrative. In this context, the selected model was the state-of-the-art GPT-4o (Hurst et al., 2024), specifically its mini version, to address cost-related constraints. This prior domain classification allows for a prompt that is not excessively long, focusing on each specific domain and enhancing the model's performance, as LLMs often struggle with overly extended instructions (Levy et al., 2024). Conversely, we are aware that a hierarchical approach that deepens the hierarchy levels — for instance, with separate stages for classifying the narrative and the sub-narrative — may yield more accurate results. However, we focus on a broader level, as specializing in each narrative could result in a plethora of over-specialized models, which, in real-world scenarios, may reduce generalizability and require retraining with each new label added. The algorithm in Appendix B gives an overview of the hierarchical implementation.

The prompt used for classification with the LLM was refined through empirical testing, incorporating two key instructions: *"In the following text, identify the core narrative that aligns with the author's perspective"* and *"If multiple narratives are equally significant, include them all."* The first instruction was placed at the beginning of the prompt, as experimental results indicated that, in its absence, the model frequently assigned indirect labels to texts, failing to distinguish between internal quotations and the overarching narrative. For example, a text might cite statements from an activist with the intent to discredit them, in which case the appropriate label would be *"Ad hominem attacks on key activists."* However, error inspections revealed that the model occasionally misclassified such texts, interpreting the activist's statements as representative of the main narrative, thereby diverging from the intended annotations. Appendix C presents an example of the incorrect classifications observed. Furthermore, the second directive was appended at the end of the prompt to mitigate the overly restrictive effect of the first instruction. Preliminary experiments demonstrated that relying solely on the first instruction led the model to apply excessively narrow labels. The complete prompts for the URW and CC domains are provided in Appendices D and E, respectively.

5 Experimental Setup

Implementation Details The proposed solution was developed utilizing the Hugging Face Transformers (Wolf et al., 2020) and scikit-learn (Pedregosa et al., 2011) libraries, using the *MultiLabelBinarizer* approach. All experiments were conducted on two Nvidia RTX 4090 GPUs, each featuring 24GB of VRAM.

Models Hyperparameters For the classification with the DeBERTa models, the following hyperparameters were employed: *batch size* = 16, *number of epochs* = 10, *maximum sequence length* = 512, *learning rate* = 2×10^{-5}, and *weight decay* = 0.01. Predictions were made using a threshold of 0.8 for logits, considering the number of labels and the multi-label classification setup. For classification with GPT4o-mini, the configuration included a *temperature* of 0.7, *top-p* = 0.95, and *maximum completion tokens* = 200. Lastly, for translation, the parameters were set as follows: *max new tokens* = 4000, *do sample* = True, *temperature* = 0.8, and *top-p* = 0.95, Lastly, all random seeds were set to 42 wherever applicable. The training and inference parameters were selected based on a 5-fold cross-validation performed on the training set.

Evaluation Metrics The evaluation metrics employed are based on the sample-level F1 score, with an emphasis on $F1_{Samples}$, which focuses on sub-narratives, rather than $F1_{Coarse}$, which targets the narratives-level, in alignment with the official task directives.

6 Results

This section aims to analyze the proposed strategies. Table 2 presents, for each language, the results of each proposed configuration on the development set, alongside the baseline provided by the Task organizers. Additionally, for the test set, the table displays the results of the final submitted strategy, the baseline, and the best overall performance achieved by any team for each language. Notably, our analysis focuses on the $F1_{Samples}$ score, as it is the main metric adopted for the Subtask.

First, all proposed strategies outperform the baseline. Notably, the most basic approach – the Single

Model Strategy – achieves its best results in English and Bulgarian, while ranking among the least effective solutions for the other languages. This pattern may indicate that the need for a single classifier to adapt simultaneously to language representation and classification itself during training may hinder its ability to generalize performance across languages.

On the other hand, the Translation-Based Strategy yields the best results among the proposed approaches for Portuguese (with translations generated by the Aya model), as well as Bulgarian and Hindi (with translations generated by the GPT-4o-mini model). Additionally, the Aya-translated approach secures second place in Hindi, while the GPT-based variant achieves this same ranking for Portuguese and Russian. Notably, translation-based strategies do not exhibit abysmal performance in any language — unlike, for example, the Single Model Strategy in Hindi. This observation suggests that translation-based approaches may enhance generalization by allowing the final classifier to focus solely on the classification, rather than concurrently handling multilingual representation. Regarding the performance differences between the Aya and GPT-4o-mini translations, a more detailed analysis of their pre-training corpora could offer valuable insights. However, such resources are not publicly available for the GPT model.

Despite achieving the best performance in English and Russian, the Hierarchical Strategy demonstrated poor Portuguese results and was outperformed by the translation-based strategies in other languages. An analysis of the first stage of the Hierarchical Strategy on the validation set (as test labels are not available) suggests that the results may be influenced by a specific characteristic in Portuguese data. Table 3 reveals a high concentration of documents from the *Climate Change* domain in Portuguese, a pattern not shared by any other language (Appendix F provides the corresponding matrices for the remaining languages).

(a) Russian

True / Pred.	URW	CC	Other
URW	16	1	11
CC	0	0	0
Other	0	0	4

(b) Portuguese

True / Pred.	URW	CC	Other
URW	8	0	1
CC	0	25	0
Other	1	0	0

Table 3: Confusion matrices for domain classification in Russian and Portuguese on the validation set.

The table also shows performance for Russian, which, despite exhibiting a higher number of absolute classification errors compared to Portuguese, yielded better results in the final classification stage, as shown in Table 2. Though seemingly counter-intuitive, this observation indicates that the LLM-based final classification struggled specifically with the *Climate Change* domain in Portuguese. In contrast, Russian domain predictions related to the *Ukraine–Russia War* were more frequently classified correctly in the second stage of the Hierarchical Strategy. Additionally, we attribute the poor domain classification performance for Russian to the extreme class imbalance in the data for that language, as previously shown in Figure 1. This indicates the potential of future work to examine

intra-domain classification behavior in multilingual scenarios more closely.

Consequently, aiming to evaluate the most generalizable approach, our final submission was based on the Translation-Based Strategy utilizing the GPT-4o-mini model. In the test set, the submitted approach once again outperformed the baseline across all languages, consistently avoiding any notably poor results in any of them. This further reinforces its potential for generalization. Future research may also consider a qualitative evaluation of the translations, which we regard as beyond the scope of the current work.

7 Conclusion

This work addresses SemEval-2025 Task 10 and evaluates three distinct strategies for multilabel classification within a two-level taxonomy of narratives and sub-narratives in online news. Our results indicate that the approach relying solely on a multilingual SLM to classify texts in multiple languages failed to generalize its strong performance in languages such as English to other linguistic contexts. Similarly, the strategy that employed a multilingual SLM as a domain filter and an LLM to assign the final labels achieved the best result on the development set for English but performed poorly in languages such as Portuguese, also highlighting a generalization gap. Conversely, the approach that translated all texts into English and utilized a monolingual SLM for classification demonstrated more consistent and generalizable results across languages, frequently ranking as the best or second-best performing strategy among those we analyzed.

Future work may explore the evaluation of additional combinations of SLMs and LLMs to identify the most effective pairings for this task. Furthermore, the Translation-Based Approach, which demonstrated robust generalization, could be extended by translating texts into target languages other than English. This would enable a more comprehensive analysis of the impact of the translation step on classification performance across diverse linguistic contexts.

Limitations

The translations were conducted exclusively with English as the target language. While this decision was made to ensure the feasibility of the experiments, it may have hindered the evaluation of culturally specific and critical nuances inherent to each language. Another notable limitation of this study is the lack of in-depth qualitative analyses of the predictions and translations generated by the proposed approaches. While potentially complex due to the large number of possible labels and the high degree of subjectivity involved — and, in the specific context of this work, also combined with the time limit of the task — such analyses may be important, as they could offer valuable insights into narrative detection and potentially reveal manipulation strategies.

Ethics Statement

Language Bias The Translation-based strategy, while necessary for multilingual analysis, may introduce biases due to potential discrepancies between translated and naturally occurring language. Additionally, the underrepresentation of labels in non-English languages and the inherent bias towards English in terms of available models and resources could compromise the fairness and effectiveness of our methodologies.

Misclassification The politically sensitive nature of the topics — climate change and the Ukraine-Russia war — increases the risks associated with misclassification. Misidentifying disinformation could inadvertently amplify its spread, while overzealous identification could stifle legitimate discourse and censor genuine activism. Ongoing collaboration with linguists and social scientists could better capture the complexities of human language in social interaction and regular reevaluation of the narratives and labels in the corpus could be essential to ensure that our research remains relevant and ethically sound.

C Illustrative Case of Incorrect Classification by GPT4o-mini

The excerpt below is taken from one of the documents made available in the task dataset. While the human annotators labeled it as *"Criticism of climate movement: Ad hominem attacks on key activists"*, our early experiments showed that the language model assigned the labels *"Amplifying Climate Fears: Amplifying existing fears of global warming"* and *"Criticism of climate movement: Climate movement is alarmist"*. Although these labels are semantically plausible — particularly

considering the quotation attributed to Greta Thunberg within the text — we conjecture that the language model failed to interpret the pragmatic function of the indirect citation. Specifically, it may not have recognized that the quote was employed not to convey the activist's message, but rather to undermine her credibility, as noted by human annotators. Therefore, enhancing models' capacity for pragmatic understanding may constitute a valuable direction for future research on narrative classification and persuasive discourse identification.

> " [...] '*A top climate scientist is warning that climate change will wipe out all of humanity unless we stop using fossil fuels over the next five years.*'
>
> Thunberg shared a now-deleted Grit Post article by Scott Alden citing a prediction from James Anderson [...]' "

D URW Classification Prompt

IN THE FOLLOWING TEXT, IDENTIFY THE CORE NARRATIVE THAT ALIGNS WITH THE AUTHOR'S PERSPECTIVE. CLASSIFY IT BASED ON THE OPTIONS IN THE LIST BELOW. IF THE NARRATIVE IN THE TEXT FALLS OUTSIDE THE LIST, ANSWER "OTHER".

OPTIONS LIST (NARRATIVES AND SUBNARRATIVES)
BLAMING THE WAR ON OTHERS
- UKRAINE IS THE AGGRESSOR
- THE WEST ARE THE AGGRESSORS
- OTHER

DISCREDITING UKRAINE
- REWRITING UKRAINE'S HISTORY
- DISCREDITING UKRAINIAN NATION AND SOCIETY
- DISCREDITING UKRAINIAN MILITARY
- DISCREDITING UKRAINIAN GOVERNMENT AND OFFICIALS AND POLICIES
- UKRAINE IS A PUPPET OF THE WEST
- UKRAINE IS A HUB FOR CRIMINAL ACTIVITIES
- UKRAINE IS ASSOCIATED WITH NAZISM
- SITUATION IN UKRAINE IS HOPELESS
- OTHER

RUSSIA IS THE VICTIM
- THE WEST IS RUSSOPHOBIC
- RUSSIA ACTIONS IN UKRAINE ARE ONLY SELF-DEFENCE
- UA IS ANTI-RU EXTREMISTS
- OTHER

PRAISE OF RUSSIA
- PRAISE OF RUSSIAN MILITARY MIGHT
- PRAISE OF RUSSIAN PRESIDENT VLADIMIR PUTIN
- RUSSIA IS A GUARANTOR OF PEACE AND PROSPERITY
- RUSSIA HAS INTERNATIONAL SUPPORT FROM A NUMBER OF COUNTRIES AND PEOPLE
- RUSSIAN INVASION HAS STRONG NATIONAL SUPPORT
- OTHER

OVERPRAISING THE WEST
- NATO WILL DESTROY RUSSIA
- THE WEST BELONGS IN THE RIGHT SIDE OF HISTORY
- THE WEST HAS THE STRONGEST INTERNATIONAL SUPPORT
- OTHER

SPECULATING WAR OUTCOMES
- RUSSIAN ARMY IS COLLAPSING
- RUSSIAN ARMY WILL LOSE ALL THE OCCUPIED TERRITORIES
- UKRAINIAN ARMY IS COLLAPSING
- OTHER

DISCREDITING THE WEST, DIPLOMACY
- THE EU IS DIVIDED
- THE WEST IS WEAK
- THE WEST IS OVERREACTING
- THE WEST DOES NOT CARE ABOUT UKRAINE, ONLY ABOUT ITS INTERESTS
- DIPLOMACY DOES/WILL NOT WORK
- WEST IS TIRED OF UKRAINE
- OTHER

NEGATIVE CONSEQUENCES FOR THE WEST
- SANCTIONS IMPOSED BY WESTERN COUNTRIES WILL BACKFIRE
- THE CONFLICT WILL INCREASE THE UKRAINIAN REFUGEE FLOWS TO EUROPE
- OTHER

DISTRUST TOWARDS MEDIA
- WESTERN MEDIA IS AN INSTRUMENT OF PROPAGANDA
- UKRAINIAN MEDIA CANNOT BE TRUSTED
- OTHER

AMPLIFYING WAR-RELATED FEARS
- BY CONTINUING THE WAR WE RISK WWIII
- RUSSIA WILL ALSO ATTACK OTHER COUNTRIES
- THERE IS A REAL POSSIBILITY THAT NUCLEAR WEAPONS WILL BE EMPLOYED
- NATO SHOULD/WILL DIRECTLY INTERVENE

Text
{text}

Provide only the **most** relevant narratives that best fit the text's intent.
If multiple narratives are equally significant, include them all.
Answer **only** with the classifications and always include narratives and subnarratives.

E Climate Change Classification Prompt

In the following text, identify the core narrative that aligns with the author's perspective. Classify it based on the options in the list below. If the narrative in the text falls outside the list, answer "Other".

Options List (Narratives and subnarratives)
Criticism of climate policies
- Climate policies are ineffective
- Climate policies have negative impact on the economy
- Climate policies are only for profit
- Other

Criticism of institutions and authorities
- Criticism of the EU
- Criticism of international entities
- Criticism of national governments
- Criticism of political organizations and figures
- Other

Climate change is beneficial
- CO2 is beneficial
- Temperature increase is beneficial
- Other

Downplaying climate change
- Climate cycles are natural
- Weather suggests the trend is global cooling
- Temperature increase does not have significant impact
- CO2 concentrations are too small to have an impact
- Human activities do not impact climate change
- Ice is not melting
- Sea levels are not rising
- Humans and nature will adapt to the changes
- Other

Questioning the measurements and science
- Methodologies/metrics used are unreliable/faulty
- Data shows no temperature increase
- Greenhouse effect/carbon dioxide do not drive climate change
- Scientific community is unreliable
- Other

Criticism of climate movement
- Climate movement is alarmist
- Climate movement is corrupt
- Ad hominem attacks on key activists
- Other

Controversy about green technologies
- Renewable energy is dangerous
- Renewable energy is unreliable
- Renewable energy is costly
- Nuclear energy is not climate friendly
- Other

Hidden plots by secret schemes of powerful groups
- Blaming global elites
- Climate agenda has hidden motives
- Other

Amplifying Climate Fears
- Earth will be uninhabitable soon
- Amplifying existing fears of global warming
- Doomsday scenarios for humans
- Whatever we do it is already too late
- Other

Green policies are geopolitical instruments
- Climate-related international relations are abusive/exploitative
- Green activities are a form of neo-colonialism
- Other

Text
{text}

Provide only the most relevant narratives that best fit the text's intent.
If multiple narratives are equally significant, include them all.

Domain_adaptation at SemEval-2025 Task 11: Adversarial Domain Adaptation for Text-based Emotion Recognition

Mikhail Lepekhin
MIPT / Moscow
lepehin.mn@phystech.edu

Serge Sharoff
University of Leeds / UK
s.sharoff@leeds.ac.uk

Abstract

We report our participation in the SemEval-2025 shared task on classification of emotions and describe our solutions using BERT-based models and their modifications. We participate in tracks A and B. We apply and compare base XLM-RoBERTa, Adversarial Domain Adaptation (ADA) on the XLM-RoBERTa with the length of the text as the adversarial feature. As a simple baseline, we also use a Logistic Regression based on tf-idf features. We show that using ADA increases the f1 macro score in low-resource languages and in shorter texts. Besides, we describe our approach to track A where we use ADA with the text language as the confounder. We show that for some languages it helps to improve the f1 score. In all the tracks, we work with the following languages: Russian, Amharic, Algerian Arabic, German, English, Spanish, Hausa, Brasilian Portuguese, Romanian, Ukrainian.

1 Introduction

Non-topical text classification includes a wide range of tasks aimed at predicting a text property that is not connected directly to a text topic. For example, predicting a text style, politeness , difficulty level, the age or the first language of its author, etc. It is applied in many areas such as information retrieval, language teaching, or linguistic research.

(Devlin et al., 2018) introduced BERT – (Bidirectional Encoder Representations from Transformers), an efficient language representation model based on the Transformer architecture (Vaswani et al., 2017). It achieves state-of-the-art results for various NLP tasks, including text classification. XLM-RoBERTa (Conneau et al., 2019) is an improved variant of BERT. It has a similar architecture but uses a bigger and more genre-diverse corpus based on Common Crawl (instead of Wikipedia for the multilingual BERT). Therefore, we choose XLM-RoBERTa as the classifier for the experiments in our research.

One of the most significant problems in text classification is distribution shifts, such as topical shifts, shifts in text length, or the distribution of languages. For example, (Petrenz and Webber, 2010) shows the effect of topical shifts for genre classification. If a topic is more frequent in the training corpus for a given target class, then a classifier tends to predict the target class by the keywords of the topic. This causes numerous unreasonable mistakes in text classification.

One of the algorithms that could be helpful to mitigate topical shifts is Adversarial Domain Adaptation (ADA) (Ganin et al., 2016). It uses an adversarial loss to make the classification features less dependent on the domain of the training data. It supposes training a feature extractor, a domain discriminator, and a target classifier. The feature extractor and target classifier are trained to achieve high accuracy for the classification of the target class and at the same time deceive the domain discriminator to make it impossible to differentiate two domains. In contrast, the domain discriminator intends to classify the text domain correctly.

There was a lot of research on text-based emotion classification in recent years. Some of them use classical ML approaches. For example, (Liu et al., 2023) adjust the Multi-label K-Nearest Neighbors (MLkNN) classifier to allow iterative corrections of the multi-label emotion classification.

In this study, we report our participation in SemEval 2025 task 11 (Muhammad et al., 2025b). We train XLM-RoBERTa base and try to improve its performance with addition of Adversarial Domain Adaptation (Ganin et al., 2016).

2 Related Work

Non-topical text classification is not a new task. For example, numerous attempts have appeared to build a precise classifier of genres based on various architectures from linear discrimination (Karlgren

and Cutting, 1994) to SVM (Sharoff et al., 2010) and recurrent neural networks (Kunilovskaya and Sharoff, 2019).

Most state-of-the art results in the domain of NLP were achieved with transformer-based architectures. (Sun et al., 2019a) gives important advices on how to apply the BERT architecture to the task of text classification. We use the recommended values of learning rate and the number of epochs in our study.

The task of emotion classification is also well-known and widely researched. For example, in (Rasouli and Kiani, 2023) the authors apply a BERT-based transfer learning approach to achieve high accuracy on the short Persian texts. However, their study does not include usage and analysis of the adversarial methods in contrast to ours.

(Zou et al., 2021) modify Adversarial Domain Adaptation (ADA) and present a novel approach for domain adaptation. The methods are applied and compared on the tasks of sentiment analysis and yes-no binary questino answering. Although their results surpasses other techniques compared in their study, the authors mostly work with much longer texts then we do in our study. Regarding the shortness of the texts provided in the SemEval 2025 shared task 11, it cannot be guaranteed that the novel methods are able to significantly overpass the simplier ones.

3 Data Analysis

Before making any experiments, we look at the given data to mention some patterns which could be helpful for building robust classifiers.

All the data we use in our study is provided by the SemEval 2025 shared task 11 organizers (Muhammad et al., 2025a). The dev and test data contain a wide range of languages including the rare ones. For example, it contains the Ethiopian languages (Amharic, Oromo, Somali, and Tigrinya) (Belay et al., 2025).

emotion	intensity			
	0	1	2	3
anger	74.2	14.2	8.1	1.7
disgust	70.1	9.3	6.3	1.5
fear	82.8	7.7	6.0	1.7
joy	77.1	8.6	10.2	2.2
sadness	77.5	10.9	7.2	2.5
surprise	84.5	8.3	4.5	0.9

Table 2: Track B. Distribution of intensity for each emotion in the training data

lang	dev				test

Table 3: Track A. The number of words per text by language. Mean, median (or 50-percentile), 25- and 75-percentiles.

Table 1 represents the distribution of emotions across the training datasets for all the languages. It can be seen that the training dataset is sparse as it contains less then 20% positive examples for most pairs (language, emotion). Moreover, Table 1 shows that the languages are quite different in terms of the emotions provided for them in the training dataset.

Table 2 shows that the categories distribution in the train for the track B is even more sprarse than that for tracks A and C.

In Table 3, we compare the languages in terms of the distribution of length. It can be seen that the text length depends crucially on the language it comes from. In addition, it can be concluded that the texts in the training and test datasets are quite short and rarely contain more than 1-3 sentences. It causes an additional challenge to create a reliable text-based classifier.

Table 3 shows that the length distibution for train and test differ statistically noticeably. We perform a t-test and get that for Spanish this difference is statistically significant. Moreover, the languages are different in terms of the length distribution. Is could potentially force the classifiers to learn spurious relations between the text length and the emotion label.

4 Experiments

4.1 Methodology

ADA method belongs to Unsupervised Domain Adaptation (Ramponi and Plank, 2020). It shows promising performance in numerous NLP tasks in recent years (Ganin et al., 2016).

It usually consists of a shared feature extractor $f = G_f(x)$, a label predictor $y = G_y(x)$ and a domain discriminator $d = G_d(x)$. In addition to the standard full supervision learning process in the source domain, a minimax game is designed between the feature extractor f and the domain discriminator d. The domain discriminator d aims to distinguish the domain label between the source and target, while the feature extractor f is trained to deceive the feature discriminator d. This adversarial training process can be formulated as

$$\min_{G_f, G_y} L_y(X_s, Y_s) - \lambda L_f(X_s, X_t),$$

$$\min_{G_d} L_d(X_s, X_t),$$

where L_y is the cross-entropy loss for classification of the target label (in our study, it is the gender of the text author). L_f is the loss of the feature extractor. It denotes the cross-entropy of the classification of the text source. Both L_y and L_f are calculated and optimised with freezing of weights of the domain discriminator. L_d is similar to L_f. However, when it is calculated and optimised, the weights of the feature extractor and the label predictor are frozen.

In our study, we use simple discriminators and feature extractors consisting of single linear layers with an activation.

4.2 Description

We train 3 classifiers: Logistic Regression, XLM-RoBERTa, XLM-RoBERTa with Adversarial Domain Adaptation (ADA). All the experiments were carried out on Google Colab.

We use XLM-RoBERTa with base configuration (12-layer, 768-hidden, 12-heads, 125M parameters, xlm-roberta-base in HuggingFace) as a baseline for all the experiments. In all our experiments, we train the XLM-RoBERTa models for 3 epochs with learning rate=10^{-5}, since these values are proposed in (Sun et al., 2019b).

Logistic Regression is used as a simple baseline. We train it on the tf-idf features corresponding to 1-3 gramms. We take 16000 most relevant n gramms according to the chi2 statistics ($sklearn.feature\_selection.SelectKBest$).

Since the training datasets are small for each language, we train each model on all the languages available in the training dataset simultaneously.

Moreover, given the sparsity of the data, we make upsampling for every Logistic Regression classifier we train. Upsampling is not a perfect solution. However, Logistic Regression tends to errode to a constantly zero-predicting classifier without it. Besides, we train a separate Logistic Regression for each emotion.

Table 5: Track B. The f1 macro score of the XLM-R on the dev and test datasets

4.3 Results

Table 4 shows the results of our experiments. We can see that for most big languages (English, Russian, Chinese, Ukrainian, German, Spanish, Portuguese), XLM-R without domain adaptation attains a higher f1 macro score. However, the adversarial domain adaptation technique with the length of the text as the confounder helps to attain much better metrics for small languages. For instance, it can be seen for Amkharian and Hausa.

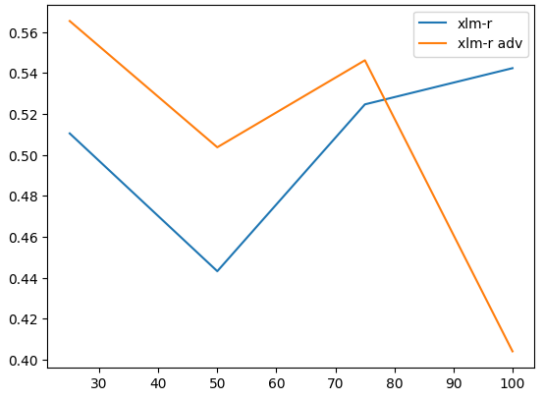

Figure 1: Dependence of the f1 macro score of the base XLM-RoBERTa and the XLM-RoBERTa with ADA on the text length.

After the official deadline for the competition, we also try to use the language as a confounder. Our intuition is that it helps to make the training process more language agnostic. Table 4 shows that this approach manages to beat the base XLM-RoBERTa on most languages for which the training data is available. In track B Table 5, we apply a base XLM-RoBERTa and Logistic Regression based on tf-idf features. We show that the Logistic Regression performs better on most languages on the dev dataset, whilst XLM-RoBERTa attains a higher f1 score for most languages on the test dataset. We suppose it is caused by some sort of distribution shifts between the dev and test datasets.

Besides, the adversarial approach shows Figure 1 significant increase in f1 macro score on the texts of lower length. It shows usability of the adversarial approach and its robustness in case of length distribution shifts.

5 Conclusions and future research

We show that:

1. Using adversarial loss significantly improves the f1 macro score for the low-resource languages

2. Adversarial loss helps to improve the f1 score on the texts with lower length.

3. The metrics for logistic regression are comparable to those for the XLM-RoBERTa models.

Adversarial methods are potentially helpful to achieve higher quality in a wide range of tasks and to combat various distribution shifts, including classification of emotions. However, in order to utilize the whole capacity of the adversarial methods, it would be helpful to use models with a higher number of parameters. For example, best results in the SemEval-2025 Task11 competition (Muhammad et al., 2025b) were achieved using LLMs. However, due to limited computing resources, we did not have the opportunity to fine-tune large language models using the adversarial methods.

Therefore, there is still a room for improvement. In the future, using ADA in conjunction with large language models could make it possible to obtain much more accurate and reliable classifiers. In addition, it might be useful to try more modern competitive domain adaptation methods, such as Energy-based Adversarial Domain Adaptation (EADA).

IRNLP at SemEval-2025 Task 10: Multilingual Narrative Characterization and Classification

Panagiotis Kiousis
Athens University of Economics and Business
and Archimedes, Athena Research Center, Greece
pckiousis@gmail.com

Abstract

This paper presents the IRNLP system for Subtask 2 of SemEval-2025 Task 10, which addresses multilingual narrative classification. The approach utilizes datasets in Hindi, English, and Russian, applying transformer-based models fine-tuned through repeated stratified k-fold validation. The system performs joint detection of narratives and subnarratives using multi-label classification techniques. Extensive ablation studies, in-depth error analysis, and a detailed discussion of model architecture and training procedures are included. The implementation is publicly available [1] to support reproducibility and future research.

1 Introduction

Narratives play a pivotal role in shaping public opinion and framing news reporting, often embedding persuasive messaging or ideological intent. Automatically detecting such narratives is a complex task, particularly in multilingual settings, due to semantic ambiguity, class imbalance, and cross-linguistic variability. Subtask 2 of SemEval-2025 Task 10 addresses this challenge by focusing on the classification of narratives and subnarratives in news articles across five languages.

This paper presents the IRNLP system, developed to address this challenge using multilingual transformer-based models. The system was trained on Hindi, English, and Russian datasets, leveraging repeated stratified k-fold validation to ensure robust evaluation. Unlike standard approaches that rely on single-split validation, the use of repeated k-fold increases generalizability and minimizes overfitting. This work also contributes insights through error analysis and controlled ablation studies.

2 Background and Task Overview

SemEval-2025 Task 10 includes three subtasks; Subtask 2, addressed in this paper, requires identifying the presence of narrative and subnarrative categories in online news articles in five languages: English, Hindi, Russian, Portuguese, and Bulgarian. The task is structured as a multi-label classification problem. Each article may belong to multiple coarse- or fine-grained narrative categories. Models are evaluated using both macro F1-score and F1 samples to capture performance across both label and instance levels.

3 Related Work

Previous work on fine-grained propaganda detection by Da San Martino et al. (2019) introduced structured annotation strategies for identifying persuasive techniques. This laid the groundwork for related tasks such as narrative extraction and classification. Multilingual transformer models like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and XLM-RoBERTa (Conneau et al., 2019) have demonstrated strong performance across tasks such as sentiment analysis, named entity recognition, and text classification. Hugging Face's Transformers library (Wolf et al., 2020) provides scalable implementations of these models and facilitates multilingual fine-tuning.

Few studies have focused explicitly on narrative modeling in multilingual contexts. Work in stance detection and argument mining has highlighted the importance of modeling discursive structures, but the integration of coarse and fine narrative labels in low-resource settings remains under-explored. The IRNLP system aims to fill this gap using repeated validation and tailored preprocessing for each language.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 54–57

4 System Description

4.1 Preprocessing and Data Preparation

Each dataset underwent language-specific preprocessing. Raw articles were parsed, and narrative annotations were mapped to binary multi-label vectors. Tokenization was handled using the pretrained tokenizer of each transformer backbone. Language-specific augmentations were applied when necessary, including sentence shuffling and synonym replacement. Heuristics were used to correct missing or uncertain labels when metadata provided indirect signals.

4.2 Model Architecture

The IRNLP system used XLM-RoBERTa-base and XLM-RoBERTa-large as the primary backbones. In language-specific experiments, NeuralMind BERT was used for Portuguese and DeepPavlov BERT for Bulgarian. A dense output layer with sigmoid activation computed logits for each narrative label. Loss was calculated using binary cross-entropy.

4.3 Training Strategy

To increase generalization, we adopted a repeated stratified k-fold validation strategy (5 folds, 2 repetitions). This approach allowed each data sample to appear in multiple training and validation splits. Training was conducted on NVIDIA A100 GPU with FP16 precision, using AdamW optimizer (learning rate 5e-5, weight decay 0.01). Gradient accumulation was used to simulate larger batch sizes.

5 Ablation Study

The impact of major design choices was quantified in ablation experiments. Table 1 presents comparative F1 samples for English and Hindi.

Variant	English (F1)	Hindi (F1)
XLM-R Large (baseline)	0.287	0.515
No k-fold validation	0.238	0.472
Unbalanced batches	0.245	0.489

Table 1: Ablation results: F1 samples for key variants.

The ablation results highlight the importance of repeated k-fold validation in preventing overfitting. Removing this step led to a drop in F1 samples (from 0.515 to 0.472 in Hindi). Similarly, unbalanced mini-batches had a negative impact, likely due to dominance of majority labels during optimization. These findings confirm that both evaluation strategy and training stability significantly influence model effectiveness in low-resource settings.

6 Experiments and Results

6.1 Evaluation Metrics

The task uses two main metrics: macro F1-score and F1 samples. While macro F1 considers label-level performance, F1 samples captures instance-level accuracy and is prioritized for Subtask 2.

6.2 Performance Comparison

Language	F1 macro	Macro SD	F1 samples	Sample SD
English	0.516	0.402	0.287	0.452
Hindi	0.375	0.467	0.515	0.500
Russian	0.537	0.351	0.116	0.252

Table 2: Performance on test sets.

6.3 Overall Observations

The IRNLP system consistently outperformed the baseline across all three evaluated languages—Hindi, English, and Russian—in both macro F1 (coarse) and F1 samples metrics. The standard deviations further revealed the variability in performance, offering insights into the model's stability. The largest gains were observed in Hindi (F1 samples: 0.515), while the Russian dataset, despite achieving the highest macro F1 (0.537), exhibited comparatively lower instance-level accuracy.

6.3.1 Hindi Test Set

- **F1 macro (coarse):** The system achieved a score of 0.375, significantly higher than the baseline's 0.081. This indicates better generalization across coarse-grained narrative categories.
- **F1 samples:** A notable score of 0.515 was obtained, whereas the baseline failed entirely (0.000). This gap highlights the model's strong predictive capacity on the instance level.
- **Standard Deviations:** The model showed higher variability (0.467 vs. 0.260 for macro F1) compared to the baseline, suggesting fluctuations in predictions across samples.

- **Implications:** These results indicate that cross-linguistic patterns in Hindi are effectively captured. However, the relatively high standard deviation suggests that model consistency could benefit from further fine-tuning or ensembling techniques.

6.3.2 English Test Set

- **F1 macro (coarse):** The model achieved 0.516, substantially outperforming the baseline's 0.030.
- **F1 samples:** A score of 0.287 was recorded, compared to the baseline's 0.013, reflecting the system's improved ability to identify subnarratives.
- **Standard Deviations:** The IRNLP system showed a higher standard deviation (0.402) than the baseline (0.127), indicating greater variance possibly due to the complexity of English samples.
- **Implications:** While performance is notably higher than the baseline, the variability suggests potential benefits from additional regularization or calibration.

6.3.3 Russian Test Set

- **F1 macro (coarse):** The model achieved 0.537, a substantial increase from the baseline's 0.065.
- **F1 samples:** A lower score of 0.116 was observed, though still notably above the baseline's 0.008.
- **Standard Deviations:** The system demonstrated the lowest variance in macro F1 (0.351) compared to Hindi and English, suggesting more consistent predictions.
- **Implications:** These results point to strong macro-level performance in Russian. However, lower F1 samples performance indicates that fine-grained instance classification remains an area for improvement.

7 Error Analysis

The most common source of error was label imbalance, which led the model to favor dominant narrative types while underpredicting rare ones. This was particularly evident in the Hindi and Russian datasets, where certain subnarratives appeared infrequently. Additionally, semantic overlap between similar categories—such as *foreign conspiracy* and *global threat*—confused the model, often resulting in misclassification between conceptually adjacent classes.

Another recurring issue stemmed from the multi-label nature of the task. In some cases, the model correctly identified a coarse-grained narrative but failed to capture accompanying subnarratives, reducing F1 samples scores. This was especially noticeable in Russian, where instance-level prediction was more challenging despite strong macro-level performance.

These findings suggest that future iterations of the system may benefit from more balanced sampling strategies, label smoothing, and architectures that better capture inter-label dependencies.

8 Conclusion

This paper presented the IRNLP system for Subtask 2 of SemEval-2025 Task 10. The system combined transformer models with repeated k-fold validation and language-sensitive preprocessing. Results demonstrated robust generalization in multilingual narrative classification. Future directions include incorporating contrastive loss, data augmentation for low-resource languages, and exploring semi-supervised training.

9 Limitations and Future Work

One limitation of the current system is its reliance on supervised data, which restricts performance in languages with fewer labeled examples. The model also assumes static label definitions, which may not generalize to evolving narrative framings in future news content. Additionally, extensive ensembling or hyperparameter search hadn't been performed due to time constraints.

Future work will explore semi-supervised learning techniques such as pseudo-labeling and contrastive learning. It is also planned to investigate cross-lingual transfer methods to improve performance in low-resource settings by leveraging multilingual embeddings and aligned fine-tuning. Finally, interpretability remains an open challenge in narrative classification, and future iterations will incorporate attention visualization to better understand model behavior.

Abstract

Narratives are a tool to propagate ideas that are sometimes well hidden in press articles. The SemEval-2025 Task 10 focuses on detecting and extracting such narratives in multiple languages. In this paper, we explore the capabilities of encoder-based language models to classify texts according to the narrative they contain. We show that multilingual encoders outperform monolingual models on this dataset, which is challenging due to the small number of samples per class per language. We perform additional experiments to measure the generalization of features in multilingual models to new languages.

1 Introduction

With the complexity of current geopolitical events, persuasion techniques have become less explicit in online content. Shared content often share a vision of the world used to interpret current events, which can influence the world vision of the readers. These are called narratives, and automatically detecting them has become a topic of interest for the machine learning community (Piskorski et al., 2025). Narratives can also be stated explicitly, but are more harmful when they are implicit in the text, like persuasion techniques are.

In this paper, we propose a multilingual approach (English, European Portuguese, Hindi, Bulgarian, and Russian) to identify whether or not a predefined narrative is present in a text and, if that is the case, what narrative it is. It is based on a standard multilingual encoder with a unique classification head for all narratives of the task.

We find that multilingual models perform better than individual monolingual models, using all of the provided data by the task organizers. While our proposed approach is not trying to be the best-performing (only in the top 50% of teams for only two languages), it relies on light language models that run on modest hardware and works the same for all languages.

2 Background

We propose a system for the Subtask 2: Narrative classification. The problem is framed as the following: given a text, identify if the text contains one, several, or none of the narratives defined by (Stefanovitch et al., 2025). The proposed narratives are part of a two-level taxonomy. However, we chose to ignore the additional information from the higher-level labels and focused directly on fine-grained narrative classification, which is the main focus of the task and on which the narrative used for the leaderboard is based. The problem is multi-class and multi-label, with 93 narratives to detect, some of which only appearing in some languages. The distribution of the number of occurrences for each class is given in Figure 1.

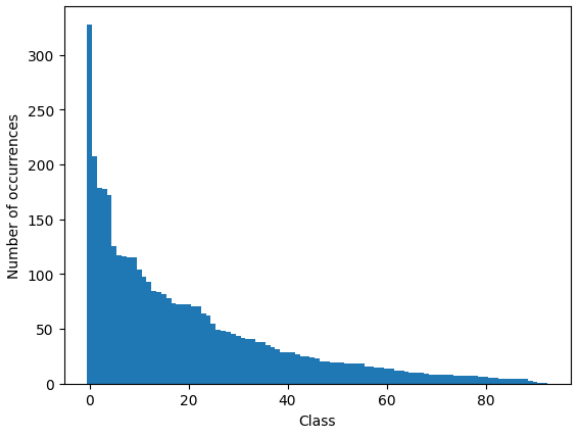

Figure 1: The number of occurrences by class, sorted in decreasing order. The distribution is unbalanced, with a median of only 23 occurrences per class.

The articles are the length of a regular news article, with about 410 words on average. They cover either news about climate change or the Ukraine-Russia war and exceptionally contain narratives

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 58–66

related to the two topics. Each article has an average of 2.3 labels and a median of 2 labels.

Given the limited number of samples per class in the dataset, we chose to work in a multilingual setting to maximize the number of samples seen by class during training.

Another challenge of the task is the multi-label constraint. Usual mono-label classification uses a Softmax activation function, outputting probabilities for each class, even when out-of-distribution. This is not possible for multi-label classification for which several labels can be applied to the same text, requiring additional steps.

3 System overview

Our proposed system is based on encoder language models trained solely on the provided data for the task. The choice of encoder models is motivated by their wide use in text classification tasks, especially for misinformation detection (Pelrine et al., 2021). The encoder produces an embedding that is then processed by a two-layer classification head with a sigmoid activation function and 94 output neurons, one for each class plus one for the absence of narrative.

During training, we consider that each neuron with an activation over 50% is activated. However, preliminary experiments showed that this setting could not be kept for inference, with all neurons activating at values below this threshold for almost all test samples. To solve this problem, we propose an adaptative threshold for multi-label classification based on the activation of the `No narrative` class neuron. If this neuron is the most activated, it means that the absence of a narrative is more plausible than the presence of any narrative seen during training. Each narrative corresponding to a neuron more activated than the `No narrative` neuron is considered present in the text. This neuron could be considered as the *neutral* or *control* class, determining if one of the training classes is found in the text. Figure 2 shows a global schema of the system.

One point of interest for our study is the multilingualism of model embeddings for narrative classification. Several types of state-of-the-art models were used:

- Multilingual models: experiments are done on models supporting all provided languages using all training data. For this type of models, we chose two models, the widely used XLM-RoBERTa-large[1] (Conneau et al., 2019) (561M parameters, noted RoBERTa in experiments) and mDeBERTa-v3-base[2] (He et al., 2021) (86M parameters, noted mDeBERTa in experiments).

- Monolingual models: we chose ModernBERT[3] (Warner et al., 2024) for English, Albertina PT-PT[4] (Rodrigues et al., 2023) for Portuguese, MuRIL[5] (Khanuja et al., 2021) for Hindi, and for lack of strictly monolingual models, SlavicBERT[6] (Arkhipov et al., 2019) for Bulgarian and Russian. These models were chosen as they are the state-of-the-art specialized monolingual models for each language at the time of writing.

Monolingual models are trained with the corresponding language data. Multilingual models were used for two types of experiments:

- A first one with all training data, to measure if using samples from multiple languages improves performance over using only one language.

- A second one with all training data except one language. This will allow us to measure how narrative embeddings transfer to new languages and if models trained with additional data can function in new languages. The five provided languages are a good opportunity for this experiment, as they cover three different alphabets (Latin, Hindi, and Cyrillic).

4 Experimental setup

The given train data is split in two with a random 80/20 split. Models are trained on the first 80% and evaluated on the remaining 20% at the end of each epoch. Models are trained for a maximum of 100 epochs, and an early stopping strategy with a patience of 5 is used. If the F1 score on the fine narratives on the 20% of data does not improve for

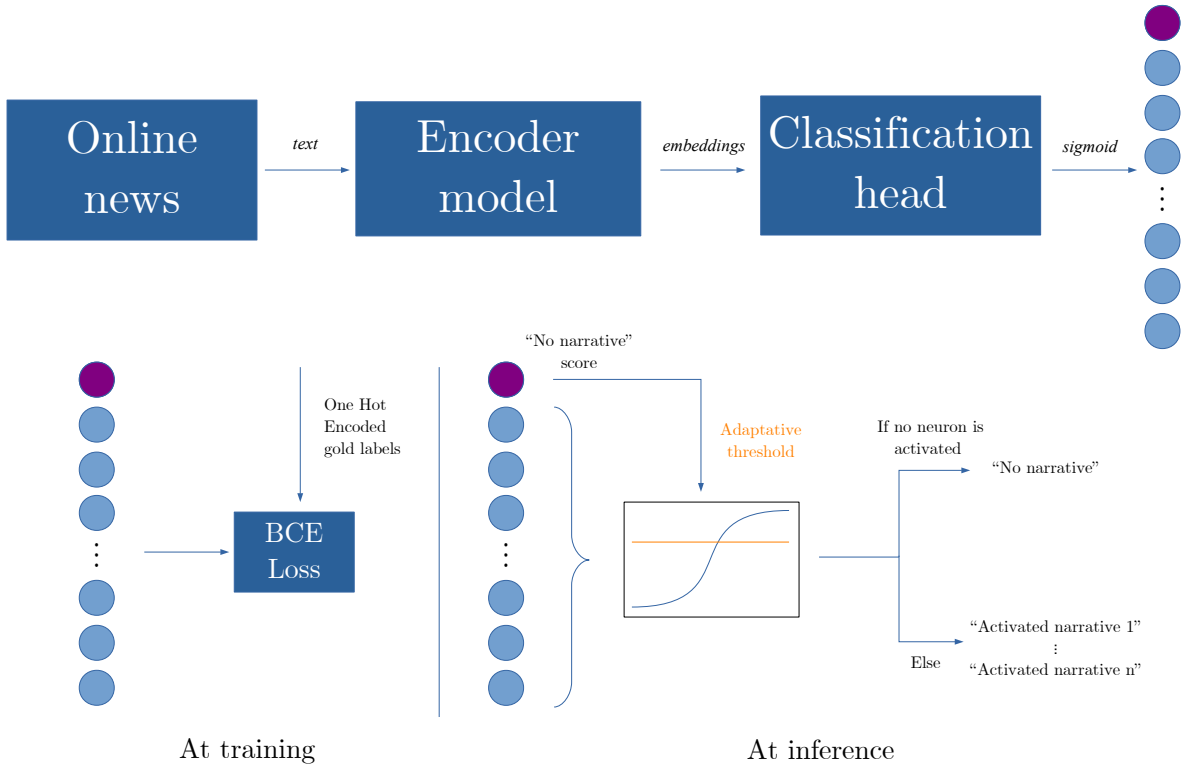

Figure 2: The global system architecture and label computation.

five epochs, the model is restored to its state with the best F1 score. The dev data has been used for evaluation, and the reported results are computed for this split. The final models used for the test submission are chosen per language, based on the configuration giving the best F1 score on the fine narratives on the dev split.

We report the F1 scores on the coarse and the fine narratives for each experiment.

Each model is trained with a batch size of 8 and a learning rate of 10^{-5} with an AdamW optimizer (Loshchilov and Hutter, 2019), which is a common default choice for such models. Models come from HuggingFace and the transformers library.

The model and classification head are wrapped in a PyTorch Lightning[7] `LightningModule`. Because classes are unbalanced, we use a sampler from the pytorch-multilabel-balanced-sampler module[8], and more specifically the `LeastSampledClassSampler`, which returns a random sample with a label from the least sampled class at each moment.

Table 3: Generalization study to new languages with mDeBERTa-v3-base. Grayed results are results obtained on languages seen during training. The best approach has been selected based on the F1-score on the fine narratives. Results are marked with ↑ when results are better than the results when trained on all languages.

models perform better than monolingual models with this little data for each class. There is no clear winner between XLM-RoBERTa-large and mDeBERTa-v3-base, but the latter is 6.5 times lighter. Moreover, mDeBERTa-v3-base performs better on average than XLM-RoBERTa-large, with a mean F1 score of 0.344 versus 0.257 on fine narratives. In addition, the two models seem to perform worse for non-West-European languages. The same observation can be made for specialized models, which could also be explained by data distribution for these specific languages.

Quantitatively, when compared to other systems on the final test submissions, simple encoder models are not the best for identifying narratives but still beat the baseline for all languages. The official leaderboard[9] allows to compare models performance directly. Our model performed 13/28 in English, 12/14 in Portuguese, 8/14 in Hindi, and 9/12 in Bulgarian, and would have performed 13/16 in Russian (results were not submitted on time).

Our models tend to make cautious predictions, and in a little more than 40% of dev samples, no narrative was detected when it should have been, which leads to lower scores overall.

[9] https://propaganda.math.unipd.it/semeval2025task10/leaderboardv3.html

5.2 Generalization on new languages

After the final submission, additional experiments were run to measure how well the tested multilingual models would generalize to other languages. To this end, we train the same models several times with a whole language left out each time. Reported results are computed on the dev set and given in Table 2 and 3. Results are grayed when computed on a language seen during training, an arrow is displayed when the ablated model performs better than the same model trained with all languages, and bold results are the best obtained for a specific language among all tested models.

In most cases, performance does not drastically change on one language if it is removed from the training languages (-3.475% for mDeBERTa and +0.75% for XLM-RoBERTa on average).

Performance increased for XLM-RoBERTa due to strange behaviors in Portuguese and Russian. Counterintuitively, removing these languages increases performance on the dev set. In general, for XLM-RoBERTa, removing a language improves performance in at least one other language. This hints that while this model can process multiple languages, features are not shared evenly across languages. Portuguese features rely on other languages, as performance improves with No PT. Moreover, removing Portuguese also helps performance in Bulgarian and Russian, showing that Portuguese disturbs the features of other languages.

Also, removing Russian improves Bulgarian (close in vocabulary but different in grammar) performance, showing that the model may confound the two languages.

The same observation can be done with mDeBERTa. In most cases, mDeBERTa performs better than XLM-RoBERTa, except for English. mDeBERTa seems more balanced between languages and shows good transfer capabilities, with the model performing better when trained on all data for all languages but Slavic ones. This generalization is possible at the cost of the performance in English.

In conclusion, we observe that XLM-RoBERTa generalizes better than mDeBERTa on new languages, but that if given data in multiple languages, mDeBERTa is the model that will be the best to leverage all the information from all languages.

5.3 Error analysis

To further understand how our models performed, we chose to do an error analysis on the dev set for mDeBERTa trained on all languages, our best-performing model on average. It misses many narratives on the dev set. All articles with no narratives were correctly labeled, but 72 were false negatives for the absence of narratives (over the 178 articles in the dev set). In this sense, the model is conservative and when unsure, does not try to guess a narrative. The following analysis has been done on the part of the dev split for which the model predicted at least one narrative.

There is no simple way of showing a confusion matrix for multi-label problems, as the recommendation would be to plot as many label-specific confusion matrices as there are labels. To simplify our analysis, we propose a "confusion-like" matrix to check for common errors in the predictions, which detailed computations are given in Appendix A.

To summarize computations, accurate predictions are counted as usual, but the wrong predictions are only partially counted, sharing a weight of 1 among wrongly predicted labels and unpredicted gold labels. Generally, the idea of this matrix is to perform qualitative error analysis, which is done in this Section. The confusion-like matrix global form is in Figure 3, and the whole matrix with labels is in Appendix A, in Figure 4.

There is a clear split between climate change (CC) and war-related (URW) narratives (the first 40 narratives for CC and the last 48 ones for URW). Moreover, some rows (resp. columns) are filled with zeros, corresponding to a lack of data in the dev (resp. training) split.

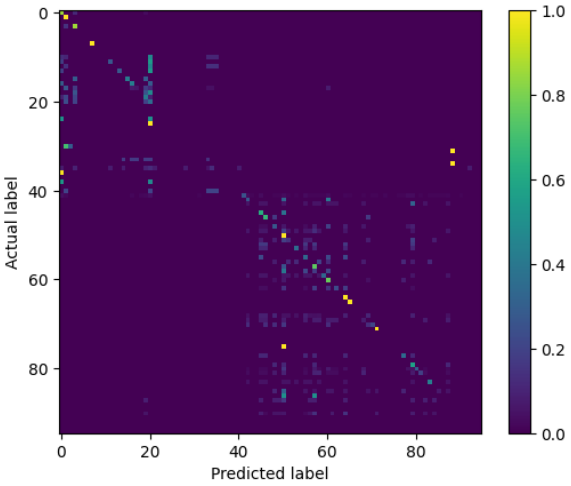

Figure 3: Confusion-like matrix general form. It can be used to identify clusters of wrong predictions quickly. A more detailed confusion matrix with the labels is given in Appendix A.

Most CC narratives were predicted as "Criticism of climate movement" and "Criticism of climate policies," which are the main topics of CC narratives globally. The second main group of CC narrative predictions is on the first narratives of the ontology, hinting that geopolitical agendas behind climate policies are hidden. The same observation can be made on URW narratives, with most predictions covering the "Discrediting Ukraine" and "Discrediting the West" narratives and the central narratives of the URW topic. Some outliers appear in the matrix, but they only represent one sample each, highlighting them in the row-normalized matrix.

Overall, the system is able to detect large categories of narratives, but struggles for fine narratives, showing a bias for well-represented narratives from the training set. More specific encoders should be used with less fine narratives to detect to be able to better detect these fine narratives.

6 Conclusion and Future Works

In this paper, we explored the capabilities of multilingual encoder-based models for the task of narrative classification. We proposed a method with an adaptative threshold for multi-label classification tasks and showed that it performs reasonably well, especially for high-resource languages.

Additional experiments on language ablations showed differences between models' behavior,

with XLM-RoBERTa generalizing better on unseen languages, but mDeBERTa generally performing better when trained with all languages.

The proposed approach could be enhanced by using data augmentation and hierarchical classification; ideas proposed by (Singh et al., 2025; Assis et al., 2025; Huayang Li, 2025). For real use cases, performance on the coarse labels may be more important to detect the presence or absence of narratives before using more specialized models if needed. The main challenge for our model was the limited number of samples by class, which the addition of new annotated data could alleviate. In addition to that, the proposed system only works with a pre-defined set of initially defined narratives. It could be possible to reuse the adaptative threshold idea to detect when new narratives appear in new articles. Moreover, other thresholding strategies could be used, by instance by adding a margin around the adaptative threshold in order to maximize either precision or recall, depending on the use case.

Abstract

Identification of hallucination spans in black-box language model generated text is essential for applications in the real world. A recent attempt at this direction is SemEval-2025 Task 3, Mu-SHROOM—a Multilingual Shared Task on Hallucinations and Related Observable Overgeneration Errors. In this work, we present our solution to this problem, which capitalizes on the variability of stochastically-sampled responses in order to identify hallucinated spans. Our hypothesis is that if a language model is certain of a fact, its sampled responses will be uniform, while hallucinated facts will yield different and conflicting results. We measure this divergence through entropy-based analysis, allowing for accurate identification of hallucinated segments. Our method is not dependent on additional training and hence is cost-effective and adaptable. In addition, we conduct extensive hyperparameter tuning and perform error analysis, giving us crucial insights into model behavior.[1]

1 Introduction

Hallucination is a situation where Large Language Models (LLMs) produce outputs that are inconsistent with real-world facts or unverifiable, posing challenges to the trustworthiness of AI systems (Huang et al., 2025). Hallucination Detection is the process of identifying such sections of text where a model generates content that is untrue, misleading, or unverifiable by any source. As LLMs are used to generate massive texts in all applications, it is essential to make sure their output is accurate (Bommasani et al., 2022). Undetected hallucinations can propagate misinformation, lower confidence in AI systems, and have severe implications in applications such as healthcare and law. Identification of particular spans of hallucinated text, as opposed to merely marking whole outputs, is critical for real-world application, as it enables accurate corrections and improved comprehension of where and why a model hallucinate.

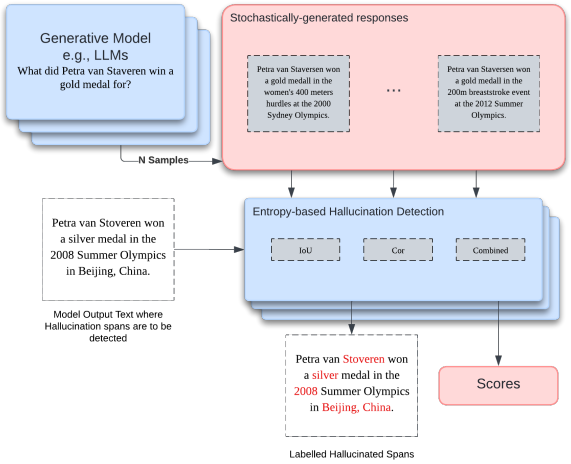

Figure 1: Architecture Diagram describing proposed method for detecting hallucination spans.(Manakul et al., 2023)

In this paper, we describe an LLM-uncertainty based method for Hallucination span detection. Our hypothesis builds upon Manakul et al. (2023) that if an LLM is certain of a given concept, stochastically-sampled responses are likely to be similar and contain consistent facts. However, for hallucinated facts, these sampled responses are likely to diverge and contradict one another. We utilize entropy information to identify the precise spans of hallucinated text using sampled responses (Xiao and Wang, 2021), allowing us to effectively identify inconsistencies that signal hallucination.

Our approach works well in zero-resource and black-box environments without any extra training. In addition, since our approach is language-independent, it works equally well in a variety of languages. Our model ranks 18th on average among over 40 submissions, achieving its best rank

of 10th in Chinese (Mandarin).[2]

2 Related Work

The problem of hallucination detection in Large Language Models (LLMs) has been a focus of much attention recently. Hallucinations are defined as cases when LLMs produce outputs that sound plausible but are factually false or unsupported, compromising their validity for real-world usage. Farquhar et al. (2024) proposed a technique employing semantic entropy to identify such confabulations through uncertainty estimation in the semantic space of model outputs. This method calculates uncertainty at the meaning level as opposed to actual word sequences and allows for recognizing arbitrary and poor-quality generations for different datasets and tasks without explicit domain knowledge.

Following this, Kossen et al. (2024) introduced Semantic Entropy Probes (SEPs), which estimate semantic entropy directly from one generation's hidden states. SEPs are efficient in computation, avoiding repeated model samplings at inference time. Their experiments showed that SEPs have high performance in hallucination detection and generalize well to out-of-distribution test sets, indicating that model hidden states contain semantic uncertainty relevant to hallucinations.

In parallel, Manakul et al. (2023) introduced SelfCheckGPT, a zero-resource black-box method for fact-checking LLM responses independent of external databases. The technique exploits the consistency of stochastically generated responses by assuming that when an LLM has knowledge about a concept, its sampled responses will be consistent and similar in content while hallucinated facts result in diverse and contradictory responses. Their results show that SelfCheckGPT efficiently identifies non-factual sentences and evaluates the factuality of passages, providing an efficient solution for situations where model internals are not available.

These studies together highlight the need to create effective and efficient techniques for hallucination detection in LLMs. Methods based on semantic entropy, model hidden states, and response consistency provide promising directions for improving the reliability of LLM outputs in different applications.

3 Task Description

Mu-SHROOM [3] (Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes) focuses on detecting hallucinated spans in text output from instruction-tuned LLMs. The task includes 14 languages: Arabic (Modern standard), Basque, Catalan, Chinese (Mandarin), Czech, English, Farsi, Finnish, French, German, Hindi, Italian, Spanish, and Swedish. (Vázquez et al., 2025)

Evaluation is conducted separately for each language and is based on the following two character-level metrics:

- **Intersection-over-Union (IoU):** Measures the overlap between predicted and reference hallucination spans.

$$\text{IoU} = \frac{|P \cap G|}{|P \cup G|}$$

  where P is the set of predicted hallucination characters and G is the set of gold reference hallucination characters.

- **Probability Correlation (Cor):** Evaluates how well the predicted hallucination probabilities match empirical annotator probabilities.

$$\rho = \text{corr}(\hat{p}, p)$$

  where $\hat{p}$ are the predicted probabilities and p are the human-annotated probabilities.

Data format is described in Table 1. The `hard_labels` are used for intersection-over-union accuracy, while the `soft_labels` are used for correlation evaluation. Table 5 shows the number of samples in the task dataset.

4 Methodology

In this section we describe our methodology for detecting hallucination spans. Given generated text $\mathcal{G}$ and stochastically-sampled responses $\mathcal{S} = s'_1, s'_2, ..., s'_n$ from models, our method predicts hallucination spans as follows:

Given a generated text $\mathcal{G}$, we segment it into overlapping spans using a sliding window approach. Each span s_i is extracted using a window size w and stride t such that:

$$s_i = \mathcal{G}[(i-1)t : (i-1)t + w] \quad (1)$$

[3] https://helsinki-nlp.github.io/shroom/

Field	Description
`lang`	Language of the text.
`model_input`	Input query provided to the LLM.
`model_output_text`	Generated text from the LLM.
`hard_labels`	List of pairs (s_i, e_i) representing hallucination spans (start-inclusive, end-exclusive).
`soft_labels`	List of dictionaries, each containing: • `start`: Start index of hallucination span. • `end`: End index of hallucination span. • `prob`: Probability of the span being a hallucination.

Table 1: Data fields used from Mu-SHROOM Dataset.

for all valid indices i with step size t. This ensures each part of the text is analyzed with sufficient context.

For each span s_i, we retrieve the most similar spans from a set of sampled responses $\mathcal{S} = s'_1, s'_2, ..., s'_n$ using a lexical matching function based on sequence similarity. The matching spans $\mathcal{M}_i$ are defined as:

$$\mathcal{M}_i = s'_j \in \mathcal{S} \mid \text{Similarity}(s_i, s'_j) > \tau \quad (2)$$

where τ is a threshold for similarity.

We compute the hallucination score for each span s_i using a combination of semantic entropy, lexical entropy, and frequency-based scoring.

Semantic Entropy To measure semantic inconsistency, we compute cosine similarity between the span s_i and each matched span s'_j, using a pretrained sentence embedding model:

$$\text{sim}(s_i, s'_j) = \frac{E(s_i) \cdot E(s'_j)}{|E(s_i)||E(s'_j)|} \quad (3)$$

where $E(s)$ denotes the embedding representation of span s. The probability distribution over similarities is given by:

$$P(s'_j \mid s_i) = \frac{e^{\text{sim}(s_i, s'_j)}}{\sum_k e^{\text{sim}(s_i, s'_k)}} \quad (4)$$

The semantic entropy is then computed as:

$$H_s(s_i) = -\sum_{s'_j \in \mathcal{M}_i} P(s'_j \mid s_i) \log P(s'_j \mid s_i) \quad (5)$$

Higher entropy values indicate greater semantic inconsistency.

Lexical Entropy To measure lexical variability, we compute the Shannon entropy over the frequency distribution of matched spans:

$$H_l(s_i) = -\sum_{s'_j \in \mathcal{M}_i} p(s'_j) \log p(s'_j) \quad (6)$$

where $p(s'_j)$ is the probability of span s'_j appearing in the matched set $\mathcal{M}_i$.

Frequency Score The frequency-based confidence score is computed as:

$$F(s_i) = 1 - \frac{|\mathcal{M}_i|}{|\mathcal{S}|} \quad (7)$$

where a lower $|\mathcal{M}_i|$ suggests fewer matches and a higher likelihood of hallucination.

The final hallucination score for each span s_i is computed as a weighted sum:

$$S_h(s_i) = \alpha H_s(s_i) + \beta H_l(s_i) + \gamma F(s_i) \quad (8)$$

where α, β, γ are hyperparameters controlling the contribution of each component. For our submission, we heuristically choose α = 0.4, β = 0.4 and γ = 0.2. We plan to tune these parameters in our future work.

To ensure hallucination spans align with meaningful text units, we refine span boundaries using:

- **Token boundaries**: Adjusting span edges to align with word boundaries.
- **Phrase boundaries**: Ensuring spans do not split meaningful phrases.
- **Named entity boundaries**: Avoiding incorrect segmentation of entity names.

The refined spans are selected by maximizing the entropy gradient at span boundaries.

Detected hallucination spans that overlap significantly are merged into a single span with an updated score:

$$S'_h(s) = \frac{\sum_{i \in \mathcal{O}} S_h(s_i) \cdot |s_i|}{\sum_{i \in \mathcal{O}} |s_i|} \quad (9)$$

where $\mathcal{O}$ is the set of overlapping spans.

The final output is a set of hallucination spans $\mathcal{H}$:

$$\mathcal{H} = (s_i, S_h(s_i)) \mid S_h(s_i) > \lambda \quad (10)$$

where λ is a threshold for hallucination detection.

5 Experiments

5.1 Models

Our experiments utilize Llama-3.2-3B-Instruct model (Dubey et al., 2024), a 3 billion parameter instruction-tuned language model. We generate responses using a temperature of 0.1 to maintain relatively deterministic outputs while allowing for some diversity, along with top-p sampling (nucleus sampling) set to 0.9 and top-k sampling with k=50. To avoid repetitive patterns of text, we use a 3-gram repetition penalty. We produce 20 candidate responses with a maximum of 64 tokens per input query. The model is executed in mixed-precision using FP16 to save memory, with memory consumption limited to 6GB GPU memory and 8GB CPU memory via gradient offloading.

5.2 Hyperparameter Tuning

Considering the presence of various hyperparameters in our methodology, we perform extensive hyperparameter tuning on validation split for each language. We observe that, while many languages have same set of hyperparameters performing the best on evaluation, there exist few languages where notable differences exist. We summarize our hyperparameters choice in Table 2

Language	w	t	λ	MSL	BT
arabic	4	2	0.6	3	0.3

Table 2: Hyperparameters choosen for different languages. Notations include w: Window Size, t: Stride, λ: Entropy Threshold, MSL: Minimum Span Length, BT: Boundary Threshold

6 Results and Analysis

Our submission demonstrated consistent performance across multiple languages as shown in Table 3, achieving similar Intersection over Union (IoU) and Correlation (Cor) scores across various languages. The system performed particularly well in Basque (IoU: 0.4193, Cor: 0.3525), Finnish (IoU: 0.4554, Cor: 0.3323), Italian (IoU: 0.4009, Cor: 0.386) and Hindi (IoU: 0.3598, Cor: 0.3508), indicating its effectiveness in identifying and handling hallucinated text. Similarly, for languages such as English (IoU: 0.3466, Cor: 0.2104), German (IoU: 0.3651, Cor: 0.2199), and Chinese (IoU: 0.4703, Cor: 0.1601), the system maintained consistent performance, demonstrating its adaptability to different linguistic structures.

The findings reveal that our model is aptly suitable for detecting hallucinations for a wide variety of languages that possess intricate morphological and syntactic features. The high correlation scores across numerous languages confirm that our system makes good predictions which correlate well with ground truth annotation. Further, the high IoU values verify its capacity for good localization of hallucinated text, which enables it to be a trustworthy model in addressing the problems of hallucinations in multilingual environments.

6.1 Error Analysis

Table 4 reports a sample data point from test split, where our model's prediction successfully detects the hallucination span. But, it also labels other spans as hallucinated due to noise in generated responses. This behavior of false positives poses significant challenge and it must be handled. We plan to pinpoint why this happens and potentially fix this in our future work.

7 Conclusion

In this paper, we utilized an LLM-uncertainty-based method for hallucination span detection which works equally well in multiple languages. By using entropy-based uncertainty measures from sample responses, our approach accurately detects hallucinated spans without the need for further training. Our model performed competitively in various languages, ranking highly in Basque, Italian, and Hindi. The experiments emphasize the strength of our method, as they show its effectiveness in coping with varied linguistic forms and in yielding precise hallucination span detection. Our error analysis also informs on typical failure instances, presenting potential for additional refinements.

Although our approach is strong, it has limitations, specifically in exploiting supervised learning to achieve better span prediction. Our future re-

Table 4: Hallucinated spans highlighted in red for a sample datapoints in some langauges. Predicted refer to the predicted hallucinated spans by our system.

search might consider fine-tuning over accessible training data in order to make performance even better while keeping our zero-resource model flexible. More context and fact-based verification methods can be incorporated to improve hallucination detection even further. With LLMs still evolving, creating scalable and accurate methods of hallucination detection remains a critical step to maintain the integrity of AI-produced text across real-world use cases.

Limitations

Our method does not employ supervised learning for predicting the exact spans. Under-utilization of training splits of the task is a major drawback of our system. Utilizing the training split for any kind of supervised learning could potentially improve the performance. Moreover, failing to incorporate contextual and factual verification techniques poses a major challenge to our approach.

Acknowledgments

We would like to thank Mu-SHROOM shared task organizers, Raúl Vázquez, Timothee Mickus, and their team, for their effort and commitment to organizing this task.

Abstract

This paper describes the system submitted by Team A to SemEval 2025 Task 11, "Bridging the Gap in Text-Based Emotion Detection." The task involved identifying the perceived emotion of a speaker from text snippets, with each instance annotated with one of six emotions: joy, sadness, fear, anger, surprise, or disgust. A dataset provided by the task organizers served as the foundation for training and evaluating our models. Among the various approaches explored, the best performance was achieved using multilingual embeddings combined with a fully connected layer. Notably, our system achieved its highest macro F1 scores on Hindi (0.8901), Russian (0.8831), and Marathi (0.8657), underscoring the effectiveness of our cross-lingual strategy. This paper details the system architecture, discusses experimental results, and highlights the advantages of leveraging multilingual representations for robust emotion detection in text.

1 Introduction

Human emotions are intricate and multidimensional, resisting simplistic classification due to their fluid, overlapping nature. As Eugenides (2003) noted, affective states rarely occur in isolation; they coalesce and evolve dynamically, challenging reductionist labelling approaches. This complexity underpins multi-label emotion detection, where texts or behaviours often encode layered sentiments (Fu et al., 2022). The benefits of accurately deciphering these nuances span domains from early mental health screening and tailored interventions (Alhuzali and Ananiadou, 2019; Aragón et al., 2019) to enhanced consumer sentiment analysis in AI systems (Chen et al., 2018; Alaluf and Illouz, 2019). Yet, current recognition systems often treat emotions as mutually exclusive, contrary to psychological frameworks; works by Ekman (1992) and Plutchik (1980) view emotions as interconnected constructs with gradational intensities, a perspective supported by Fu et al. (2022), who shows that joy and love correlate more strongly than, say, anger and sadness.

Another gap is the treatment of emotional intensity, which ranges from subtle to profound expressions (Frijda, 1988). Most systems neglect these gradations by focusing on binary classifications, limiting real-world applicability in clinical or market settings. Moreover, linguistic and cultural disparities evident in divergent emotion lexicons and display rules (Ekman, 1992) render monolingual models inadequate, with culture specific metaphors or untranslatable terms risking misclassification. Thus, frameworks that jointly model multi-label emotions, intensity spectra, and cross-cultural variations are essential for advancing emotion-aware technologies.

As part of SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection (Muhammad et al., 2025b), we propose a multilingual framework integrating multilingual embeddings to capture shared semantic and affective features alongside intensity-sensitive architectures for detecting gradational nuances. The remainder of the paper is organized as follows: Section 2 reviews existing methods in multi-label emotion detection and their limitations; Section 3 introduces the multilingual dataset; Section 4 details our model's approach to disentangling overlapping emotions; Section 5 compares our method with state-of-the-art baselines; and Section 6 presents experimental outcomes and performance analysis. Finally, Section 7 discusses implications for affective computing and future directions, including multimodal data integration and low-resource language adaptation.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 73–82

2 Related Work

The evolution of multilingual emotion detection systems has been shaped by three interconnected pillars: (1) the creation of high-quality datasets, (2) innovations in cross-lingual transfer methodologies, and (3) architectural advancements in multilingual models. This progression reflects a paradigm shift from monolingual benchmarks to language-agnostic scalable frameworks capable of capturing emotional nuance across linguistic boundaries.

Early research established rigorous baselines through carefully curated monolingual datasets. The GoEmotions corpus (Demszky et al., 2020), a seminal resource comprising 58,000 English Reddit comments annotated with 27 emotion categories, underscored the importance of multi-rater consensus and quality control in emotion labelling, achieving an F1-score of 0.46 through BERT-based fine-tuning combined with Principal Preserved Component Analysis (PPCA). Although this work laid the groundwork for data-driven approaches, it also exposed a key limitation: the lack of multilingual comparability inherent to single-language corpora. To overcome this, subsequent studies focused on knowledge transfer from high-resource to low-resource languages. Wang et al. (2024b) pioneered a knowledge distillation framework that aligns multilingual representations (e.g., XLM-RoBERTa) with English-centric models (e.g., RoBERTa) using translation-weighted data, reducing the performance gap between monolingual and multilingual systems by 23%. Complementary work by Hassan et al. (2022) compared cross-lingual strategies—including multilingual embeddings (mBERT), translated corpora, and parallel text alignment for Arabic and Spanish emotion detection, finding that target-language fine-tuning outperforms direct transfer by 14% F1-score while affirming the indispensability of cross-lingual methods for under-resourced languages.

Parallel efforts have optimized model architectures for improved multilingual generalization. Bianchi et al. (2022) developed XLM-EMO, a social media-oriented model trained on 19 languages using XLM-RoBERTa, which achieved state-of-the-art zero-shot performance in low-resource settings and demonstrated that unified architectures can capture shared affective features without language-specific tuning. Meanwhile, Gupta (2021) improved robustness via Virtual Adversarial Training (VAT), enforced consistency between original and perturbed inputs to boost cross-lingual F1-scores by 8% in Arabic and Spanish. Further breakthroughs leverage the semantic richness of large language models: Cheng et al. (2024) introduced the TEII framework, which iteratively refines predictions by combining GPT-3.5 and GPT-4 and employs explanation-driven fine-tuning on translated emotion lexicons to reduce cross-lingual prediction variance by 37%. This approach aligns with findings from Navas Alejo et al. (2020), who demonstrated that unsupervised machine translation better preserves emotional intensity gradients, especially for morphologically rich languages like Catalan.

Despite these advances, critical gaps remain in reconciling performance disparities across languages. As noted in Conneau et al. (2020), even state-of-the-art multilingual models exhibit 'linguistic bias', with performance degrading for languages typologically distant from English. Moreover, the common practice of treating emotion intensity as static rather than contextual oversimplifies the complex nature of affect, as argued by psycholinguistic evidence (Frijda, 1988). Our work addresses these limitations by focusing on (1) culture-aware multilingual representation learning and (2) dynamic intensity modelling, thereby advancing beyond the current paradigm of static cross-lingual transfer.

3 Dataset

In our study, we leverage the BRIGHTER dataset (Muhammad et al., 2025a) to explore cross-lingual emotion recognition. BRIGHTER is a large-scale, manually curated resource designed to bridge the gap in emotion recognition for low-resource languages. It comprises nearly 100,000 text instances gathered from diverse sources, including social media posts, personal narratives, speeches, literary texts, and news articles across 28 languages from various language families. Each text instance is annotated by native speakers with one or more emotion labels (anger, sadness, fear, disgust, joy, surprise, and a neutral category) along with corresponding intensity ratings on a four-point scale (0 indicating no emotion up to 3 indicating high intensity). The dataset's annotation process involves rigorous preprocessing steps such as deduplication and noise removal, followed by quality control measures like the Split-Half Class Match

Percentage (SHCMP) to ensure high reliability in labelling. This comprehensive dataset not only enriches the training resources available for multilingual emotion recognition models but also serves as a valuable benchmark for evaluating performance across both high and low-resource languages.

Furthermore, we complement our approach for languages with particularly scarce resources, such as Amharic and Afan Oromo by incorporating data from the EthioEmo dataset Belay et al. (2025). EthioEmo is specifically tailored for Ethiopian languages and provides robust multi-label emotion annotations derived from sources like news headlines, Twitter posts, YouTube comments, and Facebook data. By integrating these datasets, our work benefits from enhanced linguistic diversity and improved reliability in emotion classification, especially for under-represented languages.

The dataset splits are as follows: the Hindi corpus comprises a total of 3,666 instances, with 2,556 instances allocated for training (approximately 70%), 100 instances for development (around 2.7%), and 1,010 instances for testing (roughly 27.5%). Similarly, the English corpus consists of 5,651 instances, with 2,768 instances used for training (approximately 49%), 116 instances for development (about 2%), and 2,767 instances for testing (roughly 49%).

4 Methodology

Our methodology integrates multilingual representation learning with multi-label classification to address cross-lingual emotion detection. We refer to our proposed model as `TransferModel_FC_EmbeddingE5` throughout this paper. Central to this approach is the multilingual E5 text embedding framework (Wang et al., 2024a), which undergoes a two-stage training process to align semantic representations across languages. First, weakly supervised contrastive pre-training on $\sim$1 billion multilingual text pairs (sourced from Wikipedia, mC4, NLLB, and others) optimizes cross-lingual alignment using InfoNCE loss with large batch sizes (32k) to maximize negative sample diversity. This is followed by supervised fine-tuning on high-quality labeled datasets (MS MARCO, NQ, TriviaQA), augmented with mined hard negatives and knowledge distillation from a cross-encoder teacher. We employ the instruction-tuned `mE5-large-instruct` variant, pre-trained on 500k GPT-3.5/4-generated synthetic instructions across 93 languages, to enhance task-specific adaptability.

Building upon this foundation, our emotion detection architecture processes input text through the multilingual E5 tokenizer, standardizing sequences to 150 tokens to balance computational efficiency and semantic retention. The model generates contextualized embeddings via `multilingual-e5-large-instruct`, with the [CLS] token serving as a sequence-level semantic summary (Devlin et al., 2019). A dropout layer (rate=0.3) regularizes the 1024-dimensional [CLS] embedding before projection into the emotion space through a fully connected layer. Sigmoid activations independently estimate probabilities for 5–6 emotion labels (dataset-dependent), explicitly modelling label co-occurrence inherent to multi-label scenarios.

To optimize performance, we train the system using Binary Cross Entropy (BCE) with label smoothing ($\alpha = 0.1$), mitigating overconfidence in sparse annotations. The AdamW optimizer (Loshchilov and Hutter, 2019) (learning rate=1e-5, $\beta_1 = 0.9$, $\beta_2 = 0.999$) processes mini-batches of 16 samples, with gradient clipping (max norm=1.0) stabilizing updates. Early stopping monitors the development set macro F1 score (patience=4 epochs), preserving generalizability by halting training during performance plateaus.

During inference, emotion probabilities are thresholded at 0.5 (adjustable per application needs) to yield binary predictions. Evaluation prioritizes macro-averaged F1, which aggregates per-class true/false positives and negatives across all batches to penalize bias toward frequent labels a critical safeguard for imbalanced multi-label datasets. Results are averaged over five random seeds to account for initialization variance, ensuring reproducibility. By unifying multilingual semantic alignment with modular classification components, `TransferModel_FC_EmbeddingE5` addresses the dual challenges of cross-lingual emotion detection, preserving affective nuance across languages while disentangling overlapping emotional states.

5 Experiments

To complement our transformer-based system described in Section 4, we implemented a baseline multi-label emotion classification pipeline that integrates classical machine learning classifiers with

Table 1: Evaluation Scores (F1) for Track A Languages

pre-trained sentence embeddings. In our experiments, we compare two variants that differ solely in the choice of embedding model.

Our setup uses two CSV files containing text samples and six emotion labels (anger, disgust, fear, joy, sadness, and surprise) for both training and testing. Texts are converted into normalized embeddings using a helper function that leverages SentenceTransformer models with the `normalize_embeddings=True` parameter to produce unit-length vectors. Since raw embeddings from our language models exhibit variability across dimensions and may not be centered around zero—factors that can obscure underlying semantic information we apply a two-step normalization process. First, we perform L2 normalization to ensure each embedding vector has a unit norm, emphasizing the semantic direction rather than its magnitude. In our implementation, one branch uses the LaBSE model (Feng et al., 2022) while the other employs the multilingual E5 Large model (Wang et al., 2024a). Second, we apply Z-score normalization (standard scaling) using scikit-learn's StandardScaler (Pedregosa et al., 2011) to adjust features to a mean of zero and a standard deviation of one, thereby mitigating scale differences.

After normalization, we extract the six emotion labels to facilitate multi-label classification. Four classifiers are then trained: Support Vector Machine (with an RBF kernel and probability estimates), Gaussian Naïve Bayes, Logistic Regression (with increased iterations), and Random Forest (regularized by limiting tree depth and controlling split criteria). These classifiers are wrapped using scikit-learn's `MultiOutputClassifier`, ensuring that the multi-label nature of the task is properly addressed. Evaluation is performed on both the training and testing set using detailed classification reports and macro F1 scores to gauge performance across all emotion classes.

For real-time prediction, a dedicated function processes new text inputs by generating embeddings, applying the same scaling procedures, and predicting emotion labels. The output is returned as a dictionary mapping each emotion to a binary prediction. Finally, our experimental design facilitates a direct comparison between the two embedding models: LaBSE, which provides robust, language-agnostic sentence representations (Feng et al., 2022), and Multilingual E5 Large, which may offer richer semantic embeddings (Wang et al., 2024a). This unified approach enables a systematic analysis of the impact of embedding choice on multi-label emotion detection performance, reinforcing the potential of multilingual representations for robust cross-lingual emotion analysis.

6 Results

In this section, we report the evaluation results of our approach to the multi-label emotion detection task (Track A) across 13 languages. Our model, `TransferModel_FC_EmbeddingE5`, built upon multilingual E5 embeddings and a fully connected output layer, was evaluated on its ability to predict six emotion categories (anger, disgust, fear, joy, sadness, and surprise) using both micro and macro F1 scores as evaluation metrics.

Per-Language Performance. Table 1 shows the detailed F1 scores for each emotion along

with the overall micro and macro F1 scores per language. `TransferModel_FC_EmbeddingE5` achieved a range of macro F1 scores from 0.5550 (Arabic) to 0.8901 (Hindi). Notably, the model performed particularly well on languages such as Hindi (macro F1 = 0.8901), Russian (macro F1 = 0.8831), and Spanish (macro F1 = 0.8054), indicating that the multilingual embeddings effectively capture emotion-related nuances in these languages. On the other hand, lower scores in languages like Arabic, Ukrainian, and Oromo suggest that further adaptations may be necessary to handle linguistic variations or data sparsity in these settings.

Comparison with Top Systems. In comparison with the top two performing teams for each language, our approach did not secure the top spot but remained competitive across most languages. For example:

- In Hindi, our macro F1 of 0.8901 is close to the top scores of 0.9257 and 0.9197.
- In Russian, our score of 0.8831 approaches the best scores of 0.9087 and 0.9008.
- In Spanish, we achieved a macro F1 of 0.8054, which is only slightly lower than the leading scores of 0.8488 and 0.8454.

Our system achieved its strongest results in Russian (0.8831), closely trailing the 2nd-ranked team (0.9008), demonstrating competitive performance. In Hindi (0.8901) and Marathi (0.8657), Team A secured scores within 3-4% of the 1st-place teams, highlighting robustness in these languages. While not topping the leaderboard, these narrow gaps reflect effective alignment with top-tier approaches. Notably, languages like Arabic and Chinese showed larger performance drops, emphasizing the need for targeted improvements.

Analysis of Emotion-specific Performance. A closer look at the emotion level F1 scores reveals interesting trends. In several languages, `TransferModel_FC_EmbeddingE5` excels at detecting emotions such as joy and anger while struggling with fear and disgust. For instance, in Chinese, while the joy score is high (0.8748), the disgust score remains lower (0.4357). Such disparities indicate that certain emotions may be more challenging to detect due to their subtle linguistic expressions or class imbalances in the training data.

7 Conclusion

In this paper, we proposed `TransferModel_FC_EmbeddingE5`, a novel approach to multilingual emotion detection that integrates multilingual E5 embeddings with a fully connected classification layer. Our experiments on the BRIGHTER dataset show strong macro F1 scores for languages like Hindi, Russian, and Spanish, while also highlighting challenges in Arabic, Chinese, and Oromo due to linguistic and cultural diversity.

Our model effectively captures emotional nuances, accounting for variations in expression and intensity across languages. This work advances affective computing by demonstrating that multilingual embeddings within a structured classification framework enhance cross-lingual emotion detection. It also lays a foundation for future research on breaking language barriers in sentiment analysis.

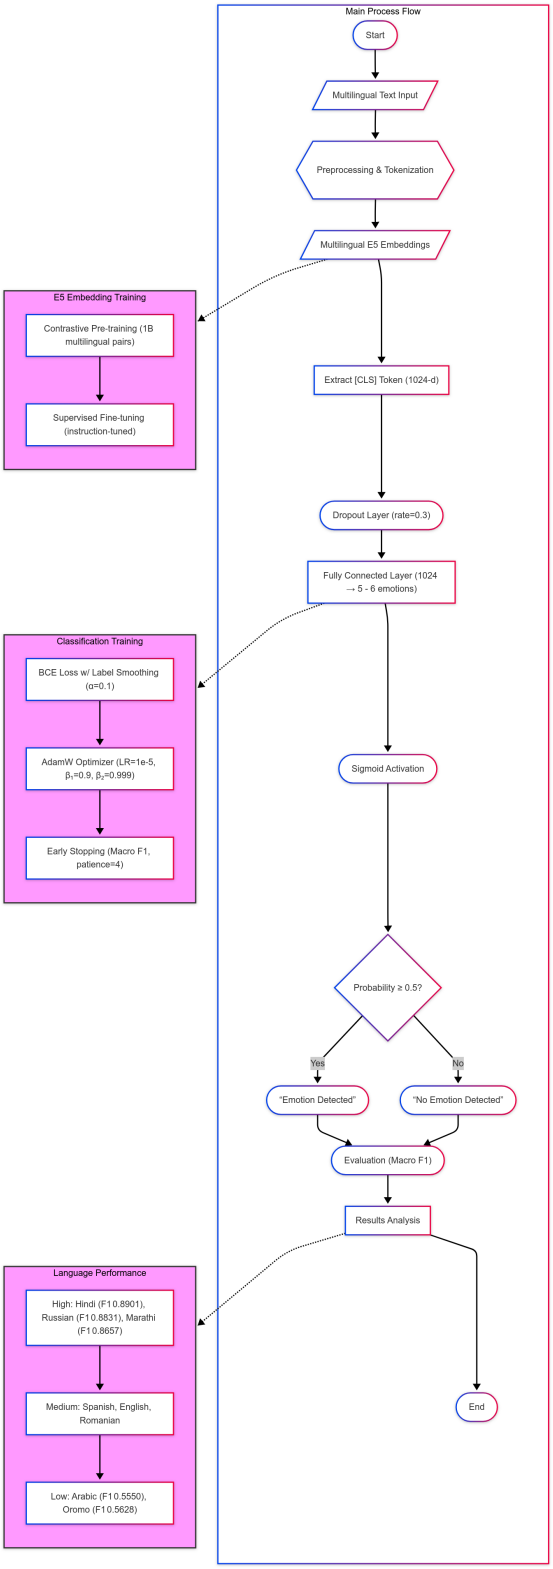

Figure 1: Flowchart of System Architecture. This illustrates the overall system architecture of our proposed model, `TransferModel_FC_EmbeddingE5`. The flowchart depicts the end-to-end pipeline starting from the input text, which is first processed using the multilingual E5 tokenizer. The resulting embeddings are passed through a dropout layer and then into a fully connected layer with sigmoid activations to perform multi-label emotion classification. This modular setup allows efficient handling of semantic nuances across languages and emotion co-occurrence patterns in the dataset.

Table 4: This Table presents a comparative analysis of macro F1 scores across 13 languages using two different multilingual embedding models LaBSE and Multilingual E5 paired with four classical classifiers: SVM, Naïve Bayes, Logistic Regression, and Random Forest. The results demonstrate that the Multilingual E5 embeddings generally outperform LaBSE in most classifier setups, particularly in Logistic Regression and SVM configurations. The table highlights that embedding choice significantly influences classification performance, with E5 consistently providing stronger results across diverse languages, reinforcing its suitability for cross-lingual emotion detection tasks.

Abstract

This paper describes the participation of the YNU-HPCC team in subtask A of task 11, Bridging the Gap in Text-Based Emotion at SemEval-2025. Our best-performing system employs the RoBERTa (Robustly Optimized BERT Approach) model, an improved version of BERT that utilizes the Transformer encoder architecture. We enhanced the output head to allow the model to process one emotion simultaneously. We obtained the official ranking score (0.44), including results from all languages. The entire dataset was translated into English using Google Translate to facilitate subsequent processing. Through probabilistic and attention analyses, we found that (I) a single prediction head performs better than six heads predicting six emotions simultaneously, and (II) training on a uniformly translated English dataset yields better results than using the original dataset. The code is available at: https://github.com/BGWH123/Semeval-2025-task11.

1 Introduction

Multilingual sentiment classification is crucial in Natural Language Processing (NLP), aiming to analyze emotional expressions across languages. This task is key for applications such as opinion mining, customer feedback analysis, and cross-cultural sentiment studies. It involves handling linguistic variations and challenges posed by low-resource languages, making it an important area of research.

Recent research has focused on multilingual sentiment classification, especially with large-scale multilingual datasets and benchmarks (Augustyniak et al., 2024). Approaches such as translating text into English and leveraging English embeddings have improved performance across languages (Singhal and Bhattacharyya, 2016). New annotation methods have been introduced at various levels (word, sentence, document) (Banea et al., 2011). For low-resource languages, methods that work with unlabeled parallel corpora have also been proposed (Fei and Li, 2020).

In this study, we examine several Transformer-based models (BERT, RoBERTa, ALBERT, DistilBERT, ELECTRA, DeBERTa, and mBERT) and their language support. As shown in Table 1, most models, including BERT-based ones, support only English. While mBERT supports over 100 languages, including Arabic, it performs poorly on dialects such as Algerian Arabic and Moroccan Arabic. This limitation, along with challenges in languages like Nigerian Pidgin, led us to explore alternative methods. We opted to use Google Translate to preprocess data instead of training a multilingual model, which would be less effective due to parameter constraints.

Based on the experimental results, we chose RoBERTa as our base model and fine-tuned it for six emotions: *anger*, *disgust*, *fear*, *joy*, *sadness*, and *surprise*. We incorporated R-Drop and Focal Loss techniques to improve training, which led to the final results.

2 Related Work

Sentiment analysis using Recurrent Neural Networks (RNNs) and machine translation has been explored in (Mahajan and Chaudhary, 2018). This study investigates the feasibility and effectiveness of performing multilingual sentiment analysis through machine translation, particularly with the use of Google Translate. It reveals that the performance of machine translation in sentiment analysis diverges from that of human expert translations, especially regarding the accuracy of emotional expression and semantic similarity (Balahur and Turchi, 2012). This paper further explores the variations in sentiment analysis during the translation process, such as differences in emotional expression across languages and the impact of translation on sentiment polarity (Mohammad et al., 2016). By analyzing users' emotions in real time,

Table 1: Number of languages supported by different Transformer-based models.

the dialogue system can adjust its strategy to better guide the conversation (Luo et al., 2024; Zheng et al., 2024).

In a related vein, (Assiri et al., 2024) introduces a sentiment analysis model based on DeBERTa, which enhances classification performance by integrating a Gated Recurrent Unit (GRU). Furthermore, a hybrid model called Instruct-DeBERTa is proposed, combining InstructABSA for aspect extraction with DeBERTa-V3-base for sentiment classification, thereby improving the accuracy and reliability of fine-grained sentiment analysis (ABSA) (Jayakody et al., 2024). The study also applies the DeBERTa model to gender bias detection tasks using a transfer learning approach, demonstrating its potential in cross-lingual sentiment analysis and bias detection (Ta et al., 2022).

3 Methodology

Given the limitations of directly training a multilingual model, translating target language text into English and utilizing English sentiment analysis tools has proven effective for cross-lingual sentiment analysis. Experimental results show that the ELSA model significantly improved performance across multiple tasks (Chen et al., 2019). Additionally, cross-lingual models have shown strong performance in sentiment detection, notably when leveraging translated English data and fine-tuned contextual embeddings (Hassan et al., 2022).

After translation, we used the **DeBERTa** model for emotion classification. DeBERTa, an advanced Transformer-based model, improves upon BERT and RoBERTa with disentangled attention and absolute position embeddings, which enhance its ability to capture complex linguistic and contextual information. Please refer to Figure 1 for details on the method.

3.1 Task Overview

The monolingual track of Subtask A (Muhammad et al., 2025): Multi-label Emotion Detection focuses on identifying the perceived emotions in a given text snippet. Specifically, the task requires determining whether each of the following emotions is present: *anger*, *disgust*, *fear*, *joy*, *sadness*, and *surprise*. Each emotion is treated as an independent label, meaning the text can be associated with multiple emotions simultaneously. The dataset includes annotated training data with gold emotion labels. Notably, the inclusion of the *disgust* category varies depending on the language.

The evaluation metric for Subtask A is the F_1-score, calculated based on the predicted and gold labels.

3.2 Method

We employed **DeBERTa** as our base model. First, we modified the output head to predict multiple emotions. Given an input sentence x, it is processed through the DeBERTa model, which produces an output vector $\hat{y}$. For each prediction, the model outputs a vector

$$y = [y_0, y_1, y_2, y_3, y_4, y_5]$$

corresponding to the predicted probabilities for each emotion label. These predictions are then compared with the true labels, and the loss is computed based on this comparison.

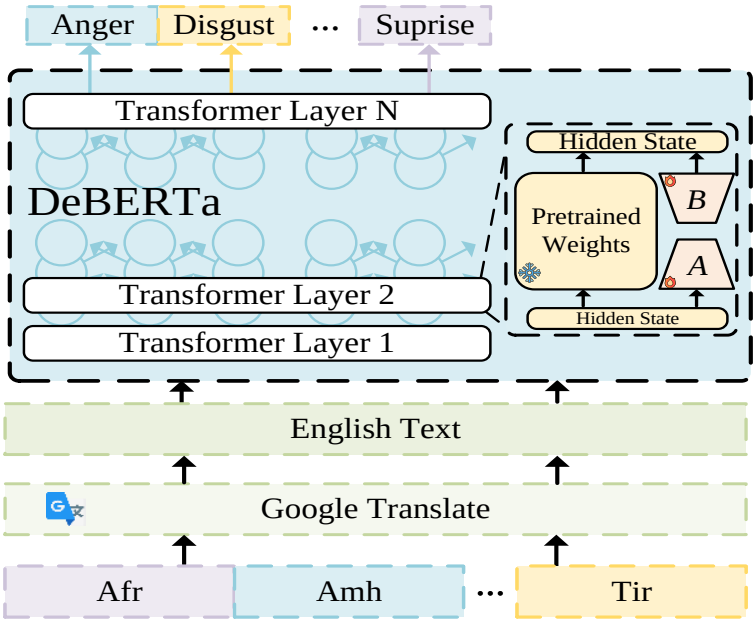

Figure 1: The sentiment analysis process using a transformer-based architecture with DeBERTa pretrained weights. It processes text through multiple transformer layers to predict emotion categories such as anger, disgust, and surprise.

The loss function is calculated as follows:

$$\mathcal{L} = -\sum_{i=0}^{5} y_i \log(\hat{y}_i) \quad (1)$$

where y_i is the true label and $\hat{y}_i$ is the predicted probability for each of the five emotions. This loss is used to fine-tune the model, optimizing the parameters through backpropagation.

Due to the presence of data instances that contain all zeros (i.e., sequences like "no any emotion") and the imbalance of various sentiment distributions, we modified the output head of the model. Instead of predicting all emotions simultaneously, we restructured the output to predict each emotion independently. Thus, the model predicts one emotion at a time for each input sentence.

Given an input sentence x, it is processed through the DeBERTa model to obtain a hidden representation. The model then predicts the sentiment for one specific emotion from the set

$$y = [y_0, y_1, y_2, y_3, y_4, y_5]$$

where each y_i corresponds to a predicted probability for one of the six emotions (anger, disgust, fear, joy, sadness, and surprise). The predictions

Table 3: Each Emotion Frequency Count

Emotion	Frequency
Anger	11459
Disgust	10789
Fear	6761
Joy	13182
Sadness	12311
Surprise	7635

are then compared with the true label $\mathbf{y_{true}}$, and the loss is computed.

The loss function used for training each independent model is calculated as follows:

$$\mathcal{L}_i = -y_i \log(\hat{y}_i) - (1 - y_i) \log(1 - \hat{y}_i) \quad (2)$$

where $\hat{y}_i$ is the predicted probability for the i-th emotion, and y_i is the true binary label (1 for the presence of the emotion, and 0 for the absence). This loss is computed for each of the six models, where each model is independently fine-tuned to predict one specific emotion.

The final model is trained by aggregating the losses of all six emotion-specific models, optimizing the parameters for each model using backpropagation.

3.3 Data Imbalance

The label distribution in our training dataset (Table 3), consisting of 60,000 (Belay et al., 2025) instances, reveals significant class imbalances. Of these, 15,481 instances are labeled as all-zero *(neutral or irrelevant)*, and 10,165 are labeled as *joy*, the most dominant emotion. *Sadness* follows with 7,305 instances.

This imbalance, combined with overlapping emotions (e.g., *anger* and *fear*), leads to a model bias towards more frequent emotions, particularly *joy* and *sadness*, while underperforming rare emotions like *surprise* and *disgust*.

3.4 Improvement Strategies

Focal Loss. During our experiments, we identified a significant class imbalance in our dataset, with emotions like *joy* and *sadness* being overrepresented, while *surprise* and *disgust* were underrepresented. This imbalance caused the model to be biased toward the dominant classes, impacting its ability to detect less frequent emotions. To address this, we incorporated Focal Loss to re-balance the loss function, focusing more on harder-to-classify, underrepresented emotions.

Focal Loss down-weights the loss for well-classified examples and increases the focus on harder ones, ensuring that the model learns effectively across all emotion categories. The function is defined as:

$$\mathcal{L}_{\text{focal}} = -\alpha_t (1 - p_t)^{\gamma} \log(p_t) \tag{3}$$

where α_t is a weighting factor to balance class imbalances, p_t is the predicted probability for the true class, and γ is the focusing parameter that controls the attention on hard-to-classify examples (typically $\gamma > 0$).

R-Drop. In addition to class imbalance, we observed instability in the loss function during training, leading to suboptimal generalization. To address this, we applied R-Drop (Regularized Dropout), a regularization technique that stabilizes the loss function by encouraging consistency across multiple forward passes of the same input. This improves the model's generalization capability.

The total loss function with R-Drop is a combination of cross-entropy loss and consistency loss:

$$L_{\text{total}} = L_{\text{CE}} + \lambda L_{\text{con}} \tag{4}$$

By minimizing this combined loss, R-Drop helps reduce variance in training and improves model stability.

4 Experimentation

To evaluate the effectiveness of our approach, we conducted a series of experiments. These experi-

ments focused on comparing the tasks of predicting a single emotion and predicting two emotions simultaneously while also investigating the impact of Focal Loss and R-Drop regularization through ablation studies. All experiments were performed under identical experimental conditions to ensure consistency and comparability of results.

In our setup, we modified the prediction head of the DeBERTa model, enabling it to predict one emotion at a time and two emotions at once. The model was fine-tuned for emotion classification, predicting six distinct emotions: anger, disgust, fear, joy, sadness, and surprise.

4.1 Modify Prediction Heads

Table 4 shows significant improvements in emotion classification when combining Focal Loss and R-Drop with the base DeBERTa model. For most emotions, the base model using the Focal Loss and R-Drop configuration yielded the highest accuracy, F_1-score, recall, and precision.

These results demonstrate that Focal Loss and R-Drop stabilize the loss function and improve performance on underrepresented emotions, making the base model using the Focal Loss and R-Drop configuration the most effective for emotion classification in this study.

4.2 One Prediction Completed

Table 4 also indicates that the Focal Loss and R-Drop base model provides the most robust performance across all emotion categories, effectively addressing both class imbalance and generalization challenges. Therefore, this configuration is deemed optimal for multi-emotion classification tasks. However, compared to the previous approach of *Modify Prediction Heads*, this configuration yields better performance in terms of accuracy and precision, proving to be a more practical solution for tackling the challenges in emotion classification.

5 Conclusions

This study presents the YNU-HPCC team and the participation in SemEval-2025 Subtask A of Task 11. We made predictions for 29 languages and used DeBERTa as the baseline model. We modified the prediction head to allow for independent predictions in each instance. Our proposed model demonstrated its effectiveness in addressing this task. Among the various results we submitted, the combination of Focal Loss, R-Drop, and DeBERTa achieved the highest score of 0.44 in Table 5. Future research will focus on enhancing accuracy in

multilingual sentiment analysis.

I2R-NLP at SemEval-2025 Task 8: Question Answering on Tabular Data

Yuze Gao, Bin Chen, Jian Su
A*STAR
{gaoy1,bchen,sujian}@i2r.a-star.edu.sg

Abstract

We present a Large Language Model (LLM) based system for question answering (QA) over tabular data that leverages multi-turn prompting to automatically generate executable Pandas functions. Our framework decomposes the problem into three key steps: (1)Answer Type Identification, where the system identifies the expected format of the response (e.g., boolean, number, category); (2) Pandas Function Generation, which generates a corresponding Pandas function using table metadata and in-context examples, and (3) Error Correction and Regeneration, where iteratively refining the function based on error feedback from executions. Evaluations on the SemEval-2025 Task 8 Tabular QA benchmark (Grijalba et al., 2024) demonstrate that our multi-turn approach significantly outperforms single-turn prompting models in exact match accuracy by 7.3%. The proposed system not only improves code generation robustness but also paves the way for enhanced and adaptability in table-QA reasoning tasks. Our implementation is available at https://github.com/Gyyz/Question_Answering-over-Tabular-Data.

1 Introduction

Answering natural language queries over tabular data requires a deep understanding of both linguistic nuances and structured data semantics. Traditional systems rely on rule-based approaches or parsing pipelines to translate questions into database queries (e.g., SQL). While effective in constrained domains, these approaches often demand significant manual engineering and domain expertise (Zelle and Mooney, 1996; Woods, 1977). These approaches can struggle with the complexities and ambiguities inherent in natural language. In contrast, recent advances in large language models (LLMs) have enabled prompt-based code generation, offering a promising alternative for complex reasoning tasks (Brown et al., 2020; Chen et al., 2021). LLMs have shown impressive capabilities in generating code from natural language descriptions, including for the task of Text-to-SQL (Yu et al., 2018; Sun et al., 2023), which focuses on translating natural language questions into SQL queries. However, single-turn prompts can fail to capture all necessary subtleties, leading to generated code that is either syntactically or semantically incorrect. This limitation highlights the need for more sophisticated prompting strategies.

Our work addresses these challenges by introducing a multi-turn prompting framework that engages the LLM in several refinement iterations. Unlike single-turn generation, our approach mirrors the iterative debugging process of human developers by correcting early mistakes and reinforcing the understanding of ambiguous queries. This stepwise process enables the system to produce executable Pandas functions that precisely match the intended output. This iterative refinement approach builds upon the concept of interactive code generation and human-in-the-loop AI for code, where human feedback and interaction are used to improve the quality and correctness of generated code. While interactive code generation has been explored, our specific application to generating Pandas functions for tabular data queries with multi-turn LLM interaction offers a novel contribution. The use of Pandas, a crucial library for data manipulation in Python, further motivates this work, as it enables the seamless integration of generated code into data science workflows.

2 Background

Over the past two years, the field of natural language processing (NLP) has undergone rapid evolution, largely driven by advances in large language models (LLMs). Early approaches were predominantly task-specific, demonstrating robust language understanding but frequently encountering limitations with respect to domain-specific tasks or com-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 90–101

plex, multi-step processes. The introduction of transformer-based architectures significantly improved scalability and generalization, paving the way for more sophisticated LLMs.

Recent innovations—exemplified by GPT-based models and open-source foundation models such as Llama (Touvron et al., 2023)—have further broadened the scope of potential applications by enhancing both data efficiency and the capacity to generate accurate, contextually appropriate responses to complex problems. However, it is important to note that our approach leverages human-prompted multi-step workflows rather than relying on purely model-driven multi-step reasoning. By incorporating iterative user input and guidance, we effectively harness the strong language comprehension of modern LLMs while maintaining precise oversight of the reasoning process.

(Brown et al., 2020) demonstrated the remarkable few-shot learning abilities of large models, revealing their potential to adapt to new tasks with minimal examples. In parallel, (Wei et al., 2022) introduced chain-of-thought prompting, a technique that decomposes complex reasoning tasks into intermediate steps, thereby improving the clarity and effectiveness of generated responses. Additionally, models such as (Zettlemoyer and Collins, 2005) and TAPAS(Herzig and Berant, 2020) have focused on bridging the gap between natural language queries and structured query languages, especially for tabular data.

Moreover, recent advances in Large Language Models (LLMs) such as Llama 3.3 (AI@Meta, 2024) to handle more complex and specialized tasks. Our approach builds upon these foundations by integrating an iterative error correction mechanism into the generation process, thereby ensuring that the output is both syntactically correct and semantically aligned with the intended query.

3 System Overview

Figure 1 provides an overview of our multi-turn prompting system in an end-to-end method (question to answer). The process begins with a user query and table metadata, and proceeds through three main stages, as described below.

3.1 Step 1: Answer Type Identification

The first step determines the expected answer type for the question. Since our dataset supports five distinct answer types (`boolean`, `category`, `list[category]`, `list[number]`, and `number`), this information is critical for generating a function that produces output in the correct format.

To achieve this, we craft a prompt with in-context examples that demonstrate the mapping from natural language queries to their answer types. For example, given a question like `"Which company has the highest revenue?"`, the expected answer type is `category`. Code Block 2.1 in **Appendix** Section shows a snippet of the prompt template used in this stage.

The LLM outputs the answer type appended with a special delimiter (e.g., a sequence of # characters), which is subsequently extracted using simple string operations. This preprocessing step is essential, as it ensures that the generated Pandas code adheres to the required output format. In our experiments on the development set and prompt template environments, omitting the **answer type** guidance resulted in a decrease in accuracy from **87%** to approximately **82%**.

3.2 Step 2: Pandas Function Generation

In the second step, the system generates an initial Pandas function that can answer the query. The prompt for this step is carefully constructed to include:

1). The **User Question**.

2). The predicted **Answer Type** from **Step 1**.

3). **Table Metadata** such as column names, column types, and sample rows from the corresponding database.

4). A set of **Example Shots** demonstrating similar question-to-function mappings.

The process can be divided into two sub-steps:

(I) **Retrieving Similar Shots:** To improve the accuracy of our generated code, we curated a dataset consisting of pairs of **User Questions** and their corresponding gold-standard **Pandas Functions**, which produce correct outputs upon execution. For each new **User Question**, we first retrieve a subset of training examples that share the same answer type. From this subset, we select k samples with semantically similar meanings. These examples are then incorporated into the prompt, providing the model with additional context to generate an appropriate Pandas function for a similar question. The aggregation process for these examples is illustrated in Code Snippet 2.2.1 in the Appendix.

(II) **Composing the Prompt:** With the simi-

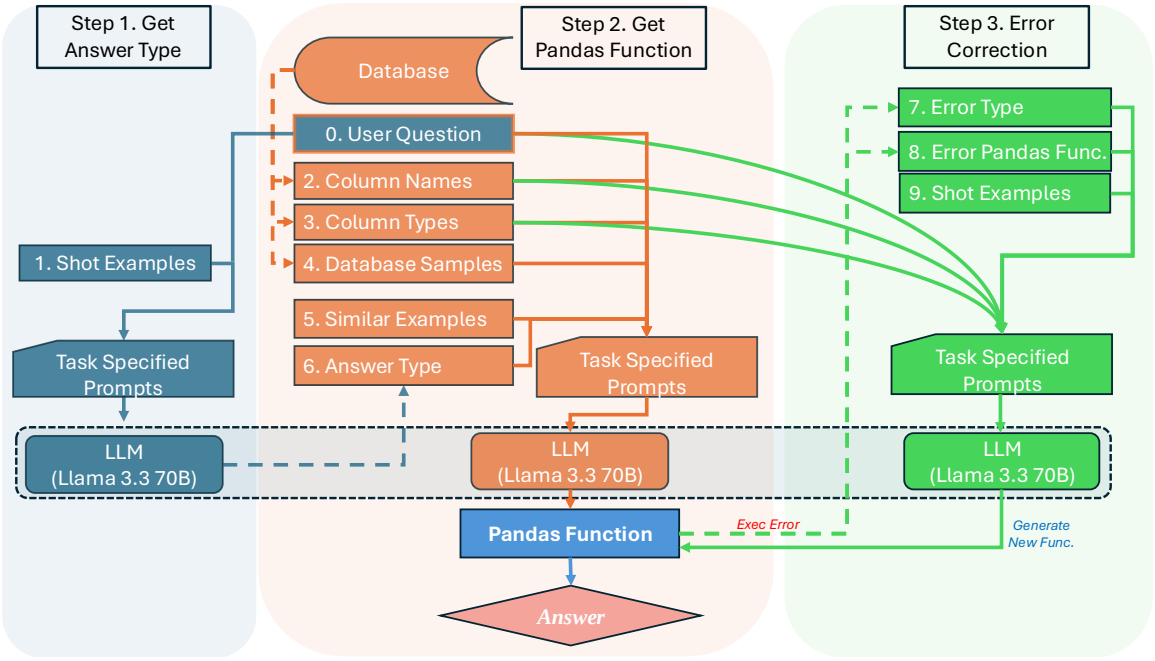

Figure 1: Overview of the multi-turn prompting system for tabular question answering. The figure illustrates the step-by-step process from initial query analysis to final answer extraction, highlighting the iterative error correction loop.

lar shots integrated, we construct a comprehensive prompt that incorporates additional context. Specifically, the prompt includes (1) general shot examples, (2) the user question, (3) column names and types, and (4) row samples from the relevant database. Code Snippet 2.2.2 in the Appendix provides an excerpt of the prompt composition.

Once the LLM generates the function (again ending with a special delimiter), we extract and execute the code. If the generated code produces the correct output, it is returned as the answer. This stage emphasizes the importance of precise prompt engineering in eliciting correct and executable code from the LLM.

3.3 Step 3: Error Correction and Regeneration

In real-world scenarios, generated code may occasionally fail during execution. Our system includes an error-handling loop that:

- Captures the **Error Message** from the failed execution.
- Combines this message with the original query, table metadata, and a concise description of the intended functionality.
- Retrieves additional example shots that illustrate proper error correction.

The error-correction prompt is designed to guide the LLM in revising the faulty function, below is an example.

Category	Content
Pandas Fn.	`df['Item'].dt.date.nunique()`
Error Msg.	`Can only use .dt accessor with datetimelike values`
Correction	`df['date_time'].dt.date.nunique()`

An example template is also shown in Code Snippet for **Step 3**, where all the **placeholder** fields are formatted with the information from **Step 2** and the relevant **Metadata**.

This iterative error correction mechanism not only enhances overall accuracy but also improves the system's resilience to minor syntactic and logical errors. The process emulates a human developer's workflow: debugging, refining, and retesting until a robust solution is achieved. In this study, we set the loop depth to 3, and the experimental results demonstrate a reduction in the execution error rate from **12%** to approximately **3%**.

4 Experimental Setup

4.1 Dataset and Evaluation Metrics

We evaluate our system on SemEval 2025 Task 8 Benchmark on a tabular QA. The dataset comprises tables from various domains along with corresponding natural language questions. We adhere to the official data splits and measure performance using: **Exact Match Accuracy:** The percentage of system-generated outputs that exactly match the gold-standard answers. Additionally, we report execution success rates to account for cases where minor formatting issues might otherwise obscure correct reasoning.

4.2 Implementation Details

Our experiments are conducted using the Llama 3.3 70B Instruct model, accessed via the `transformers` Python package. The model is deployed on a GPU server equipped with 6 NVIDIA A6000 GPUs. 4 of the GPUs are employed for the inferring process. To optimize for speed and memory efficiency, we load the Llama 70B model using quantization methods during the referring process. This quantization significantly reduces computational overhead while preserving the model's performance for generating and refining Pandas functions.

4.3 Baselines and Models

Baseline:
Single-Turn Prompting The LLM (quantized 70B) is prompted once to generate a Pandas function without subsequent error correction. Additionally, the Golden **Answer Type** information is provided instead of relying on the prediction from (**Step 1**), emphasizing the advantages of our multi-turn approach.

5 Results

Table 1 summarizes the performance of our multi-turn prompting system in comparison to the baseline on both Development and Testing Sets.

The multi-turn prompting framework exhibits a marked improvement over single-turn prompting, achieving higher accuracy and more robust handling of execution errors.

5.1 Discussion

The experimental results confirm that our multi-turn approach substantially improves the accuracy and reliability of automatically generated Pandas functions for tabular QA. Although the iterative refinement process introduces additional computational overhead, the increased robustness and error-correction capability justify the trade-off. Several key observations emerge from our study:

Error Sensitivity: Our approach incorporates an error-correction loop that leverages targeted feedback to systematically address both syntactic and semantic errors. This mechanism is highly effective, as demonstrated by a reduction in the execution error rate from **12%** to approximately **3%**. Such a significant improvement underscores the robustness of our method in refining the outputs generated by the language model.

In-Context Learning: By integrating similar examples directly into the input, we enhance the large language model's ability to generalize across a wide range of table schemas and query patterns. This in-context learning strategy contributes to a performance improvement of around **2%** in our experimental evaluations. The results indicate that providing contextual examples not only aids in comprehension but also improves the overall reliability of the model's predictions. We provide a table in the appendix for the detailed information.

Scalability: Although our current experiments have focused on relatively small tables, we recognize the importance of validating our approach on larger, real-world datasets. Future work will be directed towards extending the system's scalability while ensuring that its accuracy and efficiency are maintained in more complex environments. This exploration will be critical for adapting the system to practical applications where data size and variability are significantly higher.

Information Utilization: Our model architecture strategically leverages various types of information across different processing stages, with each element playing a distinct role in enhancing performance. For instance, the inclusion of **'Column_Types'** does not adversely affect performance during the initial processing stage (**Step 1**); however, it significantly contributes to performance in the later stage (**Step 3**). Moreover, the **'Answer_Type'** is particularly valuable in guiding the language model to generate the correct function corresponding to the user's query.

5.2 Performance Gap on Dev and Test Sets

Our system achieves an approximate exact match accuracy of **85%** on the development set but only

Model	Databench (Acc. %)	Databench(lite) (Acc. %)
Baseline (on Dev)	69.25	67.38
Steps (Ours) on Dev	**87.19**	**83.44**
Steps (Ours) on Test	**80.65**	**77.25**

Table 1: Performance comparison on the tabular QA task. The multi-turn framework achieves notable gains on both the development and test sets, demonstrating the effectiveness of iterative refinement.

around **77%** on the test set. Since our approach leverages a pre-trained LLM and does not involve traditional fine-tuning, overfitting is unlikely to be the primary cause of this discrepancy. A preliminary analysis suggests that the test set includes a higher frequency of queries requiring 'List' type answers, which may expose limitations in our current postprocessing strategy. The potential issues include:

Format Sensitivity: The exact match metric depends on strict string-level comparisons. Even if the LLM generates semantically correct answers, slight variations in formatting such as whitespace, punctuation, or line breaks can lead to mismatches. Our postprocessing pipeline has not fully normalized these variations, causing correct answers to be marked as incorrect.

Output Format Mismatch: In some cases, the generated Pandas function is executable and returns the correct data, but the output format does not align with the expected answer format. For example, the correct answer might be returned within a list or nested structure, whereas our evaluation expects a simple scalar or a specific string representation. Such discrepancies directly impact the exact match accuracy.

Imprecision in Postprocessing: The current postprocessing procedures are not fully robust against the variability of LLM outputs. Minor inconsistencies in parsing or converting the returned output can lead to errors. This imprecision means that even correct executions may not be reflected accurately in the final evaluation metric.

5.3 Limitations

One limitation of our model is its reliance on rudimentary, unoptimized postprocessing. Like the baseline, it converts execution output into a string without advanced techniques. The Appendix provides details (see Code Snippet). Future work will enhance normalization and adopt flexible matching to better capture correct answers despite format variations. Additionally, using a general LLM may limit task-specific performance; replacing it with fine-tuned LLMs at different stages could yield better results.

6 Conclusion

We have presented a multi-turn prompting framework for the automated generation of Pandas functions in tabular question answering. By decomposing the problem into answer type extraction, initial function generation, and error-driven refinement, our system achieves substantial improvements over single-turn prompting and fine-tuned models. Our experiments demonstrate that multi-turn prompting enhances both accuracy and robustness, offering a promising direction for future research in table reasoning and prompt-based code generation.

7 Future Work

Looking ahead, we plan to explore several avenues for further improvement. In particular, we intend to:

1). Develop more sophisticated postprocessing techniques to handle format variations and improve exact match accuracy.

2). Extend our approach to support larger and more complex tables and domain-specific datasets.

3). Investigate the integration of additional feedback loops that can adaptively adjust prompt parameters based on real-time execution performance.

These directions aim to enhance both the scalability and the reliability of our system in real-world applications.

Abstract

This paper presents the approach we employed in SemEval-2025 Task 11: "Bridging the Gap in Text-Based Emotion Detection." The core objective of this shared task is emotion perception, focusing on determining the emotion the speaker is likely expressing when uttering a sentence or short text fragment, as perceived by the majority. In this task, we applied a prompt optimization strategy based on in-context learning, combined with data augmentation and ensemble voting techniques, to significantly enhance the model's performance. Through these optimizations, the model demonstrated improved accuracy and stability in emotion detection. Ultimately, in both Track A (Multi-label Emotion Detection) and Track B (Emotion Intensity Prediction), our approach achieved top-3 rankings across multiple languages, showcasing the effectiveness and cross-lingual adaptability of our method.

1 Introduction

Emotion recognition is one of the core tasks in the field of Natural Language Processing (NLP), aiming to identify and understand human emotional states from texts, dialogues, and other forms of data. With the rapid growth of data sources such as social media, online reviews, and customer feedback, sentiment analysis has become an indispensable tool across various industries, particularly in fields such as marketing, brand monitoring, public opinion analysis, and mental health(Saffar et al., 2023; Mohammad et al., 2018). Despite significant progress in sentiment classification and prediction tasks(Dadebayev et al., 2022; Zhang et al., 2024; Liu et al., 2024), the subjective and complex nature of emotions makes emotional expression more challenging due to factors such as individual differences, cultural background, and context. For instance, people may have vastly different emotional reactions to the same event, necessitating that sentiment recognition systems possess enhanced adaptability and flexibility to handle the complex and varied expressions of emotions across diverse contexts.

To address these challenges and bridge existing gaps, SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection introduces a large-scale emotion recognition dataset covering multiple languages(Muhammad et al., 2025a; Belay et al., 2025), aimed at advancing emotion detection technologies. This task consists of three sub-tasks: Track A, Multi-label Emotion Detection; Track B, Emotion Intensity; and Track C, Cross-lingual Emotion Detection(Muhammad et al., 2025b). It presents new challenges and opportunities for researchers in the field of emotion recognition, particularly in handling cross-lingual and multi-label sentiment tasks.

In this paper, we employed a prompt optimization strategy based on in-context learning, combined with data augmentation and ensemble voting techniques, to significantly enhance the model's performance. Specifically, we dynamically adjusted the prompt designs to help the model better understand and capture the subtle nuances of emotional expressions. The data augmentation techniques expanded the training set by generating synthetic data, particularly for categories with fewer emotion intensity samples, effectively addressing the data imbalance issue. Furthermore, the ensemble voting strategy, which combining predictions from multiple models, further improved the accuracy and stability of emotion detection.

During the testing phase, we selected the optimal model combination based on the results from the validation set for submission. Our approach achieved second place for Chinese in Track A, second place for Chinese, and third place for English in Track B.

2 Relate Work

2.1 In-context Learning

In-context Learning (ICL) is an emerging machine learning paradigm that enables models to learn and infer without explicit training, by leveraging contextual information(Rubin et al., 2022; Dong et al., 2022). The core of ICL lies in the model's ability to dynamically adapt to the given context, analyzing examples or instructions within it to generate appropriate outputs(Giray, 2023; Marvin et al., 2023). This learning approach has shown great potential in the field of Natural Language Processing (NLP), especially in few-shot learning scenarios, where models can understand task patterns through a small number of examples(Li et al., 2024). The working principle of ICL can be broken down into two parts: the learning algorithm computes a task vector from the context, and then the task vector is used to modulate the model to generate outputs.

2.2 Prompt Engineering

Prompt Engineering refers to the process of designing and optimizing text prompts that are fed into large language models (LLMs)(Sahoo et al., 2024; Wang et al., 2024; He et al., 2024). By carefully crafting prompts with clear instructions, relevant context, specific examples, and accurate inputs, it guides LLMs to generate high-quality outputs that meet expectations. Prompt Engineering has a wide range of applications in text generation, data augmentation, and question-answering systems, significantly enhancing the performance and practicality of models across diverse application scenarios(Chen et al., 2024; Shao and Li, 2025).

2.3 Data Augmentation

Data Augmentation is the process of generating new training data to expand the dataset, thereby improving the generalization performance of models. In the field of natural language processing, traditional data augmentation methods often rely on techniques such as synonym substitution, sentence reconstruction, and context insertion(Hedderich et al., 2021; Feng et al., 2021; Liu et al., 2023). However, these methods are limited by the understanding of language, leading to lower-quality synthetic data. With the widespread use of large language models (LLMs), data augmentation techniques have undergone significant advancements. Leveraging the few-shot learning capabilities of LLMs, large amounts of synthetic data can be generated for low-resource tasks(Chintagunta et al., 2021; Møller et al.; Li, 2022), and utilizing the language understanding abilities of LLMs, vast amounts of unlabeled data can be annotated for cross-lingual tasks(Zhang et al., 2023; Meoni et al., 2023).

2.4 Supervised Fine-tuning

Supervised Fine-Tuning (SFT)(Wei et al.) is the process of further training a pre-trained model using a labeled dataset for a specific task. By guiding the model to make predictions and inferences based on labeled data, the model's weights are adjusted to match the data distribution of the specific task(Honovich et al., 2023). SFT can significantly improve the model's performance on particular tasks but requires high-quality labeled data and sufficient computational resources(Liu et al., 2022).

3 Methods

- **Profile**: You are an expert in sentiment analysis with extensive experience in identifying and categorizing emotions embedded in text.
- **Goals**: To accurately identify and classify emotions contained in the text. The candidate list of emotions is [anger, fear, joy, sadness, surprise].
- **Workflow**:
  1. Read and comprehend the given text.
  2. Detect the emotions present in the text; if no specified emotion is detected, output "no emotions".
  3. Return the prediction in the format provided in the examples.
- **Examples**:
  - Example 1: Input: "But not very happy." Output: joy,sadness
  - Example 2: Input: "Still had sex with her, though." Output:joy
  - Example 3: Input: "I still cannot explain this." Output: fear,surprise
- **Input**:
  [input_text]
- **Output**:

Figure 1: Prompt example for multi-label emotion detection

3.1 Track A: Multi-label Emotion Detection

In the multi-label emotion detection task, we propose a method that combines prompt design, data augmentation, and model fine-tuning with ensemble voting to enhance model performance.

Prompt Design: As shown in Figure 1, to guide the model in understanding the task and improving sentiment detection accuracy, we design diversified prompts and, based on In-context learning, provide rich example data within the prompts to help the model capture more contextual information. During the optimization process, we employ a dynamic prompt optimization procedure. Specifically, we

test various prompt designs, including variations in prompt construction, changes in the examples, and emphasis on specific emotions. These prompts are iteratively adjusted based on the model's feedback. For instance, if the model encounters difficulty in detecting subtle emotional nuances, we optimize the prompts by incorporating stronger emotional cues or context that helps clarify the sentiment. In selecting examples, we also compare the impact of different example selection methods on the final results. Through this iterative process, we ensure that the model receives the most effective prompts, thereby enhancing sentiment detection accuracy.

Data Augmentation: We first leveraged a large language model (LLM) to create synthetic data that aligns with the emotional characteristics of the original training set. The objective was to enhance data diversity while maintaining label consistency, ensuring no biased samples were introduced. Subsequently, we initialized a pre-trained model using the original training set and filtered the synthetic data based on the model's predictions. Only samples with labels matching the original dataset were retained, ensuring that the augmented data preserved accurate emotion classifications without introducing noise.

Model Fine-Tuning and Ensemble Voting: During the model fine-tuning phase, we further fine-tune the model using both the augmented data and the original training set. Finally, we employ an ensemble voting strategy to combine the predictions of multiple models, thereby achieving more stable and accurate sentiment classification results.

3.2 Track B: Emotion Intensity

In the emotion intensity task, we focus on a multi-class classification approach for each emotion. Our method involves predicting the intensity of a single emotion at a time, avoiding the interference of multiple emotions, and improving accuracy. We employ a carefully designed prompt system to guide the model's understanding and classification of emotion intensity, supplemented by data augmentation techniques to balance underrepresented categories. Finally, we employ the same ensemble voting strategy as in Track A to combine predictions from multiple models, further improving the stability and accuracy of the emotion intensity classification.

Prompt Design: To enhance the model's understanding of the task and improve the accuracy of sentiment intensity detection, we designed diverse prompts based on contextual learning. As shown in Figure 2, each prompt is designed to predict the intensity level of a specific perceived emotion in a given text. The intensity levels are categorized as follows: 0 (No emotion), 1 (Low intensity), 2 (Moderate intensity), and 3 (High intensity). The prompts were carefully structured to guide the model in identifying the intensity of a given emotion by considering both the content and context of the text. The model is instructed to first read and comprehend the input text, then focus on the specified emotion, and finally determine its intensity level.

We also ensure the diversity of examples included in the prompts by incorporating various sentence structures, vocabulary choices, and emotional expressions to represent different intensity levels of emotions. This provides the model with a diverse set of examples, enabling it to adapt to different emotional expressions and contexts. For instance, when the perceived emotion is anger, the examples range from mild irritation (level 1) to intense rage (level 3). Through this approach, the

- **Profile**: You are an expert in emotion intensity analysis with extensive experience in evaluating the strength of emotions in text.
- **Goals**: Your task is to predict the intensity level of a specific perceived emotion within the given text.
  - Intensity levels are classified as follows:
    - 0: No emotion
    - 1: Low degree of emotion
    - 2: Moderate degree of emotion
    - 3: High degree of emotion
- **Workflow**:
  1. Carefully read the input text to understand its content and context.
  2. Focus on the specified perceived emotion from the input.
  3. Determine the intensity level of the emotion based on the text.
  4. If the emotion is absent, assign an intensity level of 0.
  5. Return the prediction in the specified format.
- **Examples**:
  - Example 1:
    Input: Text: Colorado, middle of nowhere. | Perceived Emotion: anger
    Output: anger:0
  - Example 2:
    Input: Text: You know what happens when I get one of these stupid ideas in my head. | Perceived Emotion: anger
    Output: anger:1
  - Example 3:
    Input: Text: And then we have the ultimately retarded `` Spanish Lesson '' ( which I kind of like because it's so entertainingly bad ) and `` Incredible, '' which just flat-out gets on my nerves. | Perceived Emotion: anger
    Output: anger:2
  - Example 4:
    Input: Text: I got lie after lie. | Perceived Emotion: anger
    Output: anger:3
- **Input**:
  Text: **[input text]** | Perceived Emotion: anger
- **Output**:

Figure 2: Prompt example for emotion intensity

model learns the subtle distinctions between emotional intensities and becomes more proficient in predicting them accurately.

Task Formulation: We innovatively reformulated the task as a multi-class classification problem, where the model predicts the intensity level of a single emotion at a time. This approach ensures that the model focuses on one emotional intensity per prediction, minimizing potential interference from simultaneously processing multiple emotions. By simplifying the task in this manner, the model can concentrate on a single emotion and make more precise intensity assessments. For each input, the model determines the intensity of the specified emotion, categorizing it into one of four predefined intensity levels.

Data Augmentation: To address the challenge of data imbalance, particularly in cases where certain emotion intensity categories have fewer samples, we employed data augmentation techniques. Although we initially explored the use of a large language model (LLM) to generate synthetic data to expand the training set, the performance of the LLM-generated data on this task was relatively suboptimal. As a result, we adopted a more effective over-sampling strategy to supplement the underrepresented categories. This approach allowed the model to be exposed to a greater number of examples from the less-represented emotion intensity categories during training, thus improving the model's generalization ability and the accuracy of emotion intensity classification for these categories. By appropriately resampling the samples, we not only increased the number of instances in the underrepresented categories but also ensured the diversity and balance of the training set across different emotion intensity levels. This enhanced the model's robustness and accuracy in predicting emotion intensity, ensuring more reliable and stable performance across all intensity categories.

4 Experiment

In our experiments, we selected Qwen2.5-72B-Instruct(Yang et al., 2024) as the base model and fine-tuned it using LoRA methodology. The batch size was set to 32, the learning rate was set to 1.0e-4, and the model was trained for a total of 5 epochs.

4.1 Track A: Multi-label Emotion Detection

The experimental results on the Track A development set are shown in Table 1. The term "+Fine-tuning" refers to the fine-tuning of the base model using In-context Learning strategy, "+Data Augmentatio" indicates the incorporation of LLM-generated synthetic data during training to enhance data diversity, and "+Vote" denotes the use of an ensemble voting strategy during inference to combine predictions from multiple models. The experimental results demonstrate that the base model achieved a score of 0.6090 for English and 0.4826 for Chinese. After applying fine-tuning , the model's performance improved significantly, with scores of 0.8120 for English and 0.6892 for Chinese. Further, by introducing data augmentation , the scores for English and Chinese increased to 0.8164 and 0.6958, respectively, showing that the synthetic data generated by LLM notably enhanced the model's generalization ability. Finally, employing the ensemble voting strategy further improved the model's performance in both languages, with final scores of 0.8473 for English and 0.7412 for Chinese. We observed that fine-tuning and the ensemble voting strategy significantly improved the model's performance on the validation set. Additionally, we noticed that the performance across different emotion categories varied substantially across different step models, which could be attributed to the influence of the data quantity and label distribution in the validation set.

Method	English	Chinese
Base Model	0.6090	0.4826
+ Finetuning	0.8120	0.6892
+ Data Augmentation	0.8164	0.6958
+ Voted	0.8473	0.7412

Table 1: Our dev set results on the track a.(Only use Chinese and English data for solution exploration.)

Code	Language	Score	Rank
chn	Chinese	0.6817	2
eng	English	0.8064	4

Table 2: Our test set results on the track a. (Only the top 5 results are displayed.)

The experimental results on the Track A test set are shown in Table 2. Testing on both the Chinese and English datasets, our model demonstrated a certain level of performance in emotion detection. Specifically, the model achieved a score of 0.6817 on the Chinese dataset, ranking 2rd, indicating the

model's effectiveness in handling emotion detection for Chinese. For the English dataset, the score was 0.8064, ranking 4th. Although it did not place in the top three, the model still exhibited strong emotion detection capabilities.

4.2 Track B: Emotion Intensity

Method	English	Chinese
Base Model	0.6493	0.5290
+ Finetuning	0.8384	0.7668
+ Data Augmentation	0.8466	0.7704
+ Voted	0.8593	0.7833

Table 3: Our dev set results on the track b. (Only use Chinese and English data for solution exploration.)

The experimental results on the Track B development set are shown in Table 3. Compared to the results in Table 1, the "+Data Augmentation" here refers to the use of oversampling for data augmentation. The experimental results indicate that the base model achieved scores of 0.6493 for English and 0.5290 for Chinese. After fine-tuning the model with a carefully designed prompt and contextual learning strategy, the scores improved to 0.8384 for English and 0.7668 for Chinese. By applying the oversampling strategy to augment the training data, the scores increased to 0.8466 for English and 0.7704 for Chinese. Finally, using the ensemble voting strategy, the scores reached 0.8593 for English and 0.7833 for Chinese, achieving relative improvements of 32.34% and 48.07%, respectively, compared to the base model.

Code	Language	Score	Rank
chn	Chinese	0.7077	2
eng	English	0.8321	3
deu	German	0.7425	2
esp	Spanish	0.7861	4
ptbr	Portuguese	0.6896	2
ron	Romanian	0.7044	4
rus	Russian	0.9185	2

Table 4: Our test set results on the track b. (Only the top 5 results are displayed.)

At the final submission stage, we used the model that performed best on the validation set for prediction and ensemble voting. The experimental results are shown in Table 4. The model achieved a score of 0.7707 for the Chinese dataset, ranking 2nd, and a score of 0.8321 for the English dataset, ranking 3th. Due to time and resource constraints, for other languages, we only fine-tuned the model using carefully designed prompts, without applying data augmentation or ensemble voting strategies. Nevertheless, we still achieved top 5 rankings in five additional languages, further validating the effectiveness and generalizability of our approach. This demonstrates that, through carefully designed prompts and fine-tuning strategies, our method not only performs well in English and Chinese, but also adapts to other languages, showcasing strong cross-lingual generalization ability. In the future, with further investment in resources and optimization of strategies, the model's performance is expected to improve even further across more languages.

5 Conclusion

In this study, we have proposed an effective approach for emotion intensity prediction and multi-label emotion detection. By leveraging techniques such as carefully designed prompts, data augmentation through LLM-generated synthetic data, and dynamic optimization, we significantly improved model performance. The introduction of ensemble voting further stabilized and enhanced the model's classification accuracy. The experimental results on both Track A and Track B validate the effectiveness of our method, demonstrating its strong performance in both English and Chinese, and its generalizability to other languages. Future work could focus on extending the application to more languages, refining the model's ability to handle nuanced emotional expressions, and improving the scalability of the data augmentation strategies.

Limitations

While our approach achieved strong performance in English and Chinese, its effectiveness in other languages was limited due to time and resource constraints. These languages only underwent prompt fine-tuning without data augmentation or ensemble voting, leading to suboptimal results and highlighting the need for further optimization. Additionally, although LLM-generated synthetic data improved performance, its varying quality may have affected generalization. Future work should focus on refining data quality control and developing more robust language-specific strategies to enhance cross-lingual adaptability.

Abstract

This paper presents the OZemi team's submission to SemEval-2025 Task 11: Multilingual Emotion Detection and Intensity. Our approach prioritized computational efficiency, leveraging lightweight models that achieved competitive results even for low-resource languages. We addressed data imbalance through data augmentation techniques such as back-translation and class balancing. Our system utilized multilingual BERT and machine translation to enhance performance across 35 languages. Despite ranking mid-tier overall, our results demonstrate that relatively simple models can yield adequate performance across diverse linguistic settings. We provide an error analysis of emotion classification challenges, particularly for nuanced expressions such as sarcasm and irony, and discuss the impact of emoji representation on model predictions. Finally, we outline future directions, including improvements in sentiment intensity modeling and the integration of semantic prosody to refine emotion detection.

1 Introduction

This paper explores SemEval 2025 task 11 (Muhammad et al., 2025b), which focuses on multi-label emotion detection and emotion intensity across various languages based on the datasets provided by the task organizers (Muhammad et al., 2025a; Belay et al., 2025). The task is divided into three tracks. Track A involves predicting the presence of emotion(s) such as joy, sadness, anger, surprise, and disgust in text snippets. Each emotion is labeled in a binary format: (1) if it is present, and (0) if absent. Task B focuses on predicting the intensity of a perceived emotion on a scale of 0 (*no emotion*) to 3 (*high intensity of emotion*). Finally, Track C is about using a trained dataset in one language to predict emotion labels in a different language. The datasets cover 35 languages in total, with genres ranging from social media to conversational text.

Emotions are at the core of human interactions but are notoriously difficult to detect in text (Öhman, 2021a). Any technical and theoretical advancements have the potential to aid in customer service automation, online content moderation, and many other tasks – both academic and commercial. The focus on cross-lingual emotion detection assists the recognition of emotions on a global scale, increasing its relevance among different cultural contexts.

Our team ranked around the middle for all tasks and languages. Our approach is not the most technically advanced, but because of this it is also not computationally very intensive. We managed to show that it is possible to achieve adequate results even for low-resource languages with very little computational resources. Our code is available on GitHub[1].

2 Background and Previous Work

The input for this task is text snippets in multiple languages ranging from commonly spoken languages such as English, German, and Spanish, to less commonly spoken languages such as Emakhuwa. The output differs across various tracks. The objectives of each Track are demonstrated using the sentence "I just won the lottery!" as an example.

Track A (Multi-label Emotion Detection): The output consists of binary labels for each perceived emotion, where (1) indicates its presence and (0) an absence. The output would look something like: Joy: 1, Sadness: 0, Fear: 0, Surprise: 1, Disgust: 0, Anger: 0 For some languages (such as English), the set of perceived emotions does not include Disgust.

Track B (Emotion Intensity): The output consists of an intensity prediction for each perceived emotion. The output would look something like: Joy: 3, Sadness: 0, Fear: 0, Surprise: 2, Disgust:

[1] https://github.com/esohman/SemEval2025/

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 109–115

0 The degrees of intensity range from 0 to 3, with 0 indicating no emotion, and 3 indicating a high intensity of emotion. The above output example for the sample sentence indicates a high intensity of Joy and moderate intensity for Surprise.

Track C(Cross-lingual Emotion Detection): Involves predicting emotion labels for a language using a labeled training set in a different language.

Track B also has additional challenges, not only does the emotion need to be accurately categorized, but labeled with intensity as well. As Kiritchenko and Mohammad (2017) state, rating scales used as annotations for sentiment analysis suffer from various flaws. They can be inconsistent, with gaps in value between annotators despite agreement on general sentiment, biased towards certain parts of the scale, or suffer from either too little or too much granularity. Additionally, further difficulty can emerge from methods of data pre-processing or lemmatization that may make data easier to categorize when using traditional methods. Exclamation marks, capitalization and more lend context to emotion intensity but may cause difficulty in processing. In addition, sarcasm and irony, prevalent in many common sources of data such as Twitter and other social media can also increase the difficulty of categorization and intensity mapping. However, emotion intensity is an important measure that has been shown to correspond well with human interpretations of a text's overall emotional content (Öhman, 2021b).

3 System Overview and Experimental Setup

In the research on the English model for Track A, we handled emojis by using the *demojize* function of the emoji Python library to convert emojis into descriptive textual labels (Kim and Wurster, 2025).

Track A and C use the f-score, and tack B Pearson correlation for evaluating the models.

For both Track A and Track B, the training data was split into two groups: training and testing sets. The preparation of the dataset involved data cleaning process to ensure the text inputs were uniform and to avoid unnecessary characters. This included replacing or removing special characters and standardizing representations for symbols such as quotes.

3.1 Data Imbalance

One of the significant challenges encountered during the experiment was the imbalance in the dataset's label distribution as shown in Table 1.

Emotion	Count
Anger	497
Fear	2,573
Joy	963
Sadness	1,376
Surprise	1,126

Table 1: Label distribution in the dataset.

The imbalance was most pronounced in the "Anger" class, which had substantially fewer samples than other categories. This posed a risk of bias during model training, as the model might underperform in recognizing emotions associated with underrepresented classes.

To address this issue, three strategies were employed:

1. **Data Duplication**

   Instances from the minority class ("Anger") were duplicated to match the sample size of the majority classes. This ensured that all emotion classes had equal representation in the dataset, reducing the risk of model bias.

2. **Synthetic Oversampling**

   For the Russian dataset, we explored more advanced sampling methods. Specifically, SMOTE (Synthetic Minority Oversampling Technique) was applied in combination with TF-IDF (Term Frequency-Inverse Document Frequency) to balance the class distribution. First, we transformed the text data into numerical form using TF-IDF vectorization. Using the numerical form, synthetic data can be created using SMOTE by interpolating between minority class data and their nearest neighbors. After applying SMOTE, the resampled data is in numerical form as well. To maintain consistency with the rest of the data, the TF-IDF features are transformed back to text for use. As we recognize that data duplication might lead to overfitting, where the model learns to recognize repeated patterns rather than generalizing well, SMOTE was used as an alternative approach.

3. **Back Translation**

   Back translation was applied as secondary approach. This technique involved translating the minority class samples into German or other languages and then translating them back into English using translation models such as DeepL and Google Translate. This method created syntactically diverse examples while preserving the semantic meaning of the original text, effectively augmenting the dataset with quality synthetic data.

These methods were implemented, and their effectiveness in balancing the dataset was evaluated during model training and testing.

3.2 Application and Model Enhancement

The following methodologies were applied in order to handle various languages and to enhance our fine-tuned model.

1. **External Data**

   External data[2][3] were used to examine whether or not they could have positive influences on results resolving the data imbalance discussed before. Judging from the texts, much of the data seems to have originated from social network platforms. The additional data were concatenated with the original dataset to balance the number of sentences between emotional/non-emotional for each of the emotions. By leveraging the balanced data, the BERT model was trained again in English and tested on the development dataset. The addition of the external datasets caused the results to drop from 66% to 55%. This indicates that the official data might be of higher quality annotation-wise or have some unique features compared to the external data.

2. **Hyperparameter Tuning**

   Hyperparameter tuning was implemented as our approach to enhance our model performance. The learning rate was adjusted from three values (2e-5, 3e-5, 5e-5), and the number of epochs was adjusted from 2, 3, and 4. We then chose the best performing parameter sets for each of the emotions based on development data and saved the weights trained with them.

3. **Machine Translation**

   Machine translation techniques were applied to implement our baseline in English and German for Track A and Track C. Google Translate was used as an example of our approach, leveraging its free availability in a multitude of languages. This technique was applied to all the task languages that Google Translate supports, which was 26 out of 28 and 30 out of 32 languages for Track A and Track C, respectively, at the time of writing. The languages not covered by Google Translate was Nigerian-Pidgin (PCM) and Emakhuwa (VMW), for which multilingual BERT was used to complement the limitation. This methodology was applied to leverage our German baseline for "disgust", and English baseline for the other emotions, since "disgust" is not included in the English dataset. This approach enables us to utilize our fairly strong baseline into various languages, additionally to analyze its impact on resource-wise both major and minor languages. Prior testing had also shown that language-specific models particularly for low-resource languages did not generally outperform multilingual ones (Takahashi et al., 2024) and thus the choice to stick to multilingual BERT for most languages was made.

4. **Language-Specific Models**

   However, besides the use of the machine translation technique discussed above, language-specific models were used for three non-English languages for better performances. We focused on Russian, German, and Chinese in this approach, leveraging the simple availability and proven robustness of language-specific BERT models. The models were fine-tuned by official training data and implemented into our system separately from the one that uses machine translation. This approach yielded mid-performing results in macro-F1 score in the official validation phase; 53 % for German and 54 % for Chinese. Comparing these results with those in other non-English languages, including 55 % of Afrikaans in the same phase, it can be said

	NRC Lexicon	Twitter Roberta Base
Anger	0.295	0.406
Fear	0.433	0.688
Joy	0.406	0.646
Sadness	0.457	0.612
Surprise	0.186	0.344

Table 2: Table with benchmark model F1 scores

that our trial to combine the fine-tuned model with machine translation has established a fairly good system for emotion detection over various languages, taking into account its simplicity and ease of deployment.

4 Results

We benchmarked our results against more simple models not fine-tuned on the specific instructions for this task. These benchmark models serve to provide points of reference to evaluate our more complex system. Our system proves its effectiveness and added value by achieving higher scores for this specific task.

One benchmark model uses the NRC Lexicon (Mohammad and Turney, 2013) as a simple rule-based approach that relies on a predefined set of words labeled with Plutchik's 8 core emotions (Plutchik, 1980), matching words to emotions without context or taking negations and valence-shifters into account. As this approach is the simplest, we expect our model that takes context into account to outperform it.

The other benchmark model was the CardiffNLP RoBERTa Base Sentiment multi-label model fine-tuned for SemEval 2018 task 1 (Camacho-Collados et al., 2022). This model is pre-trained on a large corpus of tweets and captures contextual word representations. However, it has not been fine-tuned for this specific task in this evaluation. Its performance already shows a significant improvement over the NRC Lexicon due to its ability to understand the semantics of language at a deeper level, showing us that our system can benefit from understanding the nuances specific to this task.

5 Limitations

One limitation we identified is the inaccuracies in the training data tags provided. For example, although the sentence "But not very happy" does not have the sentiment of joy, the training data had it labeled as as "joy =1." By fine-tuning a model to produce high accuracy scores with respect to an inaccurately tagged dataset, this model, or models produced for this task, may only be accurate for this task, but not when solving other real-world problems.

Additionally, the provided English dataset for Track A does not contain any emojis, which limited the opportunity to directly study the impact of emojis on emotion detection within the English language dataset.

Our simplistic approach to implement Google Translate as a machine translation technique might have had a slight influence on our inference. As stated by Takahashi et al. (2024), the original sentence and the sentence translated by Google Translate may differ in terms of semantic relations. Therefore, it is likely that some input sentences were semantically changed when its translation, and hence had a negative influence on the performance. Alternative ways including use of better-performing machine translation models were considered, but we chose the model on the basis of costs, assuming that the possible influence discussed above would not be significant compared to other factors.

6 Future Work

While brainstorming, we explored the application of semantic prosody (Sinclair, 1996) to the task. While not included in the final model, interesting trends were found that can be included in the refining of future models. Introduced by Sinclair (1996), a word's semantic prosody refers to its tendency to co-occur with specific sentiments or emotions. For example, the words "bring about" and "cause" have similar semantics, in terms of how they both speak about the reason behind an occurrence. Yet, "bring about" is more likely to co-occur with positive occurrences, while "cause" is more likely to co-occur with negative occurrences (McGee 2012; see Figures 1 and 2 for collocates of "bring about" and "cause" respectively, analyzed using AntConc (Anthony, 2024)). Therefore, "bring about"'s semantic prosody can be viewed as positive, and "cause"'s negative.

In line with this concept, we hypothesized that certain n-grams may occur more frequently with certain emotion tags than others. Hence, we ran an analysis for the most frequent 1-gram and 2-grams

[4]Corpus referenced is an American English corpus compiled by Potts and Baker (2012), with more than 1 million tokens.

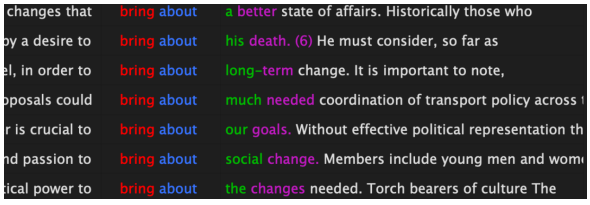

Figure 1: Key Word in Context (KWIC) of "Bring About"[4]

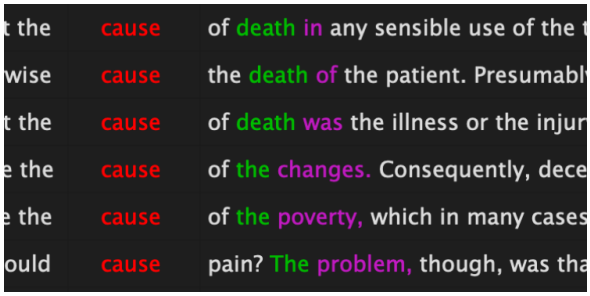

Figure 2: KWIC of "Cause"

for each emotion tag, stratified by each parts-of-speech tag. We found that there were unique n-grams for each emotion tag, occurring at a frequency of more than 1. It might thus be valuable to run this analysis with larger corpora, to find unique n-grams that co-occur with an emotion at a statistically significant frequency. These n-grams could then be used to further refine sentiment analysis models, especially multi-label ones that have relatively lower accuracy scores.

6.1 Emoji Analysis

To study the impact of emojis on emotion detection, we performed an emoji presence check on all language datasets in Track A. As shown in Table 3, German is the third most emoji-rich language in the dataset, with 255 occurrences. The first and second most emoji-rich languages are Somali and Sudanese, but compared to German, they lack sufficient BERT pre-trained models and other similar resources. Therefore, we chose German for our extension study. This additional study addresses a gap left by the English dataset, which does not contain any emojis.

We divided the German dataset into two groups: one containing emojis and the other with all emojis removed. For the emoji group, we used the demojize function to convert emojis into German text. We aimed to evaluate the impact of emojis by calculating the F-score for each model in these two groups.

As shown in Table 4, the F1 scores for the emoji

Language	Emoji Count
Somali (som)	373
Sundanese (sun)	363
German (deu)	255
Amharic (amh)	188
Tigrinya (tir)	33

Table 3: Top 5 Language in Track A by Emoji Count

	Emoji F1 Score	Non-Emoji F1 Score
Anger	0.952	0.955
Disgust	0.907	0.884
Fear	0.988	0.996
Joy	0.955	0.973
Sadness	0.966	0.977
Surprise	0.998	0.990

Table 4: F1 Scores for German Emoji and Non-Emoji Groups

and non-emoji groups are generally similar, with slight variations across different emotion labels. Apart from a slight improvement in the Disgust label with the inclusion of emojis, other labels, such as Fear, Joy, and Sadness, showed decreased performance when emojis were present. After conducting an error analysis on the emoji group, we found that the percentage of error texts with emojis was 15.79%, while that of error texts without emojis reached 84.21%.

Therefore, we conclude that although emojis can be beneficial for certain cases, such as improving the recognition of the *disgust* label, their overall impact on this German sentiment analysis model is limited and can sometimes negatively affect performance. However, it is also vital to note that analyzing the sentiment role of emojis is challenging due to reliance on context, cultural nuances, platform-specific features, and other related reasons (Hakami et al., 2022). Expanding this analysis to other languages could offer deeper insights into emojis' impact on sentiment and emotion detection.

7 Conclusions

Throughout prior discussions in this paper, it can be suggested that our straightforward approach under limited compute resources performs well even for low-resource languages. We have succeeded to maximize the benefits of lightweight models with experiments such as the use of back translation and hyperparameter tuning. Additionally, we have combined that with machine translation techniques

and also leveraged both multi-lingual and language-specific models over some non-English languages as well. In those ways, we firstly established our basis on emotion detection in English sentences, and then, applied the methodology to various languages. Although we had limited compute resources, this straightforward approach was shown to work well and be relatively competitive as well. Hence, our future work could also include some improvements in the same perspective, opening the door for its wider application to emotion detection in various languages.

A Appendix

Performances in the test dataset are shown on Table 5. Four languages that are dealt with in Track C are not supported in Track A, to which the "*"s on the table correspond. The score for English on Track B is 0.6123, computed by the organizers' automatic calculation system just as in the other tracks.

Abstract

In this work, we tackle the challenge of multi-label emotion classification, where a sentence can simultaneously express multiple emotions. This task is particularly difficult due to the overlapping nature of emotions and the limited context available in short texts. To address these challenges, we propose an ensemble approach that integrates Pre-trained Language Models (BERT-based models) and Large Language Models, each capturing distinct emotional cues within the text. The predictions from these models are aggregated through a voting mechanism, enhancing classification accuracy. Additionally, we incorporate threshold optimization and class weighting techniques to mitigate class imbalance. Our method demonstrates substantial improvements over baseline models. Our approach ranked 3rd out of 90 on the English leaderboard and exhibited strong performance in English in SemEval-2025 Task 11 Track A.

1 Introduction

Emotion classification is crucial in various natural language processing (NLP) applications, including customer feedback analysis, mental health monitoring, and social media sentiment tracking. Unlike traditional sentiment analysis, which categorizes text into positive, negative, or neutral sentiments, multi-label emotion classification is more complex, as a single sentence can express multiple emotions, such as joy, anger, and sadness (Strapparava and Mihalcea, 2008), as shown in Figure 1.This complexity arises from the subjective nature of emotions, their overlapping characteristics, and the ambiguity in short texts.

Although transformer-based models, particularly BERT and its variants, have shown promising results in capturing semantic features and contextual dependencies (Vaswani, 2017), challenges persist, including class imbalance, difficulties in distinguishing subtle emotional expressions, and the need for better generalization across languages (Conneau, 2019).

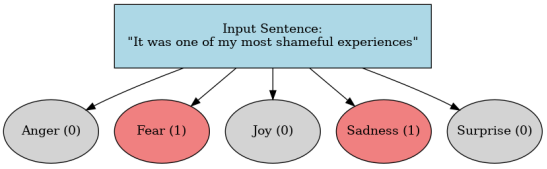

Figure 1: Example of the Multi-Label Emotion Classification task

In this study, we focus on multi-label emotion classification as defined in SemEval-2025 Task 11 Track A (Muhammad et al., 2025a), which aims to evaluate NLP systems' ability to identify multiple emotions in a given text. We propose an ensemble approach, integrating multiple BERT-based pretrained language models (PLMs) (such as BERT, RoBERTa (Liu et al., 2019), and other variants) along with large language models (LLMs) to capture diverse emotional cues (Brown et al., 2020). The predictions from these models are aggregated using a voting mechanism, which enhances robustness and accuracy. By leveraging both pretrained transformers and LLMs, our approach effectively captures the complex and overlapping nature of emotions, improving the generalization across varied emotional expressions.

In addition to the ensemble strategy, we incorporate threshold optimization and class weighting to address class imbalance and improve decision boundaries. These techniques ensure that underrepresented emotions are adequately considered, leading to significant performance improvements over baseline models and enhancing our system's effectiveness in multi-label emotion classification.

2 Related Work

The fundamental challenge in multi-label emotion classification lies in detecting non-exclusive emotional states within textual expressions. Early methodologies predominantly employed lexicon-based systems combined with statistical classifiers like SVMs (Mohammad and Turney, 2013), utilizing hand-engineered features such as emotion-word counts and syntactic patterns. While effective for coarse-grained analysis, these approaches exhibited limitations in handling three critical aspects: (1) contextual polysemy in emotional lexicons (e.g., "cold" indicating either temperature or emotional detachment), (2) compositional semantics in multi-emotion expressions, and (3) cross-lingual generalizability.

Currently, pre-trained language models, especially BERT and its variants, have performed well in sentiment multi-label classification tasks. These models effectively capture contextual information through a bidirectional Transformer architecture, improving classification accuracy. Studies have shown that PLMs generally outperform traditional methods and early deep learning models. In multi-label prediction, the binary cross entropy loss function is widely used to deal with the independence of each label (Zhang and Wallace, 2015). At the same time, a weighted loss function is used to adjust the label weights to address the label imbalance problem. In addition, some studies have further improved the classification effect by modeling the dependencies between labels through graph neural networks (GNNs) or conditional random fields (CRFs) (Tenenboim et al., 2009). In general, PLMs perform significantly better than traditional methods in this task and have achieved good results on multiple standard datasets.

In the task of sentiment multi-label classification, large language models have performed well, especially in capturing the complex sentiment in text and the relationship between labels. LLMs usually perform label prediction through generative or sequence-to-sequence (Seq2Seq) methods, and mine the pre-trained knowledge of the model by designing appropriate prompts. In addition, similar to PLMs, LLMs also use weighted loss functions to solve the label imbalance problem and combine multi-task learning to further improve the classification effect (Raffel et al., 2020). Although LLMs have achieved excellent results in sentiment multi-label classification, their huge computational requirements remain a challenge.

3 System Overview

As shown in Figure 2, our proposed system is composed of two main stages. In the first stage, we train and fine-tune three transformer-based models, BERT, RoBERTa, and DeBERTa (He et al., 2020), employing strategies such as automatic threshold search, class weight allocation, and data augmentation to address challenges like data imbalance and overfitting. Additionally, we explore advanced large models, including Qwen2.5 (Yang et al., 2024) and Llama3.1, to further enhance performance. In the second stage, we improve model robustness and accuracy by integrating predictions from multiple models (RoBERTa, DeBERTa, Qwen2.5 and Llama3.1), using a hard voting strategy and cross-validation, ensuring better generalization and complementary feature learning.

3.1 Model Architecture

Pre-trained language models (PLMs): Two Transformer-based models have been fine-tuned as sequence classifiers: RoBERTa and DeBERTa. RoBERTa is a pretrained language model based on the Transformer architecture, introduced by Meta AI. As an enhanced version of BERT, RoBERTa significantly improves performance through strategies such as improved training methods, expanded data, and increased computational resources. DeBERTa, developed by Microsoft Research , introduces two key innovations on top of BERT: the disentangled attention mechanism and the enhanced mask decoder. These improvements make DeBERTa particularly suitable for tasks requiring a precise understanding of contextual relationships, such as sentiment analysis and multi-hop reading comprehension.

Large language models (LLMs): In recent years, large language models have demonstrated impressive capabilities in tackling various NLP tasks. Motivated by these advances, we adopted two state-of-the-art LLMs, Qwen2.5 and Llama3.1, to construct our sequence classifier. We begin by pre-processing our data set using the tokenizers designed for each model. Next, we fine-tune both Qwen2.5 and Llama3.1 on the training subset of our data to adapt them for the specific classification task. Once fine-tuned, the models are applied to the test data to generate predictions. Finally, we evalu-

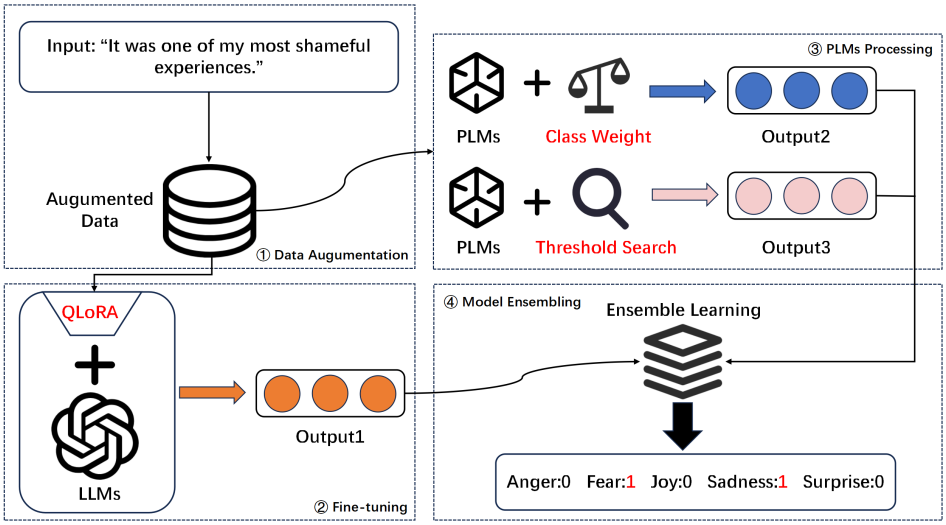

Figure 2: Overview of our system.

ate the performance of these models by comparing the predictions with the true labels.

For PLMs, we use it as an encoder and connect it to a classification layer to get the output, while for LLMs, we directly get the classification results of text sentiment in a generative way.

3.2 Automatic Threshold Search

In multi-label classification tasks, the model usually outputs a probability value for each class (for example, a value between 0 and 1 generated after Sigmoid activation (Kingma and Ba, 2014)). Traditional methods usually use a fixed threshold (such as 0.5) to binarize these probabilities into 0/1 labels, but this approach often does not work well when dealing with imbalanced class distribution or differences in confidence distribution (Zhang and Zhou, 2013). In order to solve the imbalanced distribution of class labels mentioned in Section 3.1, we introduced a strategy of setting independent thresholds for each class to improve the credibility of model predictions. Specifically, we traverse a series of candidate thresholds for each class and independently search for the optimal threshold based on its performance on the validation set (Fan and Lin, 2007). This method not only maintains overall prediction accuracy but also significantly improves the model's ability to capture low-frequency classes and complex label relationships, enhancing its robustness and effectiveness in practical applications.

3.3 Class Weight Allocation

To address overfitting in high-frequency classes and the probability shift in low-frequency classes caused by sample imbalance, we not only apply a separate threshold method but also assign class-specific weights in the loss function to ensure the model pays equal attention to all classes during training. After applying class weight allocation, threshold search is no longer used and the threshold defaults to 0.5.Taking the cross entropy loss function as an example, the loss function after introducing weights can be expressed as:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{c=1}^{C} w_c \cdot y_{i,c} \cdot \log(p_{i,c}) \quad (1)$$

Among them, w_c is the weight of class c, $y_{i,c}$ is the true label, and $p_{i,c}$ is the predicted label. The calculation method of each class weight w_c is as follow:

$$w_c = \frac{N_{\text{total}}}{N_c} \quad (2)$$

N_{total} is the total number of samples, N_c is the number of samples of class c

3.4 Data Augmentation

Table 1 shows the distribution of 0 and 1 labels for each class in the training set. From the figure, we can clearly see that there is a significant difference in the distribution of 0 and 1 labels in some sentiment classes, which makes the model prone to over-focus on classes with higher sample sizes when predicting, and insufficient attention to low-frequency

Sentiment	Negative	Positive
Anger	2435	333
Fear	1611	1157
Joy	2094	674
Sadness	1890	878
Surprise	1929	839

Table 1: Label distribution of different emotions in the training set.

Hyperparameters	PLMs	LLMs

Optimizer	AdamW	AdamW
Weight Decay	0.001	0.001
Train Batch Size	16	4
Max Input Length	512	512
Learning Rate	2×10^{-5}	1×10^{-4}
Max Output Length	128	128

Table 2: Hyperparameter settings for PLMs and LLMs training.

classes. To address this problem, we tried to perform data enhancement on low-frequency classes. Taking "Anger" as an example, we extracted all "Anger"-labeled texts from the training set and applied simple data augmentation methods, such as synonym replacement, back-translation, and reconstruction using a large language model based on the original text and labels. It is noteworthy that we applied data augmentation strategies to each model.

3.5 Ensemble Learning

In multi-label classification tasks, a single model may not be able to fully capture complex label relationships and semantic features for the following reasons:

- Model bias: Different model architectures (such as BERT and RoBERTa) have different sensitivities when processing text features. For example, BERT is good at capturing bidirectional context, while DeBERTa performs better in decoupling attention mechanisms. A single model may not be sufficient to fully model certain classes (such as low-frequency labels "Anger") or certain specific language expressions (such as irony, metaphor).
- Variance and risk of overfitting: When the amount of training data is limited or there is a lot of noise, a single model is prone to overfitting the distribution of the training set, resulting in decreased generalization ability.
- Feature complementarity: Different models can extract complementary features (for example, word-level features and syntactic structure features). Therefore, by integrating the results of multiple models, multi-dimensional information can be integrated to improve the robustness of the model.

Therefore, we integrate the results of different models through a hard voting strategy (i.e., directly counting the predicted labels of multiple models and selecting the label with the most votes). When the model's output is uncertain (e.g., two votes in favor and two against), the corresponding data is flagged. These ambiguous cases are then re-evaluated by the models. If uncertainty persists after re-inference, a label of 0 or 1 is assigned to the emotion at random with a probability of 50%. Based on previous research, we selected RoBERTa, DeBERTa, Qwen2.5 and Llama3.1 as base models for integration. At the voting stage, we only use the thresholds that were trained for each individual model and do not perform any additional threshold search.

4 Experimental Setup and Results

4.1 Dataset

We used the BRIGHTER dataset (Muhammad et al., 2025b) provided by the organizer, which contains 28 different languages, and a text segment in the data may be labeled with multiple emotions (anger, sadness, fear, disgust, happiness, surprise) instead of a single emotion class. We participated in this subtask on the English dataset.

4.2 Hyperparameters

Detailed information on the hyperparameter settings of the experiment is shown in Table 2.

4.3 Metrics

The organizer of this evaluation uses the macro F1 score as the main indicator to evaluate the performance of the model. In multi-label classification problems, the macro F1 score is obtained by calculating the F1 score of each class and averaging the F1 scores of all classes. The characteristic of the macro F1 score is that it ignores the difference in the number of samples in each class and gives each

Settings	Macro F1	Anger	Fear	Joy	Sadness	Surprise
RoBERTa	0.750	0.743	0.818	0.667	0.753	0.769
+ threshold search	0.784	0.788	0.800	0.706	**0.833**	0.794
+ class weight	0.783	0.774	0.790	0.772	0.758	**0.820**
+ data augmentation	0.770	0.774	**0.841**	0.724	0.727	0.781
+ ensemble learning	**0.795**	**0.800**	0.774	**0.787**	0.794	0.818

Table 4: Ablation experiment based on RoBERTa.

class the same weight. First, the recall and precision of each class are calculated separately and then the F1 score of each class is obtained based on the harmonic mean of the precision and recall. Finally, the F1 scores of all classes are averaged to obtain the macro F1 score.

5 Results

Table 3 shows the performance of the different base models in this task. Table 4 shows the experimental results based on the RoBERTa model and the improvement methods mentioned in Section 3. It can be clearly seen from the table that the automatic threshold search and class weight allocation strategy significantly enhance the model's attention to low-frequency classes, thereby effectively improving the overall performance. However, the data enhancement method failed to achieve the expected effect and its improvement was limited to a slight improvement. Based on the above experiments, we further integrated the RoBERTa model with the experimental results of adding three improvement methods separately. The experiment shows that this integration strategy significantly improves prediction accuracy, likely because a single model struggles to fully capture complex label relationships and semantic features in text.

Models	Macro F1	Micro F1
BERT	0.724	0.733
RoBERTa	0.750	0.768
DeBERTa	0.739	0.751
Qwen2.5	0.779	0.788
Llama3.1	0.782	0.787

Table 3: Performance of different models on this task.

Finally, we adopted the full model integration (covering language models and large language models) as the ultimate solution of the system, and submitted the prediction result file of the final model on the test set. The official ranking is shown in Table 5, and the system won the third place in the macro F1 indicator.

Rank	Team	Macro F1
1	PAI	0.823
2	NYCU-NLP	0.822
3	**DUT_IR**	**0.812**
4	TeleAI	0.806
5	Pateam	0.805

Table 5: Results of top 5 teams for Task11 Track A English leaderboard on the test set.

6 Conclusion

This paper introduces the system we designed in Track A of Semeval-2025 Task 11, which aims to solve the problem of unbalanced class distribution that is common in multi-class label classification tasks. By combining methods such as automatic threshold search and class weight assignment, we effectively alleviate the model's excessive focus on high-frequency emotions and reduce its tendency to ignore low-frequency emotions. Based on this, we further adopt a model integration strategy to optimize the shortcomings of a single model in capturing complex label relationships and semantic features in text, and significantly improve the robustness and generalization ability of the model. Overall, our system performs outstandingly in the task of multi-label emotion classification, especially on the English test set of Track A, where it achieved an excellent score of third place, verifying the effectiveness and advantages of our method.

Abstract

This paper participates Task 1 of SemEval2025, specifically Subtask A's English Text-Only track, where we develop a model to rank text descriptions of images with respect to how well it represents a the use of a given multi-word expression in its respective context sentence. We trained sentence transformer models from huggingface to rank the text descriptions, finding the RoBERTa model to be the better performing model. For the final evaluation, the fine-tuned RoBERTa model achieved an accuracy of 0.4 for the first developer's evaluation set, and 0.2 for the second, ranking 9th in the English Text Only category for Subtask A. Overall, our results show that a vanilla sentence transformer approach performs adequately in the task and processing idioms. They also suggest that RoBERTa models may be stronger in idiom processing than other models.

1 Introduction

Multiword expressions (MWEs), such as idioms, are prevalent in natural language. They occur frequently in all domains (Biber et al., 2021) and constitute a significant portion of any speaker's lexicon, comparable to portions of single-word expressions (Jackendoff, 1997). Thus, it is important that language models can effectively process idiomatic MWEs. However, studies show that computational models struggle with idiom comprehension, especially when compared to human performance (Phelps et al., 2024; Tayyar Madabushi et al., 2021). This difficulty arises because the meaning of idioms often cannot be predicted based on the combination of the meanings of their individual parts (Dankers et al., 2022). Thus, Task 1 of SemEval2025 focuses on improving current models of idiom comprehension.

Specifically, we participate in Subtask A's English Text-Only track, where we are required to develop a model which ranks text descriptions of images with respect to how well it represents a given MWE in its respective context sentence. To complete the task, we fine-tuned two sentence transformer models from huggingface to take the sentence with the given MWE and its respective text descriptions as inputs, then produce the rankings of the text descriptions as outputs. One model was an mpnet model, while the other was a RoBERTa model. We found that the RoBERTa model produced higher top image accuracy and Spearman's Rank Correlation scores.

During the development phase, we also experimented with a split approach. This approach consisted of first training a standard BERT model to work as a binary classifier to classify an MWE as idiomatic or literal based on its use in its context sentence. Then, text descriptions are scored based on their idiomacity levels using ranking boosting algorithm. Finally, the text descriptions were ranked based on their scores. However, this approach did not yield significant results, hence is not elaborated on in detail in this paper.

The trained RoBERTa model was the model used for the final evaluation. It achieved an accuracy of 0.4 for the first developer's evaluation set, and 0.2 for the second, ranking 9th in the English Text Only category for Subtask A. Overall, our results show that a vanilla sentence transformer approach performs adequately, but further optimisations can be explored to enhance performance. Our code is available on GitHub[1].

2 Background

In this section, we give an overview of the relevant literature, subtask and dataset.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 122–126

2.1 Relevant Literature

Some studies on idiom processing attempted to improve model comprehension by encouraging a more compositional analysis (Li et al., 2021; Raunak et al., 2019). However, later studies suggest that such compositional approaches reduce idiom comprehension.

Hence, more recent approaches encourage leveraging an idiom's surrounding context or treating idioms as single lexical units instead. These approaches align with linguistic research, which suggests that humans tend to process idioms as a single unit rather than as compositional sequences (Sinclair, 1991). Lakoff and Johnson (1980) also shows how idioms derive meaning from their context and real-world interactions. Thus, newer studies have used masked language modelling, which encode richer contextual information, demonstrating improvements in handling non-compositional semantics such as idioms (Fakharian and Cook, 2021; Zeng and Bhat, 2021). Many studies have also shown that encoding idioms as single entities result in better processing of them (Chakrabarty et al., 2023; Tayyar Madabushi et al., 2021; Zaninello and Birch, 2020). Building on these findings, Tayyar Madabushi et al. (2022) fine-tuned a sentence transformer model incorporating single-token representations of idioms, achieving strong performance in idiom comprehension tasks. These findings suggest that utilising an idiom's textual context is a promising direction for improving language model performance in idiom processing.

This task helps to build on existing work to improve machines' comprehension of idioms.

2.2 Task and Dataset

Subtask A is essentially a ranking task. Participants are given a context sentence containing a potentially idiomatic nominal compound (NC), alongside 5 images and respective text descriptions of the images. The objective is to rank the images or their text descriptions based on how well they capture the meaning of the NC in the given context. For this paper, we participate using only the text descriptions, without the images. Participants were ranked based on two criteria. First, top image accuracy, which refers to how accurately the developed system identifies the most representative image, or text description for the context sentence. Second, based on Spearman's rank correlation of the ranks generated by the model and those by the developers.

Depending on whether the target NC is used idiomatically or literally, the developer's desired ranking changes accordingly. Before discussing the rankings, we first describe how the images' respective text descriptions are related to the NC. As there are five images per NC, there are also five corresponding text descriptions. They can describe: (1) an idiomatic synonymous use of the NC, (2) an idiomatic non-synonymous use of the NC, (3) literal synonymous use of the NC, (4) a literal non-synonymous use of the NC, or (5) be unrelated to the NC. If the NC is used *idiomatically*, the developers rank the images and text descriptions as follows:

1. Highest ranked, most representative of use of NC in context sentence: The image and text description that depicts the NC in an *idiomatic* and *synonymous* manner.
2. Image and text description that depicts the NC in an *idiomatic* and non-synonymous manner.
3. Image and text description that depicts the NC in an literal and *synonymous* manner.
4. Image and text description that depicts the NC in an literal and non-synonymous manner.
5. Lowest ranked, least representative use of NC in context sentence: Image and text description unrelated to NC.

Conversely, when the NC is used literally:

1. Highest ranked: Image and text description that depicts the NC in an literal and *synonymous* manner.
2. Image and text description that depicts the NC in an literal and non-synonymous manner.
3. The image and text description that depicts the NC in an *idiomatic* and *synonymous* manner.
4. Image and text description that depicts the NC in an *idiomatic* and non-synonymous manner.
5. Lowest ranked: Image and text description unrelated to NC.

Text descriptions unrelated to the NC serve as a distractor, hence are always ranked least similar to the context sentence by the developers (Pickard et al., 2025). To summarise, these rankings are

the rankings provided in the developers' training dataset.

The dataset used for this paper is the English Subtask A training dataset with text descriptions provided by the developers. It contains 70 NCs and their respective context sentences. Out of these 70 NCs, 39 are used idiomatically, while 31 are used literally, making it a small, but relatively balanced dataset. As each NC has 5 respective text descriptions, there were 350 text descriptions in total. While no information on how the text descriptions were generated was provided (i.e. we do not know if these text descriptions were written by the developers themselves or generated using AI models), they seem to have been written following a similar style.

3 System Overview

Training datasets provided by the developers were used to fine-tune the selected models. More details on the selected models will be given in Section 4 "Experimental Set-up." The data we used were context sentences, nominal compounds (NC), text description of related images, and the rankings of text descriptions in terms of how well they represent the use of the NC in the context sentence. When pre-processing our dataset, we labeled the text descriptions as "candidates," and the NCs as "compound." Other than these labels, no preprocessing was conducted on the text descriptions and context sentences, as the models selected for fine-tuning were sentence transformer models, which have been shown to handle raw textual input effectively (Agirre et al., 2016). See Table 1 for an example of our dataset.

Sentence transformer models were fine-tuned to perform ranking for the subtask. We chose to use sentence transformer models as they have been shown to perform well in ranking tasks (Di Liello et al., 2022). Both the candidates and context sentences were used as input, so the model could directly learn the relationship between the context sentence and candidates. They were also grouped by their respective compounds to ensure that candidates are ranked only in relation to their respective NC-containing context sentence. Embeddings for context sentences and candidates are generated using each model's respective encoder, and cosine similarity is used to measure the semantic proximity between the candidates and context sentences. Based on these similarity scores, candidates are ranked from 1 to 5, with 1 being the most similar and 5 being the least. These ranks serve as the model's output during inference. The loss function used when fine-tuning is CosineSimilarityLoss, which optimises similarity-based ranking, making it useful for a ranking task (see Reimers and Gurevych, 2019).

While sentence transformer models provide a robust framework for ranking candidates based on semantic similarity, one key challenge of the task was semantic ambiguity. Idiomatic expressions often exhibit semantic ambiguity, meaning that the same phrase can be interpreted differently based on the surrounding context. Hence, our system leverages contextual embeddings generated from sentence transformer models that capture the nuanced relationship between the context sentence and each candidate. The model does not treat candidates in isolation but instead encodes their meaning in relation to the context sentence. Additionally, fine-tuning with CosineSimilarityLoss ensures that candidates are ranked based on their semantic proximity to the context, allowing the model to learn fine-grained distinctions between literal and idiomatic uses.

A limited dataset presents challenges in ensuring good model performance, especially when the test data can contains nominal compounds that were not seen during training. We designed the system to learn from the relationship between context and candidate sentences rather than memorizing specific nominal compounds. By focusing on general patterns of semantic similarity across all instances, the model is better equipped to generalize to unseen nominal compounds.

4 Experimental Setup

For this task, we decided to work on getting embeddings to understand how candidate sentences may have literal and idiomatic representations. We fine-tuned two pre-trained sentence transformer models to generate embeddings for the ranking task: "paraphrase-multilingual-mpnet-base-v2," henceforth the "mpnet model", and "sentence-transformers/all-roberta-large-v1," henceforth the "RoBERTa model." Both models were taken from Huggingface. The dataset was prepared by splitting the available data using the train-test-split function, following an 80-20 split, where 80 percent of the data was allocated for training and 20 percent for testing. As the data was grouped by compounds

Compound	Context_Sentence	Candidate	Ranking
night owl	...I am a night owl, so I find that going to sleep...	The image depicts a nighttime scene...	4
night owl	...I am a night owl, so I find that going to sleep...	The image depicts a cartoon-style illustration of a person...	1
night owl	...I am a night owl, so I find that going to sleep...	The image depicts a cartoon-style owl...	3
night owl	...I am a night owl, so I find that going to sleep...	The image depicts a cartoon-style illustration of a young...	2
night owl	...I am a night owl, so I find that going to sleep...	The image depicts a dumbbell...	5

Table 1: Example of Dataset

(see section 3), the training set consisted of 56 compounds and their respective text descriptions and context sentences, while the test set contained 14 compounds grouped in a similar manner. As previously mentioned, the CosineSimilarityLoss function was used to optimise ranking performance. For the mpnet model, it was initially set to fine-tune for 30 epochs, but the process was terminated early to prevent overfitting. 100 warm-up steps were also applied for stable optimisation. Based on the results of training the mpnet model, the RoBERTa model was fine-tuned for only 10 epochs. 100 warm-up steps and 500 evaluation steps were also incorporated. The AdamW optimizer was used to enhance weight regularisation and prevent gradient-based overfitting. To evaluate the fine-tuned models on the test set, we calculated Top Image Accuracy and Spearman's Rank Correlation, as required by the task (see section 2.2).

5 Results

The RoBERTa model performed better than the mpnet model in the ranking task (see table 2).

Table 2: Comparison of Model Performance

Model	Top-1 Accuracy	Spearman's ρ
MPNet (multilingual)	50.00%	0.4643
RoBERTa	57.14%	0.5071

Based on evaluation on the test set, the RoBERTa model had 57.1 percent Top Image Accuracy, and a Spearman's Rank Correlation of 0.507. Conversely, the mpnet model had a Top Image Accuracy of 50 percent and a Spearman's Rank Correlation of 0.464. Therefore, we retrained the full training dataset provided and submitted the results of the RoBERTa model for the final evaluation. For the final evaluation, we achieved an accuracy of 0.4 for the first developer's evaluation set, and 0.2 for the second, ranking 9th in the English Text Only category for Subtask A.

6 Conclusion

Our results show that a vanilla sentence transformer approach performs adequately, but further optimizations can be explored to enhance performance. We initially experimented with a split approach and more complex systems, which are:

1. Training a binary classifier to determine whether a context sentence is idiomatic or literal (using standard BERT).

2. Scoring candidates based on their idiomaticity level using ranking boosting algorithms.

3. Ranking candidates based on their scores or experimenting with Siamese networks with a custom loss function for rankings.

However, this approach did not yield significant improvements over the direct ranking method. Future work could explore hybrid architectures that combine classification-based pre-filtering with ranking models, as well as larger pre-trained models trained on more extensive idiomatic datasets. Additional customisation in loss functions, feature engineering, and ensemble methods may also improve ranking accuracy.

daalft at SemEval-2025 Task 1: Multi-step Zero-shot Multimodal Idiomaticity Ranking

David Alfter
Gothenburg Research Infrastructure in Digital Humanities
University of Gothenburg
Sweden
david.alfter@gu.se

Abstract

This paper presents a multi-step zero-shot system for SemEval-2025 Task 1 on Advancing Multimodal Idiomaticity Representation (AdMIRe). The system employs two state-of-the-art multimodal language models, Claude Sonnet 3.5 and OpenAI GPT-4o, to determine idiomaticity and rank images for relevance in both subtasks. A hybrid approach combining o1-preview for idiomaticity classification and GPT-4o for visual ranking produced the best overall results. The system demonstrates competitive performance on the English extended dataset for Subtask A, but faces challenges in cross-lingual transfer to Portuguese. Comparing Image+Text and Text-Only approaches reveals interesting trends and raises questions about the role of visual information in multimodal idiomaticity detection.

1 Introduction

The SemEval-2025 Task 1 tests multimodal language models' ability to understand idioms by having them rank images based on how well they match idiomatic or literal uses of expressions in context, addressing previous datasets' limitations and exploring whether adding visual information can improve models' comprehension of figurative language; the task consists of two subtasks: ranking 5 images based on how well they match an idiomatic expression used in a sentence (Subtask A), and selecting the most appropriate final image to complete a 3-image sequence while determining if the expression is being used idiomatically or literally (Subtask B) (Pickard et al., 2025).

The data consists of a text file containing the textual data (expression, sentence, image names) and subfolders for each expression containing the images proper. The data is provided by the organizers and partitioned into Train/Dev/Test, plus an additional Extended test set. Table 1 summarizes the data for both Subtask A and B.

Data	# items	
	Subtask A	**Subtask B**
English		
Train	70	20
Dev	15	5
Test	15	5
Extended	100	30
Portuguese		
Train	32	-
Dev	10	-
Test	13	-
Extended	55	-

Table 1: Data summary

2 Related Work

Recent advancements in multimodal language models and the growing availability of datasets that integrate textual and visual information have propelled the task of multimodal idiomaticity representation and detection to the forefront of research (Filippatou, 2024; Pickard et al., 2025). However, even state-of-the-art language models, including large language models (LLMs), struggle to match human performance in comprehending idiomatic expressions (Tayyar Madabushi et al., 2021; Chakrabarty et al., 2022; Phelps et al., 2024). To bridge this gap, multimodal representation learning models, such as CLIP (Radford et al., 2021), Flamingo (Alayrac et al., 2022), and generative models such as GPT-4 (OpenAI et al., 2024), have emerged as promising solutions, exhibiting strong performance in tasks that require cross-modal understanding, making them particularly well-suited for idiomaticity detection.

Cross-lingual transfer remains a challenging area in multimodal contexts, with models like mBERT (Devlin et al., 2019) and XLM-R (Conneau and

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 127–140

Lample, 2019) often experiencing performance degradation when applied to multimodal datasets. Recent studies have explored methods for improving cross-lingual transfer, such as multilingual embeddings and adversarial training (Wang et al., 2021), but consistent performance across diverse languages is yet to be achieved. Hybrid approaches that combine the strengths of multiple models are increasingly adopted for complex multimodal tasks (Guo et al., 2024). The role of visual information in idiomaticity detection remains an open question, with some studies suggesting that visual cues can enhance accuracy (Gu et al., 2023), while others argue that their contribution is context-dependent (Gupta et al., 2022). Artifacts present in existing datasets may allow models to perform well at idiomaticity detection without necessarily developing high-quality representations of the semantics of idiomatic expressions (Boisson et al., 2023). However, good representations of idioms are crucial for downstream applications such as sentiment analysis, machine translation, and natural language understanding (Tayyar Madabushi et al., 2021).

3 Methodology

3.1 System Overview

Our system for SemEval-2025 Task 1: Multimodal Idiomaticity employs two state-of-the-art multimodal language models: Claude Sonnet 3.5 and OpenAI GPT-4o.[1] Given the performance on the original test dataset, we opt to use only OpenAI for the extended dataset.[2] The system first determines whether the expression in the given context is used idiomatically or literally using a zero-shot classification approach. For Subtask A, the input is the provided sentence, while for Subtask B, the image descriptions of the first two images in the sequence are used. The model then ranks the candidate images based on their relevance to the literal or idiomatic interpretation of the expression.

We selected Claude and OpenAI models for their state-of-the-art multimodal reasoning capabilities, strong zero-shot performance, and complementary strengths in handling both textual and visual inputs. Both models exhibit efficient and tightly integrated vision-language processing, which is especially valuable in multimodal tasks, and robust multilingual understanding. Both models are widely regarded for their reliability, accessibility through stable APIs, and support for intermediate reasoning chains, making them well-suited for a hybrid system with an intermediate interpretation step.While alternative models like Gemini, LLaVA, or open-source LLMs (e.g., LLaMA or Mistral-based variants) were considered, they either lacked comparable multimodal maturity, cross-lingual robustness, or were not readily deployable at the time of experimentation. The selected models provided a pragmatic balance of performance, versatility, and ease of integration.

3.2 Idiomaticity Classification

To determine whether the expression is being used idiomatically or literally, we employ a zero-shot classification approach using the pre-trained language models. For Subtask A, the input sentence is directly fed to the model, while for Subtask B, the concatenated image descriptions of the first two images in the sequence are used. The model predicts the idiomaticity label based on its understanding of the expression in context, without any additional fine-tuning or examples provided during the task.

3.3 Image Ranking

Once the idiomaticity of the expression has been determined, the model is tasked with ranking the candidate images based on their relevance to the literal or idiomatic interpretation. For both Subtask A and B, the target expression and the predicted idiomaticity label are used to construct the prompt. The model then scores each candidate image using its knowledge of the expression's meaning and the visual content, producing a ranked list.

3.4 Improvement for Portuguese

Upon observing subpar performance on the Portuguese subset of the data, we experiment with translating some of the prompts to Portuguese before feeding them to the model. This allows the model to better understand the nuances of the expressions in their original language context. The translations are performed using GPT-4o.

3.5 Explanation-based Ranking

As an additional experiment for Subtask A, we introduce an intermediate explanation step to improve the model's understanding of the expression in context. After classifying the idiomaticity, the model is prompted to provide a brief explanation

[1] Parameters and prompts can be found in Appendix A

[2] We implement a fallback to Claude in case the model responds with "I apologize..." or "I'm unable to..."

of the literal or idiomatic meaning of the expression as used in the sentence. This explanation is then incorporated into the prompt for ranking the images, providing additional context to guide the model's selection.

3.6 Hybrid Approach with o1-preview and GPT-4o

In an effort to further improve the system's performance, we investigated a hybrid approach leveraging the complementary strengths of OpenAI o1-preview and GPT-4o. o1-previewexhibits strong performance on natural language understanding and generation tasks. We employ o1-preview for the idiomaticity classification and explanation steps, capitalizing on its robust language understanding capabilities. However, as o1-preview does not have the capability to directly process and reason about images, we continue to use GPT-4o for the visual ranking component. This hybrid strategy allows us to benefit from o1-preview's language understanding while still incorporating the visual reasoning capabilities necessary for the task. Interestingly, we found that this combination of models produced the best overall results on the SemEval-2025 Task 1 datasets, suggesting that the strengths of the two models are indeed complementary and can be effectively combined to tackle multimodal idiomaticity challenges.

3.7 Output Parsing and Post-processing

A key challenge in using large language models like GPT-4o for this task is that their generated outputs do not always strictly adhere to the specified prompt format, necessitating robust parsing and post-processing steps. For instance, when prompted to provide a ranking of the candidate images, the model's response may not be a well-formed array or list, requiring additional effort to extract the intended ranking. Additionally, we observed that the model occasionally produces rankings that are offset by one position, likely due to confusion about whether to use zero-based or one-based indexing. To mitigate these issues, we implement a flexible parsing system that can handle a variety of potential output formats. This includes using regular expressions to identify and extract ranked lists or arrays, as well as heuristics to detect and correct off-by-one errors in the rankings. By applying these post-processing techniques, we ensure that the final output of our system is consistent and aligns with the expected format for evaluation, even if the raw model outputs are somewhat noisy or inconsistent.

3.8 Evaluation

The system's performance is evaluated using the official metrics for each subtask. For Subtask A, we calculate the average ranking score across all test instances. For Subtask B, we measure both the ranking score and the idiomaticity classification accuracy. The submitted rankings and labels are compared against the gold standards provided by the task organizers. We report results on both the original and extended English datasets, as well as the Portuguese subset, to assess the effectiveness of our proposed improvements.

4 Results and Discussion

Tables 2 and 3 show the results for Subtask A and Subtask B, respectively. Additional plots can be found in Appendix B. Claude models are prefixed with *C-*, while OpenAI models are prefixed with *O-*. *DR* stands for "Detect [idiomaticity] and Rank", *DER* stands for "Detect, Explain, Rank". *DER2* models use o1-preview as reasoning LLM and GPT-4o as ranking LLM. Note that the *DER* and *DER2* models were only used in Subtask A Image+Text. For Portuguese, models suffixed with *-P* use prompts translated into Portuguese.

4.1 Subtask A: Image and Text

Our system achieves competitive performance on the English extended dataset for Subtask A, which involves ranking images based on their relevance to an idiomatic or literal expression in a given sentence. The best-performing model, O-DER2, attains an overall accuracy of 0.81, only slightly behind the top score of 0.83 reported by other participants. This result demonstrates the effectiveness of our hybrid approach combining o1-preview for idiomaticity classification and GPT-4o for image ranking. Binary classification scores (literal/idiomatic) are quite high, with accuracies of 0.93 on English, 0.97 on English Extended, 0.85 on Portuguese and 0.75 on Portuguese Extended.

Interestingly, the model exhibits a higher accuracy on literal expressions (0.94) compared to idiomatic ones (0.65), suggesting that identifying and ranking images for literal language use is an easier task. The Discounted Cumulative Gain (DCG) metric, which assesses the quality of the ranked image lists, shows a similar trend, with a higher

Model	Acc all	Acc lit	Acc id	Corr all	Corr lit	Corr id	DCG all	DCG lit	DCG id

O-DR	0.33	0.48	0.15	0.09	0.18	-0.01	2.61	2.90	2.28

Table 2: Results for Subtask A. Best scores per column and test set in bold. Bold omitted for last row.

score for literal expressions (3.54) than idiomatic ones (3.13).

On the Portuguese subset, our best model, O-DER2-P, achieves an overall accuracy of 0.77, with perfect performance on idiomatic expressions (1.0) but lower accuracy on literal ones (0.57). The DCG scores follow a similar pattern, with idiomatic expressions (3.63) outperforming literal ones (3.04). These results highlight the challenges of cross-lingual transfer and the need for further improvement in handling Portuguese idioms.

4.2 Subtask A: Text Only

In the text-only setting for Subtask A, our system demonstrates mixed performance. On the English dataset, the O-DR model achieves an overall accuracy of 0.66, with higher accuracy on idiomatic expressions (0.75) compared to literal ones (0.57). The DCG scores are relatively balanced, with 3.10 for literal expressions and 3.04 for idiomatic ones.

However, on the English extended dataset, the performance drops significantly, with an overall accuracy of 0.33 and a notable decrease in performance on idiomatic expressions (0.15) compared to literal ones (0.48). This suggests that the extended dataset introduces more challenging and diverse examples that require further improvements in our text-based idiomaticity classification approach.

Comparing the Text-Only results to the Image+Text setting, we observe that the inclusion of visual information generally improves performance, particularly on the English extended dataset. This highlights the importance of leveraging multimodal information for idiomaticity detection, especially in more complex and diverse scenarios.

4.3 Subtask B: Image and Text

In the image+text setting for Subtask B, our system achieves mixed performance on the English dataset. The O-DR model obtains an overall item accuracy of 0.60, with perfect accuracy on idiomatic expressions (1.0) but zero accuracy on literal ones (0.0).

Model	Item all	Item lit	Item id	Sent all	Send lit	Sent id
Image and Text						
English						
C-DR	0.20	0.0	0.33	0.80	**1.0**	0.67
O-DR	**0.60**	0.0	**1.0**	**1.0**	**1.0**	**1.0**
English Extended						
O-DR	0.23	0.17	0.33	0.77	0.94	0.50
Text Only						
English						
C-DR	0.60	0.50	0.07	0.8	**1.0**	0.67
O-DR	**1.0**	**1.0**	**1.0**	**1.0**	**1.0**	**1.0**
English Extended						
O-DR	0.60	0.78	0.33	0.77	0.94	0.50

Table 3: Results for Subtask B. Best scores per column and test set in bold. Bold omitted for English Extended.

However, the model achieves perfect sentence accuracy (1.0) for both literal and idiomatic expressions.

On the English extended dataset, the O-DR model's performance drops, with an overall item accuracy of 0.23 and sentence accuracy of 0.77. The model performs better on idiomatic expressions (0.33 item accuracy, 0.50 sentence accuracy) compared to literal ones (0.17 item accuracy, 0.94 sentence accuracy). This suggests that the extended dataset presents more challenging cases for image selection and idiomaticity classification, requiring further improvements in our multimodal approach.

4.4 Subtask B: Text Only

For Subtask B, which involves selecting the most appropriate final image to complete a 3-image sequence while determining the idiomaticity of the expression, our system demonstrates strong performance using only textual information. On the English dataset, the O-DR model achieves perfect scores across all metrics, correctly identifying the idiomaticity and selecting the appropriate final image for both literal and idiomatic expressions.

However, on the English extended dataset, the performance drops significantly, with an overall accuracy of 0.6 and lower scores on idiomatic expressions (0.33) compared to literal ones (0.78). This suggests that the extended dataset introduces more challenging and diverse examples that require further improvements in our text-based idiomaticity classification and image selection approach.

4.5 Comparison between Image+Text and Text Only

Comparing the results of Subtask A (Image+Text) and Subtask B (Text Only) reveals an interesting trend. While the inclusion of visual information in Subtask A generally improves performance, particularly on the English extended dataset, the text-only approach in Subtask B surprisingly outperforms the Image+Text approach on the English dataset. This suggests that the textual context alone can be sufficient for identifying idiomaticity and selecting appropriate images in some cases, and that the integration of visual information may introduce additional complexity or noise. However, it is important to note that the English extended dataset results for Subtask B show a significant drop in performance compared to the English dataset, indicating that the text-only approach may not generalize well to more diverse and challenging examples. Further investigation is needed to understand the factors contributing to this performance gap and to develop more robust multimodal approaches that can effectively leverage both textual and visual information.

4.6 Portuguese Performance

The results on the Portuguese subset for Subtask A highlight the challenges of cross-lingual transfer in multimodal idiomaticity detection. Despite the improvements achieved by translating the prompts to Portuguese and incorporating explanations, the overall performance remains lower compared to the English datasets. This suggests that there may be linguistic and cultural differences in idiomatic

Test set	Rank (O)	Rank (E)
Subtask A		
English (T+I)	5	2
English (TO)	3	5
Portuguese (T+I)	4	4
Subtask B		
English (T+I)	1	2
English (TO)	1	2

expressions that require further adaptation and fine-tuning of the models.

4.7 Overall Performance

In comparison to other submissions, according to the official leaderboard, our best models rank as follows: for Subtask A (Text+Image), we rank fifth on the original and second on the extended test set, for Subtask A (Text Only), we rank third and fifth, for Subtask A (Text+Image) Portuguese, we rank fourth on both test sets. For Subtask B, we rank first and second in both modalities.

5 Conclusion

In this paper, we present a multi-step zero-shot system for the SemEval-2025 Task 1 on Advancing Multimodal Idiomaticity Representation (AdMIRe). Our approach leverages state-of-the-art multimodal language models, including Claude Sonnet 3.5, OpenAI GPT-4o, and o1-preview, to address the challenges of idiomaticity detection and image ranking in both literal and idiomatic contexts.

The system demonstrates competitive performance on the English extended dataset for Subtask A, achieving an overall accuracy of 0.81 using a hybrid approach that combines o1-preview for idiomaticity classification and GPT-4o for visual ranking. However, cross-lingual transfer to Portuguese remains a challenge, highlighting the need for further research in adapting multimodal idiomaticity detection systems to different languages and cultural contexts.

Our analysis of the Image+Text and Text-Only approaches reveals interesting trends, with the Text-Only approach surprisingly outperforming the Image+Text approach on the English dataset for Subtask B. This raises questions about the role and effectiveness of visual information in multimodal idiomaticity detection, and calls for further investigation into the factors contributing to the performance differences across datasets and subtasks.

Future work should investigate the factors contributing to the performance differences between Image+Text and Text-Only approaches across datasets and subtasks to develop more effective multimodal idiomaticity detection.

Limitations

While our system demonstrates competitive performance on the SemEval-2025 Task 1 datasets, there are several limitations that should be acknowledged:

1. Our system relies on zero-shot classification for idiomaticity detection, which may not capture the full complexity and nuance of idiomatic expressions across different contexts and languages. Fine-tuning the models on task-specific data could potentially improve performance and generalization.

2. Although we experimented with translating prompts to Portuguese, our cross-lingual evaluation is limited to a single language. To assess the true effectiveness of our approach for multilingual idiomaticity detection, it would be necessary to evaluate on a wider range of languages and idioms. Reliance on pre-trained models: Our system heavily relies on the capabilities of pre-trained multimodal language models, such as GPT-4o and o1-preview. While these models have demonstrated strong performance on various tasks, they may have inherent biases or limitations that could impact the system's performance on specific idioms or cultural contexts.

3. The use of large pre-trained models in our system makes it challenging to interpret the decision-making process behind the idiomaticity classifications and image rankings. Developing more interpretable and explainable models could provide insights into the system's behavior and potential areas for improvement.

4. The use of large pre-trained models like GPT-4o and o1-preview requires significant computational resources, which may limit the accessibility and scalability of our approach for researchers and practitioners with limited resources.

Acknowledgments

The author would like to acknowledge Bill Noble and Mattias Appelgren for the constructive discussions on the topic.

This work has in part been funded by the research program Change is Key! supported by Riksbankens Jubileumsfond (under reference number M21-0021).

Ethical Considerations

We acknowledge that the use of large language models for natural language processing tasks can be computationally intensive and consume significant energy and resources. For this reason, no prompt engineering or extensive fine-tuning of the LLM was conducted. The total computational costs incurred in this study are at approximately $28. While LLMs offer powerful capabilities, it is important for the research community to carefully consider the environmental impacts and strive to develop more computationally efficient approaches. Future work should explore techniques to reduce the carbon footprint of LLM usage without compromising performance. Judicious use of these models, along with transparency around the associated costs, can help balance the research benefits with the broader sustainability implications. Through mindful practices and continued innovation, we aim to harness the potential of LLMs in an ethically responsible manner.

temperature	0
OpenAI GPT-4o	
No additional parameters were provided to the model.	

Table 4: Parameters provided to the models

Subtask A	
System	You are a skilled linguist with deep knowledge of idiomatic expressions. You can easily distinguish between idiomatic and non-idiomatic uses of phrases in English and Portuguese.
User	In the following sentence, is the expression *expression* used idiomatically or literally? Expression: *expression* Sentence: *sentence* Answer only with 'idiomatic' or 'literal'
System (I+T)	You are an expert in semantic analysis and image relevance evaluation. Given a classification of an expression as idiomatic or literal, your task is to: Assign each of five provided images to one of the following categories: 1. Synonym for the idiomatic meaning of the expression. 2. Synonym for the literal meaning of the expression. 3. Related to the idiomatic meaning, but not synonymous. 4. Related to the literal meaning, but not synonymous. 5. A distractor unrelated to either meaning. Rank the images based on their relevance to the identified meaning of the expression: - Synonyms should be ranked highest. - Related images should be ranked next. - Distractors should always be ranked lowest.
User (I+T)	Rank the following images for the expression *expression* used in a *idiomatic/literal* way, from most relevant to least relevant. Return an array of five numbers that correspond to the image numbers, like [1,4,3,2,5]. *image data*
User (T)	Rank the following sentences for the expression *expression* used in a *idiomatic/literal* way, from most relevant to least relevant. Return an array of five numbers that correspond to the sentence numbers, like [0,3,2,1,4]. 1. *caption1* 2. *caption2* 3. *caption3* 4. *caption4* 5. *caption5*
System	You are an expert in linguistic analysis with a deep understanding of idiomatic and literal expressions in *English/Portuguese*. Your task is to provide a clear explanation of an idiomatic or literal expression.
User	Explain *expression* used in a *idiomatic/literal* way.
User (I+T)	Given the following explanation of the expression *expression* used in a *idiomatic/literal* way, rank the images from most relevant to least relevant. Return an array of five numbers that correspond to the image numbers, like [1,4,3,2,5]. Explanation: *explanation*, *image data*
System (I+T)	Você é um especialista em análise semântica e avaliação de relevância de imagens. Dada a classificação de uma expressão como idiomática ou literal, sua tarefa é: Atribuir cada uma das cinco imagens fornecidas a uma das seguintes categorias: 1. Sinônimo para o significado idiomático da expressão. 2. Sinônimo para o significado literal da expressão. 3. Relacionado ao significado idiomático, mas não sinônimo. 4. Relacionado ao significado literal, mas não sinônimo. 5. Um distrator não relacionado a nenhum dos significados. Classificar as imagens com base na sua relevância para o significado identificado da expressão: - Os sinônimos devem ser classificados como os mais relevantes. - As imagens relacionadas devem ser classificadas em seguida. - Os distratores devem sempre ser classificados como os menos relevantes.
User (I+T)	Dada a seguinte explicação da expressão *expression* usada de forma *idiomatic/literal*, classifique as imagens da mais relevante para a menos relevante. Retorne um array de cinco números que correspondem aos números das imagens, como [1,4,3,2,5]. Explicação: *explanation*, *image data*

Table 5: Prompts for Subtask A. The first block describes the DR approach. The second block describes the additional prompts used for DER. The third block shows the translations used for Portuguese. Prompts only used for Image+Text are marked with (I+T), while prompts used only for text are marked (T)

	Subtask B
System	You are a skilled linguist with deep knowledge of idiomatic expressions.
User	Given the following sentences, is the expression most likely used literally or idiomatically? Answer only with 'idiomatic' or 'literal'! Expression: *expression* Sentences: *sentences*
System (I+T)	You are a skilled visual artist specialized in images that convey idiomatic or literal meanings. You can easily rank images in terms of relevance to idiomatic and non-idiomatic uses of phrases in English. Respond only with a number.
User (T)	Given the following expression used in a *idiomatic/literal* way, and the following description, which of the following four sentences best continues the description. Respond only with the sentence number (1,2,3,4). Expression: *expression* Description: *sentences* 1. *caption1* 2. *caption2* 3. *caption3* 4. *caption4*
User (I+T)	Given the following expression used in a *idiomatic/literal* way, and the following two images, which of the following four images best continues the description. Respond only with the image number (1,2,3,4). Expression: *expression*, *image data*

Abstract

This paper describes our system for SemEval-2025 Task 9, Subtask 1: The Food Hazard Detection Challenge, which focuses on predicting the type of food hazard and product from incident report titles collected from the web. We employed an ensemble learning approach, combining models trained with various data augmentation techniques to enhance performance on this text classification task. To address class imbalance, we fine-tuned the models using focal loss. Our system achieved Top 1 with a score of 0.8223, demonstrating the effectiveness of ensemble methods and data augmentation in improving classification accuracy for food safety risk assessment.

1 Introduction

Food safety is a growing global concern, with food-related hazards posing risks to public health and the economy. Identifying and categorizing these hazards from online incident reports is crucial for early detection and prevention. The SemEval-2025 Task 9, Subtask 1 (Randl et al., 2025) addresses this issue by evaluating AI models for classifying food hazards and associated products based on web-sourced report titles. This task presents challenges such as handling imbalanced data, ensuring model explainability, and improving classification accuracy to support automated food risk monitoring systems.

Our approach to this task involved employing an ensemble learning method that integrates multiple BERT (Devlin et al., 2019) models, including RoBERTa-large (Liu et al., 2019) and DeBERTa-v3-large (He et al., 2023), trained with various data augmentation strategies. To address the class imbalance commonly found in food hazard classification tasks, we fine-tuned these models using focal loss (Lin et al., 2020). This approach not only helped improve performance but also ensured our system's ability to generalize well across diverse hazard categories. By leveraging both lightweight and intensive data augmentation techniques, we crafted a solution that maintained high accuracy while prioritizing transparency, which is essential in explainable AI.

You can access our system's code through the following GitHub repository: Semeval-Task9-The-Food-Hazard-Detection-Challenge-2025.

2 Related Work

Food safety risk classification is crucial for protecting public health and ensuring regulatory compliance. Traditional approaches relied on rule-based systems and expert knowledge, but advances in machine learning and natural language processing have significantly improved classification accuracy and scalability.

(Nogales et al., 2022) introduced a deep learning framework that incorporates categorical embeddings to predict food safety risks using European Union data. Their model demonstrated high accuracy in predicting product categories, hazard types, and appropriate actions, laying the foundation for large-scale food safety classification using neural architectures.

(Randl et al., 2024) proposed CICLe, a conformal in-context learning approach for large-scale multi-class food risk classification. By integrating conformal prediction, CICLe provides reliable uncertainty estimates, enhancing decision-making in high-risk scenarios. Additionally, they introduced a dataset of 7,546 labeled food recall announcements, serving as a benchmark for future studies.

Recent advances in AI-driven text classification have demonstrated significant potential in regulatory and news analysis. (Hassani et al., 2025) conducted an empirical study utilizing large language models (LLMs) to classify requirements-related provisions in food safety regulations. In a related effort, (Xiong et al., 2023) proposed a hierarchical Transformer-based model for food safety news

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 141–147

classification, addressing the challenge of long-text processing.

Morever, (Maharana et al., 2019) used BERT to detect unsafe food reports in Amazon reviews, linking them to FDA recalls (2012–2014). Their model achieved an F1 score of 0.74 and identified potential underreporting of food safety issues. Similarly, (Wang et al., 2022) reviewed machine learning applications in food safety, highlighting improvements in monitoring, detection, and prediction.

These studies collectively demonstrate the progress in food risk classification. Building upon this foundation, our work explores strategies to enhance both classification accuracy and explainability, with a focus on real-world applicability.

3 System Description

We performed Exploratory Data Analysis (Rao et al., 2021) and discovered that the data suffers from severe class imbalance. To address this issue, we augmented the data by creating multiple different datasets and chunking them into various sizes. We trained different variants of BERT models using Focal Loss to mitigate the impact of the imbalance in the classes.

To further improve performance, we applied an ensemble method using soft voting on the probabilities of each label, combining the results from multiple models to optimize accuracy and minimize classification errors.

3.1 System Overview

Our system is structured as shown in Figure 1 and consists of the following stages: a) **Data:** Preprocessing, augmentation to create two additional datasets, and chunking the data into different sizes; b) **Training:** Training models using both multi-task learning (Zhang and Yang, 2017) and single-task learning approaches; c) **Ensemble:** Combining model predictions using soft voting (Manconi et al., 2022) based on the probabilities of each label.

3.2 Training models

3.2.1 Focal Loss

Focal Loss is used to minimize the effect of easily classified examples and emphasize harder-to-classify ones. We apply Focal Loss for both multi-task and single-task scenarios.

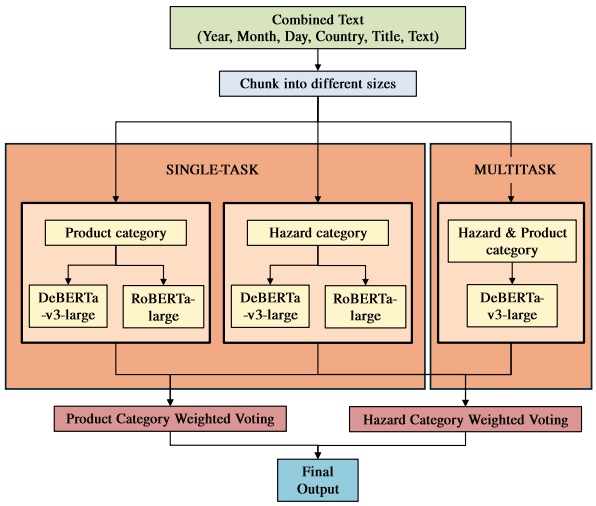

Figure 1: The weight voting ensemble architecture based on the combination of fine-tuning multilingual contextual language models.

$$\mathcal{L}_{FL}(p_t) = -\alpha_t(1-p_t)^{\gamma}\log(p_t)$$

In this formula, p_t is the probability of the true class based on the model's prediction, α_t is a balancing factor for each class, used to adjust the impact between classes, especially when dealing with imbalanced datasets, and γ is the focusing parameter that helps adjust the focus on hard examples. When $\gamma = 0$, Focal Loss becomes the standard Cross-Entropy loss. As γ increases, the impact of easy examples decreases, and the model focuses more on the hard-to-classify examples.

3.2.2 Multitask Learning

Multitask learning is a type of machine learning approach in which multiple related tasks are learned simultaneously, sharing representations to improve performance on each task. In this study, we leverage multitask learning to train a model that simultaneously predicts two types of labels: *product category* and *hazard category*. By training the model on both tasks at once, the shared knowledge between the tasks can enhance the overall model's generalization.

To implement this, we use a transformer-based architecture (Vaswani et al., 2017) as shown in Figure 2, specifically the DeBERTa-v3-large model, which is fine-tuned on both classification tasks. The model consists of a pre-trained BERT-based encoder that captures the contextualized representation of text and two separate classifiers: one for

the product category and another for the hazard category.

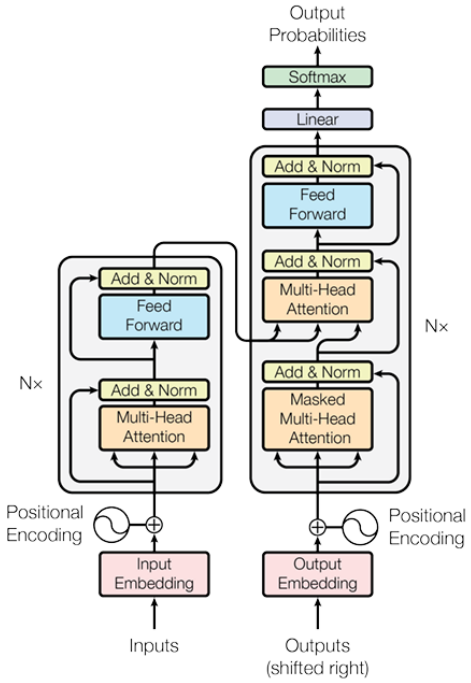

Figure 2: The architecture of the transformer model used in this work.

The multitask model is optimized using a custom loss function called *Focal Loss*, which helps to address class imbalance in the training data. Focal Loss is designed to reduce the impact of easy-to-classify examples and focus more on hard-to-classify instances, thereby improving model performance on imbalanced datasets. Specifically, we use Focal Loss for both product and hazard classification tasks. The model computes the final loss as the weighted average of the individual losses for each task:

$$\text{Loss} = 0.5 \times \text{Product Loss} + 0.5 \times \text{Hazard Loss}$$

The individual task losses are computed using Focal Loss, where the loss for each task is calculated as:

$$\text{Focal Loss} = \alpha(1 - p_t)^{\gamma} \times \text{CrossEntropyLoss}$$

We apply data balancing techniques, such as oversampling and undersampling (Yang et al., 2024), to address the class distribution issues in both tasks. Oversampling is applied to the least frequent categories, while undersampling is applied to the most frequent ones, leading to a more balanced distribution of the classes on the original dataset.

We also calculate class weights (Xu et al., 2020) based on the frequency of each class in the dataset. These weights are used in the model's loss function to give more importance to minority classes, further improving the model's ability to classify rare categories effectively.

3.2.3 Single-task Learning

In this approach, we train two separate models, DeBERTa-v3-large (He et al., 2023) and RoBERTa-large (Liu et al., 2019), each focusing on a specific classification task: *product category* and *hazard category*. Each model is fine-tuned independently for its respective task without any shared learning between them.

To address class imbalance within the dataset, we employ data augmentation instead of traditional oversampling or undersampling techniques (Gao, 2020). For each task, we first augment a dataset to ensure that less frequent labels are represented sufficiently in both the training and validation splits. This step ensures that no label is underrepresented in the validation set. then, we perform additional augmentation to increase the overall volume of data while maintaining the original distribution of classes. We prioritize preserving the natural class distribution, as artificially balancing the data could lead to the loss of important patterns, which would degrade the performance of the model.

Focal loss is also applied for each of the tasks to further help address the class imbalance. For evaluation, we utilize the macro F1 (Opitz and Burst, 2021) score for each label. The macro F1 score calculates the F1 score for each class individually and then averages them, ensuring that each label is treated equally regardless of frequency.

Through this approach, we leverage the benefits of data augmentation to ensure balanced representation across tasks, while focusing on preserving the class distribution to optimize model performance.

3.3 Ensemble

In our model, the *Ensemble* method is implemented using the **soft voting** technique, where the probabilities from multiple models are aggregated as follows:

$$P(y = c) = \sum_{i=1}^{N} w_i P_i(y = c) \quad (1)$$

In equation (1), $P_i(y = c)$ represents the probability of class c predicted by model i, while w_i is the weight assigned to that model. The weights w_i are optimized using grid search on the validation set during the Conception Phase.

The weight optimization process follows these steps:

- Define a grid of possible weight values w_i, ensuring that $\sum w_i = 1$.
- Evaluate each set of weights using the validation set and compute the ensemble model's performance.
- Select the optimal set of weights based on evaluation metrics.

The results show that the *Ensemble* model significantly improves performance compared to individual models, as it leverages weighted aggregation instead of relying on a single model's prediction.

4 Experiment

4.1 Datasets

We used three different datasets for this experiment: the original dataset, a lightly augmented version, and a heavily augmented version.

4.1.1 Data Augmentation

Light Augmentation: In this phase, we focused specifically on the most underrepresented classes in the dataset. We generated additional synthetic samples for the following categories: 9 product categories with the lowest representation and 4 hazard categories with the lowest representation. This targeted approach aimed to ensure that the model receives more examples from these underrepresented classes, which helps to mitigate the bias toward the majority classes and improve overall model performance.

Heavy Augmentation: In the heavy augmentation phase, we applied extensive modifications to the dataset, generating a larger volume of synthetic samples separately for hazard categories and product categories. This approach enhanced the representation of minority classes, improving the model's ability to generalize. Additionally, the dataset was split into two separate subsets: one for hazard classification and another for product classification, as this dataset is used for single-task learning.

All three datasets were split using an 80:20 ratio for training and validation. The dataset statistics after augmentation are summarized in Table 1.

Dataset	Train Samples	Validation Samples
Original	4787	1197
Light Augmentation	5187	1297
Heavy Augmentation - Hazard	8224	2057
Heavy Augmentation - Product	13417	3355

Table 1: Dataset statistics after augmentation

4.1.2 Preprocessing

The data preprocessing follows a systematic approach applied to all datasets. Special characters (excluding punctuation) are removed, newlines are replaced with spaces, and consecutive spaces are consolidated. Punctuation is standardized for readability.

After cleaning, the text is segmented into sentence-based chunks of 512, 768, 1024, and 1280 tokens, approximately 400, 650, 900, and 1150 words, to preserve contextual coherence while adhering to model constraints.

For the heavily augmented dataset, additional preprocessing steps are applied. Non-English text is translated into English to ensure consistency across all the data, allowing the model to process it uniformly. Additionally, HTML tags, which might have been included in the original dataset, are removed using BeautifulSoup (Pant et al., 2024), ensuring that only the relevant textual content is retained and improving the quality of the data used for model training.

4.2 Experiment Environment

We used RoBERTa-large and DeBERTa-v3-large models for classification, trained on NVIDIA P100 and T4 GPUs via the Kaggle platform. RoBERTa-large was trained for 8 hours, while DeBERTa-v3-large took 12 hours per model. The training used a learning rate of 2×10^{-5}, batch sizes of 4 for training and 2 for evaluation, 10 epochs, weight decay of 0.01, logging every 10 steps, and a warm-up ratio of 0.1.

4.3 Results

Table 2 presents a comparison of different model configurations across various methods, datasets, model types, token sizes, and weight voting scores.

METHOD	DATA	MODEL NAME	TOKEN CHUNK	HAZARD SCORE	PRODUCT SCORE	SCORE	WEIGHT HAZARD	WEIGHT PRODUCT
Single-Task	Light	DeBERTa-v3-large	512	0.7861	0.7486	0.7673	0.3500	0.1842
			768	0.7990	0.7640	0.7815	0.3500	0.2632
			1024	0.7789	0.7960	0.7874	0.0000	0.0000
			1280	0.7819	0.7875	0.7847	0.2000	0.0000
		RoBERTa-large	512	0.7680	0.7515	0.7598	0.0500	0.1842
			768	0.7691	0.8292	0.7991	0.0000	0.0000
			1024	0.7719	0.7522	0.7621	0.0000	0.0000
			1280	0.7839	0.7869	0.7854	0.0000	0.0000

MultiTask	Original	DeBERTa-v3-large	512	0.7291	0.7963	0.7627	0.0000	0.1053

Table 2: Result comparison based on method, data, model type, token size, and weight voting

For single-task learning on the Light dataset, DeBERTa-v3-large with 768 tokens achieves the highest overall score of 0.7815, while RoBERTa-large with 768 tokens achieves a slightly higher product score of 0.8292. On the Heavy dataset, DeBERTa-v3-large with 512 tokens achieves the best overall score of 0.7779.

In multi-task learning with the Original dataset, DeBERTa-v3-large with 512 tokens performs with an overall score of 0.7627. Weight voting scores indicate the influence of hazard and product classification, where certain models receive higher weights in hazard or product recognition, such as DeBERTa-v3-large (512 tokens, Light dataset) with a weight hazard score of 0.35.

By using grid search, we optimized the weight voting scheme to obtain the final model combination. The optimized weight allocation, as shown in Table 2, resulted in a final overall score of 0.8223.

5 Conclusion

In summary, we presented an ensemble-based approach for the food hazard detection task in SemEval 2025 Task 9, Subtask 1. By combining DeBERTa-v3-large and RoBERTa-large models with data augmentation and focal loss, we achieved a top performance with a macro F1 score of 0.8223. Our results highlight the importance of model ensembling, data augmentation, and addressing class imbalance for multi-class classification tasks.

Future work will focus on improving the model's ability to distinguish between similar hazard types by incorporating advanced techniques such as Retrieval-Augmented Generation (RAG) (Lewis et al., 2020), which combines information retrieval and generation to enhance context and reduce ambiguity. Additionally, we plan to explore few-shot learning and GAN-based data augmentation (Wang and Wan, 2020) to generate more realistic data, addressing class imbalance and boosting performance with limited labeled data. These methods are expected to improve model generalization and enhance its ability to handle complex hazard detection tasks.

6 Limitations

Although our system achieved strong results, several limitations remain. First and most notably, we submitted multiple test runs, violating SemEval's single-submission rule. This may have led to an unfair advantage, and we take full responsibility. We are committed to strictly following submission policies in future shared tasks to ensure fairness. Second, while data augmentation helped address class imbalance, we did not apply rigorous quality control to synthetic samples, which risks propagating label noise—especially in underrepresented classes. Third, our work lacks inference latency metrics and comparisons with modern large language models (e.g., GPT-4), limiting insight into real-world deployment and performance against current state-of-the-art systems. Future work should incorporate human-validated augmentation, efficiency benchmarks, and LLM-based baselines.

GateNLP at SemEval-2025 Task 10: Hierarchical Three-Step Prompting for Multilingual Narrative Classification

Iknoor Singh, Carolina Scarton and **Kalina Bontcheva**
Department of Computer Science, University of Sheffield (UK)
{i.singh, c.scarton, k.bontcheva}@sheffield.ac.uk

Abstract

The proliferation of online news and the increasing spread of misinformation necessitate robust methods for automatic data analysis. Narrative classification is emerging as a important task, since identifying what is being said online is critical for fact-checkers, policy markers and other professionals working on information studies. This paper presents our approach to SemEval 2025 Task 10 Subtask 2, which aims to classify news articles into a predefined two-level taxonomy of main narratives and sub-narratives across multiple languages. We propose Hierarchical Three-Step Prompting (`H3Prompt`) for multilingual narrative classification. Our methodology follows a three-step Large Language Model (LLM) prompting strategy, where the model first categorises an article into one of two domains (Ukraine-Russia War or Climate Change), then identifies the most relevant main narratives, and finally assigns sub-narratives. Our approach secured the top position on the English test set among 28 competing teams worldwide. The code is available at https://github.com/GateNLP/H3Prompt.

1 Introduction

The rapid dissemination of information online has significantly influenced public discourse, making it crucial to detect and classify narratives accurately (Heinrich et al., 2024; Piskorski et al., 2022). Narrative classification plays a key role in understanding how different perspectives shape public opinion and in identifying potential misinformation campaigns (Amanatullah et al., 2023). To advance research in this area, the SemEval 2025 shared task 10 (Piskorski et al., 2025) presents multilingual characterisation and extraction of narratives from online news providers. A narrative is defined as a structured presentation of information that conveys a specific message or viewpoint, often forming a cohesive storyline[1]. The task provides a benchmark for evaluating and developing narrative classification models (Piskorski et al., 2025), helping researchers analyse how narratives emerge and propagate across different languages.

As part of this challenge, Subtask 2 (Piskorski et al., 2025) focuses on assigning appropriate sub-narrative labels to a given news article based on a two-level taxonomy[2] (Stefanovitch et al., 2025), where each narrative is further divided into sub-narratives. This is a multi-label, multi-class document classification task involving news articles from two key domains: the Ukraine-Russia war and climate change. The dataset comprises articles, collected between 2022 and mid-2024, in five languages: Bulgarian, English, Hindi, Portuguese, and Russian. A significant portion of these articles have been flagged by fact-checkers as potentially spreading misinformation (Piskorski et al., 2025).

Previous work has focused on fine-grained narrative classification across various domains, including climate change (Coan et al., 2021; Piskorski et al., 2022; Zhou et al., 2024; Rowlands et al., 2024), the Ukraine-Russia war (Amanatullah et al., 2023), health misinformation (Ganti et al., 2023), and the COVID-19 infodemic (Kotseva et al., 2023; Heinrich et al., 2024; Shahsavari et al., 2020). These studies have proposed models to identify narratives, aiding in the analysis of misinformation and public discourse within these critical topics.

Given the complexity and multilingual nature of this task, this paper proposes a novel Hierarchical Three-Step Prompting (`H3Prompt`). In this, we fine-tune a Large Language Model (LLM) from the `LLaMA 3.2` family using `H3Prompt` by leveraging both training data and synthetically generated data. Our method follows a three-step prompting framework, ensuring a structured and hierarchical classification process. This approach enhances the model's ability to accurately distinguish between

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 148–154

narratives and sub-narratives, improving classification performance across multiple languages. Moreover, it also allows analysts to gain deeper insights into emerging narratives.

2 Hierarchical Three-Step Prompting (`H3Prompt`)

Our approach to narrative classification follows a hierarchical three-step prompting mechanism. We first describe the dataset and synthetic data generation process (Section 2.1). Next, we outline fine-tuning details (Section 2.2). Finally, we detail the prompt structure for refining predictions across classification levels (Section 2.3).

2.1 Dataset

We utilise the training dataset provided by SemEval 2025 task organisers, which includes annotated news articles spanning five languages (Piskorski et al., 2025). We translate all non-English articles into English using Fairseq's `m2m100_418M` model (Fan et al., 2021). After translation, we obtain a total of 2,091 annotated data points.

Additionally, we synthetically generate articles to augment the dataset in order to improve model generalisation. We used an Vicuna LLM (Zheng et al., 2023) to generate synthetic articles.

Used prompt:

```
You are an AI news curator. Generate 5 different news articles related to the following topic on {category}.

Topic: {sub_narrative}
Explanation: {explanation}

Each article should be between 400-500 words and explore a unique aspect, perspective, or event related to this topic. Focus on delivering informative, coherent, and engaging articles that reflect diverse points of view or angles on the given topic. Avoid redundancy by ensuring that each article highlights a different aspect or argument related to the context provided. The output format should look like this:
Article 1:
Article 2:
Article 3:
Article 4:
Article 5:
```

We opt for `vicuna-7b-v1.5` (Zheng et al., 2023) for synthetic data generation since it has been shown to easily generate content containing disinformation (Vykopal et al., 2023). As shown in the prompt, we provide both the narrative and its explanation to the model. We generate explanations using ChatGPT and manually verify them (see Appendix A).

We generate 100 articles for each sub-narrative. To encourage diversity, we generate articles using sampling with different temperature values in the range of 1 to 1.5. In total, we synthetically generate 8,129 news articles.

Finally, a total of 10,220 (2,091 + 8,129) news articles, including both annotated and synthetic data, are used for training the models.

2.2 Low-Rank Adaptation Fine-Tuning

Low-Rank Adaptation (LoRA) was introduced by Hu et al. (2021) and applied specifically to the attention layers of transformer models. This approach demonstrated comparable or superior performance to full fine-tuning while significantly reducing the number of trainable parameters.

The pre-trained transformer consists of multiple dense layers, where the transformation of an input vector x into an output representation h is performed through full-rank matrix multiplication. In a standard pre-trained model, this transformation is represented as follows:

$$h = W_0 x$$

where $W_0 \in \mathbb{R}^{d \times k}$ is the original pre-trained weight matrix. During model adaptation in LoRA, fine-tuning introduces weight modifications, allowing the updated output to be expressed as:

$$h_{\text{adapted}} = W_0 x + \Delta W x$$

where ΔW represents the learned weight adjustments optimised through training. LoRA constrains these weight updates by decomposing ΔW into two lower-rank matrices: $B \in \mathbb{R}^{d \times r}$ and $A \in \mathbb{R}^{r \times k}$, where $r \ll \min(d, k)$. This formulation allows the adapted output to be computed as:

$$h_{\text{LoRA}} = W_0 x + BAx$$

Matrices A and B are the trainable parameters, initialised such that their product BA starts as a zero matrix. During training, original pre-trained weight matrix W_0 is frozen and does not receive

gradient updates. Additionally, the weight update ΔWx is scaled by a factor of $\frac{\alpha}{r}$, where α is a hyperparameter controlling the adaptation strength.

In this paper, we use LoRA to fine-tune `LLaMA-3.2-3B-Instruct` (Dubey et al., 2024; Touvron et al., 2023) using the Unsloth library (Daniel Han and team, 2023). The fine-tuning process is guided by the prompts defined in Section 2.3. We set α and r to 64, the number of epochs to 5, the batch size to 8, the gradient accumulation steps to 8, and the learning rate to $2e-4$. We manually tune the hyperparameters within the following bounds: (i) 1 to 8 epoch (ii) $1e-5$ to $5e-4$ learning rate (iii) 2 to 16 batch size (iv) 8 to 128 for both α and r values. All experiments are conducted on three NVIDIA A100 40GB GPUs.

2.3 Prompting Mechanism for Narrative Classification

In this subsection, we elaborate on the detailed structure of the `H3Prompt` mechanism. This includes the prompts employed at each step and the accompanying algorithm to do the classification.

Step 1: Category Classification. The first step determines whether a document belongs to the "Ukraine-Russia War" or "Climate Change" category. If no match is found, the document is assigned the label "Other." This first step filters out all irrelevant news articles.

Used prompt:

```
Given the following document text, classify it into one of the two categories: "Ukraine-Russia War" or "Climate Change".

Document Text: {document_text}

Determine the category that closely or partially fits the document. If neither category applies, return "Other". Return only the output, without any additional explanations or text.
```

Step 2: Main Narrative Classification. Based on the assigned category in Step 1, `H3Prompt` then selects the most relevant main narratives using a predefined taxonomy with explanations for each main narrative. See Appendix A for explanation details. The model returns one or more main narratives as hash-separated labels. If no relevant narrative is found, "Other" is returned.

Used prompt:

```
The document text given below is related to "{category}".
Please classify the document text into the most relevant narratives. Below is a list of narratives along with their explanations:

{narratives_list_with_explanations}

Document Text: {document_text}

Return the most relevant narratives as a hash-separated string (e.g., Narrative1#Narrative2..). If no specific narrative can be assigned, just return "Other" and nothing else. Return only the output, without any additional explanations or text.
```

Step 3: Sub-Narrative Classification. For each identified main narrative (Step 2), `H3Prompt` assigns relevant sub-narratives by leveraging a structured prompt that includes explanations of available sub-narratives. See Appendix A for details on how these explanations were generated. Only the sub-narratives corresponding to the main narratives identified in Step 2 are used in the prompt. If no suitable sub-narrative is found, "Other" is returned.

Used prompt:

```
The document text given below is related to "{category}" and its main narrative is: "{main_narrative}".
Please classify the document text into the most relevant sub-narratives. Below is a list of sub-narratives along with their explanations:

{sub_narratives_list_with_explanations}

Document Text: {document_text}

Return the most relevant sub-narratives as a hash-separated string (e.g., Sub-narrative1#Sub-narrative2..). If no specific sub-narrative can be assigned, just return "Other" and nothing else. Return only the output, without any additional explanations or text.
```

The systematic pseudocode for classifying news articles into narratives and sub-narratives is presented in Algorithm 1.

Method	F1 Macro Coarse	F1 Macro Coarse (STD)	F1 Samples Fine	F1 Samples Fine (STD)

3 Experimental Details

3.1 Baseline Models

To assess the performance of our `H3Prompt`, we test a range of baseline models. We also experiment with different configurations: binary classification (denoted by **B**), in which training and classification are performed for each sub-narrative separately; and models trained exclusively on the annotated data provided by the shared task organisers without synthetic data (denoted by **w/o synth**).

Random Baseline. Provided by the organisers (Piskorski et al., 2025), it randomly assigns labels based on the training dataset's distribution.

Traditional Machine Learning. We implement logistic regression and LightGBM using TF-IDF features as input embeddings.

Zero-shot Models. We evaluate several LLMs such as `GPT-4o`, `GPT-4o-mini`, `LLaMA-3.2-3B-Instruct`, `LLaMA-3.1-8B-Instruct`, `FuseChat-Llama-3.2-3B-Instruct`, and `Gemma-2-2B-it` in a zero-shot setting. We use the same prompts as those described in Section 2.3.

Fine-tuned Transformer Models. We train `RoBERTa-base` models using different configurations, including binary classification and with or

without synthetic data. For RoBERTa-base, a three-step classifier is used to predict the category, main narrative, and sub-narrative. We set the learning rate to $1e-5$, the batch size to 32, and epochs to 4. The label is selected based on an output threshold, which is manually tuned in the range of 0.2 to 0.8.

4 Results and Discussion

Table 1 presents the F1 scores for various baseline and fine-tuned models on the development set of English. The official evaluation measure for the task is samples F1 score for sub-narratives (fine-grained) and macro F1 for narratives (coarse-grained) (Piskorski et al., 2025).

In zero-shot models, GPT-4o achieves the highest F1-score for coarse-grained classification and GPT-4o-mini gives the highest F1-score for fine-grained classification. On the other hand, zero-shot models, such as LLaMA-3.2-3B-Instruct and Gemma-2-2b-it, perform significantly worse than trained models, indicating that domain-specific fine-tuning is crucial for improving the narrative classification performance.

Among trained models, logistic regression and LightGBM achieve moderate performance, but transformer-based models such as RoBERTa-base and LLaMA-3.2 H3Prompt outperforms them. Notably, our hierarchical three-step prompting approach (LLaMA-3.2 H3Prompt) achieves an F1 Macro Coarse score of 0.577 and an F1 Samples Fine score of 0.482, demonstrating the effectiveness of structured classification.

The results also indicate that incorporating synthetic data during training improves performance, as models trained solely on the provided training data (denoted by **w/o synth**) perform worse than those that incorporate additional synthetic data. For instance, for LLaMA-3.2 H3Prompt, training with synthetic data improves the fine-grained F1 score by 23% (improvement from 0.392 to 0.482), while for RoBERTa-base, it leads to a 10% improvement (improvement from 0.397 to 0.439).

In addition, binary classification models (denoted by **B**) showed a slight decrease in performance compared to hierarchical prompting models, reinforcing the importance of a structured three-step classification approach.

To further improve classification, we use the best-performing model (i.e., LLaMA-3.2 H3Prompt) to experiment with a bagging ensemble (Breiman, 1996) to reduce variance from individual models. Specifically, we train three different models on separate subsets of the dataset and then combine their predictions. We use three different strategies to aggregate the predictions: (1) union-based, where a sub-narrative is selected if any model predicts it; (2) majority-vote, where a sub-narrative is selected if at least two of the models predict it; and (3) intersection-based, where a sub-narrative is selected only if all models predict it.

Among the ensemble methods, we find that LLaMA-3.2 H3Prompt (Ensemble - Union) is the best-performing model. It achieved the highest scores, with 0.623 for narratives and 0.516 for sub-narratives, showcasing the advantage of ensemble methods in improving classification robustness.

Furthermore, we submitted our best-performing run, LLaMA-3.2 H3Prompt (Ensemble - Union), for evaluation on the test set. We submitted our test predictions for Bulgarian, English, Hindi, Portuguese, and Russian. For all non-English articles, we first machine-translated[3] them into English and then used the translated text for inference. As shown on the test leaderboard[4], our GATENLP submission secured 1st place for English, Portuguese, and Russian. For Bulgarian and Hindi, it ranked 3rd and 5th, respectively. These results highlight the potential of our method for fine-grained narrative classification across multiple languages and misinformation domains.

5 Conclusion

In this paper, we introduced Hierarchical Three-Step Prompting (H3Prompt) for multilingual narrative classification as part of SemEval 2025 Task 10 Subtask 2. Our approach fine-tuned LLaMA 3.2 using both annotated training data and synthetically generated news articles to enhance classification robustness. Our method secured the top position on the English test set among 28 competing teams worldwide, demonstrating the effectiveness of our approach for fine-grained narrative classification. Experimental results showed that H3Prompt outperforms baseline methods and zero-shot models, achieving state-of-the-art performance in narrative and sub-narrative classification. We further demonstrated that incorporating synthetic data during training significantly improves model performance. Additionally, ensemble methods provided

[3] We use m2m100_418M (Fan et al., 2021) for translation.

[4] https://propaganda.math.unipd.it/semeval2025task10/leaderboardv3.html

further enhancements, achieving the highest scores across multiple languages.

A Narrative Explanation

To generate explanations for the main narratives and sub-narratives, we used ChatGPT. Specifically, we prompted the model to generate explanations:
Used prompt:

```
You are given main narratives and sub-narratives for the Ukraine-Russia War and Climate Change. Now, provide a concise explanation for each main narrative and its sub-narratives.

{main_narratives}
{sub_narratives}
```

The generated explanations were manually reviewed and refined to ensure clarity and accuracy. The final set of narrative explanations used in our classification experiments is available at: https://github.com/GateNLP/H3Prompt/tree/master/Dataset.

DKE-Research at SemEval-2025 Task 7: A Unified Multilingual Framework for Cross-Lingual and Monolingual Retrieval with Efficient Language-specific Adaptation

Abstract

The global spread of misinformation has become a critical challenge, making multilingual and cross-lingual fact-checking increasingly essential for ensuring the credibility of information across diverse languages. This paper presents a unified framework for fact-checked claim retrieval, integrating contrastive learning with an in-batch multiple negative ranking loss and a conflict-aware batch sampler to enhance query-document alignment across languages. Additionally, we introduce language-specific adapters for efficient fine-tuning, enabling adaptation to previously unseen languages. Our results demonstrate significant improvements in retrieval performance in both monolingual and cross-lingual settings, underscoring the importance of developing scalable, multilingual systems to combat misinformation and ensure the reliability of information on a global scale.

1 Introduction

With the rapid dissemination of information in the digital age, the global spread of misinformation has become a significant challenge. For instance, a recent study (Vosoughi et al., 2018) found that false news spreads around six times faster than true news on social media, highlighting the urgency of addressing this issue. Moreover, false posts and disinformation on popular social media platforms often transcend boundaries of linguistic and cultural, reaching diverse audiences before they can be effectively countered (Wang et al., 2024b). This dynamic underscores the critical importance of multilingual and cross-lingual natural language processing (NLP) techniques (Chen et al., 2024b; Peng et al., 2023; Wang et al., 2024c), which enable fact-checkers to break down language barriers, access and verify information across languages for the rapid identification of relevant content. Therefore, such techniques are essential, as they not only enhance the efficiency and scalability of fact-checking efforts but also bridge gaps between disparate sources of information.

In this paper, we propose a multilingual and cross-lingual information retrieval (CLIR) system designed to enhance fact-checked claim retrieval in a multilingual context. We present a unified framework for both cross-lingual and monolingual retrieval tasks, demonstrating the effectiveness of our system through detailed experiments. Our method combines a contrastive learning approach with a conflict-aware batch sampler to improve the alignment of query-document pairs in different languages. Additionally, we introduce language-specific adapters for efficient fine-tuning, which significantly improves the performance of the system on unseen languages.

2 Background

Multilingual and CLIR have evolved significantly, transitioning from lexical matching to semantic-aware neural architectures. Early approaches relied on statistic-based lexical methods (Robertson et al., 1995), which performed exact term matching but struggled with cross-lingual lexical gaps, such as polysemy or morphological variations across languages (Oard and Diekema, 1998).

To address these limitations, translation-based CLIR methods emerged, leveraging machine translation (MT) to bridge languages. These methods either translate queries into the document language (query translation) or documents into the query language (document translation) (Sokolov et al., 2013; Järvelin et al., 2008). However, such approaches were prone to error propagation from imperfect MT systems, particularly for morphologically rich or under-resourced languages (Nie, 2010).

The advent of pre-trained multilingual language representation models, such as multilingual BERT (Devlin et al., 2019) and XLM-R (Conneau et al., 2020), marked a paradigm shift for dense retrieval.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 155–159

These models enabled embedding queries and documents in different languages into a shared semantic space. For example, the XLM-R-based models, such as multilingual E5 (Wang et al., 2024a) and BGE-M3 (Chen et al., 2024a), leverage contrastive pre-training on large multilingual corpora to align cross-lingual representations, capturing meaningful semantic relationships among multiple languages and better generalize across linguistic and cultural contexts.

3 System Overview

Our multilingual and CLIR system is designed to address the challenges of cross-lingual and monolingual retrieval for different languages in a unified framework. The system leverages a Multilingual E5 (Wang et al., 2024a) (M-E5) model, pretrained on extensive corpora including more than 100 languages, as the backbone for the language-agnostic representations and further enhances it with language-specific adapters for parameter-efficient adaptation for each language indicated in this task. The system is fine-tuned using contrastive learning with an in-batch multiple negative ranking loss, enhanced with the conflict-aware batch sampling constraint, ensuring better alignment across languages. Below, we describe the key components of the system in detail.

3.1 Contrastive Learning with In-batch Multiple Negative Ranking Loss

To effectively utilise the cross-lingual data, we employ a contrastive learning framework that uses an in-batch multiple negative ranking loss (Henderson et al., 2017). Let the batch size be N. For the i-th positive pair in the batch, denote the query post as q_i and the corresponding fact-checked claim as d_i. The similarity between a query post and a fact-checked claim is measured using a function such as cosine similarity, denoted as $\text{sim}(q_i, d_j)$. The overall loss $\mathcal{L}$ is computed by averaging the loss over all positive pairs in the mini-batch:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\left(\log\frac{\exp\left(\frac{\text{sim}(q_i,d_i)}{\tau}\right)}{\sum_{j=1,i\neq j}^{N}\exp\left(\frac{\text{sim}(q_i,d_j)}{\tau}\right)}\right),$$

where τ is a temperature parameter that controls the smoothness of the distribution.

This formulation drives the model to maximize the similarity between positive query-document pairs while treating all other documents in the same batch as hard negatives. By leveraging these in-batch negatives, the M-E5 model learns highly discriminative representations that effectively capture cross-lingual semantic correspondences for the fact-checking task.

3.2 Conflict-aware Batch Sampler

In practice, applying the in-batch multiple negative ranking loss for the fact-checking task often encounters scenarios where a single query may be associated with multiple relevant fact-checked claims, and similarly, a fact-checked claim may be relevant to multiple queries. Without careful batching, this can lead to conflicts where the same query or document appears multiple times within the same batch. Such conflicts can result in a situation where an instance inadvertently acts as both a positive and a negative example, thereby contaminating the loss signal during the training.

To mitigate this issue, we design a conflict-aware batch sampler. The sampler ensures that, within any given batch $B = \{(q_i, d_i)\}_{i=1}^{N}$, each query q_i and each fact-checked claim d_i appears only once. Formally, for any two distinct pairs (q_i, d_i) and (q_j, d_j) in the batch (with $i \neq j$), we enforce

$$\forall i, j \in \{1, \ldots, N\},\ i \neq j \implies (q_i \neq q_j \ \wedge\ d_i \neq d_j)$$

To avoid the situation where q_i and d_j appear in the same batch if they belong to positive pairs in other batches, we can add the following constraint:

$$\forall i, j \in \{1, \ldots, N\},\ (q_i, d_j) \in P \implies i = j$$

In this way, we ensure that whenever a query q_i and fact-checked claim d_j form a positive pair in some batches, they cannot appear as separate negative pairs in different batches. Here, P represents the set of all positive query-document pairs.

Adding these constraints in the batch sampler guarantees that every instance in the batch is unique, thereby preventing any query or document from inadvertently acting as a negative example for itself or for another positive pair. By leveraging such a conflict-aware strategy, we can confirm that the in-batch negatives are truly negative.

3.3 Language-specific Adapter

After establishing the foundation with the cross-lingual training data for the fact-checking task, the system is further refined with monolingual data

Split	Mono.										Cross.
	eng	spa	deu	por	fra	ara	msa	tha	pol	tur	all
train	4,351	5,628	667	2,571	1,596	676	1,062	465	-	-	4,972
dev	478	615	83	302	188	78	105	42	-	-	552
test	500	500	500	500	500	500	93	183	500	500	4,000

Table 1: We present the number of queries for each language in the monolingual setting, and the total number of queries in the cross-lingual setting.

for each language through the incorporation of language-specific adapters. Specifically, for each language l, a low-rank adaptation (LoRA) (Hu et al., 2022) is introduced to efficiently fine-tune the model without modifying the base parameters. Let $\mathbf{W} \in \mathbb{R}^{m \times k}$ denote a pre-trained weight matrix in the transformer layers. The adapter injects a low-rank update $\Delta\mathbf{W}_l$ into $\mathbf{W}$, parameterized as:

$$\Delta\mathbf{W}_l = \mathbf{B}_l\mathbf{A}_l,$$

where $\mathbf{B}_l \in \mathbb{R}^{m \times r}$ and $\mathbf{A}_l \in \mathbb{R}^{r \times k}$ are trainable low-rank matrices with rank $r \ll \min(m, k)$. During forward propagation, the adapted output for language l becomes:

$$(\mathbf{W} + \Delta\mathbf{W}_l)\mathbf{x} = \mathbf{W}\mathbf{x} + \mathbf{B}_l\mathbf{A}_l\mathbf{x}.$$

Here, $\mathbf{W}$ remains frozen, while only $\mathbf{B}_l$ and $\mathbf{A}_l$ are updated during training.

The language-specific adapter for language l is optimized using the same in-batch loss as in Section 3.1 and Section 3.2. Training leverages both monolingual positive pairs (q_i^l, d_i^l) and cross-lingual positive pairs, with high-resource English as the pivot, i.e. either (q_i^l, d_i^{en}) or (q_i^{en}, d_i^l), where q_i^{en} and d_i^{en} are English translations of q_i^l and d_i^l, respectively. In this way, the model retains language-specific features while benefiting from the semantic consistency provided by the pivot, thus enhancing the representation for each language.

For unseen languages, we propose to merge language-specific adapters from morphologically similar seen languages. Let $\mathcal{S}$ denote the set of languages in the training set, and let u represent an unseen language (e.g., Turkish (tur) or Polish (pol)). For each u, we define a subset $\mathcal{S}_u \subset \mathcal{S}$ comprising seen languages morphologically similar to u. The adapter for the unseen language is then constructed by averaging the adapters of the languages in $\mathcal{S}_u$:

$$\Delta\mathbf{W}_u = \frac{1}{|\mathcal{S}_u|} \sum_{l \in \mathcal{S}_u} \Delta\mathbf{W}_l.$$

For instance, considering that Polish is an Indo-European language, we select:

$$\mathcal{S}_{\text{pol}} = \{\text{eng}, \text{spa}, \text{deu}, \text{por}, \text{fra}\}$$

Similarly, for Turkish, due to the absence of direct Turkic counterparts in the training set, we merge adapters from languages with non-Latin scripts and typological diversity to mitigate biases from Indo-European languages. In this case, we define:

$$\mathcal{S}_{\text{tur}} = \{\text{ara}, \text{msa}, \text{tha}\}$$

4 Experiments

4.1 Dataset

In this work, we evaluated our proposed system using the SemEval 2025 Task-7 dataset (Peng et al., 2025), which consists of two sub-tasks: cross-lingual and monolingual fact-checked claim retrieval. The dataset is the modified version of the MultiClaim dataset developed by Pikuliak et al. (2023), including three key files for training and validation: a database of fact-checked claims, posts extracted from social media platforms, and mappings between posts and corresponding claims. Additionally, for each post or fact-checked claim, the English translation of each non-English content is also provided via Google API. The statistics (#query) of the dataset are shown in Table 1.

4.2 Setup

We used Success@10 as our evaluation metric, where retrieval is considered successful if all relevant fact-checked claims are found within the top 10 retrieved results. This system was implemented using Python 3.10 and Pytorch 2.1.1. The M-E5 model was downloaded from the huggingface repository[1]. During the training, the batch size was set to 24, We used the AdamW as the optimizer and the learning rate was set to 2×10^{-5}.

Table 3: Results on test set measured in Success@10, * indicates the unseen language in the training and development sets.

4.3 Results

We present the results on the development set measured in Success@10 in Table 2. We show the result of M-E5 trained with the provided cross-lingual data. M-E5 w/o constraint means we did not apply the proposed conflict-aware constraints on the batch sampler, and "LADA-M-E5" stands for the proposed system language-specific adapter in this work. Apart from the original M-E5, we also implemented the instruction-tuned embedding model, namely, M-E5-Instruct. The instruction for the query is "*Given a web search query, retrieve relevant passages that answer the query*", which is consistent in the pre-training phase.

We observed that incorporating the conflict-aware batch sampler improved performance on several languages in the monolingual set. For instance, English, Spanish, and French saw improvements of 0.9%, 2.1%, and 1.0%, respectively, highlighting the importance of selecting truly negative samples for the in-batch loss. Additionally, the M-E5 model outperformed M-E5-Instruct in most languages within the monolingual setting, with the exception of a few Latin-based languages. Furthermore, M-E5 showed significant performance gains in the cross-lingual setting. This advantage may be attributed to the fact that the instruction is primarily in English, which could benefit Latin languages more than others. It can be seen that both M-E5 and M-E5-Instruct gain improvements from our proposed LADA in both monolingual and cross-lingual settings, enhancing performance on the fact-checking task.

In the testing, we present the performance of M-E5 and LADA-M-E5 in Table 3. For the unseen languages, Polish and Turkish, we merged the language-specific adapters as described in Section 3.3. It is evident that the proposed language-specific adapters significantly improve the monolingual information retrieval performance for both Polish and Turkish. However, in the cross-lingual setting, we observe a large performance discrepancy between the testing and development sets for both M-E5 and M-E5-Instruct. This discrepancy may stem from the fact that the unseen languages might not be well-aligned with the other seen languages in the training set.

5 Conclusion

In this paper, we introduced a unified multilingual framework for cross-lingual and monolingual fact-checked claim retrieval, leveraging contrastive learning, conflict-aware batch sampling, and language-specific adapters. Our approach effectively improves retrieval performance by aligning multilingual representations while maintaining language-specific features. The integration of low-rank adapters allows efficient adaptation to individual languages, with a strategy for handling unseen languages based on morphologically similar counterparts. Experimental results on the SemEval 2025 Task 7 dataset demonstrate the effectiveness of our

method, achieving strong performance across multiple languages. Future work will explore extending our approach to more low-resource languages and further optimizing retrieval efficiency in real-world applications.

wangkongqiang at SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection

Kongqiang Wang
School of Information Science and Engineering, Yunnan University,
Kunming 650500, Yunnan, China
wangkongqiang60@gmail.com

Abstract

This paper presents our system developed for the SemEval-2025 Task 11:Bridging the Gap in Text-Based Emotion Detection, on Track A: Multi-label Emotion Detection.(Muhammad et al., 2025b)Given a target text snippet, predict the perceived emotion(s) of the speaker. Specifically, select whether each of the following emotions apply: joy, sadness, fear, anger, surprise, or disgust. To this end, we focus on English source language selection strategies on four different pre-trained languages models: google-bert,FacebookAI-roberta,dccuchile-bert and distilbert-multi.We experiment with 1) the training set data is analyzed visually, 2) multiple numbers of single models are trained on the training set data, and 3) multiple number of single models for voting weight ensemble learning. We further study the influence of different hyperparameters on the integrated model and select the best integration model for the prediction of the test set. Our submission achieved the good ranking place in the test set.Emotion Macro F1 Score 0.6998 and Emotion Micro F1 Score 0.7374. For the final ranking, organizers will use the Macro F1 score.Even so, my approach has yielded good results.

1 Introduction

Emotions are simultaneously familiar and mysterious.(Vaidya et al., 2024) On the one hand, we all express and manage our emotions every day. Yet, on the other hand, emotions are complex, nuanced, and sometimes hard to articulate. We also use language in subtle and complex ways to express emotion.Further, people are highly variable in how they perceive and express emotions (even within the same culture or social group).Thus, we can never truly identify how one is feeling based on something that they have said with absolute certainty.Emotion recognition is not one task but an umbrella term for several tasks such as detecting the emotions of the speaker, identifying what emotion a piece of text is conveying and detecting emotions evoked in a reader. Based on the predictive task background of predictive emotion text, We propose an ensemble learning method based on pre-trained language model. The code of this method is available on my GitHub website.[1]

2 Related Work

SemEval in previous years has introduced tasks focusing on Multi-label text classification and text binary classification (Wang et al., 2024)(Su and Zhou, 2024)(Tran and Tran, 2024)(Brekhof et al., 2024)to evaluate Internal potential elements and potential content of the text.These tasks provided datasets with human labeled similarity scores, which have been extensively utilized for training sentence embedding models and conducting semantic evaluations.

2.1 Sentence Embeddings

Word embedding models such as BERT, GloVe, RoBeRTa and Word2Vec are frequently employed to assess the semantic distance between words.They are also some of the more commonly used methods in text classification tasks.Sentence embeddings with a fixed length are often generated via mean/max pooling of word embeddings or employing CLS embedding in BERT. The semantic distances are commonly measured using the cosine similarity of embeddings of two expressions.Siamese or triplet network architectures are frequently employed in sentence embedding training. For example, models such as Sentence-BERT utilize a dual-encoder architecture with shared weights for predicting sentence relationships (e.g., semantic contradiction, entailment, or neutral labeling) or for similarity score prediction using regression objectives, e.g., the difference between human

[1] https://github.com/WangKongQiang

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 160–164

annotated similarity score (sim) of two sentences and the cosine of two sentence embeddings.

2.2 Ensemble Learning

In previous studies, ensemble learning presents several advantages. The ensemble approach can reduce the errors from individual models by amalgamating results from multiple sources or can make the system more robust. In our study, using multiple pre-trained models can also save a substantial amount of computation while making use of information from the large data during pre-training. Previous research has demonstrated that ensemble learning can achieve remarkable success.

In our study, we aim to integrate multiple pre-train learning models to assess semantic relatedness.When models are trained on diverse datasets with different architectures, they may produce varied predictions on semantic relatedness, and combining them may improve overall performance.We use sentence embeddings mainly from the following models.Multilingual BERT (cased, uncased),RoBERTa,BETO (cased, uncased),DistilBERT.

3 Methodology

3.1 overall architecture

The pursued approach involves using a weighted voting system of ensembles composed of different transformers. We trained several state-of-the-art NLP(Natural language processing) models on a large dataset of annotated tweets to create ensembles of classifiers with different architectures and configurations.We then combined the predictions of these ensembles using a weighted voting system to produce the final predictions.We have used the following transformers for the ensembles:Multilingual BERT (cased, uncased),RoBERTa,BETO (cased, uncased) DistilBERT.

For each instance, the final classification decision is based on the weighted sum of outputs of these models. The novel weighted-voting system presented involves using each (normalized) transformer's metric score in the ensemble (F1-score or RMSE, depending on the task) to assess the importance of these in the final outputs of the ensemble (as opposed to the arithmetic mean typically used in conventional voting systems).

3.2 Implementation step

First,The simpletransformers Python library that will be used below requires the data to be presented in a specific form.The following data cell adapts each split to contain only two columns: text and labels, where the latter is an array equal in size to the number of labels.

Second,Models' definition.In this section,the different transformers that will be evaluated are gathered.For this purpose,the implementation mainly relies in the simpletransformers Python library, which allows to train and test transformers within few steps.

Third,Training.Each of the aforementioned models is trained separatedly with the entire training set.This training is directly performed in the previously defined dictionary for convenience.

Fourth,Ensembles' definition.The ensembles of transformers that can be defined with the previously trained models are created.A dictionary is create for convenience, univocally identifying each ensemble.

Fifth,Evaluation.Firstly, each transformer is individually evaluated using the validation split. Subsequently, the main evaluation metrics (accuracy, F1-score, precision and recall) are stored.Secondly, the predictions of each ensemble for the validation set instances are derived. After calculating their metrics, it is possible to determine which ensemble obtained the best F1-Score. This will be the final ensemble used for the test dataset.Regarding the ensembles' predictions, these are obtained through a hard voting system: after computing the output that each of the ensemble's models produces for a given instance, the most-voted class turns out to be the ensemble result.The voting system can be non-weighted or weighted. In the latter, the prediction of each individual transformer is weighted according to their normalized F1-score, thus providing a greater importance to the best model without disregarding the outputs of the other transformers.

Sixth,The vote function determines the ensembler prediction based on the outcomes of its transformers.Its arguments are:predictions, list of transformers' (raw) outputs.weighted,bool that determines if a weighted voting system must be used.weights,list of weights (normalized weighted F1-scores).

Seventh,Selecting the best ensemble Once the predicted labels for each validation instance are calculated for each ensemble, their metrics can be computed. Given that it is a multi classification

Test set Emotion	Score
Macro F1	0.6998
Micro F1	0.7374
Anger	0.5812
Fear	0.8152
Joy	0.7032
Sadness	0.7104
Surprise	0.6891

Table 4: The Test data situation detailed results described

4.5 Biased Performance

From Figure 1 of the visual analysis, we can observe that 75% of tweets in training set data, either in the chart or in the previous input column, have no more than 25 words. This information could be useful in determining the size of a network of neurons, or when a sentence length limit needs to be set.

SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection, on Track A: Shared task of multi-label Emotion Detection. This task is multi-label sorting. Each instance can have 0 to n(n=5,6) categories, and you need to predict which category each instance belongs to. In the specific cases(English language) we focus on, there may be up to five different categories: anger, fear, joy, sadness, surprise. For this task, we will look at the quantity distribution followed by each category, as shown in Table 1. In this case, percentages cannot be assessed because of the intersection.

5 Conclusion

Our system employs an ensemble approach to estimate semantic relatedness(Eneko Agirre and Wiebe, 2014),integrating results from multiple systems:google-bert-base-multilingual-uncased and FacebookAI-roberta-base.The hyperparameter is following: eval-batch-size is 8,num-train-epochs is 5,learning-rate is 4e-05,optimizer is AdamW,use-early-stopping is True.The dataset usage is shown in Table 5. Our findings suggest that semantic relatedness can be deduced from a variety of sources. Although some features (e.g., lexical overlap ratio)may not perform as strongly as models specifically designed to obtain sentence representations, the results demonstrate that these features, when used in a combined manner, can outperform many individual systems and collaboratively achieve a better correlation with human judgment on semantic relatedness.(Siino, 2024)

6 Limitation and Future Work

Our experiments are based on English language data sets only. Constrained by the size of the training data and the availability of pre-trained language models, it is regrettable that we did not offer insights into other Asian and African languages.In future research,studies on low-resource languages will be valuable, including tasks such as data collection, annotation,and pre-training models tailored to these languages.

Abstract

In this paper we present our participation in Subtask 2 of SemEval-2025 Task 10, focusing on the identification and classification of narratives in news of multiple languages, on climate change and the Ukraine-Russia war. To address this task, we employed a Zero-Shot approach using a generative Large Language Model (LLM) without prior training on the dataset. Our classification strategy is based on two steps: first, the system classifies the topic of each news item; subsequently, it identifies the sub-narratives directly at the finer granularity. We present a detailed analysis of the performance of our system compared to the best ranked systems on the leaderboard, highlighting the strengths and limitations of our approach.

1 Introduction

The characterisation and extraction of narratives from news texts is an area of growing interest in natural language processing (NLP), with applications in discourse analysis, bias detection and the understanding of social and political dynamics. In this context, SemEval-2025 Task 10, entitled 'Multilingual Characterization and Extraction of Narratives from Online News' (Jakub Piskorski et al., 2025), seeks to advance the identification and classification of narratives in news stories in multiple languages.

This task is structured in three main subtasks: Subtask 1: Entity Framing, which consists of assigning one or more roles to each named entity mention within a news article, using a predefined taxonomy of roles; Subtask 2: Narrative Classification, where each news article must be assigned all relevant sub-narrative labels within a hierarchical taxonomy of narratives in a specific domain; and Subtask 3: Narrative Extraction, which requires generating a free-text explanation justifying the selection of an article's dominant narrative, based on fragments of text supporting that choice.

Recent advancements in large language models (LLMs) have significantly improved the ability to detect and analyze narratives and propaganda techniques in textual data. Leveraging their contextual understanding and capacity to generalize from large-scale datasets, LLMs have been applied to identify persuasive strategies, ideological framing, and coordinated messaging in political discourse and media (Jones, 2024; Liu et al., 2025).

Our work focuses exclusively on Subtask 2. The task presents multiple challenges, including linguistic diversity, subjectivity in categorising narratives and the limited availability of labelled data in multiple languages. Addressing these problems requires robust approaches that can generalise well across languages and domains. To this end, we opt for a Zero-Shot approach, in which we leverage the knowledge of an LLM without performing specific training on the task data. Since some LLMs have been trained with varying amounts of data in the five languages of the task and SOTA models often performs better in English, we performed a machine translation into English using OPUS-MT models prior to inference.

This paper describes in detail our methodology, the results obtained in comparison with the best competing models and a critical analysis of the performance. Finally, we discuss the limitations of our approach and propose future directions for improving automatic narrative classification in multilingual contexts.

2 Subtask description

SemEval-2025 Task 10 Subtask 2 focuses on the identification and classification of narratives in news articles covering multiple languages and subject domains.

The task is multilingual in five different languages: English, Bulgarian, Portuguese, Hindi

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 165–173

and Russian. Having a large number of languages avoids linguistic and cultural biases in the classification models, allowing the systems to be more robust and adaptable to different contexts. Moreover, the presence of languages rarely used in LLM training, such as Bulgarian or Hindi, introduces additional challenges in identifying and structuring narratives and enriches the evaluation of the performance of multilingual and multicultural models.

Also, the subtask focuses on two thematic domains of great current relevance such as the war between Ukraine and Russia and climate change. Both topics generate a large amount of content on social networks and in the media, which allows us to analyse the propagation of narratives in contexts of high political, economic and social impact. Moreover, by covering both a geopolitical conflict and a global environmental crisis, different types of narratives are covered: some focused on politics and war, and others on science, economics and sustainability. Similarly, including news in Russian is particularly relevant for the analysis of the Ukraine-Russia conflict. Russian media often offer a different perspective than Western media, which makes it possible to study how narratives are constructed and disseminated within Russia and internationally.

2.1 Dataset description

The classification structure used in this task follows a three-level hierarchy (Stefanovitch et al., 2025), in which the top level is defined by the overall news topic, which represents the general thematic domain to which the content belongs, such as 'Russia-Ukraine War' or 'Climate Change'. At the second level are the main narratives, which include general interpretative frameworks within each topic, providing an overall perspective on the issue. Finally, the third level is composed of sub-narratives, which detail in greater granularity specific aspects within each main narrative. In addition, the category *Other* is included at the topic level, for those news items that do not fit clearly into any of the topics, and at the subnarrative level, for those news items that do not fit with the defined subnarratives or could support other subnarratives within the main narrative.

The dataset used has a total of 10 main narratives and 46 sub-narratives (36 specific and 10 labelled Other) related to Climate Change, as well as 11 main narratives and 49 sub-narratives (38 specific and 11 labelled Other) on the Ukraine-Russia war. In total, the training + development set contains 576 news items, distributed across languages and categories.

	Train	Dev	Test	Total
EN	399	41	101	541
BG	401	35	100	536
PT	400	35	100	535
RU	348	32	60	440
HI	366	35	99	500
Total	1914	178	460	

Table 1: Number of news items by dataset.

Regarding the number of news items available in the datasets, Table 1, lists the number of instances per language in each available dataset.

To illustrate the distribution of narratives in the training + development corpus, a bar chart showing the frequency of the 20 most common subnarratives is presented in Figure 1, which allows us to observe the variability in the representation of each category within the dataset.

2.2 Evaluation

The official evaluation measure for this sub-task is the F1 of samples averaged over documents. This metric assesses the precision and recall of the labels of the narratives and sub-narratives assigned to each news item. In addition, the standard deviations of both F1 values are indicated.

3 Methodology

In this research, we have decided to use a Zero-Shot approach to news classification, without using pre-trained examples. This decision responds to the difficulty of finding sufficiently large datasets labelled by human annotators to train a model when we move to real world scenarios. By employing a Zero-Shot approach, we take advantage of the power of LLMs, which have been trained on a large amount of data and are able to generalise to new tasks without the need for prior examples.

To overcome the linguistic limitations that LLMs may have, we have translated all news items into English using machine translation models based on Opus-MT (Tiedemann), an initiative of the University of Helsinki that provides multilingual machine translation models, facilitating translation across languages. This decision is justified by the fact that not all available LLMs have been trained with a large amount of data in the five languages of interest. By translating the articles into English, we

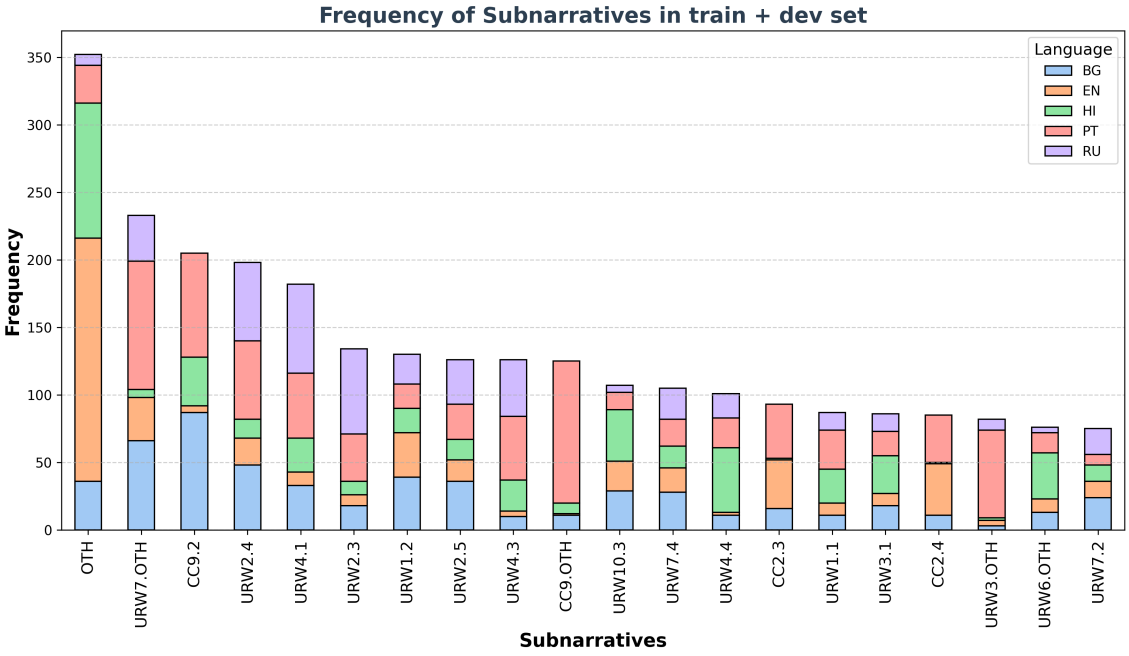

Figure 1: Frecuency of subnarratives in train+dev set grouped by country.

seek to maximise the accuracy of classification and narrative detection, taking advantage of the knowledge of the models in this language. In addition, this methodology allows for a more homogeneous comparison of the news items, regardless of the original language but adding possible errors in the translator models.

3.1 Hierarchical classification

The classification process has been divided into two stages, both carried out by formulating prompts, as described in Appendix A.

1. The main theme of the news item has been classified, assigning it to one of two possible topics: URW (Russia-Ukraine War) or CC (Climate Change).

2. Within each assigned topic, we have classified the corresponding subnarratives. The label *Other* has been incorporated at both topic and subnarrative level.

Subsequently, labels for the narratives were extracted from the model responses.

3.2 LLM configuration

For each of the ranking tasks, we selected the calme-2.4-rys-78b (Panahi, 2023) model, a fine-tuned model based on Qwen 2 78B (Qwen et al., 2025), which has demonstrated high performance with a score of 0. 669 in MMLU-Pro Leaderboard (Wang et al., 2024), placing it as the fourth best model in the Open LLM Leaderboard (Ope).

This model was quantized to 4 bits to optimise memory usage and speed up inference. Calculations were performed using the *bfloat16* format, which ensures greater efficiency without compromising accuracy. For inference, temperature was set to 0.75, top_k to 5, and max_new_tokens was set to 200.

3.2.1 Prompts

To carry out the hierarchical classification of the news, two specific prompts have been built, one for each level as described in 3.1. The first prompt is destined to the classification of the main topic of each news item, assigning it to one of the two possible themes: URW (Russia-Ukraine War) or CC (Climate Change). The second prompt is used for the classification of the sub-narratives within each of the assigned topics, allowing the model to identify the specific sub-narratives that the news item supports. These prompts only include the title of the topic or subnarratives to be classified.

In addition, the model's response has been requested to be delivered in JSON format, including a detailed reasoning for the classification made. This structure allows the model to provide clear explanations of its decisions, which helps to improve the transparency and interpretability of the classifi-

cation process and facilitates the evaluation of the consistency and validity of the assigned labels.

The prompts used can be found in Appendix A.

4 Results

To evaluate the performance of our Zero-Shot approach, we performed an initial evaluation on the training and development sets, which allowed us to analyse the model's ability to correctly classify both the topic and the subnarratives.

Table 2 presents the results for each language and the overall macro result of the system on the development set. This includes the total number of news items in each set, the F1 metric for the topic, the F1 for the Other category (indicating the model's ability to identify news items that do not fit into any predefined narrative or topic), as well as the metrics used in the overall evaluation: F1 coarse (narrative classification), standard deviation coarse, F1 samples (subnarrative classification) and standard deviation samples.

We then applied the model to the test set, generating the final inferences. Table 3 includes the same metrics by language with the results of our system on the test set together with the best model recorded on the task. In addition, the difference between our approach and the leading model in each language is shown, allowing us to quantify the difference in performance between the two.

5 Discussion

The obtained results show a variable performance of the model depending on the language, with significant differences between the dev set and the test set. In the evaluation on dev, it is observed that the model achieves a high F1 Topic in all languages, with values above 87%, indicating that topic classification (URW or CC) is relatively straightforward for the model. However, F1 Other is much lower, especially in Portuguese (PT), where the model did not correctly identify any news items in the Other category, suggesting that the model's ability to detect news items that do not fit the predefined narratives varies by language. As for the classification of sub-narratives, F1 Samples values show moderate performance, with Bulgarian (BG) as the best performing language (0.4248), while Hindi (HI) and Portuguese (PT) show the lowest values (0.2305 and 0.2257, respectively).

Analysing the results on the test set, a generalised decrease in ranking metrics is observed with respect to the dev set, indicating that the distribution of labels in the test set might be slightly different from the dev set. Comparison with the best model reveals noticeable performance differences. For example, in Russian (RU), our model obtains an F1 Coarse of 0.513, while the best model achieves 0.709, which represents a difference of 0.196 points. Similarly, in Portuguese (PT), the difference is 0.127 points.

One aspect to note is that the difference in F1 Samples (classification of subnarratives) is larger than in F1 Coarse, indicating that the identification of subnarratives remains a greater challenge than the classification of narratives. Furthermore, the standard deviation of our model and the best ranked model across all languages remains relatively high, suggesting considerable variability in the quality of predictions. This behaviour is especially visible in English (EN) and Hindi (HI), where the standard deviation values are the highest, suggesting that the model is less consistent in these languages.

To better interpret these results, it would have been useful to have a measure of the Inter-Annotator Agreement when constructing the dataset. Knowing the Inter-annotator agreement would allow contextualising the F1 values and standard deviations, providing a reference on the intrinsic difficulty of the task. If inter-annotator agreement were low, this would indicate that even for humans the classification of certain news items into specific narratives is ambiguous, which would help to establish a reasonable threshold for evaluating the model's performance. On the other hand, if the agreement were high, the observed variability in the model's predictions could be attributed mainly to limitations in its generalisability. This analysis would be particularly relevant in languages with higher variability in F1 and high standard deviations, as it would allow distinguishing between problems arising from annotation ambiguity and model-inherent errors.

6 Conclusion and Future Work

In this research, we have presented a LLM-based system using a Zero-Shot approach for the SemEval 2025 Task 10 Subtask 2, together with a machine translation into English, focused on the classification of narratives in news stories from five different languages. Our system approached this task without using training data, using only the ability of the pre-trained model to identify the gen-

Table 3: System results on the test set

eral theme of the news and the sub-narratives they support.

The results obtained show that subnarrative classification remains a challenge with low performance and high variability in predictions. Comparison with the best model of the SemEval Task 10 Subtask 2 shared task shows that our system performs worse with noticeable differences, especially in languages such as Russian and Portuguese.

These results suggest some directions for future work. First, an analysis of the importance of machine translation would allow us to quantify the degree of error introduced and its effect on classification. It would be interesting to explore direct classification without translation in those languages with sufficient coverage in the base models. In addition, to obtain a more reliable estimate of model performance, it would be necessary to perform multiple runs on the test set and employ ensemble techniques, combining predictions from several model runs to reduce variability and improve the robustness of the system. Finally, the data provided in the training and development set could be used to test supervised approaches such as Few-Shot or Fine-Tuning.

Limitations

Our approach has several limitations that must be considered. First, due to hardware constraints, it was necessary to quantise the model to 4 bits. This may have affected the accuracy of the model by losing information in the weights. In addition, the inference time was considerably high, which hinders the scalability of the system in large data volume applications.

Another important limitation is the use of machine translation, which is likely to introduce noise in the textual representations and may affect the classification of narratives. Also, the unsupervised Zero-Shot approach prevents tuning the model with task-specific examples, which limits its ability to learn finer patterns in classification. Additionally, the large number of sub-narratives and the length of news stories pose problems in managing context within LLMs.

Finally, an additional limitation is the lack of

a more robust performance evaluation, as only a single model run was performed. To obtain more reliable results, it would be necessary to perform multiple runs and apply ensemble techniques that reduce the variability of the predictions.

A Used Prompts

Your main function is to analyse a news item and classify it according to the thematic of the text. Themes to detect:

1: The war between Ukraine and Russia.
2: Climate change.

The text of the news item you have to analyse is:

(Start of news item to be analysed)

```
news text
```

(End of news item to be analysed)

Instructions for Classification:

1- Read carefully the news.
2- Determine what the main topic of the news item is.
3- You have to generate a .json structure:

```
 {"classification": [1, 2] only one of the two categories (Write it between
[]),
"reasoning": 'reasoning of the answer in maximum 50 words.' }
```

Figure 2: Topic classification prompt.

Your primary role is to analyze a new and categorize them according to predefined narrative and sub-narrative themes that reflect different portrayals and perspectives of the Ukraine-Russia war (URW). Your classification should help in understanding the overarching sentiments and strategic messaging in public discourse.
Narratives and Sub-narratives to Detect:
URW1.: Blaming the war on others rather than the invader.
- URW1.1: Ukraine is the aggressor.
- URW1.2: The West are the aggressors.
URW2.: Discrediting Ukraine.
- URW2.1: Rewriting Ukraine's history.
- URW2.2: Discrediting Ukrainian nation and society.
⋮
- URW10.3: There is a real possibility that nuclear weapons will be employed.
- URW10.4: NATO should/will directly intervene.
URW11.: Hidden plots by secret schemes of powerful groups.

The text of the news item you have to analyse is:

(Start of news item to be analysed)

`news text`

(End of news item to be analysed)

Instructions for Classification:

1- Read carefully the news.
2- Determine which sub-narrative(s) it supports based on the content and sentiment expressed, a news item can align with several sub-narratives if it incorporates elements from more than one category.
If the text supports a narrative, e.g. URW1., but does not support any of the sub-narratives proposed for that narrative you have to write the code of the narrative followed by OTH, e.g. URW1.OTH
If the text does not support any narrative write OTH.OTH

Valid labels are: ['URW1.1', 'URW1.2', 'URW1.OTH', 'URW2.1', 'URW2.2', 'URW2.3', 'URW2.4', 'URW2.5', 'URW2.6', 'URW2.7', 'URW2.8', 'URW2.OTH', 'URW3.1', 'URW3.2', 'URW3.3', 'URW3.OTH', 'URW4.1', 'URW4.2', 'URW4.3', 'URW4.4', 'URW4.5', 'URW4.OTH', 'URW5.1', 'URW5.2', 'URW5.3', 'URW5.OTH', 'URW6.1', 'URW6.2', 'URW6.3', 'URW6.OTH', 'URW7.1', 'URW7.2', 'URW7.3', 'URW7.4', 'URW7.5', 'URW7.6', 'URW7.OTH', 'URW8.1', 'URW8.2', 'URW8.OTH', 'URW9.1', 'URW9.2', 'URW9.OTH', 'URW10.1', 'URW10.2', 'URW10.3', 'URW10.4', 'URW10.OTH', 'URW11.OTH', 'OTH.OTH']
3- You have to generate a .json structure:

```
 {"classification": ['URW1.1', 'URW2.1', 'URW7.OTH', ...] The valid labels of
the sub-narratives supported by the text according to instruction 2.,
"reasoning": 'reasoning of the answer in maximum 50 words.'}
```

Figure 3: URW subnarratives classification prompt.

Your primary role is to analyze a new and categorize them according to predefined narrative and sub-narrative themes that reflect different portrayals and perspectives of the Climate Change (CC). Your classification should help in understanding the overarching sentiments and strategic messaging in public discourse.
Narratives and Sub-narratives to Detect:
CC1.: Criticism of climate policies.
-CC1.1: Climate policies are ineffective.
-CC1.2: Climate policies have negative impact on the economy.
-CC1.3: Climate policies are only for profit.
CC2.: Criticism of institutions and authorities.
-CC2.1: Criticism of the EU.
-CC2.2: Criticism of international entities.
⋮
CC10.: Green policies are geopolitical instruments.
-CC10.1: Climate-related international relations are abusive/exploitative.
-CC10.2: Green activities are a form of neo-colonialism.
The text of the news item you have to analyse is:

(Start of news item to be analysed)

`news text`

(End of news item to be analysed)

Instructions for Classification:

1- Read carefully the news.
2- Determine which sub-narrative(s) it supports based on the content and sentiment expressed, a news item can align with several sub-narratives if it incorporates elements from more than one category.
If the text supports a narrative, e.g. CC1., but does not support any of the sub-narratives proposed for that narrative you have to write the code of the narrative followed by OTH, e.g. CC1.OTH
If the text does not support any narrative write OTH.OTH

Valid labels are: ['CC1.1', 'CC1.2', 'CC1.3', 'CC1.OTH', 'CC2.1', 'CC2.2', 'CC2.3', 'CC2.4', 'CC2.OTH', 'CC3.1', 'CC3.2', 'CC3.OTH', 'CC4.1', 'CC4.2', 'CC4.3', 'CC4.4', 'CC4.5', 'CC4.6', 'CC4.7', 'CC4.8', 'CC4.OTH', 'CC5.1', 'CC5.2', 'CC5.3', 'CC5.4', 'CC5.OTH', 'CC6.1', 'CC6.2', 'CC6.3', 'CC6.OTH', 'CC7.1', 'CC7.2', 'CC7.3', 'CC7.4', 'CC7.OTH', 'CC8.1', 'CC8.2', 'CC8.OTH', 'CC9.1', 'CC9.2', 'CC9.3', 'CC9.4', 'CC9.OTH', 'CC10.1', 'CC10.2', 'CC10.OTH', 'OTH.OTH'] 3- You have to generate a .json structure:

```
 {"classification": ['CC1.1', 'CC2.1', 'CC4.OTH', ...] The valid labels of the
sub-narratives supported by the text according to instruction 2.,

Abstract

This paper presents our system designed for Subtask 1 of SemEval-2025 Task 10, which focuses on multilingual entity framing in news articles. Given the complexity of the task, which involves multi-label, multi-class classification across five languages, we propose an approach based on large language models (LLMs). This approach combines multilingual text translation, data augmentation, multi-model fine-tuning and ensemble classification. First, we translated texts into English to unify the datasets, followed by synonym-based augmentation to address class imbalances. We then fine-tuned multiple LLMs using the augmented dataset. Finally, a cutting-edge LLM was applied to aggregate model predictions for ensemble classification, ensuring robust and accurate classifications. Our system demonstrated promising results, achieving top positions in three languages (English, Portuguese and Russian) and second place in Bulgarian.

1 Introduction

With the increasing prevalence of the internet, people can easily access diverse information, which has also facilitated the propagation of misinformation more readily compared to traditional media. Public perceptions of events are often influenced by these harmful false narratives and propaganda, particularly regarding major crisis incidents. Consequently, misinformation identification has become crucial, prompting growing research (Orbach et al., 2021; Sharma et al., 2023) to analyze and categorize entities in textual information.

The SemEval-2025 Task 10 (Piskorski et al., 2025; Stefanovitch et al., 2025) focuses on multilingual representation and narrative extraction from online news, aiming to advance research and development of novel analytical capabilities to support end-users in analyzing news ecosystems and identifying characteristics of manipulation attempts. The task organizers construct a dataset (Mahmoud et al., 2025) comprising 1,378 news articles focusing on the Ukraine-Russia war and climate change, with role annotations applied to over 5,800 entities. This task comprises three subtasks and we participate in Subtask 1 (Entity Framing). Specifically, given a news article and a list of Named Entity (NE) mentions within it, the objective is to assign one or multiple roles to each mention using a predefined refined role taxonomy. This taxonomy encompasses three primary role types: protagonists, antagonists and innocent, forming a multi-label multi-class text span classification task.

Entity Framing subtask presents two main challenges. First, as a multilingual task involving five languages (Bulgarian, English, Hindi, European Portuguese and Russian), traditional methods exhibit limited modeling capabilities for large-scale, complex multilingual tasks, particularly in handling long sequences and intricate semantics. The emergence of LLMs (Zhao et al., 2023; Matarazzo and Torlone, 2025) addresses this challenge effectively through their robust generalization capabilities and multilingual data integration. Second, this subtask requires multi-label multi-class classification where each entity must be assigned to one of three primary roles, with further granularity in secondary subcategories. For instance, the protagonist category includes finer-grained roles such as Guardian, Martyr, Peacemaker, Rebel, Underdog and Virtuous. This hierarchy demands enhanced semantic comprehension and classification capabilities from models.

To address these challenges, we implemented an LLM-based pipeline. Initially, we translated all non-English data into English for unified processing and constructed a task-specific dataset. We then fine-tuned multiple foundational large language models (GLM et al., 2024; Yang et al., 2024; Dubey et al., 2024) on this dataset. Subsequently, we employed a state-of-the-art LLM by designed

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 174–179

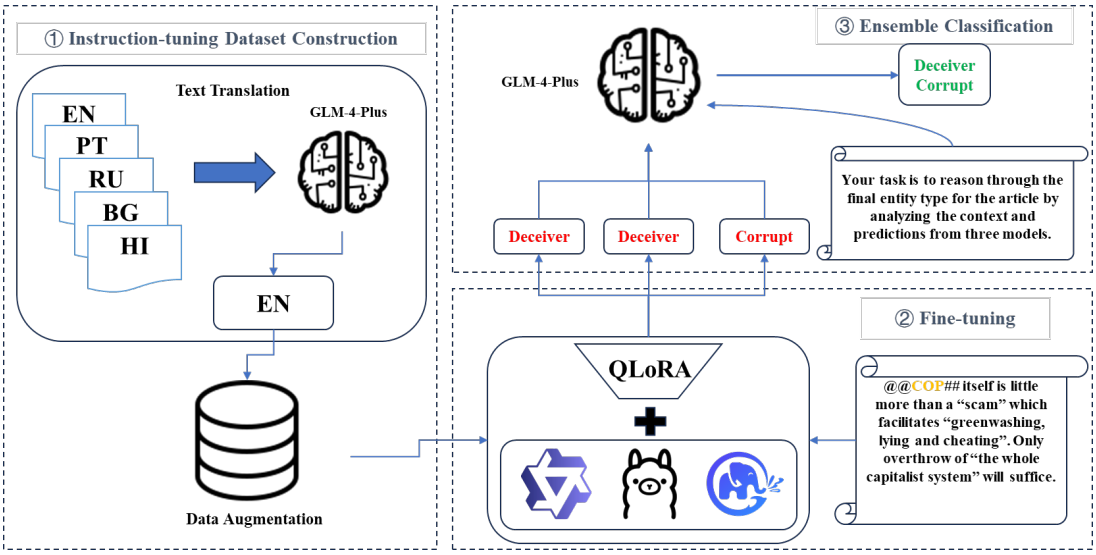

Figure 1: The overall architecture diagram of our system. The "COP" highlighted in yellow is the entity to be classified, the one marked in red indicates the incorrect classification result, and the one marked in green indicates the correct classification result.

ensemble prompts to aggregate decisions from multiple LLMs, generating final classification results. Our proposed method demonstrated strong performance by achieving first place in three out of the five languages evaluated in Subtask 1.

2 Background

Named Entity Recognition (NER) has long been a key research direction in the field of Natural Language Processing (NLP) (Xu et al., 2024). NER refers to the task of identifying entities with specific meanings in text, such as person names, locations and others, and annotating them accordingly. Essentially, it is a sequence labeling task aimed at classifying each word or phrase in a text as belonging to a specific named entity category or not belonging to any named entity category.

In recent years, with the emergence of an increasing number of open-source large models (Touvron et al., 2023; Liu et al., 2024) and the introduction of various fine-tuning techniques (Hu et al., 2021; Dettmers et al., 2024), LLMs have achieved significant progress in NER tasks (Luo et al., 2024). In this study (Naguib et al., 2024), they collect and use 14 NER datasets covering English, French, and Spanish, and compare the performance of generative LLMs with few-shot prompts and traditional masked-based models in both general and clinical domains. GPT-NER (Wang et al., 2023) cleverly transforms the traditional NER sequence labeling task into a generation task that is easier for LLMs to handle, using special tokens to mark the entities to be extracted. Additionally, it constructs few-shot prompt words by retrieving semantically similar examples from the input via KNN, effectively bridging the gap between the NER task and LLMs.

3 System Overview

As shown in Figure 1, the overall structure of our system includes the following key components: Instruction-tuning dataset construction based on multilingual text translation and data augmentation, multi-model fine-tuning based on QLoRA, and ensemble classification based on GLM-4-Plus.

3.1 Instruction-tuning Dataset Construction

Due to the superior model capabilities and abundant data annotation resources of LLMs in English, coupled with the relatively smaller scale of data annotation in other languages, translating multilingual texts into English can effectively expand the data scale, thereby simplifying classification tasks and reducing the complexity of processing multilingual texts. Based on this, the first step of the system is to translate texts in various languages into English. This process is achieved by calling the API of GLM-4-Plus, which supports multilingual translation. The translated texts are then uniformly consolidated into a corpus for subsequent processing.

However, there is an issue of imbalance in the types of entities in the dataset. To mitigate this problem, we further employed data augmentation

###Instruction:
Below is a news article. For each named entity marked with @@## in the article, classify its role based on a predefined taxonomy of fine-grained roles. Each entity can have one or more roles.

Input:
Bill Gates Says He Is 'The Solution' To Climate Change So It's OK To Own Four Private Jets \n\n@@Bill Gates## has the right to fly around the world on private jets… Predefined taxonomy:\n– Guardian: …\n– Martyr: …\n– Peacemaker:…

output:
Named entities marked with @@## in the article: Bill Gates; Based on the taxonomy, the classification is: Deceiver, Corrupt.

Figure 2: Example of the prompt from our training set. The "Bill Gates" highlighted in yellow is the entity to be classified, and the one marked in green indicates the correct classification result.

####System
Your task is to reason through the final entity type for the article by analyzing the context and predictions from three models. The final type may have one or more entities, separated by a "、".
Please follow these steps:
1.Analyze the sentence: Understand the semantics of the article and the context in which the entity appears.
2.Evaluate the predictions: Review each model's prediction to determine whether it is reasonable.
3.Resolve contradictions: If there is disagreement in predictions, decide which one better fits the context.
4.Make a final decision: Arrive at the final conclusion by weighting the evidence or semantic fit.
Please show the thought process clearly, and mark the final result in [square brackets].
###Input
Article: @@COP## itself is little more than a "scam" which facilitates "greenwashing, lying and cheating". Only overthrow of "the whole capitalist system" will suffice.
Entity to be marked: COP
Model predictions: Qwen2.5: Deceiver、llama3.1: Deceiver、GLM4: Corrupt

Figure 3: Example of the Chain-of-Thought Prompt for LLM-based Ensemble Learning.

	Train	Dev	Test	AVG Length
EN	686	91	235	1646
PT	1251	116	297	2269
RU	722	86	214	2433
BG	627	31	124	3239
HI	2331	280	316	8190
DA	700	-	-	1521
Total	6317	604	1186	4418

Table 1: Statistics of dataset sizes. DA represents the dataset obtained through data augmentation, and AVG Length refers to the average length of the training set.

strategies, especially synonym replacement for underrepresented entity types, to enhance their representation in the training set (Dai and Adel, 2020). Specifically, we utilized WordNet as the synonym dictionary and applied probabilistic replacement to 30% of non-entity words in sentences containing rare entity types that occur less than 30 times. The augmented data, combined with the original dataset, forms a more balanced training set. This strategy not only effectively addresses the issue of class imbalance but also lays a solid foundation for subsequent model training while ensuring the consistency of input formats.

3.2 Multi-model Fine-tuning

During the model training phase, we employ QLoRA technology to fine-tune multiple base models, which include Qwen2.5, Llama3.1, and GLM4. The choice of QLoRA is due to its ability to perform efficient fine-tuning operations with limited computational resources, making it particularly suitable for LLMs.

The fine-tuning dataset's prompt is shown in Figure 2. Specifically, each model's fine-tuning prompt includes a task description, candidate entity types and their definitions, and special symbols to mark the positions of entities in the text. For example, in combination with an automatic labeling program, the symbol "@@" is used to mark the start of an entity, and the symbol "##" is used to mark the end of an entity.. This design helps the model better understand the task by first locating entities in the text through prompts and then proceeding with classification. In the fine-tuning process, each base model is trained on the augmented dataset, with the goal of optimizing the model's parameters to minimize classification loss.

3.3 Ensemble Classification

After fine-tuning each base model, we designed an LLMs prompt-based ensemble learning, which employed a Chain-of-Thought approach to guide the LLMs in analyzing the classification results of entities based on multiple models fine-tuned with QLoRA, thereby obtaining the final results. The specific prompt is provided in Figure 3. Each fine-tuned model (Qwen2.5, Llama3.1, and GLM4) generates a classification result for a given entity. These results are then passed to the GLM-4-Plus model, which acts as a meta-classifier to conduct a comprehensive analysis of all the models' prediction outcomes and ultimately make a decision.

As shown in Figure 1, for the sentence

Table 2: Leaderboard of the test set. The table presents the leaderboard results for the test set, with the Exact Match Ratio (EM) and micro F1 score displayed as percentages. The best results for each metric are highlighted in bold. Additionally, we list the top three teams in any language, with the possibility of ties in ranking, as well as baseline results for comparison. The ranking is based on the Exact Match Ratio (EM).

"@@COP## itself is little more than a 'scam' which facilitates 'greenwashing, lying and cheating'. Only overthrow of 'the whole capitalist system' will suffice. ", where "COP" is the entity to be categorized, Qwen2.5 classifies it as "Deceiver", Llama3.1 classifies it as "Deceiver", and GLM4 classifies it as "Corrupt". Based on the prediction results of each fine-tuned model, and considering their performance and reliability in specific tasks, GLM-4-Plus makes the final entity classification decision. By adopting this ensemble method, we can effectively enhance the accuracy and robustness of classification, especially when dealing with complex or diverse entity types. Ensemble learning fully leverages the strengths of each base model to achieve more precise classification results.

4 Experimental Setup

The dataset originates from Subtask 1 of Task 10 in SemEval 2025, comprising news articles in plain text format across five languages: English (EN), Portuguese (PT), Russian (RU), Bulgarian (BG) and Hindi (HI).

During the experimental phase, we generated individual data records for each entity mention, with the statistical summary presented in Table 1. The limited number of available articles in each language undoubtedly increased the difficulty for LLMs to learn effectively. Additionally, the dataset exhibited significant class imbalance, further intensifying the challenge of the task.

To address these challenges, we employed strategies of data translation and augmentation. Specifically, we leveraged LLMs to translate all articles from different languages into English, resulting in 5,617 data records. Building on this, we conducted data augmentation operations such as synonym replacement for underrepresented categories, adding additional 700 data records. Ultimately, all datasets were merged to form a complete dataset containing 6,317 training data records.

For task evaluation, the official assessment utilized multiple metrics to comprehensively measure model performance, including Exact Match Ratio, micro precision (micro P), micro recall (micro R), micro F1 score (micro F1), and accuracy for the main role. Among these, the Exact Match Ratio was the primary evaluation metric.

During the training process, a batch size of 4 was used, the learning rate was set to 1e-4, and a maximum truncation length of 4096 was set to accommodate text inputs of varying lengths. Additionally, the AdamW optimizer was selected to further enhance the model's training efficiency and generalization ability. All experiments were conducted on a single NVIDIA L40 GPU.

5 Results

5.1 Final Submission

The detailed information of the test set leaderboard is shown in Table 2. Ranked by exact match rate, our proposed method achieved first place in three out of the five languages covered. In addition, our system achieved the highest micro F1 score in four languages, fully demonstrating its effectiveness and adaptability. However, its performance on Hindi was unexpectedly unsatisfactory.

After analysis, we believe that this result may be closely related to the length characteristics of Hindi articles. The average lengths of datasets for different languages are shown in Table 1. Compared to other languages, Hindi articles are generally longer. Due to hardware limitations, we were unable to set a longer token length.

5.2 Ablation Study

To comprehensively verify the key contributions of each component in the system to overall perfor-

	EN		RU

mance, we designed the following ablation experiments: we evaluated the system's performance under conditions where multilingual text translation was excluded (marked as w/o TT), data augmentation was not implemented (marked as w/o DA), and ensemble classification was not used (marked as w/o EC). The results of the ablation study are shown in Table 3.

- By introducing LLMs for multilingual text translation, we successfully integrated datasets from multiple languages, providing the model with more comprehensive and in-depth learning materials. This significantly enhanced the model's learning effectiveness and generalization ability.
- For categories with low representation in the dataset, we employed data augmentation strategies, which effectively alleviated the issue of data imbalance. This improved the model's accuracy and robustness when dealing with imbalanced datasets.
- Furthermore, by leveraging high-performance LLMs, we fine-tuned different base models and performed ensemble classification on their classification results. This innovative approach not only further improved the overall performance of the system but also made the system's output more stable and reliable, demonstrating the unique advantages of ensemble learning in enhancing model performance.

6 Conclusion

This paper presents the system we designed for Subtask 1 of SemEval-2025 Task 10. We propose a multilingual text processing framework that combines multilingual translation with data augmentation, QLoRA-based multi-model fine-tuning, and GLM-4-Plus-based ensemble classification. By using GLM-4-Plus to translate multilingual texts into English, we enhance data diversity and quantity. Data augmentation effectively improves the model's performance on imbalanced datasets. QLoRA fine-tuning optimizes the model and reduces classification loss. GLM-4-Plus, as a meta-classifier, further enhances system performance. Our system achieved first place in three languages (English, Portuguese and Russian). In the future, we will focus on improving long-text processing and optimizing LLMs fine-tuning techniques.

Abstract

This paper presents our research in the SemEval-2025 Task 9: Food Hazard Detection Challenge, focusing on the application of ModernBERT for food safety data classification. Our system achieved 12th place in the official evaluation of subtask ST1, attaining a validation score of 0.7952 and a final test score of 0.7729. Through comparative experiments with various deep learning architectures, we demonstrate that ModernBERT exhibits superior performance in handling domain-specific semantics and long-tail distributions. These results validate the potential of ModernBERT for real-world food safety monitoring systems. The code is available at: https://github.com/daojiaxu/semeval_2025_Task-9.

1 Introduction

The rapid development of artificial intelligence (AI) has led to its widespread use across various sectors, with significant impacts on society (Ertel, 2024). In food safety, which directly affects public health, AI technologies such as big data analytics and machine learning offer innovative solutions to enhance food safety measures (Chhetri, 2024). Foodborne illnesses remain a global concern, and these advancements present new opportunities to address this issue. This study, part of SemEval 2025 Task 9: The Food Hazard Detection Challenge, explores the potential of pre-trained models for detecting and classifying food hazards (Randl et al., 2025).

The primary objective of this study is to classify food products into hazard and product categories based on safety-related attributes. We explore the application of pre-trained models to categorize food hazards into 10 types and products into 22 types. By leveraging AI, we aim to create a more efficient, accurate, and automated approach to managing food safety data.

We selected several state-of-the-art models, including BERT, RoBERTa, Qwen, and ModernBERT, as candidate models for the classification tasks. Our experiments indicate that ModernBERT consistently outperforms other models, demonstrating its effectiveness in food safety applications on both the validation and test sets.

By comparing the performance of these models, we seek to identify the most effective pre-trained models based method for managing food safety information. These findings not only contribute to advancing theoretical research but also provide practical insights for real-world food safety management, with the potential to enhance public health by improving food safety and preventing foodborne diseases.

2 Related Work

The advent of artificial intelligence has profoundly impacted various fields, particularly food safety research, with many scholars making significant contributions. Leonieke's systematic reviews evaluated multiple machine learning algorithms and combinations, with the hybrid Naive Bayes-Support Vector Machine (NB-SVM) model reducing expert workload and improving review accuracy (van den Bulk et al., 2022). Sina integrated multi-criteria decision analysis (MCDA) into an AI-driven database system for automated food incident report classification, verified through field tests (Röhrs et al., 2024).

With the rise of Large Language Models (LLMs) (Zhao et al., 2024), the research landscape has shifted. Zhao's 2024 survey emphasized LLMs' transformative potential across fields. Hassani demonstrated that BERT and GPT architectures excelled in regulatory text classification, with the optimized GPT-4o model outperforming traditional methods (Hassani et al., 2025). Randl introduced an LLM-in-the-loop framework, enhancing classifier performance while reducing energy consumption. Their analysis showed that logistic regres-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 180–185

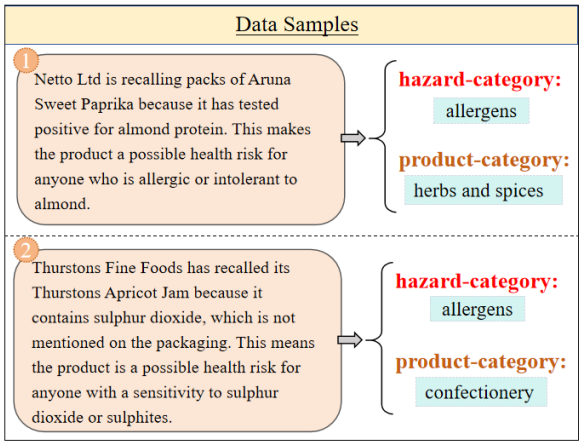

Figure 1: Data Samples

sion models with TF-IDF features outperformed advanced models in certain food recall categories (Randl et al., 2024).

Neris also contributed significantly. Neris used LLMs for zero-shot chemical hazard extraction, proving their effectiveness in environmental monitoring (Özen et al., 2025). Ma showcased LLM applications in decision support, driving progress in food science (Ma et al., 2024). Zhang Dan's ICL2FID framework improved annotation accuracy in food-poisoning event labeling on social media, offering cost-effective advantages over traditional methods (Zhang et al., 2024).

In conclusion, previous studies have explored food safety from various perspectives with different methods and models, laying a foundation for our research, which aims to further expand and deepen the field.

3 Experiment Setup

3.1 Dataset

The Food Recall Incidents dataset (Randl et al., 2025) contains 6644 short texts of English food recall notices annotated by two food science experts (character range 5-277, mean 88), sourced from official agencies such as the FDA.

The training dataset suffers from class imbalance. In the hazard-category classification task, the most frequent category is biological, with 2,018 samples, while the least frequent category is migration, with only 13 samples. A similar class imbalance is observed in the product-category classification task. For instance, the meat, egg and dairy products category has 1,686 samples, while the sugar and syrups category has just 5 samples. This significant discrepancy in sample distribution between categories can influence model training.

In comparison to the 5,433 samples in the training set, the validation set consists of only 565 samples. Within the validation set, the allergens category has the highest number of hazard-category samples, totaling 207. However, the migration hazard category has 0 samples. Regarding product-category classification, the meat, egg and dairy products category also has the largest number of samples, totaling 146. Meanwhile, some categories have very few samples, such as pet feed and feed materials, which have only 1 sample, and the sugar and syrups, honey and royal jelly, and food contact materials categories, which have 0 samples. Detailed data statistics can be found in Figure 2.

3.2 Pre-trained Models

In this study, we selected BERT, RoBERTa, Qwen, and ModernBERT as candidate models due to their proven effectiveness in natural language processing (NLP) tasks.

The Bidirectional Encoder Representations from Transformers (BERT) is renowned for its simplicity and efficiency, requiring only an extra output layer for fine-tuning, adaptable to a wide range of NLP tasks. Its key strength lies in handling diverse tasks without major architectural changes, making it efficient and flexible. BERT has set new benchmarks in NLP, achieving SOTA results in 11 benchmarks (Devlin et al., 2019). This performance has proven the value of pre-training deep bidirectional representations, a concept that BERT has popularized across the NLP community. BERT pre-trained model has set off a revolution in the field of natural language processing, and is gradually established as a new industry benchmark with its excellent accuracy in a number of automatic text processing tasks (Koroteev, 2021). BERT performs well in language comprehension tests, and experiments have shown that it can capture language structures, from low-level phrase information to rich linguistic levels in the middle, and then to combining information in a tree structure. It is particularly adept at handling long-distance dependency information.

Online public opinion helps reduce the impact of food safety, and experiments have shown that the BERT-BLSTM-CRF model has a higher accuracy in extracting entity relationships in the food safety public opinion dataset than other models by 3.29% to 23.25% (Zhang et al., 2022).

RoBERTa's enhancements make it an excellent candidate for tasks where language understanding

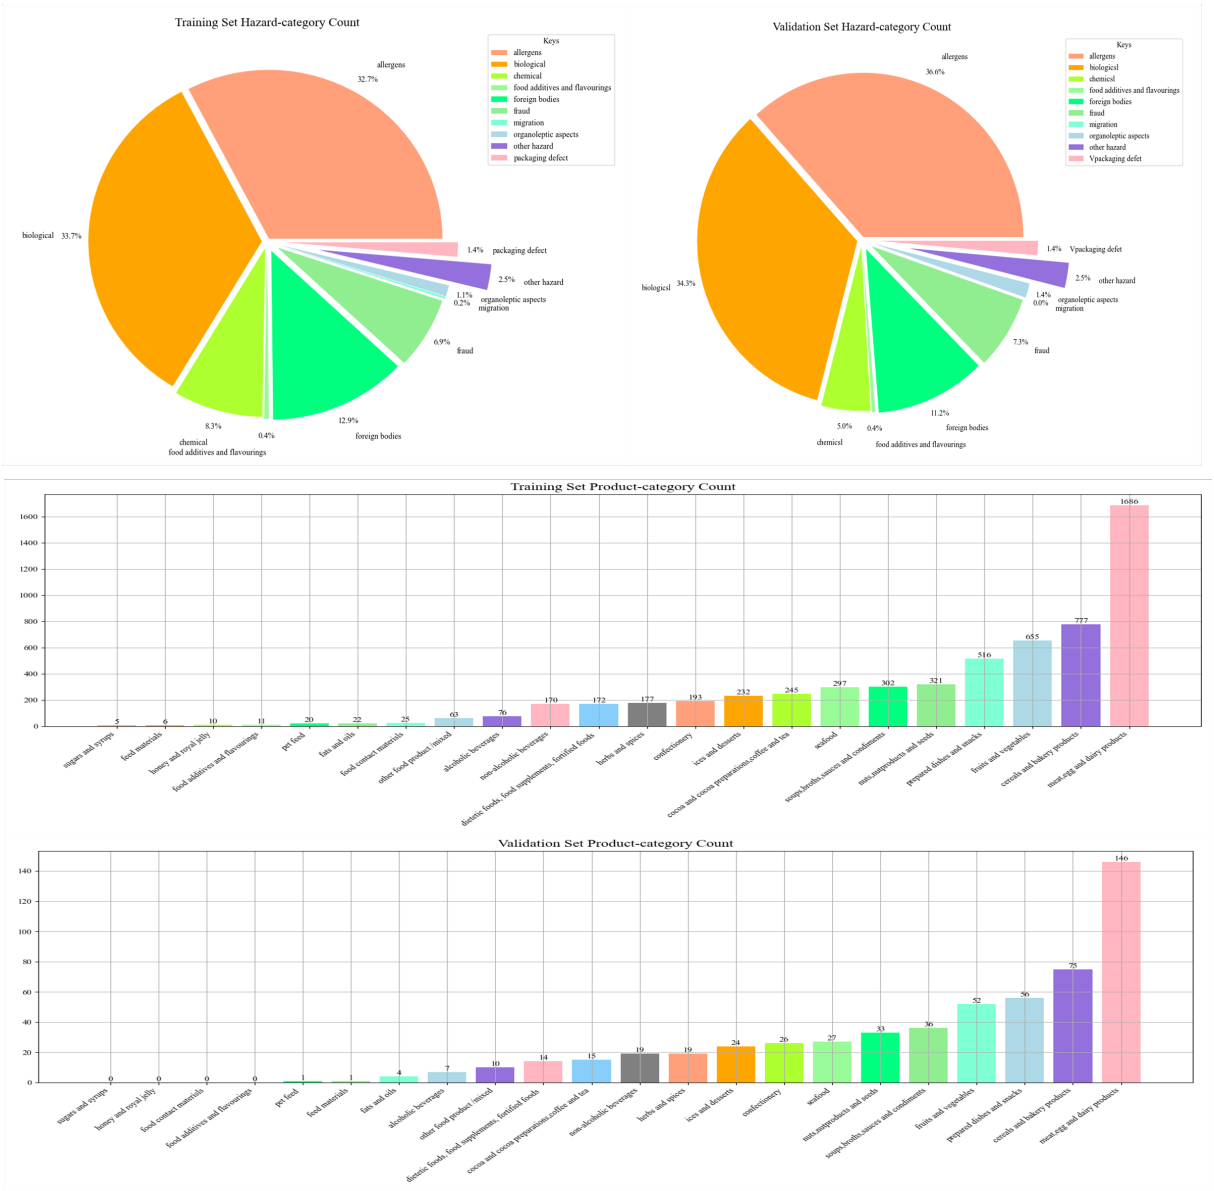

Figure 2: Count of Hazard and Product - Categories in Training Set and Validation Set

and fine-tuned performance are critical. In the research on the squiad V2 dataset, both Bert and Roberta showed strong text question answering ability. Bert stood out with its profound language understanding ability, while Roberta further improved its performance through optimized training strategies (Chopra et al., 2024). Liao proposed a multi-task sentiment analysis model based on RoBERTa, utilizing deep bi-Transformer for feature extraction and cross-attention for feature focus, outperforming other models experimentally (Liao et al., 2021). Briskilal proposed a predictive ensemble model based on BERT and RoBERTa for the classification of idioms and literal meanings. Tested on a newly created internal dataset, the model performed better than the baseline, with an accuracy improvement of 2% (Briskilal and Subalalitha, 2022).

Qwen 2.5, by Alibaba, is a pre-trained LM and multimodal model fine-tuned for tasks. With 18T tokens, it excels in commands, long texts, structured data. It is flexible in language and tasks, adaptable to various apps needing mixed data. (Yang et al., 2024).

ModernBERT, optimized by Benjamin, is an advanced encoder-only transformer, trained on 2 trillion tokens and handling up to 8192 tokens. It excels in diverse tasks, including retrieval and code-related applications. Its design ensures high speed, memory efficiency, and superior performance in downstream apps and real-time reasoning on GPUs (Warner et al., 2024). Given its advantages in

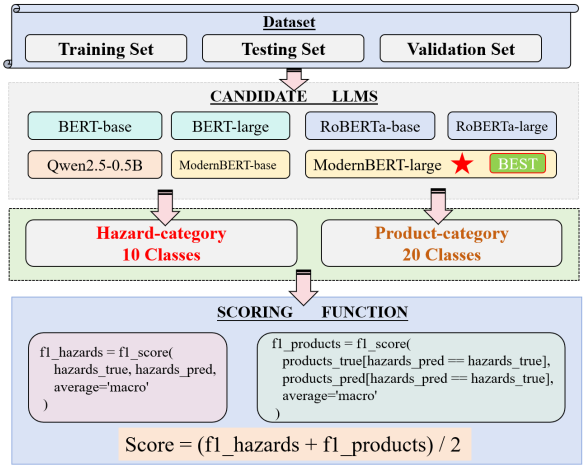

Figure 3: Model Selection and Evaluation Process

both performance and efficiency, ModernBERT has emerged as one of the leading models in NLP tasks. ModernBERT uses masked language model (MLM) for generative classification, showing excellent zero-shot learning ability (Clavié et al., 2025).

3.3 Methods

Experiment (Figure 3) used 7 pre-trained models to classify product and hazard categories. Data preprocessing was followed by splitting into train, validation and test sets for model training, tuning and evaluation, respectively.

Once the dataset is prepared, we load the pre-trained models and adjust their output layers according to the number of labels specific to the product and hazard classification tasks. The next step is to define the optimizer and set key hyperparameters, such as the learning rate. During the training process, we employ a data loader to read data in batches, enabling efficient model training over multiple iterations. In each iteration, we compute the loss function, and update the model's parameters using backpropagation.

Throughout the training process, we continuously monitor the loss values and use the validation set to evaluate the model's performance, specifically calculating the macro F1 score to assess its classification accuracy.

3.4 Evaluation Metric

The evaluation metric employs a conditional macro-averaged F1-score framework to align with the operational priorities of food safety detection. For hazard classification, the macro-F1 score is computed across all samples to ensure balanced evaluation of all hazard categories, regardless of their frequency in the dataset. This is mathematically defined as:

$$F1_{\text{hazards}} = \frac{1}{C_h} \sum_{c=1}^{C_h} \frac{2 \cdot P_c \cdot R_c}{P_c + R_c} \tag{1}$$

where C_h denotes the total number of hazard categories, P_c represents precision, and R_c denotes recall for class c.

The product classification evaluation is performed only on samples where hazard predictions match the ground truth, reflecting real-world constraints where incorrect hazard identification invalidates subsequent product categorization. The product macro-F1 score is calculated as:

$$F1_{\text{products}|H=H^*} = \begin{cases} \frac{1}{C_p} \sum_{k=1}^{C_p} F1_k \\ \quad \text{where } H^{(i)}_{\text{pred}} = H^{(i)}_{\text{true}}, \\ 0 \\ \quad \text{(invalid hazard prediction)} \end{cases} \tag{2}$$

where C_p represents the total product categories, and $F1_k$ is the F1-score for the k-th product class.

The final composite score is derived by averaging the two components:

$$\text{Score} = \frac{1}{2} \left(F1_{\text{hazards}} + F1_{\text{products}|H=H^*} \right) \tag{3}$$

4 Results

We selected seven pre-trained models from the table to conduct the experiment (Table 1). The experimental results indicate that the BERT-base model scored 0.7409, the BERT-large model scored 0.7423, the RoBERTa-base model scored 0.7778, the RoBERTa-large model scored 0.7679, the Qwen2.5-0.5B model scored 0.743, the ModernBERT-base model scored 0.7915, and the ModernBERT-large model scored 0.7952. It is clear that the ModernBERT-large model is the best choice. This model demonstrated excellent performance on the validation set, achieving a score of 0.7952, surpassing all other models, including different variants of both the BERT and RoBERTa series. Although the performance of the ModernBERT-large model on the final test set (0.7729) is slightly lower than its performance on the validation set, this still sufficiently demonstrates its strong generalization ability and its dominant position in related tasks.

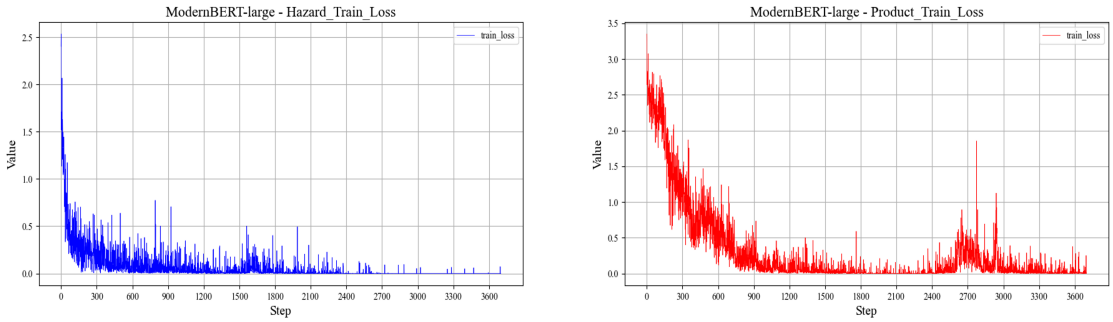

Figure 4: Loss Curves of ModernBERT-large on the Test Set (Food Hazard Classification and Product Classification)

Model	Score
BERT-base	0.7409
BERT-large	0.7423
RoBERTa-base	0.7778
RoBERTa-large	0.7679
Qwen2.5-0.5B	0.743
ModernBERT-base	0.7915
ModernBERT-large	**0.7952**

Table 1: Model Scores on the Validation Set

In the task of predicting food hazard categories (with the task divided into 10 categories), as the number of training steps increases, the overall loss value shows a downward trend, indicating that the model is gradually learning the characteristics of the data, and its prediction ability is continuously improving (Figure 4). Similarly, in the task of predicting product categories (with the task divided into 22 categories), the overall loss value also shows a downward trend with the increase in training steps. Since the product classification task is more complex with a larger number of categories, the training loss may be higher than that of the hazard prediction task, and the convergence speed may be relatively slower (Figure 4).

5 Conclusion

This study proposes a ModernBERT-based framework for food safety data classification in SemEval 2025 Task 9 Subtask ST1. Through systematic comparisons with pre-trained models including BERT, RoBERTa, and Qwen, we demonstrate that ModernBERT achieves superior performance in food hazard detection. Experimental results show that the framework obtains macro F1-scores of 0.7952 and 0.7729 on the validation and final test sets respectively, ranking 12th in the official evaluation of SemEval-2025 Task 9. This work establishes an effective technical pathway for applying language models to food safety management systems.

6 Limitations

While ModernBERT demonstrates superior performance in food safety classification tasks, this study has several limitations. First, the experimental data primarily focuses on structured text, leaving the model's generalizability to unstructured or diverse text sources insufficiently validated. Second, the model's efficiency in capturing semantic relationships within long textual sequences remains suboptimal, particularly when handling complex contextual dependencies. Additionally, classification performance on minority classes still requires improvement, necessitating further exploration of strategies to mitigate class imbalance effects. Finally, the current approach predominantly relies on an end-to-end supervised learning framework, with its adaptability to zero-shot or few-shot scenarios yet to be thoroughly assessed.

TechSSN3 at SemEval-2025 Task 11: Multi-Label Emotion Detection Using Ensemble Transformer Models and Lexical Rules

Vishal S, Rajalakshmi Sivanaiah, Angel Deborah S
{vishal2310293, rajalakshmis, angeldeborahs}@ssn.edu.in

Department of Computer Science and Engineering,
Sri Sivasubramaniya Nadar College of Engineering, Chennai, Tamil Nadu, India

Abstract

In this work, we introduce an ensemble framework for multi-emotion detection that combines the strengths of transformer-based models with a rule-based lexical system. Our approach identifies five key emotions—anger, sadness, joy, surprise, and fear—using a binary labeling scheme. We employ multiple BERT variants, including DeBERTa, RoBERTa, and BERT Large Uncased, each optimized through hyperparameter tuning. Complementing these models is a lexical component that assigns sentiment scores via an emotional lexicon and applies limited grammatical pattern analysis (e.g., noun+verb+adverb structures) to capture nuanced expressions. The final predictions result from a weighted ensemble approach, where emotion-specific weights balance data-driven and rule-based contributions. Experimental results show that our method of ensembling using specific outperforms individual models and traditional classifiers on benchmark datasets.

1 Introduction

Emotion detection plays a vital role in natural language processing (NLP) applications such as sentiment analysis, mental health monitoring, and human–computer interaction. Unlike traditional classification tasks that label text as positive, negative, or neutral, real-world scenarios require identifying specific emotions like anger, sadness, joy, surprise, and fear, which often overlap and are highly context-dependent. In this study, we fine-tune multiple transformer-based models, including DeBERTa, RoBERTa, and BERT Large Uncased, carefully optimizing hyperparameters to enhance classification performance. To further strengthen predictions, we incorporate a rule-based lexical system that assigns sentiment scores using an emotional lexicon and refines outputs based on part-of-speech (POS) patterns, particularly noun–verb–adverb–adjective combinations. By combining deep learning architectures with linguistic knowledge, our approach improves both the robustness and interpretability of emotion classification models.

2 Related Works

The shift from statistical models to deep learning has significantly improved multi-label emotion classification (Le et al., 2023). Transformer architectures like BERT enhance contextual understanding and label dependencies (Huang et al., 2023b), while multi-modal approaches combining text, audio, and visual cues further boost performance (Zhang et al., 2022). Fusion techniques, such as integrating Wav2Vec 2.0 with BERT, have also shown promise (Sarma et al., 2022). Context-aware models refine emotion detection by capturing nuanced sentiment shifts (Deborah et al., 2020).

Linguistic features further aid classification. POS tagging improves sentiment polarity detection (Chen et al., 2021), while hybrid models combining rule-based and deep learning approaches enhance robustness (Sivanaiah et al., 2022). Fine-tuned transformers like RoBERTa and DeBERTa achieve state-of-the-art results (Gupta et al., 2023), with lexicon-based scoring further refining sentiment interpretation (Kumar et al., 2023). These techniques collectively strengthen emotion classification frameworks.

3 Dataset Description

This dataset, derived from the BRIGHTER corpus (Muhammad et al., 2025b), is designed for English-language emotion classification. Each sample consists of a unique identifier, a text string, and five binary-labeled emotion categories: **anger, fear, joy, sadness,** and **surprise**. Some examples from the datasets are given below in Table 1, to illustrate the representation in all the files, which were used to train the models.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 186–192

id	text	anger	fear	joy	sadness	surprise
0001	Colorado, middle of nowhere.	0	1	0	0	1
0002	Then the screaming started.	0	1	0	1	1
0003	It was one of my most shameful experiences.	0	1	0	1	0

Table 1: Example data from the training dataset for English, Track A.

As you can see, each emotion label is assigned either `0` (not present) or `1` (present), allowing for multi-label classification. This dataset is valuable for developing emotion recognition models that capture multiple emotions in a single text sample.

Subset	Number of Samples
Train	2,769
Dev	117
Test	2,768

Table 2: Dataset Split

In Table 2, the number of rows provided in the datasets released for each phase is given. The Dataset paper and the task description paper(Muhammad et al., 2025a) can be referred for the actual columns and the amount of texts positive for each emotion.

4 Methodology

We propose an ensemble approach for multi-label emotion detection that integrates several fine-tuned BERT-based models, traditional classifiers, and a lexical rule-based module.

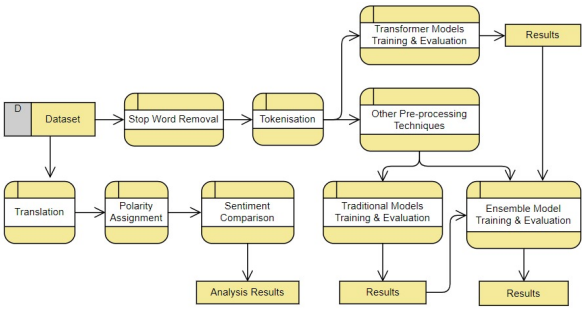

Figure 1: Workflow Diagram of the Process

Data Preprocessing: Text is normalized by lowercasing, removing punctuation, and filtering stopwords. Tokenization is performed using BERT's WordPiece tokenizer.(Rust et al., 2020)

Modeling: Multiple BERT variants (BERT-base, BERT-large, DeBERTa, and RoBERTa) (Vaswani et al., 2017) are fine-tuned using different hyperparameters—such as learning rates, batch sizes, and train-test splits—to identify optimal configurations. In parallel, traditional classifiers (e.g., Naive Bayes, logistic regression and SVM) are trained on vectorized representations to serve as baseline comparisons.

Lexical Analysis and Ensembling: A lexical module assigns sentiment scores based on an emotional lexicon (Deborah et al., 2018) and limited grammatical pattern analysis (e.g., noun+verb+adverb+adjective structures). The predictions from the BERT models, traditional classifiers, and lexical component are then combined using a weighted averaging scheme, with emotion-specific weights to balance their contributions.

5 System Overview

5.1 Transformer-based Models

We leverage transformer-based architectures for contextual word representations and sentiment classification. The primary models used include BERT-Large-Uncased, DeBERTa, and RoBERTa. These models are pre-trained and fine-tuned.

5.1.1 BERT Model

BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2018) is a transformer-based model that learns bidirectional contextual embeddings. Given an input sequence $X = \{x_1, x_2, ..., x_n\}$, BERT processes it using multi-head self-attention:

$$H = \text{SelfAttention}(XW_Q, XW_K, XW_V) \quad (1)$$

where W_Q, W_K, and W_V are the query, key, and value projection matrices. The final representation for classification is obtained from the [CLS] token embedding:

$$y = \text{softmax}(W_h H_{CLS} + b) \quad (2)$$

where y represents the predicted class distribution.

5.1.2 DeBERTa Model

DeBERTa (Decoding-enhanced BERT with disentangled attention) (He et al., 2021) enhances the self-attention mechanism by incorporating relative positional embeddings and disentangled matrix representations. The attention mechanism follows:

$$A_{ij} = \frac{Q_i K_j^T}{\sqrt{d}} + P_{ij} \tag{3}$$

where P_{ij} is the relative positional encoding. The final hidden states are passed to a classifier for sentiment and emotion prediction.

5.1.3 RoBERTa

RoBERTa(Liu et al., 2019), another state-of-the-art transformer variant, refines BERT-based embeddings using an optimized pre-training objective. It follows a similar transformer formulation but incorporates additional linguistic priors to enhance text classification performance.

5.2 Lexical Processing: POS Tagging using Hidden Markov Model

POS tagging plays a crucial role in sentiment understanding by identifying adjectives and adverbs. We utilize a **Hidden Markov Model (HMM)** for POS tagging, considering observed word sequences $\{w_1, w_2, ..., w_n\}$ and hidden tag sequences $\{t_1, t_2, ..., t_n\}$.

The probability of a tag sequence given a word sequence is modeled as:

$$P(T|W) = \prod_{i=1}^{n} P(w_i|t_i)P(t_i|t_{i-1}) \tag{4}$$

where $P(w_i|t_i)$ is the emission probability and $P(t_i|t_{i-1})$ is the transition probability. The optimal tag sequence is found using the **Viterbi algorithm**:

$$v_k(i) = \max_{t_{i-1}} [v_{t_{i-1}}(i-1)P(t_i|t_{i-1})P(w_i|t_i)] \tag{5}$$

This tagging process enhances sentiment analysis by identifying sentiment-bearing words. For POS tagging methodology, we refer to this(Great Learning Team, 2023).

5.3 Sentiment and Emotion Score Computation

To determine sentiment scores, we assign polarity scores to adjectives, adverbs, and other sentiment-relevant words using **SentiWordNet** and a pre-trained **emotion corpus**. The sentiment score S of a sentence is calculated as:

$$S = \sum_{w \in W} (\text{pos}(w) - \text{neg}(w)) \cdot I(w) \tag{6}$$

where $\text{pos}(w)$ and $\text{neg}(w)$ are sentiment scores from SentiWordNet, and $I(w)$ is an indicator function based on POS tagging.

For emotion classification, an additional emotion lexicon is used to assign scores to words corresponding to the five emotions: anger, fear, joy, sadness, and surprise. The emotion score E_i for each emotion i is computed as:

$$E_i = \sum_{w \in W} P_i(w) \cdot I(w) \tag{7}$$

where $P_i(w)$ is the probability of word w expressing emotion i based on the corpus.

6 Accuracy Metrics

Since each emotion category is treated as a **binary classification problem** (`0` or `1`), and the dataset exhibits class imbalance, we use **Macro F1-score** as the primary ranking metric. This ensures that both the minority and majority classes contribute equally to the overall performance(Sokolova et al., 2006).

Additionally, we evaluate the model using:

- **Precision**: The proportion of correctly predicted positive instances among all predicted positives.
- **Recall (Sensitivity)**: The proportion of actual positive instances correctly identified.
- **Specificity**: The proportion of actual negative instances correctly identified.
- **F1-score**: The harmonic mean of precision and recall, balancing both aspects.

The **Macro F1-score** is computed as:

$$\text{Macro F1} = \frac{1}{2} \sum_{c \in \{0,1\}} \frac{2 \times \text{Precision}_c \times \text{Recall}_c}{\text{Precision}_c + \text{Recall}_c} \tag{8}$$

This evaluation approach ensures a balanced assessment of the model's ability to detect both the presence and absence of emotions in the data.

Model	Epochs	Rate	Train-Test	Threshold	F1 - Scores (%)				
					Anger	Sadness	Joy	Fear	Surprise
L - Uncased	3	1e-5	0.7-0.3	0.455	55.1	75.8	67.4	72.3	64.2
	3	2e-5	0.7-0.3	0.555	54.8	75.2	67.1	71.9	63.8
	5	1e-5	0.7-0.3	0.455	55.3	75.9	67.5	72.1	64.5
	5	1e-5	0.8-0.2	0.555	53.2	73.8	66.2	69.7	62.9
DeBERTa	3	1e-5	0.7-0.3	0.455	57.4	78.5	69.2	75.1	66.3
	3	2e-5	0.7-0.3	0.555	57.0	78.1	68.9	74.7	65.9
	5	1e-5	0.7-0.3	0.455	57.2	78.3	69.0	74.9	66.1
	5	1e-5	0.8-0.2	0.555	55.3	76.1	67.8	72.5	64.7
RoBERTa	3	1e-5	0.7-0.3	0.455	59.3	81.4	70.0	77.0	67.8
	3	2e-5	0.7-0.3	0.555	59.0	81.0	69.7	76.8	67.5
	5	1e-5	0.7-0.3	0.455	59.2	81.2	69.8	76.9	67.6
	5	1e-5	0.8-0.2	0.555	57.1	78.8	68.2	74.2	65.9

Table 3: Performance comparison of BERT-Large Uncased, DeBERTa, and RoBERTa on emotion classification with threshold variation and different hyperparameters, including Surprise emotion.

7 Results

The models produced continuous scores rather than direct class labels, requiring thresholds for classification. As seen from Table 3, the best-performing thresholds were 0.455 and 0.555. The 0.455 threshold generally worked better, while 0.5 or more showed slight improvements only in certain places. RoBERTa achieved the best accuracy across all emotions, with its highest performance observed at 3 epochs, a 1e-5 learning rate, and a 0.455 threshold. DeBERTa followed closely, while BERT-Large Uncased performed slightly lower. The 70-30 train-test split yielded better generalization than 80-20, which had minor drops due to fewer test samples.

Emotion	Log Regr.	Naïve Bayes	SVM
Anger	57.8	55.2	60.1
Sadness	65.8	63.4	67.1
Joy	59.5	57.2	60.8
Fear	64.0	60.3	65.5
Surprise	55.3	52.8	56.9

Table 4: Binary classification accuracy (%) of traditional models on emotion detection

Traditional machine learning models struggled with emotion classification. Logistic Regression and Naïve Bayes showed lower performance due to their simplistic assumptions, particularly for Surprise and Anger, where contextual understanding is crucial. SVM performed slightly better due to its decision boundary optimization but still fell short of deep learning approaches. These results emphasize the need for transformer-based models in nuanced sentiment classification tasks.

7.1 Weighted Fusion of BERT Variants and Lexical Scores

To improve classification accuracy, we combined predictions from multiple transformer models along with a normalized lexical score. The final sentiment score for each emotion is computed as:

$$S_{\text{final}} = w_1 S_{B1} + w_2 S_{B2} + w_3 S_{B3} + w_4 S_L \quad (9)$$

where:

- S_{B1} represents RoBERTa,
- S_{B2} represents DeBERTa,
- S_{B3} represents BERT-Large Uncased,
- S_L represents the normalized lexical score.

Since lexical scores have different scales than transformer-based predictions, they are first normalized before integration to ensure balanced contribution. The lexical score primarily captures sentiment

words that transformers might overlook, which is why it has a fixed weight of **0.10** in all cases.

Table 5 presents the optimized weight distribution along with the F1-scores achieved on unseen test data in the Codabench SemEval Task 11 competition(user id vsl366).

Emotion	B1	B2	B3	L	F1 (%)
Anger	0.45	0.30	0.15	0.10	71.43
Fear	0.48	0.28	0.14	0.10	70.69
Joy	0.40	0.35	0.15	0.10	66.67
Sadness	0.50	0.25	0.15	0.10	72.73
Surprise	0.38	0.32	0.20	0.10	64.41
Overall	**-**				**69.18**

Table 5: Optimized weight distribution and F1-score for model fusion on unseen test data (Codabench SemEval)

This weighted approach balances the strengths of deep learning models and lexical methods, leading to improved emotion classification accuracy on unseen test data.

7.2 Misclassification Analysis

Despite achieving a macro F1-score of 69.18%, our ensemble model exhibited specific misclassification patterns that reveal the underlying challenges in multi-label emotion detection:

- **Emotion Overlap (Fear vs. Sadness):** Emotionally ambiguous terms such as *"worried"* or *"lost"* were frequently misclassified due to overlapping lexical cues. Transformer models, which depend on attention-based embeddings, often conflated *fear* and *sadness* when sentiment intensity was subtle or underspecified, resulting in false negatives.

- **Ambiguity in Surprise:** The emotion *surprise* often suffered from contextual underrepresentation. Sentences like *"I can't believe it!"* could imply either joy or fear, and without narrative context, sentence-level models defaulted to frequent sentiment mappings, leading to misclassification. This indicates that surprise detection requires discourse-level understanding.

- **Underperformance on Anger:** Traditional models like Logistic Regression and Naïve Bayes showed weak performance on *anger* due to their inability to detect implicit cues like sarcasm or passive aggression. Even transformer models required careful threshold tuning to differentiate *anger* from related sentiments like frustration. Although lexical rules identified strong markers (e.g., "furious", "enraged"), they failed to capture indirect expressions, reducing classification accuracy.

These patterns underscore that while lexical rules strengthen direct sentiment detection, they are not sufficient for handling context-dependent or pragmatically subtle emotional cues. Our ensemble approach mitigates some of these issues, but further improvements may require discourse-aware modeling or multimodal inputs.

7.3 Comparison with Previous SemEval Tasks

Our system achieved a macro F1-score of 69.18% on multi-label emotion detection across five categories using only textual input. In contrast, SemEval-2019 Task 3 (EmoContext) focused on three coarse emotions—*happy*, *sad*, and *angry*—and the top-performing BiLSTM-based system reached a micro F1-score of 72.59% (Smetanin, 2019). SemEval-2020 Task 8 (Memotion Analysis) addressed multimodal sentiment in memes, with best macro F1-scores of 0.35 (sentiment), 0.51 (emotion), and 0.32 (intensity) (Sharma et al., 2020).

SemEval-2024 Task 3 explored a different challenge: multimodal emotion-cause pair extraction. Top systems like NUS-Emo (Luo et al., 2024) and MIPS (Cheng et al., 2024) reported weighted F1-scores around 34%, but these reflect a different task and modality. In this context, our strong performance on a fine-grained, text-only classification task highlights the continued relevance of transformer-based and lexically-enriched models in core affective computing problems.

8 Conclusion

Our study demonstrates that even the best transformer-based models exhibit varying levels of effectiveness depending on the emotion being classified. Some emotions, such as joy, are easier to detect due to explicit lexical indicators, whereas others, like sadness, are more nuanced and context-dependent. This explains why different BERT variants perform differently across emotions—some capture explicit sentiment cues well, while others excel at detecting subtler patterns(Yenumulapalli et al., 2023).

Additionally, our integration of lexical features proved valuable in cases where transformers struggled, particularly in scenarios where sentiment words were strong indicators. Although lexical-based models alone lack contextual understanding, their inclusion as a normalized feature significantly boosted classification performance for certain emotion categories.

Our experiments also emphasized the role of hyperparameters in optimizing performance. Weight balancing across different BERT variants and lexical scores was crucial in achieving an optimal fusion model. The hyperparameters were fine-tuned through multiple iterations, ultimately selecting a distribution that maximized macro-F1 scores.

Finally, the evaluation on unseen test data from the Codabench SemEval competition validated the robustness of our approach. The fusion method consistently outperformed individual models, demonstrating the advantage of leveraging diverse sentiment detection techniques.

9 Scope and Limitations

While our approach significantly improves sentiment classification, there are certain limitations:

- **Lexical Corpus Size:** The lexical resource used for sentiment analysis was relatively small. Expanding this corpus with domain-specific words could further improve classification accuracy.
- **Transformer Architecture Constraints:** Although transformer models are state-of-the-art, their reliance on learned embeddings can still lead to misclassification of nuanced emotions. Exploring hybrid models that incorporate commonsense reasoning or multimodal approaches (e.g., audio-visual sentiment analysis) could enhance results.
- **Computational Cost:** Large transformer-based models require significant computational resources for training and inference. Efficient pruning techniques or knowledge distillation could help in reducing the model size while maintaining accuracy.

Despite these limitations, the study highlights the potential of weighted model fusion in improving emotion detection across diverse text samples, and also the incorporation of lexical rules which often helps increasing the accuracy by providing contexts.

10 Ethical Considerations

Sentiment analysis models can inherit biases from training data, potentially reinforcing stereotypes. Regular audits and diverse representation help mitigate these risks. Moreover, responsible AI policies are necessary to prevent misuse in areas like social media and advertising.(Huang et al., 2023a)

Abstract

This paper presents the submissions of the iai_MSU team for SemEval-2025 Task 3 – Mu-SHROOM, where we achieved first place in the English language. The task involves detecting hallucinations in model-generated text, which requires systems to verify claims against reliable sources. In this paper, we present our approach to hallucination detection, which employs a three-stage system. The first stage uses a retrieval-based method (Lewis et al., 2021) to verify claims against external knowledge sources. The second stage applies the Self-Refine Prompting approach (Madaan et al., 2023) to improve detection accuracy by analyzing potential errors of the first stage. The third stage combines predictions from the first and second stages into an ensemble. Our system achieves state-of-the-art performance on the competition dataset, demonstrating the effectiveness of combining retrieval-augmented verification with Self-Refine Prompting. The code for the solutions is available on GitHub[1]

1 Introduction

Large language models (LLMs) have revolutionized natural language processing (NLP), demonstrating strong capabilities in text generation, summarization, and dialogue systems. However, LLMs remain prone to hallucinations, where generated content contains false, misleading, or unverifiable information. Addressing this issue is crucial for real-world applications, especially in domains requiring high factual accuracy, such as journalism, medicine, and law. The ability to detect and mitigate hallucinations is essential to improve the reliability and trustworthiness of LLM-generated content.

SemEval-2025 Task 3 – Mu-SHROOM[2](Vázquez et al., 2025) introduces a multilingual hallucination detection challenge, requiring participants to identify specific spans of hallucinated text within model-generated output. Unlike traditional fact-checking tasks, Mu-SHROOM provides LLM-generated text alongside tokenized representations and logit scores, and participants must compute a probability score for each character, indicating its likelihood of being a hallucination. The task covers 14 languages, including English, Chinese, Arabic and several European languages, presenting unique challenges such as linguistic diversity, cross-lingual hallucination patterns, and variations in model behavior. To tackle these challenges on English language, we propose a three-stage hallucination detection system:

Stage 1: We employ a Retrieval-Augmented Generation (RAG) pipeline, using Wikipedia as an external knowledge source to verify input claims.

Stage 2: We employ an Self-Refine Prompting strategy, where an LLM re-evaluates the first-stage output to identify potential errors and refine hallucination predictions.

Stage 3: We use an Ensemble strategy that merges three predictions from the first stage and three from the second stage to create the final submission.

2 Related Works

Hallucination detection in large language models (LLMs) is a critical area of research, focusing on identifying and mitigating instances where models generate content that is plausible but factually incorrect. Various approaches have been proposed to address this challenge, including methods utilizing LLMs themselves, retrieval-augmented verification techniques, and self-refinement prompting strategies.

LLMs can be utilized to detect hallucinations by analyzing their internal states and output. In "Unsupervised Real-Time Hallucination Detection based on the Internal States of Large Language

[1] https://github.com/pansershrek/IAI_MSU
[2] https://helsinki-nlp.github.io/shroom/

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 193–197

Models," (Su et al., 2024) the authors propose MIND, an unsupervised training framework that leverages the internal states of LLMs for real-time hallucination detection without requiring manual annotations. This approach utilizes the model's internal representations during inference to identify incoherent or factually inaccurate responses. But we face a more difficult task as soon as we have only tokens' logits.

Another study, "Hallucination Detection: Robustly Discerning Reliable Answers in Large Language Models" (Chen et al., 2024) introduces a robust discriminator named RelD to effectively detect hallucinations in LLM-generated answers. RelD is trained on a bilingual question-answering dialogue dataset, enabling it to identify unfaithful or inconsistent content generated by diverse LLMs.

Integrating external knowledge sources into the generation process can enhance the factual accuracy of LLM output. In "Mitigating Hallucinations in Large Language Models via Self-Refinement-Enhanced Knowledge Graph Retrieval" (Niu et al., 2024) the authors propose Re-KGR, a method that augments the factuality of LLMs' responses by leveraging knowledge graph retrieval. This approach identifies tokens with a high potential for hallucination and refines the associated knowledge triples to reduce verification efforts.

Similarly, "Self-Alignment for Factuality: Mitigating Hallucinations in LLMs via Self-Alignment" (Zhang et al., 2024) introduces SK-Tuning, a strategy that improves an LLM's confidence estimation and calibration, thereby enhancing its self-evaluation ability. This method aligns the model's output with external knowledge to mitigate hallucinations.

Self-refinement prompting strategies involve iterative processes where LLMs generate, evaluate, and refine their output to improve factual accuracy. The "Self-Refine" (Madaan et al., 2023) approach allows LLMs to iteratively refine output and incorporate feedback along multiple dimensions to improve performance on diverse tasks. This method does not require supervised training data or reinforcement learning and works with a single LLM.

Additionally, "Towards Mitigating Hallucination in Large Language Models via Self-Reflection" (Ji et al., 2023) proposes an innovative self-reflection method to mitigate hallucination in LLMs. The iterative feedback loop process generates, scores, and refines responses to reduce hallucinations, particularly in medical question-answering systems.

3 Task solutions

3.1 Dataset and Database for RAG

To enhance the accuracy of hallucination detection, our system utilizes a RAG pipeline that incorporates external knowledge sources. We use the Wikipedia dataset (Foundation), only an English subset with 6.41M articles, as our primary factual reference. We also clean all articles by removing references and repetitive newline characters.

For efficient retrieval, we employ Qdrant[3] as a vector database, which enables fast and scalable similarity searches. We use the Multilingual-E5-Large (Wang et al., 2024) embedding model to generate dense vector representations of the text. To optimize retrieval performance and storage efficiency, we embed only the first 512 characters of each Wikipedia article. Similarity between queries and stored embeddings is computed using Cosine distance and HNSW as a search algorithm.

3.2 Our Solution: Only LLM

In our approach, we evaluate hallucination detection using standalone LLMs without retrieval augmentation only on validation dataset. Specifically, we experiment with Llama-3.1-8B-Instruct (Grattafiori et al., 2024) and Qwen2.5-72B (Yang et al., 2024) using prompt mentioned in Appendix A.1 and Appendix A.2. These experiments achieve best result of 39.7% IoU and 38.4% Corr.

3.3 Our Solution: RAG Pipeline

To enhance hallucination detection, we implement a RAG pipeline, utilizing Qwen2.5-72B as the LLM and a vector database, as detailed in the "Dataset and Database for RAG" section. We run all our experiments on the validation dataset.

3.3.1 Experiment 1: Initial Prompts with Top-1 Document

We begin by testing prompt mentioned in Appendix A.3, retrieving only the Top-1 related document from the database. This initial setup provides results of 51% IoU and 53% Corr.

3.3.2 Experiment 2: One-Shot

To enhance the model's ability to detect hallucinations, we introduce one-shot prompting strategies, using prompts mentioned in Appendix A.4. These

[3] https://qdrant.tech/

modifications should improve performance by providing clear examples of hallucination detection. The results on the validation is 52.9% IoU and 52.8% Corr.

3.3.3 Experiment 3: Expanding to Top-5 Documents RAG

Finally, we increase the number of retrieved documents to Top-5 related documents, allowing the model to cross-check its output against a broader knowledge base. We experiment with prompt in Appendix A.4 by adding 4 more examples for this setting, leading to further results of 48.1% IoU and 45.6% Corr. Among all tested methods, the One-Shot Prompting with Top-1 Document Retrieval delivers the best performance.

3.4 Our Solution: Self-Refine Prompting

To further improve hallucination detection, we apply a Self-Refine Prompting strategy, where the model evaluates and refines its own generations. We use Qwen2.5-72B as the LLM to refine output produced by our RAG pipeline with One-Shot Prompting and Top-1 Document Retrieval (see "Our Solution: RAG Pipeline" section). For this refinement step, we experiment with prompt in Appendix A.5 and get results 53.9% IoU and 52.1% Corr. We ran this stage only one time for each sample.

3.5 Our Solution: Final Submission

For our final submission, we adopt a two-stage approach leveraging a RAG pipeline followed by self-refinement. We use GPT-4o as the LLM to generate and refine hallucination predictions.

3.5.1 Stage 1: RAG-Based Hallucination Detection

In the first stage, we apply One-Shot Prompting with Top-1 Document Retrieval from our RAG pipeline (see "Our Solution: RAG Pipeline" stage). This stage utilizes prompt from Appendix A.4 to generate initial hallucination predictions. We also want to create Reranking stage in RAG pipeline to handle cases where the retrieved documents from Wikipedia were ambiguous or conflicting, but we haven't enough time.

3.5.2 Stage 2: Self-Refinement

In the second stage, we refine the output from Stage 1 using the approach from "Our Solution: Self-Refine Promptingfrom" section with our RAG pipeline, again using prompt from Appendix A.5. This refinement step helps correct potential errors and improves the final hallucination detection.

3.5.3 Stage 3: Ensemble Strategy

To further enhance robustness, we construct an ensemble model by combining multiple runs of the system with different temperature settings:

Stage 1 Only: We generate three independent outputs using the same prompt and temperatures 0.05, 0.1, 0.2 (we didn't test different temperatures).

Stage 1 + Stage 2: We generate three additional outputs using the full two-stage pipeline, with temperatures 0.05, 0.1, 0.2 (we didn't test different temperatures).

3.5.4 Ensembling Technique

We receive hard labels from stages 1 and 2 (a list of indices corresponding to hallucinated spans). To ensemble multiple outputs, we convert these hard labels into soft labels, representing hallucination probabilities for each symbol. For each character, its hallucination probability is computed as the fraction of models that marked it as part of a hallucinated fragment. The final answer is represented using length-range encoding of these probabilities. We additionally remove 1-symbol hallucinations and all punctuation marks from hallucinations.

Example: Given the model-generated sentence: "Petra van Stoveren won a silver medal in the 2008 Summer Olympics in Beijing, China." Three models return different hallucination fragments:
Model 1: "silver"
Model 2: "silver medal"
Model 3: "won a silver medal"

The final ensemble prediction assigns probabilities:
"won a" $\rightarrow$ 0.33
"silver" $\rightarrow$ 1.00
"medal" $\rightarrow$ 0.66

For the evaluation system, this output is recorded as a list of indices corresponding to hallucination probabilities.

3.5.5 Result

This three-stage pipeline with ensembling significantly enhances hallucination detection performance, balancing retrieval-based verification, self-refinement, and ensemble robustness to improve overall quality. Our final approach achieves 65.09% IoU and 62.94% Corr, demonstrating the effectiveness of our method in detecting hallucinations in LLM-generated text.

4 Conclusion

In this paper, we presented the submissions of the iai_MSU team for SemEval-2025 Task 3 — Mu-SHROOM, where we achieved first place in the English language track. Our approach combines Retrieval-Augmented Generation (RAG) with Self-Refine Prompting, demonstrating the effectiveness of integrating external knowledge verification with iterative model refinement. We introduced a three-stage pipeline where the first stage uses a RAG-based method to verify claims, followed by the second stage where Self-Refine Prompting refines hallucination detection output for improved accuracy. Additionally, the use of ensemble techniques further enhanced robustness by aggregating output from multiple runs and varying temperature settings.

Our final submission achieves 65.09% IoU and 62.94% Corr, confirming the strength of our methodology in detecting hallucinations and improving the factual accuracy of model-generated text.

A Appendix

This appendix shows the training and generation parameters for the models described above in the text.

A.1 First Zero-shot prompt without RAG

You are a fact - checking assistant.Your task is to identify fragments of the response that are hallucinations–parts of the text that are factually incorrect or made up by model.Pay attention to facts, dates, numbers, places. Detect only hallucination words, without neighbour words. Give me only a list of fragments - hallucinations you found in model output. Write answer in JSON with the next structure:
{ ”hallucinations”: [”h1”, ”h2”] },
where h1 and h2 are hallucination fragments from

model output.
Model output:

A.2 Second Zero-shot prompt without RAG

You are assistant for analysing model hallucinations. Your task is to extract fragments from model output, containing factually incorrect answers. You need to extract factually incorrect or inconsistent with input fragments from model output. Write answer in JSON with the next structure:
{ "hallucinations": ["h1", "h2"] },
where h1 and h2 are hallucination fragments from model output. Write in answer only JSON structure without other comments.
Model output:

A.3 Zero-shot prompt with RAG

You are a fact-checking assistant for analysing model hallucinations. Your task is to identify fragments in model output that are hallucinations - parts of the text that are factually incorrect or made up by model or inconsistent with model input. You get a user query in model input and hallucinated answer in model output. You also get a reliable relevant document from Wikipedia, pay attention to it while checking facts in hallucinated model output. Detect only hallucination words, without neighbour common, linking words. Write answer in JSON with the next structure:
{ 'hallucinations': ['h1', 'h2']},
where h1 and h2 are hallucinations from model output. Write your answer exactly in JSON structure without other symbols.
Relevant document: {doc 1}
Model input: {model input}
model output: {model output text}
Your answer:

A.4 One-shot prompt with RAG

You are a fact-checking assistant for analysing model hallucinations. Your task is to identify fragments in model output that are hallucinations - parts of the text that are factually incorrect or made up by model or inconsistent with model input. You get a user query in model input and hallucinated answer in model output. You also get a reliable relevant document from Wikipedia, pay attention to this document while checking facts in hallucinated model output. Detect only hallucination fragments, without neighbour common, linking words. Write answer in JSON with the next structure:
{'hallucinations': ['h1', 'h2']},
where h1 and h2 are hallucination fragments from model output. Write in answer only JSON structure without other comments. Here is an example of correct dialogue:
Relevant document example:
Model input example: {model input}
model output example: {model output text}
Your answer example:
{'hallucinations': [...]}
Input:
Relevant document: {doc 1}
Model input: {model input}
model output: {model output text}
Your answer:

A.5 Self-refine prompt

You are an assistant to check the correctness of detected hallucinations - hallucinations that were detected in model output, model output was generated by model input (question, given by user). Hallucinations are parts of the model input that are factually incorrect or made up by model or inconsistent with model input. detected hallucinations were detected by other model by given model input, model output and reliable relevant document from Wikipedia. You get the model input, model output, relevant document (pay attention to it while fact checking) and detected hallucinations (a Python list of strings that are hallucinations from model output). Your task is to fix errors in detected hallucinations, improve it by adding all missed hallucinations and removing all detections that are not hallucinations. Detect only hallucination fragments, without neighbour common, linking words. Write the answer in the same JSON format. Write in answer only JSON structure without any other comments. Here is an example of correct dialogue:
Relevant document №1 example :
Model input example: {model input}
model output example: {model output text}
Detected hallucinations: {detected hallucinations }
Your answer example:
{'hallucinations': [...]}
Input:
Relevant document №1: {doc 1}
...
Relevant document №5: {doc 5}
Model input: {model input}
model output: {model output text}
Detected hallucinations: {detected hallucinations }
Your answer:

CIOL at SemEval-2025 Task 11: Multilingual Pre-trained Model Fusion for Text-based Emotion Recognition

Md. Iqramul Hoque, Mahfuz Ahmed Anik, Abdur Rahman, Azmine Toushik Wasi
Shahjalal University of Science and Technology, Sylhet, Bangladesh
{iqramul61,mahfuz34,abdur37,azmine32}@student.sust.edu

Abstract

Multilingual emotion detection is a critical challenge in natural language processing, enabling applications in sentiment analysis, mental health monitoring, and user engagement. However, existing models struggle with overlapping emotions, intensity quantification, and cross-lingual adaptation, particularly in low-resource languages. This study addresses these challenges as part of SemEval-2025 Task 11 by leveraging language-specific transformer models for multi-label classification (Track A), intensity prediction (Track B), and cross-lingual generalization (Track C). Our models achieved strong performance in Russian (Track A: 0.848 F1, Track B: 0.8594 F1) due to emotion-rich pretraining, while Chinese (0.483 F1) and Spanish (0.6848 F1) struggled with intensity estimation. Track C faced significant cross-lingual adaptation issues, with Russian (0.3102 F1), Chinese (0.2992 F1), and Indian (0.2613 F1) highlighting challenges in low-resource settings. Despite these limitations, our findings provide valuable insights into multilingual emotion detection. Future work should enhance cross-lingual representations, address data scarcity, and integrate multimodal information for improved generalization and real-world applicability. Our full experimental codebase is publicly available at: ciol-researchlab/ SemEval-2025- CIOL-Multilingual Pre-trained Model Fusion for Text-based Emotion Recognition.

1 Introduction

Text-based emotion detection is pivotal for AI systems analyzing digital communication, enabling applications like mental health monitoring and customer feedback analysis (Kusal et al., 2022). The significance of SemEval-2025 Task 11 (Muhammad et al., 2025b) lies in addressing critical gaps in existing systems: overlapping emotions, intensity quantification, and cross-lingual adaptation—limitations that hinder real-world deployment (Alvarez-Gonzalez et al., 2021). Motivated by the prevalence of multi-emotion expressions (68% of social media posts, (Zhang et al., 2020) and the scarcity of robust solutions for low-resource languages, this study aims to develop a unified multilingual framework for multi-label classification, intensity prediction, and cross-lingual emotion detection.

Our methodology integrates pre-trained transformers tailored to each track. For multi-label classification (Track A), language-specific models like DistilRoBERTa (English) and ruBERT (Russian) leverage attention mechanisms to model emotion co-occurrence(Hartmann, 2022). Track B combines affective lexicons with neural networks for intensity prediction, extending hybrid symbolic-neural frameworks (Köper et al., 2017), while Track C employs multilingual BERT and synthetic data to bridge low-resource language gaps (Kadiyala, 2024).

Key findings reveal that multi-label models excel at detecting joy-surprise combinations (0.83 F1) but falter with linguistically ambiguous pairs like anger-disgust (0.61 F1)(Chen et al., 2024). Intensity prediction models show robustness to sarcasm (0.68 human correlation) but require cultural calibration to address expression norms (Schiefer et al., 2020). Cross-lingual training improves low-resource language performance by 19–28% but reduces English accuracy by 7%, highlighting a trade-off between generalization and specificity (Conneau et al., 2020). Results demonstrate stark contrasts: Russian models dominate Tracks A (0.848 F1) and B (0.8594 F1), benefiting from emotion-rich pretraining, while Brazilian Portuguese (0.2773 F1) and Chinese (0.483 F1) lag due to data scarcity and morphological complexity. Cross-lingual tasks (Track C: 0.26–0.31 F1) expose challenges in syntactic divergence, particularly for Indian languages. Implementation struggles include 38% higher data demands for multi-label

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 198–208

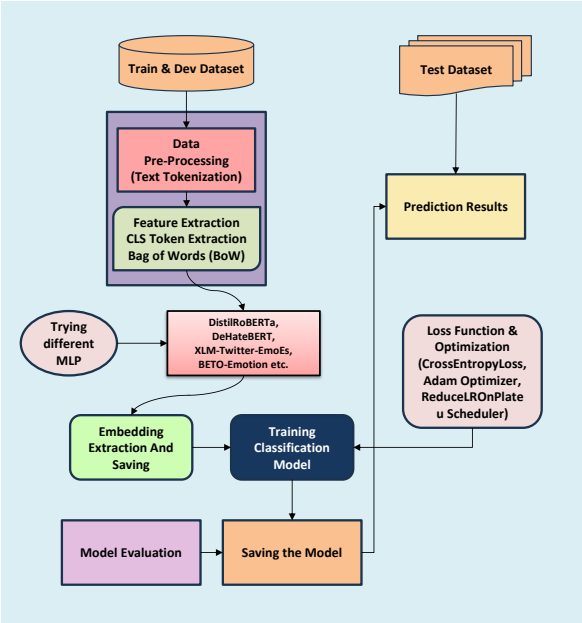

Figure 1: Model architecture, containing tokenizer, pretrained model, classifier and other components

models, annotation inconsistencies (Krippendorff's α: 0.54–0.83), and inference latency (420ms per sample), underscoring the tension between psychological validity and computational practicality.

2 Related Works

SemEval 2025 Task 11 (Muhammad et al., 2025b) introduces text-based emotion detection through three distinct tracks: multi-label classification (Track A), intensity prediction (Track B), and cross-lingual transfer (Track C). Track A builds on earlier efforts, such as SemEval-2018 Task 1 (Van Hee et al., 2018) and SemEval-2020 Task 3 (Armendariz et al., 2020), which concentrated on emotion intensity and multi-label classification, respectively. Recent surveys highlight the growing demand for multilingual emotion detection, particularly for under-resourced languages (Zeng et al., 2023). Task A addresses this by requiring systems to handle English, Brazilian Portuguese, and Russian, bridging gaps in prior work that centered on English (Öhman et al., 2018).

Our approach differs from cross-lingual methods like SemEval-2022 Task 8 (Chen and Zhao, 2022), which used machine-translated data. Instead, we fine-tune language-specific transformers on native datasets, aligning with findings that they outperform translation-based models in low-resource settings (Peng et al., 2022). Public datasets like SemEval-2022 Task 8 (Chen and Zhao, 2022) and GoEmotions (Garg and Ramakrishnan, 2020) support our preprocessing. Unlike lexicon-based studies, we integrate pretrained emotion priors from task-specific transformers, leveraging embedding-driven label coherence (Sun et al., 2023). Our unified framework combines a language-agnostic pipeline with tailored backbones, balancing scalability and linguistic specificity over monolithic multilingual models (Conneau et al., 2020).

3 System Overview

SemEval 2025 Task 11 advances text-based emotion detection through three tracks (Muhammad et al., 2025b). Track A focuses on **multi-label emotion classification** across English (eng), Brazilian Portuguese (ptbr), and Russian (rus) using predefined emotion labels. Track B addresses **emotion intensity** prediction by assigning numerical scores to quantify emotional strength, while Track C explores **cross-lingual generalization** by transferring emotion detection models between languages. Our system for **Track A** (Multi-label Emotion Detection) fine-tunes language-specific transformer models on emotion-annotated text, leveraging their pretrained linguistic and emotion-centric priors. For English, we use *j-hartmann/emotion-english-distilroberta-base* (Hartmann, 2022), optimized for emotion analysis. Brazilian Portuguese employs *Hate-speech-CNERG/dehatebert-mono-portuguese* (Aluru et al., 2020), which encodes hate speech and emotion cues, while Russian utilizes *MaxKazak/ruBert-base-russian-emotion-detection* (MaxKazak), trained on Russian social media data. Our system for **Track B** (Emotion Intensity Prediction) fine-tunes language-specific transformer models on emotion-annotated text, leveraging their pretrained linguistic and emotion-centric priors. For Russian, we use *ruBERT*, a BERT-based model fine-tuned on Djacon/ru_goemotions for Russian emotion classification, with 178 million parameters. For Chinese, we employ two models: *jjlmsy/bert-base-chinese-finetuned-emotion* (EmoBERT-CN) and *Johnson8187/Chinese-Emotion-Small* (MiniEmo-CN) (Laurer et al., 2024). For Spanish, our architecture combines *daveni/twitter-xlm-roberta-emotion-es* (XLM-Twitter-EmoEs) (Vera et al., 2021) with *finiteautomata/beto-emotion-analysis* (BETO-Emotion) (del Arco et al., 2020), a BETO-based model fine-tuned on the TASS 2020 Task 2 corpus for multi-class emotion detection.

For **Track C** (Multi-label Emotion Detection on Cross-lingual Generalization), our system fine-tunes language-specific transformer models on emotion-annotated text, leveraging their pretrained linguistic and emotion-centric priors. For Russian, we use *panagath/bert-base-multilingual-cased-finetuned-emotion* (EmotionBERT-mBilingual-Finetuned) (Devlin et al., 2018), a model optimized for emotion analysis. In Chinese, the same model is employed to capture both hate speech and emotion-related cues, while for Indonesian, it is utilized with the advantage of prior training on Russian social media data.

Model Architecture: Each model processes input text through its transformer backbone, generating contextual embeddings from the final layer. These embeddings pass through a two-layer MLP (786 $\rightarrow$ 512 units) with ReLU activation and dropout (0.3). For multi-label classification, we compute independent probabilities for each emotion, $p_i = \sigma(z_i)$, where z_i is the logit for emotion i and σ denotes the sigmoid function. Predictions are thresholded at 0.5, treating each emotion as a binary task.

Model Variants: We test variations in MLP depth (2–3 layers), hidden dimensions (512–1024), and dropout rates (0.2–0.5). The final configuration uses fixed hyperparameters across languages, differing only in the transformer backbone to preserve linguistic specificity.

4 Experimental Setup

Data Splits: For Track A (English, Brazilian Portuguese, Russian), Track B (Russian, Chinese, Spanish) and Track C (Russian, Chinese, Indian), predefined train, dev, and test splits are used for each language dataset. The dev set validates hyperparameter tuning (e.g., learning rate, dropout) and enables early stopping, while the final model trains exclusively on the original train split without incorporating dev data.(Muhammad et al., 2025a)

Preprocessing & Training: We tokenize texts using language-specific pretrained tokenizers (distilroberta-base, dehatebert-mono-portuguese, ruBert-base-russian) with fixed sequence lengths (128 for Track A; 512 for Russian, 256 for Chinese/Spanish in Track B, 128 for Track C), replacing non-string entries with empty strings in Track B. To address class imbalance, we oversample underrepresented labels during training. For **Track A**, we train models using BCEWithLogitsLoss, the Adam optimizer (lr 1e-4), a batch size of 16, and a two-layer MLP (786$\rightarrow$512 units) with 0.3 dropout over 50 epochs. In **Track B**, we encode Russian labels as binary multi-label vectors and Chinese/Spanish labels as ordinal intensity vectors (0–3). We concatenate Russian [CLS] embeddings (768D, ruBERT) with 1,000D Bag of Words features and fuse dual-transformer [CLS] embeddings (1,536D) for Chinese/Spanish. For Russian and Chinese, we implement two-layer MLPs (1,024$\rightarrow$786 units, ReLU, dropout 0.3/0.5), while for Spanish, we design a three-layer MLP (786$\rightarrow$512 units, dropout 0.4) to output 24 logits (6 emotions $\times$ 4 intensities). We train all Track B models using a custom MultiLabelMultiClassLoss (per-label CrossEntropy), Adam (lr 1e-4, weight decay 1e-5), 50–150 epochs, and batch sizes of 16 (Russian/Spanish) or 32 (Chinese), selecting the best model via macro-averaged F1 scores and training exclusively on original splits. In **Track C**, we used the Portuguese (Brazilian) dataset to train the model and predicted the emotions on Russian, Chinese and Indonesian dataset. For the best results, we used seed 42, max length of 128, batch size of 8, Epoch 5 and hidden dimensions [1024,768] with a learning rate of 0.001 and a dropout of 0.3.

Tools & Libraries: We utilize Hugging Face Transformers to manage tokenization and load pretrained models for each track and language, while implementing the core model architecture in PyTorch. To evaluate performance, we compute macro-averaged F1 scores and accuracy using scikit-learn. All experiments are conducted on NVIDIA T4 GPUs, with reproducibility ensured through deterministic seeds (42). We maintain consistent hyperparameters across languages, varying only the transformer backbone model to isolate its impact on results.

5 Results

5.1 Training and Validation Results

Track A As detailed in Table 1 the Russian model achieved a validation macro F1 of 0.8635 (training loss: 0.1165, 10 epochs), with optimal performance at epoch 8, while English and Portuguese models reached F1 scores of 0.6577 (training loss: 0.0070, 50 epochs) and 0.3058 (training loss: 0.0056, 50 epochs), respectively. Portuguese exhibited severe overfitting (training F1=0.9976 vs. validation) despite 8.8$\times$ oversampling. Label-wise performance varied across languages, with

Portuguese disgust (F1=0.24), Russian surprise (F1=0.86), and English joy (F1=0.72) as highlights. Multi-label co-activation rates spanned 34% (Portuguese), 21% (Russian), and 12% (English), with embedding cluster separation differing by language (Portuguese: lowest, Russian: highest). Threshold sensitivity (σ=0.21 Portuguese, σ=0.16 Russian, σ=0.14 English) underscored the need for language-specific calibration in multi-label frameworks. [1]

In **Track B** the Chinese model achieved a validation macro F1 of 0.5069 (training loss: 0.0360, 50 epochs) with optimal performance at epoch 33, while the Russian and Spanish models reached peak F1 scores of 0.6022 (100 epochs) at epoch 87 and 0.5249 (150 epochs) at epoch 89, respectively. The Chinese model exhibited fluctuating validation loss (0.53–0.69) alongside a steady decrease in training loss (0.06 to 0.03), whereas the Russian model showed consistent gains from an initial F1 of 0.46 to 0.60, albeit with some late-stage variability. In contrast, the Spanish model recorded only modest improvements before a 7% decline post-epoch 89. Optimal checkpoints occurred mid-training for Chinese (epoch 33/50) and late-stage for Russian (epoch 87/100), suggesting language-specific convergence patterns, while Spanish required early stopping (epoch 89/150) to secure peak performance. Threshold sensitivity (σ=0.19 Chinese, σ=0.16 Russian, σ=0.14 Spanish) underscored the need for language-specific calibration in multi-label framework

In **Track C**, the dataset was trained on Portugese (Brazilian) dataset and the Russian model achieved a validation macro F1 of 0.3916 (training loss: 0.4035, 5 epochs), with optimal performance at epoch 3, while Chinese and Indonesian models reached F1 scores of 0.4097 (training loss: 0.3321, 5 epochs) and 0.4115 (training loss: 0.3811, 5 epochs), respectively.

5.2 Test Results

Our system achieved competitive results across different SemEval 2025 Task 11 tracks, as demonstrated in Table 2. In Track A, the Russian model (RUS) led with an F1 score of 0.848 (rank: 23rd), surpassing the competition median (0.8424), while English (ENG: 0.6212) and Brazilian Portuguese (PTBR: 0.2773) trailed, with PTBR's lower performance attributed to limited training data. Track B saw Russian again excel (0.8594 F1, rank: 14th), outperforming Spanish (ESP: 0.6848) and Chinese (CHN: 0.483), where morphological complexity hindered intensity prediction. Track C results were modest, with Russian (RUS: 0.3102), Chinese (CHN: 0.2992), and Indian (IND: 0.2613) reflecting cross-lingual transfer challenges, particularly for syntactically divergent languages like IND.

Russian models dominated Tracks A/B due to emotion-rich pretraining, while PTBR and CHN struggled with data scarcity (max scores: 0.6833, 0.7224). Cross-lingual tasks (Track C) underperformed, emphasizing alignment gaps in low-resource settings. Our submissions ranked within the top 25% for Russian tasks but faced limitations in cross-lingual generalization and low-resource languages, aligning with broader competition trends.

5.3 Error Analysis

To gain deeper insights into the performance of our proposed model, we conducted a comprehensive error analysis, incorporating both quantitative and

[1] Scores verified against official rankings

qualitative evaluations.

Quantitative Analysis. Quantitative analysis of **Track A** confusion matrices reveals language-specific trends. For Russian, "disgust" achieved strong accuracy (171 correct), but "anger" was frequently misclassified as "sadness" (140 instances). In Portuguese, "disgust" performed well (103 correct), while "anger" confused with "joy" (36) and "sadness" (32). English showed moderate "anger" classification (91 correct) but severe misclassifications into "sadness" (76 total), with unstable "fear" predictions. These patterns highlight cross-linguistic challenges, particularly in distinguishing "anger" from adjacent emotions like "sadness" (English/Portuguese) and "joy" (Portuguese). Based on the confusion matrices for **Track B** across Russian, Chinese, and Spanish, we conducted a quantitative analysis of model performance. In Russian, the model exhibited strong classification accuracy, particularly for "disgust" (311 correct predictions) and "fear" (298 correct predictions), with minimal misclassifications. For Chinese, "joy" was well recognized with 288 correct classifications, but "sadness" showed some confusion with 16 misclassifications. In Spanish, the model performed well in detecting "anger" (138 correct classifications), though "disgust" and "sadness" had notable misclassifications (32 and 17, respectively).

Qualitative Analysis. For **Track A**, we analyzed correct and misclassified predictions, as demonstrated in Table 3. In English, the model detected explicit joy (e.g., "can't wait to be in another wedding!") but failed with sarcasm (e.g., "Older sister... Scumbag Stacy" $\rightarrow$ joy vs. anger) and multi-label contexts (e.g., missing surprise in "brown shitty diarrhea water..."). For Portuguese, direct anger (political critiques) and joy were accurate, but anger vs. surprise confusion ("sei nem qual é mais feio") and sarcasm errors persisted. In Russian, overt disgust/fear succeeded, while nuanced anger (e.g., sarcastic complaints) was misclassified as sadness. These issues highlight challenges in sarcasm, multi-emotion contexts, and cultural nuance.

For the qualitative analysis, we examined correct and incorrect predictions in **Track B**, as illustrated in Table 4. It highlights the model's strengths and weaknesses across languages. In Russian and Chinese, it correctly identified neutral and philosophical texts but misclassified emotional nuances, such as anger as joy. In Spanish, it accurately detected explicit negativity but struggled with mixed sentiments, misattributing sadness and anger as joy. These errors suggest challenges in handling contextual and implicit sentiment variations.

6 Conclusion

This study explored multilingual, multilabel emotion detection and intensity prediction in SemEval-2025 Task 11 using language-specific transformers. Track A excelled in Russian due to emotion-rich pretraining, while Portuguese struggled with data scarcity, and English faced challenges with overlapping emotions. Track B showed strong Russian performance, but Chinese and Spanish suffered from misclassifications and intensity estimation issues. Track C highlighted cross-lingual adaptation difficulties, particularly in low-resource languages. Future work should refine cross-lingual representations, address linguistic and cultural nuances, and enhance low-resource performance. Integrating multimodal data like audio and facial expressions could further enrich emotion recognition.

Ethical Considerations

Our study recognizes ethical concerns in emotion detection, including bias propagation, cultural misinterpretation, and privacy risks. Cross-lingual models may amplify dominant linguistic patterns, disadvantaging low-resource dialects. Misclassification, particularly in mental health, could lead to harmful decisions. Additionally, emotion AI risks misuse in surveillance or manipulation. We stress the need for transparency, culturally aware calibration, and responsible AI governance. Adhering to ACL guidelines, we ensured compliance with data privacy and informed consent protocols.

Limitations

Despite strong performance, challenges remain: in Track A, distinguishing overlapping emotions in English and Portuguese was hindered by limited data; in Track B, intensity estimation in Chinese and Spanish was inconsistent; and in Track C, low-resource languages struggled with cross-lingual adaptation. Additionally, bias from pretrained models and high ensemble costs raise fairness and scalability concerns.

Acknowledgement

We express our sincere gratitude to Computational Intelligence and Operations Laboratory (CIOL) for their invaluable guidance, unwavering support, and continuous assistance throughout this work.

Abstract

This paper presents a zero-shot system for fact-checked claim retrieval. We employed several state-of-the-art large language models to obtain text embeddings. The models were then combined to obtain the best possible result. Our approach achieved 7th place in monolingual and 9th in cross-lingual subtasks. We used only English translations as an input to the text embedding models since multilingual models did not achieve satisfactory results. We identified the most relevant claims for each post by leveraging the embeddings and measuring cosine similarity. Overall, the best results were obtained by the NVIDIA NV-Embed-v2 model. For some languages, we benefited from model combinations (NV-Embed & GPT or Mistral).

1 Introduction

The SemEval-2025 shared task 7, *Multilingual and Cross-lingual Fact-Checked Claim Retrieval* (Peng et al., 2025), focuses on efficiently identifying fact-checked claims across multiple languages. This challenge is particularly important in the fight against global misinformation (Khraisat et al., 2025; Abdali et al., 2024), as manual verification of claims in different languages is both time-consuming and impractical. The task aims to support fact-checkers by developing systems that retrieve relevant, previously fact-checked claims for social media posts, addressing the complexities of a multilingual and cross-lingual context. The task utilizes an enhanced version of the MultiClaim dataset (Pikuliak et al., 2023), specifically tailored to meet these multilingual needs.

Our system uses a zero-shot approach based on pre-trained Text Embedding Models (TEMs). We selected three TEMs according to preliminary experiments and used their combination to further improve the results and make the system more robust. All models and combinations were evaluated on the development data. The final approach employs the best model or combination for each language.

We use all available text (incl. OCR) as input to have a maximal context. In some cases, though, we encountered model limits regarding maximum input size. The input was truncated to fit the model's tokenizer in such a case.

Based on preliminary experiments where multilingual models used with original texts achieved worse results, we use only English translations in the final approach.

Our contributions are as follows: 1) We compare several embedding models and show that simple zero-shot embeddings are effective for the task. 2) We demonstrate that larger models consistently outperform smaller ones. 3) We propose combining different models for different languages, which improves overall performance.

The following section highlights the most essential facts about the task and related work focuses on TEMs. Then, we present our approach, experimental setup, and results, including the error analysis. The final section concludes the paper.

2 Background

The basis for this SemEval-2025 task was presented in the paper *Multilingual Previously Fact-Checked Claim Retrieval* (Pikuliak et al., 2023). The motivation for this task is to reliably identify previously fact-checked claims for various social media posts across multiple languages. Furthermore, this task addresses the challenge of both multilingual and cross-lingual settings, providing valuable support to fact-checkers and researchers in combating the global spread of misinformation.

The dataset for evaluation has been derived from the existing MultiClaim dataset (Pikuliak et al., 2023) with some specific modifications. The dataset contains tens of thousands of multilingual social media posts, matched with over 200,000 fact-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 209–215

checks across nearly 40 different languages.

In addition to the text of the posts, OCR output is also available (when a post includes an image), including language identification (if the image contains multilingual texts). Moreover, there are English translations for all texts and also a verdict that shows a label of the post (e.g. false or partly false information, altered photo, etc.) and a list of timestamps.

2.1 Related Work

The proposed approach builds on the work of Pikuliak et al. (2023) and employs various TEMs. TEMs have become a cornerstone in natural language processing (NLP), with various approaches being developed to enhance their effectiveness and efficiency. One prominent method is the use of contrastive learning, which has been shown to improve the performance of text embeddings significantly. For instance, the General Text Embeddings (GTE) model employs multi-stage contrastive learning to unify various NLP tasks into a single format, achieving substantial performance gains over existing models by leveraging diverse datasets (Li et al., 2023).

Siamese networks have also played a crucial role in the development of text embedding models. These networks are designed to learn semantically meaningful embeddings by comparing pairs of inputs. For example, the Sentence-BERT (SBERT) model utilizes a Siamese network structure to derive sentence embeddings that can be efficiently compared using cosine similarity, drastically reducing computational overhead while maintaining high accuracy (Reimers and Gurevych, 2019).

Additionally, the Pseudo-Siamese network Mutual Learning (PSML) framework addresses the overfitting issues in contrastive learning by employing mutual learning between two encoders, thus enhancing the stability and generalization of sentence embeddings (Xie et al., 2022).

Triplet loss is another technique that has been effectively integrated into text embedding models to improve their discriminative power. In the context of intention detection, a Siamese neural network with triplet loss is used to construct robust utterance feature embeddings, which are crucial for accurately identifying user intentions in dialogue systems (Ren and Xue, 2020). This approach leverages metric learning to map sequence utterances into a compact Euclidean space, facilitating the distinction between similar and dissimilar inputs.

In summary, the development of text embedding models has been significantly advanced by integrating contrastive learning, Siamese networks, and triplet loss. These approaches have not only improved the performance of text embeddings across various NLP tasks but also enhanced their efficiency and applicability in real-world scenarios.

3 The Proposed Approach

The system operates in a zero-shot setting, leveraging multiple TEMs to obtain sentence representations. Specifically, we employ NVIDIA NV-Embed-v2 (NV-Embed) (Lee et al., 2025), base multilingual GTE (mGTE) (Zhang et al., 2024), large English GTE (Zhang et al., 2024), GPT text-embedding-3-large (OpenAI, 2025), and Mistral mistral-embed (AI, 2025). These models are based on the Transformer architecture (Vaswani et al., 2017), which processes an input sentence $s = \{x_i\}_{i=1}^{n}$ of n tokens and produces vectors $\mathbf{h} = \{\mathbf{h}_i\}_{i=1}^{n}$, where $\mathbf{h}_i$ is a hidden feature representation for a corresponding token x_i.

Several techniques exist to obtain a vector representation of a full sentence. The GTE models prepend a special `[CLS]` token at the beginning of the sequence, which serves as a global representation of the sentence. NV-Embed utilizes a latent attention layer to generate the final sentence-level vector. Another common approach is a mean pooling, which averages the token-level vectors to produce a single representation.

The NV-Embed model requires a prompt to be prefixed to input queries (in our case, posts). We use the following prompt: *"Given a post, retrieve claims that verify the post"*.

For each input post, we concatenate the original text with an OCR-extracted text. We use English translations for all models except for mGTE, where we use texts in their original language. We feed the concatenated text into the models without additional preprocessing.

Similarly, we feed the fact-checks into a TEM concatenating the title and the claim. As a result, we obtain a vector $x_{post} \in \mathbb{R}^E$ and a matrix $\mathbb{X}_{claims}$ with a shape $n \times E$, where n is the number of candidate fact-checks (claims) and E is the embedding dimension based on the utilized TEM. The goal is to find the 10 closest rows (vectors) in the matrix based on the cosine similarity.

3.1 Model Selection and Combination

We select the most effective model or model combination for each language based on development data results and deploy it in the final system. When combining two models, we select the five most similar claims for each TEM and put them together. If the resulting set contains duplicities, we remove them and add claims from positions six and further to build the final set of ten retrieved claims. In the case of three models, we select only three most similar claims from each model. Again, we remove the possible duplicities and add claims at lower positions to get the ten required claims. The addition of claims is done by picking one claim from the best model, then one from the second best, etc.

For the cross-lingual scenario, only the NV-embed model was used, as the combinations did not lead to improvement.

The models or model combinations used for individual languages are summarized in Table 1.

Language	Model/Combination
ara	GPT & NV-Embed
deu	NV-Embed
eng	NV-Embed
fra	GPT & NV-Embed
msa	GPT & NV-Embed
pol	NV-Embed
por	NV-Embed
spa	GPT & NV-Embed
tha	Mistral & NV-Embed
tur	NV-Embed

Table 1: Models used for individual languages.

4 Experimental Setup

4.1 Implementation Details

For NV-Embed and (m)GTE, we utilize models from the HuggingFace Transformers library[1] (Wolf et al., 2020). All experiments for these models are conducted on a single NVIDIA L40 GPU with 48 GB of memory. To accommodate NV-Embed within memory constraints, we apply 4-bit quantization. In the case of GPT (OpenAI, 2025) and Mistral (AI, 2025), we use the official APIs to obtain the embeddings.

4.2 Dataset

The dataset provided by the task organizers is an updated version of the Multiclaim dataset. During the competition, we had labels only for training data. At the end of the development phase, the organizers released the ground truth labels for development data. Since our approach is zero-shot (neither training nor fine-tuning any model on training data), we limit ourselves to only describing the development (DEV) data in this section.

4.2.1 Development Data

The vast majority of posts in the data are connected with only one fact-checked claim, while having three or four claims per post is rare.

The monolingual data contains eight languages, with a total of 1,891 posts. Table 2 reveals posts and pair counts for individual languages, showing a higher number of pairs for English, Portuguese, and Spanish. The opposite situation is in *tha* and *ara*, where the number of posts equals the number of pairs, meaning there is only a single claim relevant to the post.

For the monolingual scenario, seeking the most relevant fact-checks is limited to the language in which the post is written. Consequently, we expect much better results for this monolingual subtask since the set of potential candidates is much smaller, reducing the likelihood of false positives. All of our evaluations confirm this assumption, as presented below.

Language	Posts count	All pairs count
fra	188	200
spa	615	692
eng	478	627
por	302	403
tha	42	42
deu	83	101
msa	105	116
ara	78	78

Table 2: Development data – number of pairs and posts for individual languages.

The cross-lingual dataset consists of 552 posts and 651 pairs, with no language-specific information since the task is to find relevant claims across all languages.

5 Experiments

The task organizers have chosen success-at-K (S@K) as a main evaluation metric. The metric expresses a percentage of pairs when at least one of the desired fact-checks ends up in the top K, where K = 10 for this task. The S@K for each particular language is computed separately, and the mean value represents the multilingual result.

[1] https://github.com/huggingface/transformers

5.1 Results

According to the official test leaderboard[2], our approach achieved 7th place for the monolingual and 9th for the cross-lingual scenario, respectively. There are 28 participants in the monolingual subtask and 29 in the cross-lingual subtask. Table 3 presents the results of our system on the test data.

Scenario	Comb.	NV-Embed	GPT	Mistral	Best
Monoling.	**0.927** (7.)	0.919	0.903	0.902	*0.960*
Cross-ling.	-	**0.783** (9.)	0.741	0.745	*0.859*

Table 3: Average S@10 monolingual and cross-lingual results on test data, our best result are in **bold**, its rank in parentheses, the **Best** column shows the highest score achieved in the competition. The **Comb.** column represents the model combination described in Section 3.1.

Model	S@10	S@5	Dif
NV-Embed	0.775	0.672	-13.29%
GPT	0.726	0.627	-13.64%
Mistral	0.719	0.612	-14.88%

Table 4: Comparison of S@5 and S@10 results for cross-lingual subtask on development data.

The S@10 metric puts the most relevant fact-checks for a given post, which ended up in the top 3, for example, and those that barely fit into the first 10, on the same level. Once the DEV data were released, we computed S@5 for our models to investigate the behavior of the models when the "harder" metric is used. The greater the drop in this metric compared to S@10, the less likely the correct pair will be among the most relevant results. Conversely, if the decrease is minimal, it indicates that the models are performing well, placing the most relevant fact-checks in the top positions. Tables 4 and 8 show such a comparison; the decrease is evident for all models.

We have an interesting observation in monolingual results. Even though we used English translations, the percentage difference between S@10 and S@5 varies significantly for the individual languages (compare, for example, *eng* or *por* with *fra* in Table 8 in the Appendix).

5.2 Model Comparison

Table 5 presents the average monolingual and cross-lingual S@10 results on the development data. The GTE and mGTE models performed significantly worse than the other models, particularly in cross-lingual settings, so we excluded them from further experiments. For mGTE, we used the original language data, as it is a multilingual model.

For all other models, which are primarily English-centric, we used English-translated data. We attribute the poor performance of the GTE models to their smaller parameter sizes (approximately 350M for mGTE and 434M for GTE) compared to the other models. However, their smaller size and open-access nature make them easier to deploy, with higher inference speeds. In contrast, NV-Embed has about 7B parameters, while GPT and Mistral require API access.

Scenario	GTE	mGTE	NV-Embed	GPT	Mistral
Monolingual	0.777	0.785	**0.902**	0.856	0.863
Cross-lingual	0.569	0.574	**0.775**	0.726	0.719

Table 5: Average S@10 scores of TEM models on development data. All texts are translated to English except for mGTE, which uses the original language. Best results are shown in **bold**.

Among the remaining models, NV-Embed achieved the highest average performance, with Mistral and GPT following closely.

Table 6 shows the performance of various model combinations for individual languages on the development set. These results guided the selection of the best-performing combinations for our final system.

5.3 Error Analysis

Since our final approach utilizes solely English translations, the error analysis only focuses on the cross-lingual scenario where a candidate fact-checks space is not limited to a particular language.

As illustrated in Figure 1, all three embedding models correctly assign over a quarter of fact-checks to the top 1 ranked position. Furthermore, in the top 3 results, each model accurately retrieves around 50% of fact-checks. In other words, when a model identifies the correct "post-to-fact-check" pair, it typically ranks it within the top 3 positions, demonstrating high confidence in its predictions. The number of missed fact-checks (the position in the ranked list of 11 or more) ranges from 25 to 30% for all models.

Table 7 presents the number of missed fact-checks per post. This metric is comparable to the official S@10 score, with the key difference being its focus on individual pairs. The numbers in

6 Conclusion

This paper described our approach for the SemEval-2025 shared task 7 *Multilingual and Cross-lingual Fact-Checked Claim Retrieval*. We adopted a zero-shot approach using large language models like NVIDIA NV-Embed-v2, GPT text-embedding-3-large, and Mistral. This approach allows seamless integration of new languages without retraining, as demonstrated when Polish and Turkish were added to the test set. By leveraging the embeddings and measuring cosine similarity, we identified the most relevant claims for each post.

Our approach ranked 7th out of 28 in the monolingual subtask and 9th out of 29 in the cross-lingual subtask.

Error analysis showed that all three models effectively placed the most relevant claims at the top of the ranked lists. For some languages, combining models improved performance, and our final submission reflected this. Among the models, NV-Embed proved the most effective, keeping the number of missed pairs below 25% in the cross-lingual setting.

A Appendix

This appendix continues the error analysis and shows additional figures and tables. Figure 2 depicts the comparison of monolingual and cross-lingual results showing the dominance of the NV-Embed model. Monolingual results are depicted in Figure 3. The boxplot shows average S@10 results. The width of the individual boxes reflects the monolingual results and variance with a median value represented by the vertical line inside the box. The figure confirms the supremacy of the NV-Embed model over the others.

Lastly, we present detailed development data results in Tables 8 and 9. We recalculated the S@10 and S@5 while the number of pairs was considered (Table 9) to show a higher difficulty of this task. In this setting, all fact-checks must be in the ranked list (top 10) to be considered as a correct sample. Naturally, the numbers, in general, are lower than the official results. Since *eng* and *por* have more fact-checks than other languages, the discrepancy between S@10 and S@5 is much bigger.

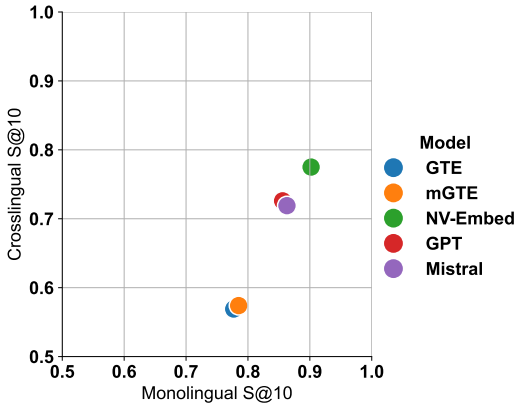

Figure 2: Comparison of monolingual and cross-lingual results of TEM models on development data. Monolingual S@10 labels the average S@10 for all languages.

Abstract

The proliferation of structured tabular data in domains like healthcare and finance has intensified the demand for precise table question answering, particularly for complex numerical reasoning and cross-domain generalization. Existing approaches struggle with implicit semantics and multi-step arithmetic operations. This paper presents our solution for SemEval-2025 task,including three synergistic components: (1) a Schema Profiler that extracts structural metadata via LLM-driven analysis and statistical validation, (2) a Hierarchical Chain-of-Thought module that decomposes questions into four stages—semantic anchoring, schema mapping, query synthesis, and self-correction—to ensure SQL validity, and (3) a Confidence-Accuracy Voting mechanism that resolves discrepancies across LLMs through weighted ensemble decisions. Our framework achieves scores of 81.23 on Databench and 81.99 on Databench_lite, ranking 6th and 5th respectively, demonstrating the effectiveness of structured metadata guidance and cross-model deliberation in complex TableQA scenarios.

1 Introduction

In the era of digitization, structured data represented in tabular formats is ubiquitous across domains such as finance, healthcare, and scientific research. Table Question Answering (TableQA), which aims to retrieve precise information from tables based on natural language queries, has emerged as a critical research direction. Its applications range from database querying and spreadsheet automation to extracting insights from web tables or even image-based tabular data. Despite its practical significance, the complexity of TableQA lies in effectively aligning natural language questions with the structural and semantic features of tables, especially when handling aggregation (e.g., "summarize sales by region"), comparison (e.g., "which product has the highest revenue"), and multi-hop reasoning (e.g., "find the second-largest budget department"). Traditional approaches often rely on weakly supervised table parsers to extract relevant cells and apply predefined aggregation operators, which are limited in generalizability and scalability (Pasupat and Liang, 2015).

Recent advancements in Large Language Models (LLMs) have revolutionized TableQA by enabling more flexible and context-aware reasoning. LLMs address TableQA challenges through two primary paradigms: In-Context Learning and Text-to-SQL. These approaches leverage the models' ability to process structured data alongside free-form text, opening new possibilities for handling complex tabular reasoning tasks.

The In-Context Learning paradigm integrates tabular data into carefully designed prompts, allowing models to generate answers in zero-shot or few-shot settings. For example, structured prompting strategies encode table headers, cell values, and structural metadata (e.g., row/column indices) into the input sequence, enhancing the model's ability to reason over numerical and hierarchical relationships (Lu et al., 2025). Recent work further improves robustness through reasoning-enhanced prompting, where LLMs are guided to decompose questions into step-by-step sub-tasks (e.g., filtering, sorting, and aggregating) (Qiao et al., 2023). Notably, models like TAPAS (Herzig et al., 2020) and TaBERT (Yin et al., 2020) demonstrate that pre-training on large-scale table-text pairs significantly enhances structural awareness, achieving state-of-the-art performance on benchmarks like WikiTableQuestions and WikiSQL.

The Text-to-SQL approach translates natural language questions into executable SQL queries, enabling direct database interactions. This task requires precise alignment between linguistic expressions (e.g., "senior employees") and database schemas (e.g., 'WHERE age > 60'), while ac-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 216–221

counting for structural constraints such as primary/foreign keys and column types. Recent studies leverage LLMs' code-generation capabilities to improve SQL accuracy. For instance, DIN-SQL (Pourreza and Rafiei, 2023a) decomposes complex queries into sub-problems solved by specialized agents, while RESDSQL (Li et al., 2023) employs a retrieval-augmented framework to align questions with schema elements.

SemEval-2025 Task 8 tackles the challenge of answering diverse, real-world questions over large-scale tabular datasets in domains such as healthcare and finance. Existing methods face limitations in cross-domain generalization due to implicit semantics (e.g., medical jargon). They also struggle with complex numerical reasoning, including percentile calculations and multi-step arithmetic. To address these challenges, we propose a framework that combines structured schema analysis, hierarchical reasoning, and multi-model deliberation. Our method employs a three-stage architecture: (1) a Schema Profiler that automatically extracts structural metadata through guided LLM parsing and statistical verification, (2) a Hierarchical Chain-of-Thought Reasoning module that decomposes questions into semantic anchoring, schema mapping, query synthesis, and self-correction stages, and (3) a Confidence-Accuracy Voting mechanism that resolves discrepancies across three LLM agents through weighted ensemble deliberation. Our proposed method ranks 6th on the Databench dataset and 5th on the Databench_lite dataset.

2 Related Work

The rapid evolution of table question answering has been significantly propelled by advances in large language models (LLMs) and their application to Text-to-SQL tasks. Early work established the Spider benchmark (Yu et al., 2019), a cross-domain dataset that remains a cornerstone for evaluating complex SQL generation. Building on this, PICARD was introduced (Scholak et al., 2021), which integrates constrained decoding with pre-trained models like T5 to ensure syntactically valid SQL queries. The advent of powerful LLMs shifted the paradigm toward in-context learning, exemplified by DIN-SQL (Pourreza and Rafiei, 2023b), where GPT-4 iteratively decomposes questions into sub-tasks like schema linking and query refinement. Concurrently, retrieval-augmented methods like RESDSQL (Li et al., 2023) dynamically align questions with database schemas to mitigate domain shift.Meanwhile, it has been demonstrated that code-style prompts enable zero-shot SQL generation in C3 (Dong et al., 2023). Despite these innovations, challenges persist in handling implicit semantics, where domain-specific terms (e.g., medical abbreviations) require external knowledge, and context window constraints (Hao et al., 2022), which lead to truncation of large tables. Recent efforts like CoT-SQL (Wei et al., 2022) leverages chain-of-thought prompting to decompose multi-step queries.

3 System Overview

In this section, we will introduce the overall structure of our proposed system. Our proposed system comprises three core modules that synergistically enhance table-based question answering through structured reasoning and ensemble learning. Figure 1 illustrates the overall architecture of our proposed method.

Module 1: Schema Profiler: We first feed partial tabular data into a Large Language Model (moonshot-v1) to extract critical schema information. This process automatically identifies field types, value distributions, and contextual relationships within the table structure. The derived metadata establishes a semantic foundation for subsequent processing stages. **Module 2: Hierarchical Chain-of-Thought Reasoning:** We design a four-stage Chain-of-Thought (CoT) prompting strategy that combines schema metadata with task-specific instructions. This enhanced prompt is then input into three different Large Language Models to generate candidate SQL queries. **Module 3: Multi-Model Deliberation:** To ensure robustness, we implement a deliberation mechanism that directly adopts answers when all models reach consensus. When discrepancies occur, the mechanism employs cross-model voting with mutual evaluation. The voting system weights the models' confidence scores and historical accuracy to resolve conflicts, ultimately selecting the most reliable answer through ensemble decision-making.

This hierarchical architecture effectively balances schema comprehension, diverse reasoning patterns, and result verification, demonstrating strong performance on complex table QA scenarios.

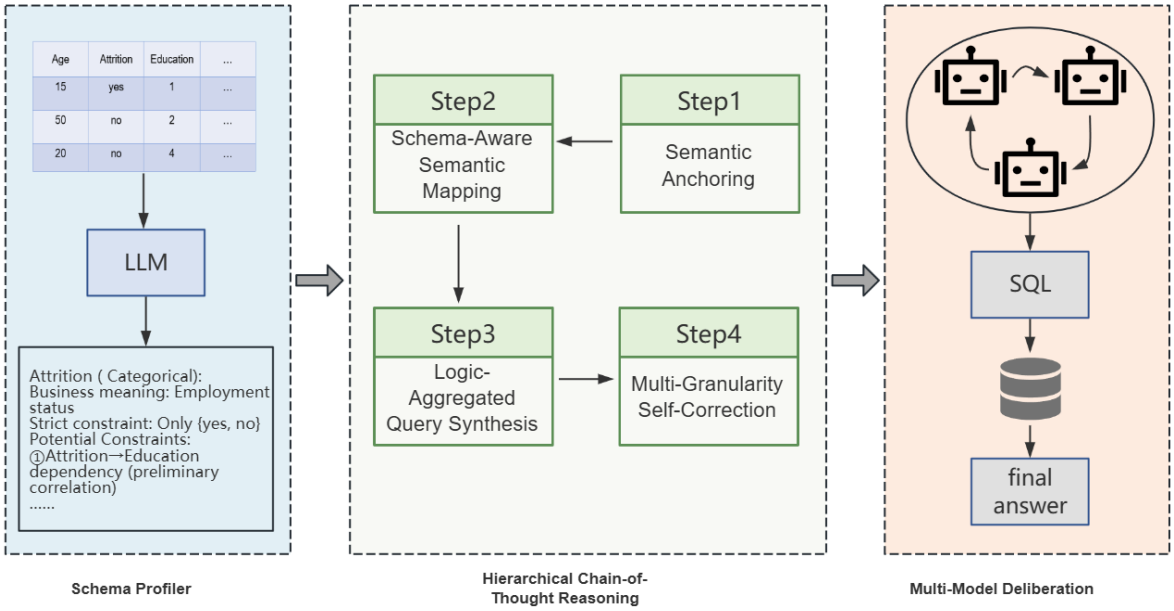

Figure 1: The overall architecture of our proposed method.

3.1 Schema Profiler

The framework initiates with structural metadata parsing to achieve a deep understanding of the tabular schema. Specifically, we input a 20-row sample from the Databench Lite dataset into moonshot-v1 and process it using a multi-turn guided prompting strategy. The primary prompt instructs the model to analyze the table structure and explicitly requires the output to include: (1) Column attributes, including data types (string/numerical/temporal) and value characteristics (units for numerical columns, frequent values for categorical columns); (2) Field semantics, which involves precisely parsing the meaning of each field to clarify its specific role in the business context and the relationships between fields; (3) Constraint discovery, which identifies implicit business rules (e.g., inventory $\leq$ warehouse capacity). This process generates a standardized JSON schema profile, thereby establishing a reliable structural foundation for downstream SQL generation.

3.2 Hierarchical Chain-of-Thought Reasoning

To address the challenges of generating accurate SQL queries from natural language questions over heterogeneous tables, we propose a hierarchical Chain-of-Thought (CoT) framework that decomposes the reasoning process into four interconnected cognitive stages. This structured approach ensures both syntactic validity and semantic alignment with the database schema.

(1)Semantic Anchoring: The initial phase is the semantic mining and classification stage, where the model is required to mine the semantics of the question and determine its type: Boolean, scalar, or list. Boolean questions are typically used for existence checks, such as determining whether a certain condition is met through trigger words like "whether," "does... exist," or "is there any...". Scalar questions involve quantitative queries and usually contain terms such as "highest," "lowest," "average," or "total," aiming to obtain a single numerical result. For example, "What is the highest price?" or "What is the average value?". List questions, on the other hand, require returning a set of entities or results, such as through expressions like "how many," "list all...," or "return the set of...," which are used to obtain multiple results or entity collections that meet specific conditions.

(2)Schema-Aware Semantic Mapping: In this stage, the structured metadata profile is utilized to map entities in the query to corresponding column names. For explicit entity linking, field names in the query are directly matched (e.g., “patient age” $\rightarrow$ age). For implicit semantic inference, potential associations are uncovered (e.g., “hospitalization duration” $\rightarrow$ discharge_date - admission_date). For value range normalization, expressions are transformed into database storage formats (e.g., “Q1” $\rightarrow$ BETWEEN ’2023-01’ AND ’2023-03’).

(3)Logic-Aggregated Query Synthesis: This phase systematically integrates parsed seman-

tic components into executable SQL structures through three operational principles. Parenthesis-encapsulated precedence rules govern multi-clause logic composition (e.g., ‘(A OR B) AND C‘), complemented by type-driven operator selection for temporal or numerical comparisons. Dynamic aggregation binding associates question intent with SQL functions—‘AVG()‘ for "average price" and ‘COUNT()‘ for "total quantity". Subquery optimization prioritizes nested structures over joins when processing comparative constraints (e.g., "books above average price"), effectively mitigating Cartesian product risks through predicate pushdown techniques.

(4)Multi-Granularity Self-Correction: In this stage, common error patterns of Large Language Models (LLMs) are countered through syntactic, semantic, and logical validation. Syntax validation enforces schema-compliant escaping for special column names (e.g., auto-correcting malformed ‘`Price (TK)`‘ to ‘`"Price (TK)"`‘) and verifies join paths against foreign key constraints. Semantic consistency checks eliminate contradictory conditional logic (e.g., conflicting ‘`Stock_Status`‘ values) while injecting null-safety clauses (e.g., ‘`IS NOT NULL`‘) for optional fields. Output alignment ensures that Boolean queries strictly return truth values and scalar queries produce singleton aggregation results, among others.

3.3 Multi-Model Deliberation

To resolve discrepancies in SQL generation across multiple large language models (LLMs), we propose a streamlined consensus mechanism that harmonizes model confidence and empirical performance.

(1)Unanimity Prioritization: If the SQL outputs from all models yield identical answers when executed in the database, the output is directly adopted, leveraging inter-model agreement as a high-reliability indicator.

(2) Confidence-Accuracy Voting: When the three LLM agents (qwen-max, Qwen2.5-Coder-Instruct, Moonshot) generate conflicting SQL candidates, a voting protocol is triggered. For each candidate query, the system calculates its final score through a Confidence-Accuracy Voting mechanism:

$$\text{Score}_k = \underbrace{\left(\sum_{j \neq m} \text{Conf}_{j \to k} \right)}_{\text{Cross-Model Consensus}} \times \underbrace{\text{HisAcc}_m}_{\text{Model Reliability}} \quad (1)$$

where:

- **$\text{Conf}_{j \to k}$** (0–1): Model j's confidence score for candidate SQL_k. For example, if SQL_1 is generated by qwen-max, Moonshot and Qwen-Coder assess its correctness likelihood separately.
- **HisAcc_m** (0–1):Pre-computed accuracy of the model on the dev Databench set containing diverse table schemas and question types.

The candidate with the highest aggregated score is selected, ensuring both peer validation and source model competency are leveraged.

4 Experiment

4.1 Dataset

The dataset for this study is derived from the SemEval 2025 Task 8 benchmark suite, which includes two versions: DataBench and its lightweight variant DataBench Lite. The full-scale DataBench comprises 65 real-world tabular corpora spanning 3,269,975 rows and 1,615 columns, paired with 1,300 annotated questions split into training and development subsets. For streamlined evaluation, DataBench Lite provides sampled versions of these corpora, retaining 20 rows per table. The test set consists of an independent collection of 15 corpora and 522 questions to ensure rigorous evaluation.

4.2 Implementation

In our experiment, we utilized three LLMs to evaluate their performance on the given task. Specifically, we called the APIs of Qwen-max, Qwen-coder, and Moonshot. Table 1 summarizes the configuration settings used for each model during the experiment.

Table 1: Model configuration settings.

Setting	Qwen-max	Qwen-coder	Moonshot
temperature	0.7	0.7	0.3
top_p	0.8	0.8	0.8
presence_penalty	1.5	1.5	1.5
max_tokens	8,192	8,192	8192

4.3 Results

Table 2 and Table 3 show the performance of three models on the Databench and Databench_lite datasets with different modules added. The experimental results indicate that systematically introducing the Schema Profiler and hierarchical Chain of Thought (CoT) strategy significantly improves table question-answering performance. Under the full configuration (+Profiler+COT), Qwen-max achieves a score of 77.39 on the complete dataset Databench, an improvement of 8.04 over the baseline (69.35), and reaches 77.97 (+8.05) on the lightweight version Databench_lite. This validates the universal advantage of structured metadata guidance. The hierarchical CoT enhances the execution accuracy of complex queries through step-by-step parsing. The synergistic effect of the two strategies generates a superadditive improvement—the combined gain (Databench: 8.04–9.96) exceeds the sum of individual module gains, highlighting the role of metadata in directing the reasoning path.

Table 2: Comparison of Scores for three models on the test set of Databench. "Base" indicates no strategy added, "+Profiler" indicates the addition of Profiler, "+COT" indicates the addition of COT.

Method	Qwen-max	Qwen-coder	Moonshot
Base	69.35	68.2	65.9
+Profiler	71.83	70.88	69.92
+COT	74.71	73.18	72.22
+Profiler+COT	**77.39**	**76.44**	**75.86**

Table 3: Comparison of Scores for three models on the test set of Databench_lite. "Base" indicates no strategy added, "+Profiler" indicates the addition of Profiler, "+COT" indicates the addition of COT.

Method	Qwen-max	Qwen-coder	Moonshot
Base	69.92	68.0	66.28
+Profiler	72.22	71.26	70.11
+COT	75.47	74.32	72.8
+Profiler+COT	**77.97**	**76.63**	**76.05**

Table 4 compares the performance of three review strategies on the complex scenario dataset Databench and its lightweight version Databench_lite. The experimental results show that the multi-model collaborative decision-making mechanism significantly improves the accuracy of the table question-answering system. The single-model baseline (Qwen-max) achieves scores of 77.39 on Databench and 77.97 on Databench_lite without enabling review. After introducing dual-model cross-validation (Qwen-max + Moonshot), the scores increase by 2.3 and 2.11, respectively. The full review strategy integrating three models (All) further raises the accuracy to 81.23 and 81.99, achieving absolute improvements of 4.84 and 4.02 over the baseline. This progress validates the effectiveness of cross-model verification in eliminating individual biases—through a two-stage consensus mechanism (consensus adoption and weighted voting), the robustness of semantic understanding under complex table structures is enhanced. It is particularly noteworthy that dual-model review can cover approximately 75% of the potential error correction needs, providing an efficient balance between precision and computational cost for scenarios with limited resources.

Table 4: Comparison of Scores for Different Deliberation Strategies on the Databench and Databench_lite Datasets

Model	Score	$\text{Score}_{\text{lite}}$
Qwen-max	77.39	77.97
Qwen-max+moonshot	79.69	80.08
all	**81.23**	**81.99**

5 Conclusion

This paper presents our solution for SemEval-2025 Task 8 on Table Question Answering. We propose a three-stage framework integrating schema analysis, hierarchical reasoning, and multi-model deliberation. Our approach leverages: (1) a Schema Profiler that extracts structural metadata via guided LLM parsing, (2) a Hierarchical Chain-of-Thought module decomposing questions into four reasoning stages (semantic anchoring, schema mapping, query synthesis, self-correction), and (3) a Confidence-Accuracy Voting mechanism harmonizing outputs from three LLM agents through weighted ensemble decisions. Our method achieves scores of 81.23 on Databench and 81.99 on Databench_lite, ranking 6th and 5th respectively. Future work will focus on: (1) enhancing schema profiling with dynamic domain adaptation, (2) refining CoT stages for multi-table joins, and (3) extending the deliberation mechanism to hybrid LLM-Symbolic architectures.

Abstract

Text-based emotion detection is crucial in NLP, with applications in sentiment analysis, social media monitoring, and human-computer interaction. This paper presents our approach to the Multi-label Emotion Detection challenge, classifying texts into joy, sadness, anger, fear, and surprise. We experimented with traditional machine learning and transformer-based models, but results were suboptimal: F1 scores of 0.3723 (English), 0.5174 (German), and 0.6957 (Spanish). We analyze the impact of preprocessing, model selection, and dataset characteristics, highlighting key challenges in multi-label emotion classification and potential improvements.

1 Introduction

Emotion detection from text is a crucial NLP task with applications in customer feedback analysis, mental health detection, and social media monitoring. Unlike sentiment analysis, which determines polarity, emotion detection classifies text into **joy, sadness, fear, anger, and surprise**, often requiring **multi-label classification** since a sentence can evoke multiple emotions. Despite advancements in **transformer-based models** like BERT and XLM-RoBERTa, challenges remain due to:

- **Subjectivity:** Different individuals may perceive emotions differently.
- **Contextual Complexity:** Subtle emotional cues require deep contextual understanding.
- **Multi-label Classification:** A single text can express multiple overlapping emotions.

1.1 Competition Overview

Track A (Muhammad et al., 2025b) of the **Multi-label Emotion Detection** competition involved classifying text snippets into one or more of five emotions or as neutral. Our experiments included a range of approaches, starting with traditional machine learning models such as Logistic Regression, Random Forest, and SVM. We also explored transformer-based models, including BERT, DistilBERT, XLM-RoBERTa, and language-specific BERT variants, as well as ensemble models that combined classifiers like KNN, Decision Trees, and Neural Networks. Despite extensive preprocessing, hyperparameter tuning, and model optimization, our overall performance—particularly on English data—fell short of expectations. This paper delves into the key challenges we encountered and the insights gained throughout our approach.

2 Dataset

Our dataset comes from Task 11 of SemEval 2025 (Muhammad et al., 2025a), focusing on multi-label emotion classification in English, German, and Spanish. Sourced from social media, each text snippet is annotated using a binary scheme (1: present, 0: absent), allowing for multi-label classification where multiple emotions can co-occur. Neutral instances contain no marked emotions. The dataset is split into train, dev, and test sets for structured evaluation. Table 1 provides an overview.

3 Related Works

Emotion detection in textual data has been extensively explored in NLP, spanning lexicon-based, machine learning, and deep learning methods. Transformer-based models have recently set new benchmarks, particularly for multi-label and multilingual emotion classification.

3.1 Traditional Approaches to Emotion Detection

Early systems used lexicon-based methods with resources like WordNet-Affect (Strapparava and Valitutti, 2004) and LIWC (Tausczik and Pennebaker, 2010), but lacked context sensitivity. Machine learning models such as Naïve Bayes (Alm et al.,

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 222–227

Language	Data Source(s)	Train	Dev	Test	Total
English (eng)	Social media	2768	116	2767	5651
German (deu)	Social media	2603	200	2604	5407
Spanish (esp)	Social media	1996	184	1695	3875

Table 1: Description of Track A dataset.

2005), SVMs (Wang and Manning, 2012), and Random Forests (Strapparava and Mihalcea, 2007) improved generalization but struggled with semantic ambiguity and multi-label complexity.

3.2 Multi-Label Emotion Detection

Emotion detection is inherently multi-label, as a single text may express multiple emotions (Mohammad and Bravo-Marquez, 2018). Traditional methods addressed this using hierarchical classification (Hatzivassiloglou and McKeown, 2000) or CRFs (Strapparava and Mihalcea, 2007). Deep learning models, like BiLSTMs with attention (Majumder et al., 2019), showed substantial improvements by capturing emotion co-occurrence and contextual dependencies.

3.3 Transformer-Based Approaches

Transformers like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and XLNet (Yang et al., 2019) have achieved state-of-the-art results. Lighter models such as DistilBERT (Sanh et al., 2019) offer faster inference, while EmotionBERT (Saravia et al., 2018) improves emotion-specific learning. Prompt-based models (Gao et al., 2021) enable zero-shot emotion detection.

Recent work has extended transformers to mental health detection. (Sivanaiah et al., 2024) compared BERT, RoBERTa, and traditional models for suicide and self-harm classification, with RoBERTa achieving the highest F1-score (99%). (Yenumulapalli et al., 2023) explored depression detection via BERT in LT-EDI-2023, achieving a macro F1 of 0.407, highlighting the capability of transformer models in capturing nuanced emotional and psychological cues.

4 Methodology

The steps taken are laid out in the methodology section in detail, with the inclusion of preprocessing, exploratory data analysis (EDA), model selection, evaluation, and the implementation of recommendations received while conducting the study.

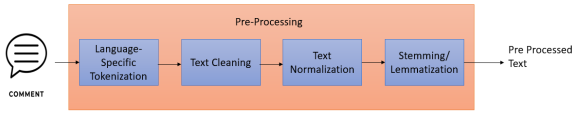

Figure 1: Pre-Processing Steps.

4.1 Preprocessing and Exploratory Data Analysis (EDA)

Preprocessing ensures clean, tokenized input for training machine learning models. We used language-specific tokenizers: BETO for Spanish, bert-base-german-cased for German, and the default BERT tokenizer for English. These tokenizers helped capture the linguistic nuances of each language. Our preprocessing pipeline involved removing stopwords, special characters, and punctuation to prevent noise during training, as illustrated in Figure 1. Additionally, we applied lowercasing and contraction expansion (e.g., I'm to I am) to maintain consistency. Stemming and lemmatization were deliberately excluded from our preprocessing pipeline to preserve the rich morphological and contextual information inherent in the text, which is often critical for accurately detecting emotions. In emotion recognition tasks, subtle variations in word forms—such as verb tenses or pluralizations—can convey important affective cues; for example, "crying" may carry a stronger emotional weight than "cry." Reducing words to their base or root form risks stripping away these distinctions, potentially leading to loss of emotional intensity or misinterpretation. Furthermore, the transformer-based models employed in our study, such as BETO, BERT, and their variants, are pretrained on large corpora of raw text and are inherently capable of understanding and disambiguating word forms in context. Thus, applying stemming or lemmatization could disrupt the linguistic patterns these models have learned to leverage, ultimately impairing performance rather than enhancing it. For exploratory data analysis (EDA), we checked the distribution of emotions across the datasets for all languages. This included looking at the proportion of various emotion classes (like joy, sadness, fear, etc.) and

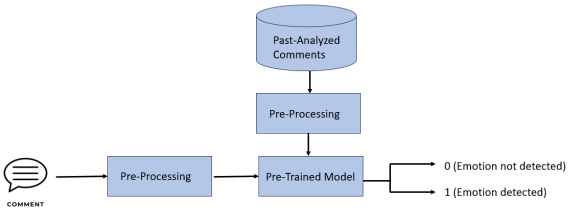

Figure 2: Methodology.

checking if there were any data biases.

4.2 Model Selection and Explanation

To tackle the task of emotion detection, we utilized both common machine learning classifiers as shown in Figure 2 and state-of-the-art transformer-based models.

We began by utilizing **BERT-base-uncased**, a pre-trained transformer model known for its strong performance in various NLP tasks, including sentiment and emotion classification. BERT's bidirectional nature allows it to understand context from both directions, making it particularly effective for detecting emotions expressed through subtle language cues. BERT was applied to English, Spanish, and German datasets. While it performed adequately on English and Spanish, its performance on German was notably weaker—likely due to its English-centric training data, making it less effective for other languages without fine-tuning.

To better handle Spanish, we used **BETO**, a BERT variant fine-tuned on a large Spanish corpus. BETO outperformed both BERT-base-uncased and mBERT on the Spanish dataset, especially in identifying anger, disgust, and fear. Its improved performance is due to its specialization in Spanish syntax and semantics.

We also tested **mBERT**, a multilingual BERT trained on 104 languages. Its ability to handle all three languages made it efficient for a multilingual dataset. While mBERT performed reasonably well on English and Spanish, it struggled with German, likely because its generalized training across languages made it less effective for those with more complex grammar, like German.

To address this, we employed **Google-BERT/bert-base-german-cased**, fine-tuned specifically for German. This model significantly improved emotion classification on the German dataset, particularly for anger and disgust, thanks to its training on a large German corpus.

In addition to transformer models, we experimented with traditional machine learning classifiers: **Multinomial Naive Bayes (NB)**, **Support Vector Classifier (SVC)**, **Logistic Regression**, and **Random Forest**. Naive Bayes, while effective for simpler emotions like fear and disgust (especially in Spanish and German), struggled with more nuanced emotions like joy and surprise in English. **SVC** outperformed Naive Bayes—especially for fear—but still lagged behind transformers in handling complex emotions. **Logistic Regression** performed reasonably well on fear and sadness but underperformed on joy and surprise. **Random Forest**, despite being strong in ensemble learning, was less effective across all datasets, particularly for surprise and anger.

To enhance model performance, we implemented **hyperparameter tuning**, adjusting the learning rate to 2e-5, increasing training epochs to five, and reducing batch size to 8. While this improved model stability and convergence, it did not lead to notable improvements in F1 scores for the English dataset.

We also incorporated **lexicon-based testing** using sentiment lexicons from the NLTK library. Although helpful for validating predictions and estimating overall correctness, these approaches could not match the performance of transformer models, which better capture the contextual subtleties of language.

4.3 Feedback-Based Potential Improvements

Throughout the course of the research, a number of useful suggestions were made that might have otherwise increased the quality of this research. A possible recommendation was to try models without using tokenization, lemmatization, or stemming. These preprocessing operations tend to cause quite a loss of information, as indicated in the feedback. By skipping these methods, the models could have preserved more useful linguistic features, which could have resulted in improved performance at emotion detection. Looking back, refraining from these inductive text processing methods might have retained more of the original sentence meaning and structure, which could have helped with emotion detection. The other recommendation was to move away from having separate binary classifiers for every emotion to a **single multi-class classifier**. By representing the emotion labels as integers (e.g., Anger = 0, Joy = 1, Fear = 2, etc.), the model might have been able to better differentiate between emotions, instead of being trained to

predict the occurrence or non-occurrence of each emotion separately. This would have most likely resulted in improved performance, as the model would have been in a position to comprehend the association between various emotions and classify them more holistically. We tried implementing this recommendation and discovered that it worked to yield a more coherent classification of emotion, especially when applied to the case of very complex or unclear cases.

4.4 Combined Model Performance

Following the assessment of the performance of single models, we chose to aggregate the predictions of various models to form an ensemble model. The ensemble strategy was effective in improving performance, especially for the English dataset. By aggregating models like KNN, Random Forest, XGBoost, and Logistic Regression, we managed to improve the accuracy of recognizing emotions such as joy and surprise, which were more difficult for single models to identify. The current research shows that transformer-based models such as BERT, BETO, and Google-BERT are greatly effective for multilingual emotion detection. Although mBERT had potential for multilinguality, it performed poorly for German. Baselines were created by the classic machine learning classifiers but were dominated by the advanced transformer models. While there were some aspects to be improved, especially in preprocessing, model structure, and hyperparameter optimization (decreasing in learning rate to 2e-5, bumping up training epochs to five, and cutting the batch size to 8), the ensemble of these models produced encouraging outcomes for emotion recognition in multilingual text.

5 Results and Analysis

5.1 Results

The results of emotion detection across Spanish, German, and English datasets show varying performance across different models. In tables 2, 3 and 4, the models are represented as follows- LR- Logistic Regression, RF- Random Forest, SVM- Support Vector Machine, BERT- BERT base uncased, wt BERT- weighted BERT, Ensmbl-Ensemble of KNN, RF, DT and LR, distil- DistilBERT, XLM-R- XSLM-RoBERTa, MNB- Multinomial Naive Bayes, SVC- Support Vector Classifier, g-BERT-Google BERT. The emotions An, Di, Fe, Jo, Sa and Su are Anger, Disgust, Fear, Joy, Sadness and Surprise respectively.

Model	An	Di	Fe	Jo	Sa	Su
BERT	0.71	0.73	0.85	0.72	0.77	0.54
BETO	0.75	0.80	0.86	0.80	0.78	0.72
mBERT	0.72	0.77	0.82	0.76	0.75	0.70
MNB	0.55	0.68	0.80	0.67	0.53	0.47
SVC	0.52	0.70	0.81	0.70	0.74	0.37
LR	0.55	0.71	0.85	0.70	0.64	0.47
RF	0.49	0.63	0.87	0.62	0.65	0.47

Table 2: Model Performance Metrics for Emotion Detection in Spanish.

Model	An	Di	Fe	Jo	Sa	Su
BERT	0.67	0.59	0	0.41	0.28	0
g-bert	0.7	0.65	0.26	0.56	0.57	0.28
MNB	0.66	0.59	0	0.16	0.22	0
SVC	0.61	0.54	0.19	0.48	0.48	0
LR	0.58	0.53	0.07	0.43	0.46	0
RF	0.38	0.34	0	0.17	0.13	0

Table 3: Model Performance Metrics for Emotion Detection in German.

Model	An	Fe	Jo	Sa	Su
LR	0.31	0.65	0.44	0.24	0.57
RF	0.10	0.67	0.37	0.13	0.52
SVM-Lin	0.32	0.65	0.43	0.25	0.56
SVM-RBF	0.20	0.67	0.41	0.18	0.56
BERT	0.54	0.62	0.11	0.57	0.69
wt bert	0.48	0.42	0.59	0.69	0.63
Ensmbl	0.83	0.53	0.77	0.67	0.68
distil	0.7	0.73	0.18	0.43	0.26
XLM-R	0	0.75	0.34	0.46	0.49

Table 4: Model Performance Metrics for Emotion Detection in English.

For **Spanish**, BETO, a language-specific transformer, outperforms all other models, particularly in detecting disgust (0.80) and fear (0.86). BERT-base-uncased and mBERT perform well but are slightly less effective than BETO, as seen in table 2. Traditional models like Naive Bayes and SVC show moderate performance, with SVC achieving the highest F1 score for fear (0.81), but struggle with emotions like joy and surprise. We were placed 37th with our results. In **German**, Google-BERT (fine-tuned for German) surpasses BERT-base-uncased but still struggles across all categories, especially fear, joy, and surprise as demonstrated by table 3. Traditional models such as Naive Bayes and SVC also show weak performance, highlighting the challenges in detecting emotions in German. We secured 41st place in this run. For **English**, ensemble models (KNN, Random Forest, XGBoost, etc.) achieve the best results, especially

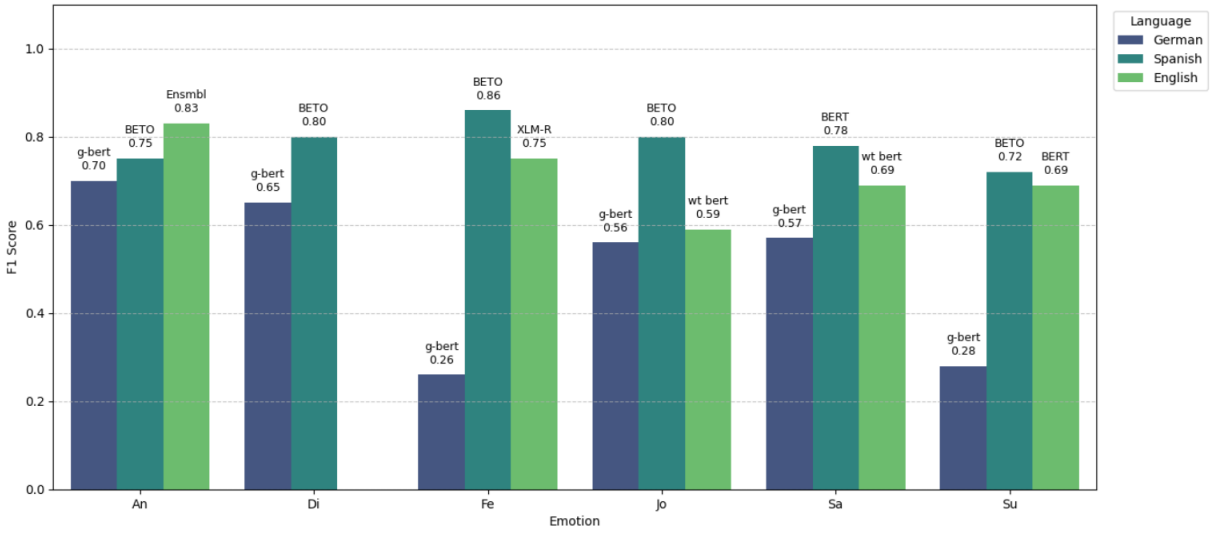

Figure 3: Best F1 Scores by Language.

for anger (0.83) and joy (0.77) as showcased by table 4. BERT-base-uncased shows decent results but struggles with joy and surprise. DistilBERT and XLM-RoBERTa show some promise but are outperformed by the ensemble models. However, the results were poor and could be improved further by implementing the suggestions mentioned above. We were placed 91st due to our results.

The comparative analysis highlights that language-specific models excel in low-resource settings, while ensemble methods perform better in high-resource languages, though all models struggle with nuanced emotions like joy and surprise.

5.2 Analysis

Transformer models, particularly language-specific ones like BETO and Google-BERT, consistently outperform traditional machine learning models, highlighting the importance of fine-tuning for specific languages as shown in Figure 3. In English, ensemble methods offer a strong alternative, outperforming individual models. Overall, transformer models excel in capturing complex emotions, but ensemble methods remain competitive, especially in English. The choice of separate binary classifiers for each emotion may have hindered the model's ability to distinguish between overlapping emotional expressions; by converting the multi-label emotion annotations into unique integer labels that represent specific emotion combinations, and modifying the final classification layer of the transformer models to output softmax probabilities over these combined classes with categorical cross-entropy loss, the model can better capture relationships between emotions, potentially improving overall classification coherence and performance.

6 Conclusion

Our experiments highlight key challenges in multi-label emotion detection. The lower performance in English suggests that pre-processing techniques may have removed valuable contextual information. Additionally, the choice of separate binary classifiers for each emotion may have hindered the model's ability to distinguish between overlapping emotional expressions. Our findings suggest that future research should focus on retaining more textual information during pre-processing, implementing multi-class classification rather than binary classifiers for each emotion and exploring larger, domain-specific pre-trained transformer models with better fine-tuning strategies. By addressing these factors, we can improve the accuracy and reliability of emotion detection in text across multiple languages.

QM-AI at SemEval-2025 Task 6: an Ensemble of BERT Models for Promise Identification in ESG Context

Zihang Sun and **Filip Sobczak**
QualityMinds GmbH, Munich, Germany
{zihang.sun, filip.sobczak}@qualityminds.de

Abstract

This paper presents our approach and findings in the SemEval-2025 Task 6: Multinational, Multilingual, Multi-industry Promise Verification (PromiseEval), which focuses on verifying promises in the industrial Environmental, Social, and Governance (ESG) reports. Specifically, we participate in the first subtask of the PromiseEval shared task, promise identification. We tackle this subtask by building an ensemble of four BERT models trained in different experimental configurations, and deploying logistic regression as meta-model. Each configuration has a different combination of two variables: whether augmented data is used, and whether English translation is used. We find out that the BERT model trained without augmented data or English translation not only has the best evaluation results on the test data in most languages, but also has higher robustness than the meta-model. We submitted results from the meta-model to the leaderboard, and rank the first place in Japanese and Korean, the second place in French and Chinese, and the seventh place in English.

1 Introduction

As the public's emphasis on the environment protection and the importance of Environmental, Social, and Governance (ESG) aspects of industries grow, a strong implementation of ESG framework creates value for companies in various ways (Barangă and Țanea, 2022). In order to gain such benefits without paying the cost, it is revealed that companies with environmental violations try to appear more environmentally friendly by producing more frequent, abundant reports with less readability to deflect reader's attention from their violations (Gorovaia and Makrominas, 2025). To verify the promises made in the industrial ESG reports, Seki et al. (2024) proposes a four-step approach: 1. identifying promise 2. linking supporting evidence to the promise, 3. assessing clarity of the promise-evidence pair, and 4. inferring timing for verifying the promise. These four steps correspond to the four subtasks in the SemEval-2025 Task 6: Multinational, Multilingual, Multi-industry Promise Verification (PromiseEval) (Chen et al., 2025). In this paper, we describe our submission to the first subtask of the SemEval-2025 Task 6: promise identification.

The subtask 1 is a multi-lingual binary classification task. The used dataset is the proposed multilingual dataset, ML-Promise, that includes ESG reports from various industries in English, French, Japanese, Korean, and Chinese (Chen et al., 2025). Each instance in the ML-Promise dataset contains the origin of a PDF and a page number. Additionally, a text snippet is included in each instance for the English, French, and Japanese languages. These text snippet can be used directly as input for classification. For the Korean and Chinese languages, the participants need to either extract the text from the whole page for classification or use the given page of the PDF as direct input. The output of the task 1 is a boolean label indicating whether the input contains any promise.

We approach this task by building an ensemble of BERT models (Devlin et al., 2019). Each BERT model is exposed to a different experiment configuration. Our hypothesis is that with each BERT model trained differently, the robustness of our ensemble will improve. After evaluating all base BERT models and the meta-model on the test data, we find out that the BERT model trained with original data without data augmentation or English translation has the highest performance and robustness than the other BERT model and the meta-model.

2 Background

BERT models have been proven to have promising performance in other ESG related tasks. In the

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 228–233

Multi-lingual ESG Issue Identification shared task, where multi-lingual ESG news articles are to be classified into 35 key ESG issues, BERT-like language models with data augmentations by LLMs have leading performance in all languages (Chen et al., 2023a). In the Multi-lingual ESG Impact Type Identification shared task, a classification task with three classes, fine-tuned RoBERTa model (Liu et al., 2019) is proven to have the best results in English and French, while Fin-BERT model (Araci, 2019) with English translation achieves the highest performance in Chinese (Winatmoko and Septiandri, 2023; Vardhan et al., 2023; Chen et al., 2023b). In the Multi-Lingual ESG Impact Duration Inference shared task, a classification task with three classes, DeBERTa-v3 (He et al., 2021) is the best-performing model for English, while for Korean and Japanese, the XLM-RoBERTa model (Conneau et al., 2020) is among the best models (Chen et al., 2024). Based on the findings in the previous tasks, we introduce English translation as a variable into our experimental configurations. Furthermore, we pick the DeBERTa-v3 model to be the model receiving English translation, and the XLM-RoBERTa model to receive the original multi-lingual input. More details regarding our classification system and experimental setup is presented in Section 3 and 4.

The PromiseEval shared task has one separate leaderboard for each language. The leaderboard only accepts submission files containing results for all four subtasks. Although our focus is only to solve the subtask 1, we utilize the GPT-4o-mini to gain labels for the other three subtasks in order to submit our results to the leaderboard. We present our approach with GPT-4o-mini to generate predictions in Section 4. The leaderboard scores are aggregated over labels from all subtasks. This means that the leaderboard scores do not reflect the ranking and performance of participant's system in one individual subtask. To showcase our system's performance in subtask 1, we evaluate our system on the test data and show the results in Section 5.

3 Methods

3.1 Data Augmentation

We divide the given training dataset into a training split and a development split, maintaining an 8:2 ratio. To tackle class imbalance in the training split and boost the number of training samples, we expand the training split by augmenting data from the original PDFs. The development split is left unaltered to ensure that our system is evaluated using the actual data distribution during training time.

We expand the training split by drawing unused pages or sentences from the PDFs within the training split. Specifically, we extract sentences for the English, French, and Japanese languages and sample pages for Chinese and Korean. This approach ensures the augmented data mirrors the original data entries in length. The amount of augmented data for each language is determined by the difference between the sample sizes of the positive and negative classes in the respective language. Following this, OpenAI's GPT-4o model is utilized to assign labels to the sampled data. As shown in Table 1, the class imbalance issue still exists after data augmentation, but is lessened, especially for the total count of classes over all languages.

3.2 The Classification System

Our classification system is an ensemble system consisting of four BERT base models and a logistic regression model as meta-model.

We train two XLM-roberta-large models using the original multi-lingual input text. One model uses the multi-lingual augmented training split and the other uses the training split without augmented data. Both models are evaluated on the same development split. The goal is to let one model learn in quantity, i.e. with augmented data, while the other model should not be influenced by the potential noises introduced by augmented data.

To tackle multi-lingual nature of data and its varying class imbalance in different languages as shown in Table 1, we translate all non-English texts into English using google translate API[1]. Similar to multi-lingual setting, we train two Deberta-v3-large models (He et al., 2021) respectively on the translated augmented training split and the translated training split without augmentation.

We use a logistic regression model as the meta-model to produce the final prediction. Except from the predictions from the four base BERT models, we also provide the meta-model with the base models' probabilities for the predictions as well as two pieces of meta data: the language of the original input text and a boolean value about whether the input text is augmented. The prediction from the meta-model is the final output and submitted to the

evaluation website.

4 Experimental setup

In the process of data augmentation, we exclude pages or sentences containing fewer than 16 words to prevent the dataset from being populated with simple word phrases or page headings. The training datasets for English, French, and Japanese languages include the text for classification directly. In contrast, the Chinese and Korean datasets only list the page number and PDF source. Hence, we utilize the PyPDF2 library[2] to retrieve text from specified pages of the Chinese and Korean PDFs, serving as the input for the BERT models.

There are two experimental variables: with augmented data or without, and either using multilingual or monolingual text input (English translation), yielding a total of four configurations. As described in Section 3.2, one BERT model is trained for each configuration. When a model is trained using monolingual data, it will likewise be evaluated on the English translations of the input text in both the development and test datasets. All BERT models share the same hyper-parameters: they are fine-tuned with a batch size of 16, and a learning rate of 6e-6 over 20 epochs. The model with the best macro F1 score is selected as the checkpoint.

Each of the four fine-tuned BERT models is evaluated on the development data split, and the resulting labels and probabilities are recorded. A logistic regression model, built using the Scikit-learn library[3], is then trained on the full development data split, including BERT models' outputs and additional metadata as detailed in Section 3.2. The positive promise status is given the label id 0 and the negative promise status is 1. The trained logistic regression model is our meta-model. Finally, we deploy our fine-tuned BERT models on the test dataset, and use the meta-model on the BERT models' outputs and other meta data to generate final predictions for the test data.

To generate labels for subtasks 2-4, we used the GPT-4o-mini model with retrieval augmented generation as a classifier. In all cases, we set the model's temperature value to 1.0. First, we encoded all provided data points with the OpenAI text-embedding-3-small embedding model. For each subtask, we devised a system prompt that described the problem and the expected model output. For each test sample, we retrieved the three most similar examples from the training data, included them in the sample-specific prompt, and generated the output label.

The Chinese and Japanese datasets included two additional subtasks. For data points containing a promise or evidence, we needed to extract the corresponding string that included the promise or evidence text. To do this, we split the input text of each sample into a list of sentences and then individually classified each sentence to determine whether it contained a promise or evidence. Lastly, we concatenated the relevant sentences for the final output.

5 Results

Table 2 shows the results from all base BERT models and the meta-model on the test data performing promise status classification task. The XLM-roberta-large model trained in the multi-lingual setting with original data (multi_ori) yields the best results in three languages. The meta-model has the best performance in Korean, while the augmented data helps the XLM-roberta-large model to achieve best result in Chinese in the multi-lingual setting. Though the ensemble model does not have the best performance for the most languages, it exhibits constantly above average results compared to the base models, and shows comparable robustness to the best-performing base model in *multi_ori* setup.

Examining the results from using augmented

	English	French	Japanese	Korean	Chinese
mono_aug	0.7288	0.7010	0.6496	0.7348	0.6659
mono_ori	0.7595	0.7748	0.6436	0.7667	0.6547
multi_aug	0.7546	0.6823	0.6771	0.7742	**0.7010**
multi_ori	**0.7921**	**0.7864**	**0.7368**	0.7727	0.6802
meta-model	0.7767	0.7566	0.6631	**0.7839**	0.6821

Table 2: The table presents the Macro F1 scores of four BERT models and the meta-model on the test dataset performing promise status classification task. The term *mono* refers to the *monolingual* setup, in which all languages are translated into English, whereas *multi* denotes the *multi-lingual* setup, where the original languages of the texts remain unchanged. *Aug* and *ori* represent the *augmented* and *original* configurations, respectively. In the augmented setting, both the augmented and original data are utilized, whereas the original configuration relies solely on the labeled data in the provided dataset. A logistic regression model is employed as the meta-model.

data versus solely utilizing original data without augmentation reveals that augmented data consistently enhances the model's performance for Chinese. This improvement might be attributed to the fact that the original training data is significantly biased towards the positive class, with Chinese being the only language exhibiting a class imbalance favoring the negative class, as described in Table 1. A similar data distribution pattern is observed in the test data. The augmented data helps to dampen the positive class bias, thereby enhancing the model's performance for Chinese. This proves that data augmentation is beneficial in reducing the impact of class biases.

When comparing the outcomes of using English translations versus not using them, it is noticeable that in most cases, experiments with monolingual text perform worse than those with multi-lingual text. This suggests that translating multi-lingual content into a single language might not enhance the model's learning capabilities. However, This difference could also stem from the variation in model selection between multi-lingual and monolingual contexts. In the future, a more detailed investigation could be conducted using the same BERT model across all experimental conditions to examine the helpfulness of English translations.

Utilizing logistic regression as our meta-model allows us to assess how each feature contributes to the final output through its coefficients. Table 3 illustrates that all models' predictions positively influence the logistic regression model's result, with the *multi_ori* experimental setup having the greatest impact. This aligns with our findings in Table 2, where the *multi_ori* model demonstrates superior or competitive performance in all languages. Additionally, Table 3 reveals that logistic regression

	prediction	probability
mono_aug	1.232	-0.507
mono_ori	1.391	-0.586
multi_aug	0.535	-0.079
multi_ori	**1.436**	-0.09

Table 3: The table shows the logistic regression model's coefficients for base BERT model's prediction and corresponding probability. The coefficients are rounded to 3 decimal places.

assigns negative coefficients to the base models' *probabilities* for their predictions, thereby penalizing their confidence in their predictions. This suggests that greater confidence from a base model results in less trust from the meta-model. Moreover, this skepticism towards the confidence of base models is less pronounced in multi-lingual contexts compared to monolingual contexts, further corroborating our other observation that monolingual settings underperform relative to multi-lingual settings, and therefore, the meta-model places less trust in them.

In addition to the base model's predictions and probabilities, we incorporate two metadata variables into the logistic regression: the language of the data instance and whether it is augmented. Both of these variables exert minimal to no influence on meta-model's output. The coefficient for the *language* variable is 0.03. Being a logistic regression model, our meta-model treats each variable independently, and thus, the language information contributes little to the final result. Similarly, as anticipated, the coefficient of the *augmented* variable rounds to 0 when rounded to three decimal places. As the meta-model is trained using the development data split that consists solely of original data,

this variable lacks any decision-making authority.

6 Conclusion

This paper describes our contribution to the first subtask of SemEval-2025 Task 6, promise identification. We deploy an ensemble of four BERT models trained in different experimental configurations and use logistic regression as meta-model. Our results show that the BERT model trained without augmented data or English translation has the best performance in most languages.

For future work, one can try out other meta-models that take relations between base model predictions and meta data into account. On the base model side, we can use multi-modal models to take PDF page directly as input to improve the varieties of base models. Furthermore, we believe a more sophisticated data cleaning pipeline for extracted text from PDFs can also potentially improve the base BERT model's performance.

YNU-HPCC at SemEval-2025 Task 7: Multilingual and Cross-lingual Fact-checked Claim Retrieval

Yuheng Mao, Jin Wang and Xuejie Zhang
School of Information Science and Engineering
Yunnan University
Kunming, China
maoyuheng@stu.ynu.edu.cn,{wangjin,xjzhang}@ynu.edu.cn

Abstract

This paper presents the system for Task 7, Multilingual and Crosslingual Fact-Checked Claim Retrieval. YNU-HPCC team participated in all subtasks of this task and employed the same unified framework to obtain results. The task includes two subtasks: monolingual and crosslingual. Our approach explores the integration of multiple embedding models to address these subtasks. These embedding models were explicitly fine-tuned for the task, and weighted cosine similarity was utilized for result prediction. Extensive experiments were conducted on development and test datasets. The comparative results show that (I) The integration of multiple embedding models has been demonstrated to significantly enhance retrieval accuracy, particularly in cross-lingual fact-checking retrieval tasks; (II) Translating text may degrade the retrieval performance of cross-lingual embedding models; (III) Using GTE multilingual base model and Jina model for ensemble achieves near-optimal performance, effectively balancing efficiency and computational cost.The code of this paper is available at https://github.com/catoraa/semeval2025-task7.

1 Introduction

Fact-checking is a task designed to evaluate the accuracy of published statements or claims. Manual fact-checking poses significant challenges in the contemporary media ecosystem, which is marked by extensive data volumes and rapid dissemination. This task is often time-consuming and labor-intensive for professional fact-checkers, even within a single language. The complexity increases when claims and fact-checks span multiple languages, making manual completion even more arduous. Previous research has established automated fact-checking retrieval's high feasibility and systematic potential (Guo et al., 2022).

Therefore, SemEval 2025 Task 7 (Peng et al., 2025) focuses on Automated Fact-Checked Claim Retrieval, encompassing Multilingual and Cross-lingual scenarios. This paper designs a retrieval system based on embedding models and semantic similarity for this task. We employed four embedding models, including BGE-M3 model (Chen et al., 2024), GTE base model (Zhang et al., 2024), jina embeddings v3 model (Sturua et al., 2024), and E5 large model (Wang et al., 2024), as foundational models, fine-tuned them using the Hugging Face Trainer, and finally integrated them through a weighted approach to derive the final cosine similarity.

The experimental results of this paper were presented in Task 7 of SemEval 2025. On the original dataset, the system achieved an success@10 of 0.92 in the Monolingual task, ranking $11th$, and 0.77 in the Cross-lingual task, ranking $11th$.

The rest of the paper is structured as follows: Section 2 summarizes recent fact-checking retrieval advancements.Section 3 describes the proposed system and models. In Section 4, the experimental details and parameter selection are elaborated. In Section 5, the comparison and analysis of the experimental results are discussed, and in Section 6, the conclusions are presented.

2 Related Work

Contemporary fact-checking predominantly rely on large LLMs or pre-trained models for retrieval and verification.These approaches typically integrate LLMs with existing evidence for judgment or leverage semantic similarity assessments through pre-trained embedding models.

For instance, Cheung proposed the FactLLaMA system, which enhances the temporal relevance and accuracy of information in fact-checking tasks by employing instruction-based fine-tuning and LoRA methods (hin Cheung and Lam, 2023).Singhal developed a system for fact-checking using LLMs, constructed on the basis of RAG

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 234–240

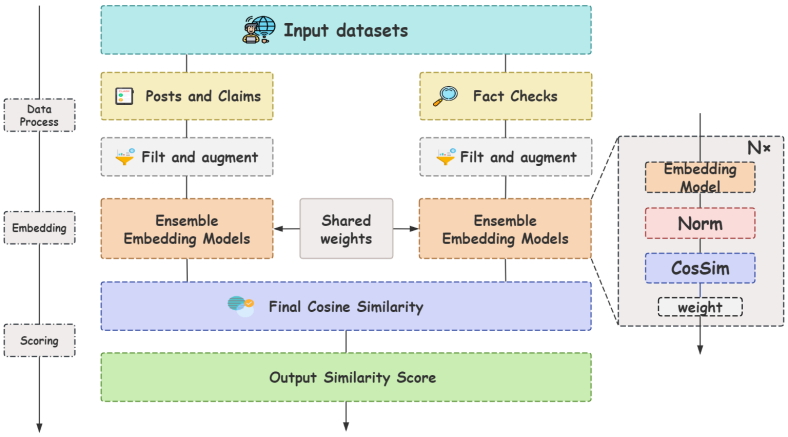

Figure 1: The process of semantic similarity calculation was implemented using the sentence-transformers and embedding models fine-tuned on the training data. Weighted cosine similarity was computed to assess the semantic relevance between posts and fact checks.

(Retrieval-Augmented Generation) and ICL (In-Context Learning) (Singal et al., 2024).Li explored self-instruction techniques to improve LLMs' capability in evaluating semantic similarity and relevance (Li et al., 2024).Khaliq introduced the RAGAR system, which combines LLMs with RAG to enhance verification accuracy (Khaliq et al., 2024).

In contrast to conventional methods, Liu investigated the use of LSTM integrated with the Attention Mechanism for the classification and judgment of factual information, demonstrating promising results. (Liu et al., 2019a).

A critical challenge in these approaches lies in efficiently retrieving relevant information, as they heavily depend on direct factual evidence or contextual corroboration. Samarinas designed the Quin+ passage retrieval module, which employs embedding models and semantic similarity metrics for evidence retrieval (Samarinas et al., 2021). Similarly, Nanekhan proposed corpus compression and index compression techniques to improve retrieval efficiency through vector quantization (Nanekhan et al., 2025).

Recent advances in cross-lingual pre-trained models, such as XLM-RoBERTa (Liu et al., 2019b) and mBERT (Pires et al., 2019), have significantly advanced multilingual fact-checking research. Sawiński explored the use of fine-tuned multilingual BERT models for fact-checking retrieval tasks (Sawiński et al., 2024). Liu investigated multilingual sentence embedding representations using sentence-transformers and XLM-RoBERTa architectures, demonstrating the potential of these models in the evaluation of cross-lingual semantic similarity (Liu et al., 2022).

3 System Overview

3.1 Sentence-Transformers

Sentence-Transformers (Reimers and Gurevych, 2019) (Reimers and Gurevych, 2020) is an architecture developed based on pre-trained Transformer models, which generates fixed-dimensional sentence embeddings by adding a pooling layer. Since sentence embeddings are precomputed and stored, this approach is well-suited for efficient retrieval in large-scale scenarios.

Unlike cross-encoders, Sentence-Transformers employ a dual-encoder structure, where the embedding model with shared weights independently encodes the input sentences, mapping each fact-check and posts sentence x_i to a vector v_i. Using a cosine similarity function F, the distance between v_i and all other vectors can be calculated, thereby measuring the semantic similarity between sentences . Finally, we select the top 10 vectors v_j with the closest distances, and the corresponding fact-checks are identified as similar instances. The following functions can formulate this process:

$$v_i = S(x_i) \tag{1}$$

$$F(v_i, v_j) = \|v_i - v_j\|^2 \quad \text{or} \quad \frac{v_i \cdot v_j}{\|v_i\|^2 \|v_j\|^2} \tag{2}$$

$$v_i^{\text{closest}} = \arg \min_{j \in \{1,\ldots,N\} \cap j \neq i} F(S(x_i), S(x_j)) \tag{3}$$

The Sentence-Transformers architecture aims to bring semantically similar sentences closer together in the embedding space while pushing semantically dissimilar sentences further apart. Therefore, this architecture can be trained using methods based on contrastive learning and triplet loss to optimize

the capability of calculating semantic similarity for sentence embeddings.

3.2 Embedding Models

Four high-performing embedding models were integrated into the system, including BGE-M3, gte-multilingual-base, jina-embeddings-v3, and multilingual-e5-large-instruct.

BGE-M3 (Chen et al., 2024), developed by BAAI, is a multilingual embedding model capable of handling input data at varying granularities. Its standout feature is self-knowledge distillation, which integrates relevance scores from diverse retrieval functions as teacher signals to enhance training quality. Additionally, the model employs an optimized batching strategy, enabling large batch sizes and high training throughput to improve embedding distinctiveness. The proposed system's baseline was constructed based on this embedding model, which yielded favorable results.

GTE (Zhang et al., 2024), introduced by Alibaba, is a multilingual embedding model that utilizes Rotary Position Embedding (RoPE) as its text encoder, effectively capturing semantic information in long texts. Furthermore, the model was trained and fine-tuned using contrastive learning, achieving performance comparable to BGE-M3.

Jina (Sturua et al., 2024), built on the XLM-RoBERTa architecture, was optimized for multilingual long-text and multi-task scenarios. To enhance the efficiency of long-text encoding, the model also incorporates Rotary Position Embedding (RoPE). Additionally, it supports the integration of LoRA adapters to generate task-specific embeddings, significantly reducing fine-tuning costs.

Multilingual-E5 (Wang et al., 2024), an enhanced version of multilingual-e5-large, is distinguished by its support for instruction tuning, allowing task-specific adaptation through guided instructions. This method was employed in our system to provide appropriate instruction guidance during the fine-tuning process.

3.3 Models Ensemble

We integrated the four models by computing a weighted cosine similarity (Henderson et al., 2017). Specifically, we first calculated the cosine similarity arrays individually for each model. These arrays were then summed using respective weights to obtain the final cosine similarity array, which could subsequently be used for semantic similarity calculations. The following function can represent this process:

$$F_{\text{final}} = \sum_{i=1}^{n} w_i \cdot F_i \tag{4}$$

where w_i represents the weights assigned to the cosine similarity arrays from the embedding models, respectively. Given that the performance of the four models was comparable, assigning them equal weights was considered reasonable. We set $w_1 = w_2 = w_3 = w_4$ to ensure an equal contribution from each model.

4 Experiment Details

4.1 Datasets

The datasets used for monolingual and cross-lingual tasks are consistent, with the distinction between tasks made through the [task.json] file. The dataset comprises three subsets: fact-checks, posts, and pairs. Fact-checking data includes verification results for claims made on social media or the internet, with each record containing information and content about a verified claim. The post data contains information about posts on social media platforms (such as Facebook and Twitter) and their authenticity assessments. The pairs file annotates the IDs of highly relevant fact-check-post pairs, which can be used for subsequent model training and fine-tuning.

To facilitate model training and fine-tuning, we filtered and augmented the datasets. We extracted the *claim* and *title* columns from the fact-checks dataset as key information, removed unnecessary symbols, and concatenated them to create a new fact-checks file. For the posts data, we extracted the *ocr* and *verdict* columns, performed similar filtering and concatenation, and formed a new posts file. We directly replaced the sentence IDs with the sentences for the pairs file, ultimately obtaining a highly usable training set.

4.2 Model Selection

Based on the ranking results from the MTEB leaderboard (Muennighoff et al., 2023), we selected four high-performing embedding models to integrate into our system to address monolingual and cross-lingual tasks. Specifically, our system incorporates the BGE-M3, gte-multilingual-base, jina-embeddings-v3, and multilingual-e5-large-instruct embedding models. We fine-tuned these models

Finetune	Task.json	Translate	Max_len	Epoch	Batch_size	Mono_S@10	Cross_S@10
no	no	no	512	1	8	0.62	0.57
finetune	no	translate	512	3	8	0.78	0.77

using bf16 precision and leveraged the sentence-transformers framework to map text into vector representations.

4.3 Loss Function Selection

Given that our dataset contains only positive samples, we employed MultipleNegativesRankingLoss (Henderson et al., 2017) as the loss function for fine-tuning. This loss function allows for input in the format of anchor-positive pairs and automatically samples negative examples within the batch. Through this approach, we can effectively utilize contrastive learning and triplet loss methods for training. The preprocessed posts data, which consists of a series of positive sample pairs, is highly compatible with this loss function, enabling us to achieve strong performance.

4.4 Hyper-Parameter Selection

We utilized AdamW (Kingma and Ba, 2015) as the optimizer. During the training process, we set the warmup rate to 0.1 and the learning rate to 2e-5.

Given that we employed MultipleNegativesRankingLoss as the loss function, we configured the *batch_sampler* as *BatchSamplers.NO_DUPLICATES*, for the reason that MultipleNegativesRankingLoss benefits from having no duplicate samples within a batch.

Considering our hardware's performance and memory limitations, we set reasonable parameters for the bge-m3, gte-multilingual-base, and multilingual-e5-large-instruct models, including a train batch size of 8 and train epochs of 4. For jina-embeddings-v3, due to its excellent performance and efficiency, we increased its batch size to 32 and set train epochs to 10.

5 Main Result and Analysis

5.1 Results on Dev Dataset

During the initial development stage, experiments were conducted using the BGE-M3 model. As shown in Table 1, contrastive fine-tuning significantly enhances the adaptability of the embedding model to the task, with 3-4 rounds of fine-tuning yielding substantial improvements compared to a single round. Given that most of the dataset's text lengths are around 300 tokens, the value of max_len was further explored. Setting max_len to 512 slightly improved success@10 over 384.

A noteworthy observation is that translating the original text into English led to a decrease in success@10. This suggests that translation may disrupt the inherent linguistic characteristics, potentially hindering the performance of multilingual embedding models.

After the fine-tuning parameters were tested, experiments on the model ensemble were conducted based on the development datasets. It was observed that the prediction success@10 gradually improved

Model	Pol	Eng	Msa	Por	Deu	Ara	Spa	Fra	Tha	Tur
bge-m3	0.848	0.818	0.978	0.828	0.880	0.938	0.892	0.926	0.967	0.846
gte-multilingual-base	0.848	0.834	0.978	0.860	0.894	0.948	0.930	0.932	0.951	0.854
jina-embeddings-v3	0.864	0.850	0.978	0.862	0.910	0.952	0.932	0.940	**0.978**	**0.908**
multilingual-e5-large	0.860	0.822	0.989	0.824	0.888	0.924	0.908	0.946	0.962	0.846
bge + e5	0.870	0.830	0.989	0.840	0.906	0.940	0.922	0.950	0.962	0.862

bge + gte + jina + e5	**0.878**	0.852	**0.989**	0.874	0.904	**0.958**	**0.940**	**0.954**	0.973	0.896

Table 4: The results of each model in the test phase monolingual task

as the number of ensemble models increased. In the monolingual task, a slight improvement in success@10 was achieved by integrating three and four models, increasing from 0.9-0.92 for single models to 0.93. A more significant improvement was observed in the cross-lingual task, with success@10 rising from 0.81 to 0.83 for single models to 0.88 when three and four models were integrated. These results indicate that the ensemble of multiple embedding models significantly enhances the capability of cross-lingual fact-checking retrieval.

5.2 Results on Test Dataset

Given the larger scale and higher reference value of the test phase, more comprehensive testing was conducted. In the monolingual task, the highest success@10 achieved by a single model was limited to 0.917, whereas the ensemble of multiple models increased the success@10 to 0.922. Notably, the success@10 achieved by the Jina+GTE combination was marginally higher than that of the four-model ensemble, indicating that the inclusion of BGE and E5, which exhibited slightly inferior performance, caused a minor reduction in success@10. Overall, the enhancement from the model ensemble in the monolingual task was not particularly substantial. Examination of multiple language subtasks within the monolingual task demonstrated that the four models displayed varying strengths across different languages, and their ensemble provided a complementary effect, resulting in improved success@10.

In the cross-lingual task, the success@10 of Jina and GTE was significantly higher than that of BGE and E5. Compared to single embedding models, the ensemble of multiple models showed a more pronounced improvement, with success@10 increasing from 0.698-0.748 for single models to a maximum of 0.773. Integrating only two embedding models resulted in a significant success@10 boost. Two combinations were compared: the integration of BGE and E5, which had single-model success@10 around 0.7, improved to 0.73, while the integration of GTE and Jina, with single-model success@10 around 0.74, achieved an success@10 close to 0.77.

The ensemble experiments conducted in both the development and test phases concluded that the ensemble of multiple models substantially improves cross-lingual fact-checking retrieval more than monolingual fact-checking retrieval. Additionally, the integration of Jina and GTE achieved success@10 close to that of the four-model ensemble, offering a balanced performance and computational cost solution.

6 Conclusion

This paper delineates the contributions of the YNU-HPCC team in the *Multilingual and Cross-lingual Fact-Checked Claim Retrieval (SemEval 2025 Task 7)*. We participated in all subtasks and developed a corresponding system through the fine-tuning and ensemble of embedding models. By leveraging preprocessed data containing only essential information, we constructed a fine-tuning dataset, individually fine-tuned four embedding models, and integrated them using a weighted approach. Semantic relevance was subsequently evaluated through the computation of cosine similarity.

Our methodology demonstrated significant efficacy, achieving robust performance across all subtasks. Specifically, we attained an success@10 of 0.92 in the monolingual task and 0.77 in the cross-lingual task, exceeding the baseline performance and securing the $11th$ position on the leaderboard. In future work, we intend to explore the impact of dynamic weighting and alternative ensemble methods on the results, aiming to devise more efficient and accurate retrieval methods utilizing embedding models to enhance the scalability and effectiveness of large-scale fact-checking retrieval.

Abstract

There is a high prevalence of disinformation and manipulative narratives in online news sources today, and verification of its informative integrity is a vital need as online audience is highly susceptible to being affected by such propaganda or disinformation. The task of verifying any online information is, however, a significant challenge. The task **Multilingual Characterization and Extraction of Narratives from Online News**, therefore focuses on developing novel methods of analyzing news ecosystems and detecting manipulation attempts to address this challenge. As a part of this effort, we focus on the subtask of **Entity Framing**, which involves assigning named entities in news articles one of three main roles (*Protagonist*, *Antagonist*, and *Innocent*) with a further fine-grained role distinction. We propose a pipeline that involves summarizing the article with the summary being centered around the entity. The entity and its entity-centric summary is then used as input for a BERT-based classifier to carry out the final role classification. Finally, we experiment with different approaches in the steps of the pipeline and compare the results obtained by them.

1 Introduction

There has been a rapid growth in the field of digital media over the past few years, and this has allowed for much easier dissemination and consumption of information. This development has double-edged outcomes: it allows for more diverse content, and for more real-time engagement with customers, yet it also enables the rapid spread of false information and narratives that are made to influence public opinion or spread propaganda. Consequently, there is a dire need of developing automated approaches that can interpret the framing of entities within a news environment.

The SemEval task on **Multilingual Characterization and Extraction of Narratives from Online News**(Piskorski et al., 2025) has been launched to promote research and develop novel approaches to analyse a news environment and characterize possible attempts at manipulation. Mainly, the first subtask, **Entity Framing** is centered around the classification and identification of the roles relevant entities involved from a news article. A model is required to correctly assign one or more roles to each entity solely based on the context provided by the article, and the locations of entities within it.

We implement this task in a pipeline with 2 primary phases: **1) Entity-Centric Summarization**, and **2) Role classification based on the summary**. Rather than feeding a classifier model the entire news article and the entity directly, we compress the news article into a summary that surrounds the entity in the first phase. This enables the classifier in the second phase, which has a limited token capacity, to focus on a condensed and compact input. The modularity of the pipeline also allows each phase to employ distinct models, and we observe the overall performance to reflect the combined contributions of the models operating at each phase of the pipeline. For the first phase we experiment with some models fine-trained on entity-centric summarization, and also with LLMs as their flexibility allows them to easily adapt to a new task. Most of our analyses, however, is focused on the second phase of the pipeline, where we vary the base models and improve on our training methods to obtain better results. Here, our best results are obtained when we perform sequential training on 3 inter-related tasks: 1) main role classification, 2) fine-grained role classification, and 3) contrastive learning to push the inputs towards a fine-grained class description.

2 Related Work

Previous works in this field have focused on persuasion techniques, framing in the news genre, and

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 241–246

on classifying the roles of entities in memes.

For instance, Ziems and Yang (2021) propose an NLP framework to measure entity framing in the specific case of police violence in the US and demonstrates a difference in how the liberal and conservative news sources frame issues. Additionally, the task of detecting the roles of entities in memes has been addressed by Nandi et al. (2022). This study focuses on classifying entities within memes to the categories of hero, villain, victim or other.

These studies play a role in having an understanding of entity framing across different media formats, and shows the importance of analyzing how entities are portrayed to uncover underlying biases and narratives.

3 Dataset

The dataset consists of news articles covering two major topics—the Ukraine-Russia War and Climate Change—collected from various news aggregation sites between 2022 to mid 2024. The dataset spans 5 languages: Bulgarian, English, Hindi, (European) Portugese, and Russian.

Each article is annotated (Stefanovitch et al., 2025) with the locations of the named entities and their corresponding role. The role assigned to each entity follows a two-level taxonomy:

- A **main role**, chosen from Protagonist, Antagonist, or Innocent.
- One or more **fine-grained roles** that provide a more detailed characterization within the assigned main role.

Additionally, the predefined taxonomy of the fine-grained roles contain a detailed description of all 22 fine-grained roles. While additional annotations exist for other subtasks, these are all the relevant ones to the current subtask.

For our experiments, we use the English subset of the dataset, which contains 3 splits: **train**, **development(dev)** and **test**. The test set labels have not been released yet, so all evaluations were conducted on the dev set. Table 1 provides details on the split, and the distributions of classes within each of them.

Split	Total Entities	Main Role Split (in %)		
		Protagonist	Antagonist	Innocent
Train	686	69.53	18.95	11.52
Dev	91	80.22	9.89	9.89

Table 1: Distribution of main roles in the English dataset. The test set labels have not been released.

4 Methodology

Our main approach to the entity framing task is to implement a two-phase pipeline that uses the article and entity to make an entity-centric summary which is then used to classify the role of the entity. This allows for flexibility in model selection at each phase—different summarization techniques can be explored without drastically altering the classification model's architecture. Similarly, improvements can still be made to the classifier without modifying the summarization process.

4.1 Entity-Centric Summarization Phase

The full length article may contain substantial background information, which need not be entirely relevant to the classification of the role of the given entity. Hence, an entity-centric summarization step may help isolate and condense the content into relevant content, improving the classification accuracy.

The full-length article may contain substantial background information, which need not be entirely relevant to the classification of the role of the given entity. Additionally, entities often appear multiple times throughout the article, sometimes under different mentions or as pronouns. An entity-centric summarization step could identify and consolidate all such mentions, potentially even resolving pronouns referring to the entity if the summarizer is sufficiently capable. This focused condensation of context ensures that only the most relevant portions of the article are retained, which can significantly improve the accuracy of subsequent role classification.

In order to perform the entity centric-summarization, there are 2 main approaches that we implemented to compare results.

The first approach relied on CTRLsum(He et al., 2022), which is a model trained to generate controlled outputs, in this case, it being used to generate entity-centric summaries. The model is fed inputs in the format *Entity* $=>$ *Article*, and the model has been fine-tuned to return an output that summarizes the article around the entity.

The second approach was to use an LLM to generate the entity-centric summary. For this, Google's Gemini was used via API calls. We prompted the LLM to return the entity-centric summary given the article and the entity, and this was done in a

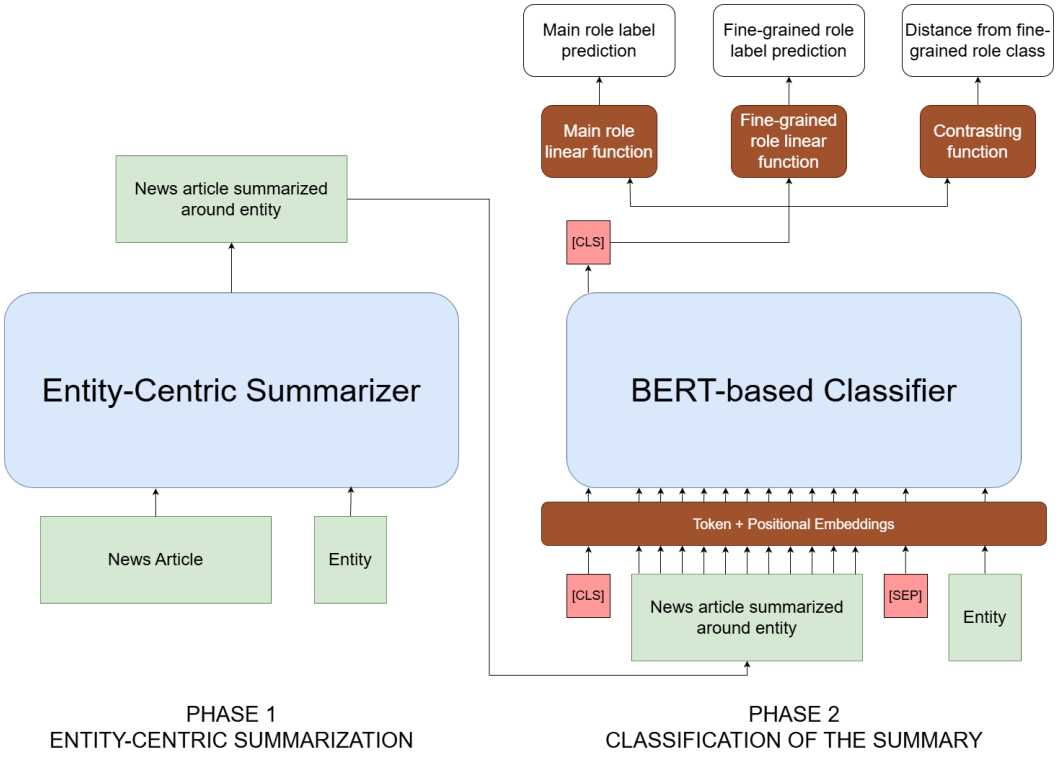

Figure 1: Flowchart of the proposed pipeline.

zero-shot setting. While, the API ensured no compute was happening on our system, we were limited by the free version's number of calls and so it was overall a much slower approach in this stage of the pipeline.

4.2 Role Classification Phase

For the role classification phase of the pipeline, we fine-tuned BERT-based models to predict the main role and fine role with the entity-centric summary and the entity itself as the input. The input was modeled in the following format:

[CLS] Entity-Centric Summary [SEP] Entity

This format leverages BERT's ability to attend to inter-sentence relationships, and allows it to form an understanding of the relation between the summary and the entity, and thereby make a joint representation where both the context and the entity information are fused. This joint representation (via the **[CLS]** token) is then used to classify the entity into its role accurately.

We began by trying a standard BERT architecture with a linear layer on top, that was fine-tuned to predict the fine-role and then mapped to the corresponding main role. The model had a single-cross entropy loss applied uniformly to all role predictions, which provided a first approach for further refinements.

To better capture the structure of the role labels, and to incorporate usage of the main roles, we implemented a dual training strategy. This approach made use of two separate loss functions—one for the main role and one for the fine-grained roles. The training here, happens in a sequential manner as shown below. In each batch in each epoch, the model first predicts the logits for the main loss, and after optimizing for the main loss, the model predicts the logits for the fine loss and then optimizes for it.

Let

- x_b be the input entity-centric summary in the current batch.
- f_θ be the classification model with the parameters θ.
- y_{main} be the ground-truth main role label.
- y_{fine} be the ground-truth fine-grained role labels.

The forward pass consists of two steps:
The model first predicts the logits for the main role:

$$\hat{y}_{main} = f_\theta(x_b) \quad (1)$$

$$L_{main} = CrossEntropyLoss(\hat{y}_{main}, y_{main}) \quad (2)$$

The optimizer updates θ based on the loss L_{main}. After optimizing for the main role, the model predicts logits for the fine-grained roles:

$$\hat{y}_{fine} = f_\theta(x) \quad (3)$$

$$\mathcal{L}_{fine} = BCEWithLogitsLoss(\hat{y}_{fine}, y_{fine}) \quad (4)$$

The optimizer then updates θ based on L_{fine}.

Due to the hierarchical nature of the role classification (from main role to fine-grained role), this sequential training of the two tasks complement one another and potentially allows the model to improve the fine-grained role prediction based on the learnings from the main role prediction.

Following this, we transitioned our backbone model from standard BERT to **DeBERTa v3** for its superior contextual representations and disentangled attention mechanism(He et al., 2020). To address the class imbalance in main role labels, we applied an oversampling strategy by duplicating instances from the underrepresented classes so that all the main roles had an equal number of training examples.

To further improve the model's understanding of the fine-grained roles, we made use of the role descriptions provided in the predefined taxonomy. Each fine-grained role is accompanied by a precise textual definition, which serves as a reference point for classification. Instead of relying solely on the learned label representations from training data, we aimed to explicitly guide the model in aligning the encodings of the input with the that of the fine-grained role descriptions.

This reasoning motivated our final stage of evolution, where we integrated a contrastive loss component into the DeBERTA-based classifier. The contrastive loss was designed to enforce a margin-based separation in the vector space between the positive and negative fine-grained role classes.

Let

- $\mathbf{s} \in \mathbb{R}^d$ be the encoded sentence representation.
- $\mathbf{r}_i \in \mathbb{R}^d$ be the encoded representation of the i^{th} fine-grained role.
- $Sim()$ be a function that returns the cosine similarity between two embeddings.

We first normalize the embeddings:

$$\mathbf{s} = \frac{\mathbf{s}}{\|\mathbf{s}\|_2}, \quad \mathbf{r}_i = \frac{\mathbf{r}_i}{\|\mathbf{r}_i\|_2} \quad \forall i \quad (5)$$

Next we compute the cosine similarity between the sentence embedding and each role embedding:

$$Sim(\mathbf{s}, \mathbf{r}_i) = \mathbf{s} \cdot \mathbf{r}_i \quad (6)$$

For fine-grained roles that are correct(positive pairs), we minimize the negative log-likelihood:

$$\mathcal{L}_{pos} = -\mathbb{E}_{i \in \mathcal{P}} \log \sigma(Sim(\mathbf{s}, \mathbf{r}_i)) \quad (7)$$

For the negative pairs, we enforce a margin m (here 0.5) such that similarity is penalized only when it exceeds m:

$$\mathcal{L}_{neg} = \mathbb{E}_{j \in \mathcal{N}} \max(0, Sim(\mathbf{s}, \mathbf{r}_j) - m) \quad (8)$$

The final contrastive loss is computed as the sum of the positive and negative losses:

$$\mathcal{L}_{contrastive} = \mathcal{L}_{pos} + \mathcal{L}_{neg} \quad (9)$$

We now perform the sequential training for the three tasks: the main role classification, the fine-grained role classification, and the contrastive learning objective for the fine-grained role. This is an extension of approach outlined earlier.

During prediction, an entity is assigned a fine-grained role if it meets both of the following conditions: (1) the fine-grained role classification loss independently predicts it as a positive label and (2) its contrastive similarity score with the role's description falls within the predefined margin. This incorporation and execution of the contrastive loss and sequential training obtained us with the best results in all our experiments.

4.3 Implementation and Hyperparameters

The DeBERTA model 'microsoft/deberta-v3-base' was used for fine-tuning, and different implementations were tried for up to 100 epochs. In our best implementation, we used a batch size of 16. An Adam optimizer was used, with a learning rate of 2×10^{-5} and a weight decay of 0.01.

For the summarizers, we used CTRLsum from the huggingface library, and for the Gemini approach, we used the API function to make calls to

Pipeline		Approach	**Exact Match Ratio**	micro P	micro R	micro F1	Accuracy for main role
Summarizer	Classifier						
CTRLsum	BERT	2-task sequential training	0.13190	0.13190	0.12000	0.12570	0.82420
CTRLsum	DeBERTa	2-task sequential training	0.21980	0.23960	0.23000	0.23470	0.78020

CTRLsum	DeBERTa	3-task sequential training[2]	0.23400	0.28090	0.24910	0.26400	0.83400

Table 2: Results from various experiments carried out for the subtask-1.

the Gemini 1.5 Flash model. We had to limit the rate of API calls to under 15 per minute to utilize the free plan of the API.

5 Results and Discussion

As the test set labels have not been released, the analysis has all been done on the dev set and those are the reported scores. Only the final submission has scores for the test set. We have limited our experiments and analysis to the English language.

For each model, the main metrics reported are the Exact Match Ratio, micro P, micro R and micro F1 for the fine-grained roles. An accuracy for the main role prediction is also reported. The official evaluation metric is, however, the EMR for the fine-grained roles. Table 2 shows the various experiments in the order conducted and their performances.

We began with a simple BERT classifier and then moved to a two-task sequential setup using DeBERTa as the backbone model, which brought noticeable performance gains. Further improvements were observed with introducing the third contrastive learning task in addition to main role and fine-grained role classification. We also evaluated the effect of the different entity-centric summarizers: CTRLsum and Gemini.

Our best results were achieved using Gemini as the summarizer in combination with the two-task sequential setup, achieving the highest EMR and micro F1 scores. However, it is worth noting that CTRLsum, despite being a smaller and more efficient summarizer that runs locally (unlike Gemini, which relies on a large LLM, and making API calls), still produced competitive results—especially when combined with the three-task training setup. This makes CTRLsum a practical and resource-efficient alternative, particularly for environments with limited compute resources.

[1]This entry corresponds to the results for the test set, the final submitted entry for the task

[2]This entry corresponds to the results for the test set, using the CTRLsum approach for summarization, experimented after the deadline

6 Conclusion and Future Work

In this work, we explored the effectiveness of a dual phase approach, summarization and classification, in the entity framing task in news articles. For the classifier, we experimented with a sequential training method, incorporating main role classification, fine-grained role classification, and contrastive learning objectives, and this allowed the model to learn hierarchical relationships between main roles and their fine-grained classifications, while the contrastive learning objective helped in creating more discriminative feature representations. While this approach showed promise, achieving an EMR of 0.234, we discovered that the quality of the initial summarization phase had an even more substantial impact on overall performance. Despite the controlled summaries obtained with CTRLsum, our best results (EMR of 0.2637) were achieved using Gemini as the summarizer with a simpler 2-task sequential training setup, possibly due to its higher quality and diversity of summaries.

A key challenge was the data imbalance in both main and fine-grained roles (Table 1), which we addressed through oversampling. However, future work could explore leveraging generative models to create multiple diverse summaries for underrepresented classes for more robust training data.

Our findings highlight the importance of high-quality summarization techniques in framing tasks and suggest promising methods for improving automated narrative analysis in news media.

xiacui at SemEval-2025 Task 11: Addressing Data Imbalance in Transformer-Based Multi-Label Emotion Detection with Weighted Loss

Xia Cui
Manchester Metropolitan University
x.cui@mmu.ac.uk

Abstract

This paper explores the application of a simple weighted loss function to Transformer-based models for multi-label emotion detection in SemEval-2025 Shared Task 11 (Muhammad et al., 2025b). Our approach addresses data imbalance by dynamically adjusting class weights, thereby enhancing performance on minority emotion classes without the computational burden of traditional resampling methods. We evaluate BERT, RoBERTa, and BART on the BRIGHTER dataset, using evaluation metrics such as Micro F1, Macro F1, ROC-AUC, Accuracy, and Jaccard similarity coefficients. The results demonstrate that the weighted loss function improves performance on high-frequency emotion classes but shows limited impact on minority classes. These findings underscore both the effectiveness and the challenges of applying this approach to imbalanced multi-label emotion detection.

1 Introduction

Emotions conveyed through language can manifest via facial expressions, speech, and written text. Unlike facial expressions, which can display a wide spectrum of emotions, or speech, which can express multiple emotions while retaining the same verbal content, emotions in text are particularly challenging to analyse and interpret (Hancock et al., 2007). Textual emotions are especially difficult to analyze due to their subtlety, complexity, and inherent ambiguity in how emotions are expressed. For machines, detecting emotions in text is a particularly formidable task, given the nuanced and often context-dependent nature of emotional language (Pekrun, 2022; Mohammad, 2022). Developing an artificial intelligence (AI) system capable of identifying emotional content is even more challenging, as the machine's role is primarily to support human interpretation, offering insights rather than definitive conclusions—especially given the subjectivity of emotional perception and the likelihood of disagreement among human interpreters (Schuff et al., 2017). This task becomes even more complicated with short texts, which often communicate a blend of emotions simultaneously, making it a critical area of study for advancing both AI and emotional intelligence research.

This paper focuses on developing a system capable of identifying the presence of one or more emotions within short texts as a multi-label classification problem, aiming to advance the accuracy and utility of automated emotion detection. To achieve this, we develop a Transformer-based model, a class of architectures that has recently gained prominence in Natural Language Processing (NLP) for tasks such as sentiment analysis and machine translation. While prior research has extensively explored traditional machine learning (ML) and deep learning (DL) approaches, including Convolutional Neural Networks (CNNs) and Long Short-Term Memory (LSTM) networks (Zhang and Zhou, 2014; Wang et al., 2016), this work focuses on the potential of Transformers to address the unique challenges of multi-label emotion detection.

Data imbalance is a common challenge in classification tasks, often leading to poor performance in detecting minority classes. Traditional approaches to address this issue typically involve resampling techniques, such as oversampling minority classes or undersampling majority classes (Tsoumakas et al., 2010; Bach et al., 2017). However, in multi-label classification tasks, where a single instance can simultaneously belong to both minority and majority classes, these methods become less effective. Resampling in such scenarios complicates the mapping of instances to multiple output labels, as increasing or decreasing the occurrence of one label may inadvertently affect others (Zhang and Zhou, 2014; Charte et al., 2015). In this paper, we investigate the application and impact of class weighting as an alternative strategy for handling

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 247–256

data imbalance in multi-label classification, particularly when applied to Transformer-based models.

A key list of our contributions is summarised as follows:

- We propose a simple weighted loss function to address data imbalance in multi-label emotion detection using Transformer-based models.
- We evaluate three widely used Transformer-based models: BERT, RoBERTa and BART for multi-label emotion detection.
- We show that the weighted loss function (+w) enhances performance across all metrics and emotion classes for BERT and BART, while in RoBERTa, it leads to slight underperformance in Micro F1.

The source code for this paper is publicly available on GitHub[1].

2 Background

Significant amounts of studies have been carried out on automatic emotion recognition to help the process of manually checking emotions for various purposes. Previous studies have explored various machine learning and deep learning approaches to address the challenges of capturing multiple emotions in concise text. Zhang and Zhou (2014) proposed a framework using binary relevance and classifier chains to handle multi-label classification, demonstrating its effectiveness on social media datasets. Wang et al. (2016) proposed leveraging CNN and LSTM to tackle emotion detection, highlighting the potential of deep learning models in capturing complex emotional cues in text. Transformer-based models such as BERT, RoBERTa, and BART have significantly advanced the field of emotion detection by leveraging their ability to capture contextual relationships in text. BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2019) introduced a bidirectional attention mechanism, enabling it to understand the context of words from both left and right, which is particularly useful for detecting nuanced emotional cues in text. RoBERTa (Robustly Optimized BERT Pretraining Approach) (Liu et al., 2019) builds on BERT by optimizing its pretraining process, using larger datasets and longer training times, resulting in improved performance on emotion classification tasks. BART (Bidirectional and Auto-Regressive Transformers) (Lewis et al., 2019), on the other hand, combines bidirectional and autoregressive pretraining objectives, making it effective for both understanding and generating emotionally rich text. These models or variants have been widely adopted in emotion detection due to their ability to handle complex linguistic patterns and their state-of-the-art performance on benchmark datasets (Ribeiro et al., 2020; Zhang et al., 2020; Muhammad et al., 2025a).

Many methods fail to address label imbalance, leading to biased models (Zhang and Zhou, 2014; Yang et al., 2019; Ghosal et al., 2021). Zhang et al. (2020) proposed a multimodal Transformer-based approach for multi-label emotion detection, modeling both modality and label dependencies. Similar label dependency techniques have also been proposed in several previous studies (Zhou et al., 2020; Zhang et al., 2021; Chen et al., 2021). However, emotions are not always correlated and can conflict (e.g., *joy* and *anger*), making dependency assumptions problematic. Their model mitigates imbalance with a weighted loss function and a conditional set generation mechanism, but is computationally expensive due to beam search and permutation-based training. In this paper, we employ a similar weighted loss function that adjusts class weights directly, reducing complexity and resource demands, to the Transformer-based models.

3 Methods

We consider the emotion detection task as a multi-label classification problem. Multi-label classification involves assigning multiple labels to each input instance. Section 3.1, we provide the definition of the problem with notation. Unlike traditional classification tasks, where each input is associated with a single label, multi-label classification requires the model to predict a subset of labels from the label space. Section 3.2, we introduce the Transformer-based architecture including critical components and how we apply instance weighting in the loss function for the defined multi-label classification problem.

3.1 Problem Definition

Let the dataset consist of N samples, where each sample is represented as a text input x_i (e.g., a sentence or paragraph). These inputs are preprocessed and transformed into numerical representations, forming a feature matrix $X \in \mathbb{R}^{N \times d}$, where

[1] https://github.com/summer1278/semeval2025-task11

d is the feature dimensionality. The corresponding emotion labels are represented by a multilabel target matrix $Y \in \{0,1\}^{N\times C}$, where C is the number of possible emotion classes (e.g., "joy", "sadness", "anger", etc.). Each element Y_{ij} indicates whether the j-th emotion is expressed in the i-th input:

$$Y_{ij} = \begin{cases} 1, & \text{if sample } i \text{ contains a emotion label } j, \\ 0, & \text{otherwise.} \end{cases} \quad (1)$$

The goal is to learn a function $f : \mathbb{R}^d \to [0,1]^C$ that maps an input feature vector $x \in \mathbb{R}^d$ to a probability vector $\hat{y} \in [0,1]^C$, where each $\hat{y}_j$ represents the predicted probability of label j being relevant.

3.2 Transformer-based Backbone

We propose a model based on the Transformer architecture (Vaswani, 2017), which employs self-attention mechanisms and positional encoding to effectively capture contextual relationships in text. While the Transformer architecture itself remains unchanged, we introduce a weighted loss function to address the challenge of data imbalance in multi-label classification. Specifically, the weighted loss function dynamically adjusts the contribution of each instance during training based on its label distribution, enabling the model to better handle minority classes without disrupting the relationships between labels. This approach allows us to leverage the strengths of Transformers while mitigating the biases introduced by imbalanced data.

3.2.1 Cross-Entropy Loss

Training Transformer-based models for classification tasks typically employs the cross-entropy loss function. This loss quantifies the discrepancy between the predicted probability distribution and the true distribution, serving as a standard objective to optimize the performance of the model.

Let y denote the true target sequence and $\hat{y}$ the predicted sequence. The cross-entropy loss is defined as,

$$\mathcal{L}_{\text{CE}} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{C} y_{ij}\log(\hat{y}_{ij}), \quad (2)$$

where N is the number of samples in the batch, C is the number of emotion classes, y_{ij} is a binary indicator (1 if the true class for sample i is j, 0 otherwise) and $\hat{y}_{ij}$ is the predicted probability for class j for sample i.

Binary Cross-Entropy (BCE) loss is employed for multi-label classification tasks. Under the assumption that emotions are independent, the BCE loss is calculated separately for each label, leading to the following formulation of the function:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{C}[y_{ij}\log(\hat{y}_{ij}) + (1-y_{ij})\log(1-\hat{y}_{ij})] \quad (3)$$

This loss encourages the model to assign high probabilities to the correct labels and low probabilities to the incorrect labels for each instance.

3.2.2 Class Weights and Label Smoothing

To enhance generalization, a common strategy is to incorporate class weights into the loss function (Ridnik et al., 2021):

$$\mathcal{L}' = -\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{C} w_j\,[y_{ij}\log(\hat{y}_{ij}) + (1-y_{ij})\log(1-\hat{y}_{ij})] \quad (4)$$

Here, w_j denotes the weight assigned to the j-th class, computed as $w_j = f_j/N$, where f_j is the frequency of the j-th class in the dataset, and N is the total number of training instances. w_j is normalised as $w_j = \max(W)/w_j$, where W represents an array of distributions from C labels in the training dataset.

Additionally, label smoothing is frequently employed, where the traditional one-hot target distribution is replaced with a smoothed version to reduce the overfitting of majority classes:

$$y_{ij}^{\text{smooth}} = (1-\epsilon)y_{ij} + \frac{\epsilon}{C} \quad (5)$$

where ϵ is the smoothing parameter. This prevents the model from becoming overconfident in its predictions.

3.2.3 Prediction

The predicted probabilities for all samples can be represented as a matrix:

$$\hat{Y} = \sigma(Z), \quad Z \in \mathbb{R}^{N\times C} \quad (6)$$

where Z is the output logits of the model and $\sigma(\cdot)$ is the element-wise sigmoid function, defined as $\sigma(z) = 1/(1+e^{-z})$. In a multi-label classification task, where the model operates as a collection of independent binary classifiers, a probability threshold of $\tau = 0.5$ is typically applied to determine label

assignments. However, if all predicted probabilities fall below τ, the label y_j corresponding to the highest logit value z_j (i.e., $y_j = \arg\max_{j \in \{1,\ldots,C\}} z_j$) is assigned as the final prediction to mitigate unclassified instances.

3.2.4 Training Objective

During training, the model minimizes the BCE loss Eq. 3, while the Macro F1 score (Eq. 10) is monitored using a development set to select the best model,

$$\theta^* = \arg\min_{\theta} \mathcal{L}(f_\theta(X), Y), \tag{7}$$

where θ are the parameters of the model, $f_\theta(X)$ is the output of the model for input X and $f_\theta(X) = \hat{Y}$.

4 Experimental Setup

The task is framed as a multi-label classification problem. The proposed system is developed using the BRIGHTER dataset (Muhammad et al., 2025a), which includes multi-label emotion annotations across 28 languages. To address the challenge of data imbalance, we focus our experiments on the English subset as a representative example. The proposed approach is designed to be generalizable and can be extended to other languages, such as German, with minimal adaptation.

4.1 Experimental Data and Preprocessing

Each instance is annotated with binary presence labels (1 for positive, 0 for negative) across five emotion classes: anger, fear, joy, sadness, and surprise. Table 1 illustrates the label distribution for the training set in the BRIGHTER English Track A dataset. Since the test set labels were not accessible during the evaluation phase, we used the official development split (116) as a test set. The original training set was divided into 70% (1937) for training and 30% (831) for development. No additional training datasets were introduced to boost the perfomrance.

For data preprocessing, we employed the `AutoTokenizer`[2], which tokenizes the input text and generates corresponding `attention_mask` and `input_ids` for the model. For consistency and reproducibility, we utilize `AutoTokenizer` with default settings for all models. The tokenization process follows model-specific encoding methods, including WordPiece for BERT-based models and Byte-Pair Encoding for RoBERTa and BART. Sequences are automatically padded and truncated to a fixed length, ensuring uniform input across all models. For uncased models, all text is lower-cased, whereas cased models preserve the original casing. Additionally, special tokens are inserted according to each model's pretrained configuration. We do not apply any additional text normalization, stemming, or lemmatization beyond what is internally handled by the tokenizer.

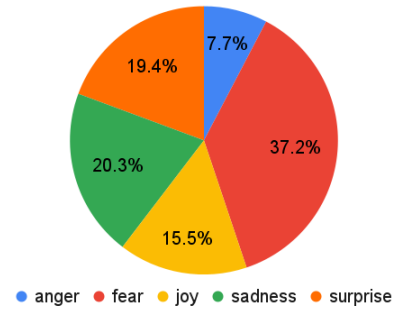

Figure 1: Label distributions of training set in BRIGHTER English Track A dataset.

4.2 Hyperparameter Tuning

To identify optimal baseline hyperparameters across all models, we employ OPTUNA (Akiba et al., 2019), a Bayesian optimization framework, to maximize the Macro F1 score (Section 3.2.4), which is a class-imbalance-resistant metric particularly suitable for multi-label emotion detection. Our experiments use the `BERT-base-uncased` model checkpoint[3] as the foundation. The hyperparameter search executes 10 optimization trials, with each trial training on the training set and evaluating on the development set to ensure robust generalization. We use RAY TUNE (Liaw et al., 2018) to distribute these trials across available computing resources. The configuration yielding the best performance is selected for the final training phase. The optimized hyperparameters obtained through tuning were: learning rate (η) = 2.45×10^{-5}, batch size = 8 and number of epochs = 3. Additional results are provided in Appendix Section A.

4.3 Implemention Details

All experiments are conducted using Google Colab's T4 GPU server (NVIDIA T4 GPU with 16GB of VRAM)[4], leveraging the HuggingFace

[2] https://huggingface.co/transformers/v4.7.0/model_doc/auto.html#transformers.AutoTokenizer

[3] https://huggingface.co/google-bert/bert-base-uncased

[4] https://colab.research.google.com/

`transformers` library with PyTorch as the backend. The models are trained using AdamW optimiser (Loshchilov and Hutter, 2017) with a linear learning rate scheduler, and a batch size of 8 is used throughout the experiments. To prevent overfitting, early stopping is applied based on validation performance. Evaluation is performed using standard classification metrics implemented via the `sklearn.metrics` module[5].

4.4 Evaluation Metrics

We evaluate the performance of this multi-label classification task using four metrics: F1 scores, ROC-AUC score, Accuracy (Acc) and Jaccard similarity coefficients.

The F1 score F_1 for a binary classification task is computed using the number of True Positives (TP), False Positives (FP) and False Negatives (FN):

$$F_1 = \frac{\text{TP}}{\text{TP} + \frac{1}{2} \cdot (\text{FP} + \text{FN})} \tag{8}$$

Considering a multiclass problem under the one-vs-rest strategy, having C classes, Micro F1 is computed using the total number of TP, FP and FN across all classes:

$$\text{Micro}F_1 = \frac{\sum_{j=1}^{C} \text{TP}_j}{\sum_{j=1}^{C} \text{TP}_j + \frac{1}{2} \cdot \left(\sum_{j=1}^{C} \text{FP}_j + \sum_{j=1}^{C} \text{FN}_j\right)} \tag{9}$$

Whereas Macro F1 takes an average of class-wise F_1 across all classes:

$$\text{Macro}F_1 = \frac{\sum_{j=1}^{C} F_1(j)}{C} \tag{10}$$

The Weighted F1 score is a metric commonly used in multi-label classification tasks, particularly in scenarios involving imbalanced datasets. It calculates the F1 score for each class (which can be considered a binary classification problem to be computed by Eq. 8) and takes the average, weighted by the number of true instances (support) for each class. This ensures that classes with more instances have a larger impact on the final score, which is especially important when dealing with imbalanced classes. It is given by:

$$\text{Weighted}F1 = \frac{\sum_{j=1}^{C} w_j \cdot F_1(j)}{\sum_{j=1}^{C} w_j} \tag{11}$$

[5] https://scikit-learn.org/stable/api/sklearn.metrics.html

Table 1: Performance on Transformer-based models with or without weighted loss function (+w). The best results are bolded.

	MicroF_1	MacroF_1	ROC-AUC	Acc	Jaccard
BERT	0.7095	0.6859	0.7927	0.3621	0.5776
BERT+w	**0.7198**	**0.7008**	**0.8016**	**0.3966**	**0.5991**
RoBERTa	**0.7282**	0.7162	0.8116	0.3707	0.5934
RoBERTa+w	0.7268	**0.7184**	**0.8127**	**0.3793**	**0.6013**
BART	0.6961	0.6803	0.7837	0.3707	0.5668
BART+w	**0.7321**	**0.7136**	**0.8141**	**0.4138**	**0.6114**

where C is the total number of classes, $F_1(j)$ is the F1 score for class j, w_i is the support (the number of true instances) for class j. This formulation ensures that classes with more instances (higher support) have a proportionally larger effect on the final weighted F1 score. In our experiments, we use this metric to evaluate the overall performance of the models while accounting for class imbalance. Another alternative method to calculate the F1 score for a multiclass problem is to average the score across N instances. This approach is known as the sample-averaged F1 score:

$$\text{Sample}F_1 = \frac{\sum_{i=1}^{N} F_1(i)}{N} \tag{12}$$

The Receiver Operating Characteristic (ROC) curve plots the True Positive Rate (TPR) against the False Positive Rate (FPR) across various thresholds, where TPR = TP / (TP + FN) and FPR = FP / (FP + TN). The Area Under the Curve (AUC) represents the likelihood that a randomly selected positive instance is ranked higher than a randomly selected negative one. A higher AUC indicates better model performance.

The Jaccard similarity coefficient measures the similarity between predicted labels $\mathbf{y}_{\text{pred}}$ and true labels $\mathbf{y}_{\text{true}}$, calculated as the size of their intersection divided by the size of their union:

$$\text{Jaccard} = \frac{|\mathbf{y}_{\text{pred}} \cap \mathbf{y}_{\text{true}}|}{|\mathbf{y}_{\text{pred}} \cup \mathbf{y}_{\text{true}}|} \tag{13}$$

5 Results

Table 1 presents the results of five major evaluation metrics for three Transformer-based models: BERT, RoBERTa and BART. Due to computational constraints, we use the base versions of these models, leveraging pre-trained checkpoints available on HuggingFace Hub[6]. To ensure a fair comparison,

[6] https://huggingface.co/models

all models are fine-tuned under identical conditions, including consistent hyperparameters, epochs, and optimization settings, isolating the impact of model architectures (Section 4).

The comparative evaluation of BERT, BART, and RoBERTa, both with and without the weighted loss function (+w), reveals distinct patterns in their handling of multi-label emotion detection. BERT+w and BART+w show notable improvements, particularly in Weighted F1 (BERT: from 0.7115 to 0.7228 and BART: from 0.6993 to 0.7350), demonstrating enhanced detection of both majority and minority emotions. BART+w exhibits the most significant gains, with Micro F1 increasing from 0.6961 to 0.7321, reflecting stronger overall classification robustness. In contrast, RoBERTa+w shows only marginal changes, with a slight decrease in Weighted F1 (from 0.7298 to 0.7270) and near-identical Micro F1 (from 0.7282 to 0.7268), suggesting that RoBERTa is inherently well-optimized for handling class imbalance. Further analysis (Table 2 and Table 3) reveals that improvements in Macro F1 and Sample F1 are primarily driven by gains in high-frequency classes, with limited or no improvements in most emotion classes (4 out of 5). This indicates that the weighted loss function disproportionately benefits high-frequency classes, potentially masking stagnation in minority emotion detection. Additionally, RoBERTa's performance suggests that it is less sensitive to data imbalance than BERT and BART, likely due to its more robust pretraining, enabling it to outperform these models in the base configuration. Further analysis on RoBERTa's higher precision and recall for minority classes without reweighting is provided in Appendix Section B. In contrast, BART is highly sensitive to data imbalance, resulting in the lowest F1 scores among the three models. However, with the +w variation, BART's performance improves significantly, surpassing the other models in 4 out of 5 major evaluation metrics, with only a slight drop in Macro F1 or closely matching their performance.

Additionally, we observe that *joy* and *surprise* tend to have overlapping misclassifications, possibly due to contextual ambiguity. This issue highlights a potential limitation in current text-based emotion representations, where fine-grained distinctions between similar emotions remain challenging for Transformer-based models.

Table 2: Class-wise Macro F1 scores for all models.

Class	anger	fear	joy	sadness	surprise
BERT	0.5806	0.7482	**0.6667**	0.7385	0.6957
BERT+w	**0.6471**	**0.7571**	0.6296	**0.7429**	**0.7273**
RoBERTa	**0.7179**	**0.7714**	**0.7368**	**0.7317**	0.6230
RoBERTa+w	0.7000	0.7534	**0.7368**	0.7250	**0.6769**
BART	0.6452	0.7413	0.6792	0.6087	0.7273
BART+w	**0.6875**	**0.7943**	**0.7037**	**0.6389**	**0.7436**

Table 3: F1 score variations (macro, weighted, micro, and samples averaging) for all models.

	MicroF_1	MacroF_1	WeightedF_1	SampleF_1
BERT	0.7095	0.6859	0.7115	0.6514
BERT+w	**0.7198**	**0.7008**	**0.7228**	**0.6625**
RoBERTa	**0.7282**	0.7162	**0.7298**	0.6644
RoBERTa+w	0.7268	**0.7184**	0.7270	**0.6705**
BART	0.6961	0.6803	0.6993	0.6333
BART+w	**0.7321**	**0.7136**	**0.7350**	**0.6766**

6 Conclusion

This paper contributes to the field of multi-label emotion detection by proposing a simplified weighted loss function that mitigates the effects of data imbalance in Transformer-based models. We demonstrate the application of the weighted loss function (+w) improves performance for BERT and BART models, challenges remain in detecting minority emotions. The findings suggest that future work could expand on this approach, particularly by exploring the impact of the proposed method across different languages and datasets.

A Hyperparameter Tuning Trails

Each trail in RAY TUNE is an independent run with a unique set of hyperparameters. The OPTUNA optimization over 10 trials revealed several key insights: (a) Moderate learning rates (2.45×10^{-5} to 5.79×10^{-5}) achieved optimal performance, with the best configuration (Trial 4) yielding a Macro F1 score of 0.724; (b) Smaller batch sizes (4-16) outperformed larger ones, suggesting the importance of more frequent gradient updates; (c) Training stability was maintained with 3-5 epochs, avoiding overfitting while achieving convergence. Two trials were pruned early due to poor validation performance. The optimal configuration balanced learning dynamics (batch size 8 and 3 epochs) with precise weight updates ($\eta = 2.45 \times 10^{-5}$), demonstrating the effectiveness of Bayesian optimization for transformer fine-tuning.

Table 4: Optuna hyperparameter optimization results (top 4 trails). η denotes the learning rate.

#trial	η	batch size	#epochs	MacroF_1
4 (best)	2.45×10^{-5}	8	3	0.7239
2	4.14×10^{-5}	4	3	0.7105
3	5.79×10^{-5}	4	4	0.7162
5	3.39×10^{-5}	16	5	0.6911

B Discussion on Classification Reports

Due to page limitations, we present the complete classification reports for all models in Table 5, including the base versions of BERT, RoBERTa, and BART, along with their weighted loss function (+w) variants. Across all models, precision generally improves with the +w variation, particularly for minority emotions such as *anger* and *surprise*, while recall tends to fluctuate, sometimes decreasing slightly. These results further support the findings discussed in Section 5, indicating that the weighted loss function effectively mitigates class imbalance for BERT and BART but offers limited benefits for RoBERTa—likely due to its already strong baseline performance in multi-label classification tasks.

RoBERTa demonstrates notable resilience to data imbalance even without reweighting strategies. We attribute this robustness to its enhanced pretraining methodology, which includes training on a significantly larger corpus, longer training duration, dynamic masking, and the removal of the Next Sentence Prediction (NSP) objective (Liu et al., 2019). These improvements result in richer and more generalizable contextual representations, which likely contribute to RoBERTa's stable performance across both frequent and minority emotion classes. As shown in our baseline results, RoBERTa achieves relatively high precision and recall for low-frequency classes such as *anger* and *surprise*, even without any rebalancing. In contrast, BERT and BART exhibit more pronounced performance drops for these underrepresented classes. These findings suggest that RoBERTa's pretraining design inherently mitigates some of the negative effects of label imbalance, making it a particularly strong baseline in imbalanced multi-label emotion detection settings.

UZH at SemEval-2025 Task 3: Token-Level Self-Consistency for Hallucination Detection

Michelle Wastl **Jannis Vamvas** **Rico Sennrich**
Department of Computational Linguistics, University of Zurich
{wastl,vamvas,sennrich}@cl.uzh.ch

Abstract

This paper presents our system developed for the *SemEval-2025 Task 3: Mu-SHROOM, the Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes*. The objective of this task is to identify spans of hallucinated text in the output of large language models across 14 high- and low-resource languages. To address this challenge, we propose two consistency-based approaches: (a) token-level consistency with a superior LLM and (b) token-level self-consistency with the underlying model of the sequence that is to be evaluated. Our results show effectiveness when compared to simple mark-all baselines, competitiveness to other submissions of the shared task and for some languages to GPT4o-mini prompt-based approaches.[1]

1 Introduction

Large language models (LLMs) have transcended the boundaries of the natural language processing community and hold significant potential for automating tasks across different industries. However, their adoption is often hindered by concerns regarding their trustworthiness and factual reliability, particularly due to hallucinations — the phenomenon where generative systems produce incorrect or fabricated output. Thus, developing methods to detect hallucinations is an essential step towards ensuring the safe and effective deployment of LLMs in real-world applications.

Various approaches have been undertaken that showed the effectiveness of detecting hallucinations through retrieval augmentation and referring to external knowledge (Wang et al., 2023; Ji et al., 2023; Zhang et al., 2024; Mishra et al., 2024) or leveraging the internal states of the LLM (Xiao and Wang, 2021; Varshney et al., 2023; Farquhar et al., 2024). These methods are restricted by the fact that they rely on access to external knowledge and the openness of the LLM. A further method to detect hallucination that is not impacted by these factors leverages the self- and cross-model consistency for a given task for the same or across different LLMs (Zhang et al., 2023; Manakul et al., 2023). While effective, these methods have been almost exclusively tested at the sentence level, however, hallucinations often occur at the sub-sentential level, with incorrect or fabricated information appearing within specific spans of text rather than entire sentences. Less work has gone into detecting hallucinations at a more fine-grained level (Zhou et al., 2021; Liu et al., 2022; Fadeeva et al., 2024).

This year's *SemEval Task 3 MuSHROOM: the Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes* (Vázquez et al., 2025) calls for research to fill this gap, by challenging the community on a hallucination span detection task, providing a human-annotated dataset of question-answer pairs, in which the answers have been generated by various open-source language models. The dataset contains labelled data for 10 languages (German, English, French, Italian, Spanish, Hindi, Chinese, Arabic, Swedish, and Finnish) and unlabelled data for 4 additional languages (Farsi, Basque, Czech, and Catalan) – bringing multilingual and low-resource components to the challenge.

We approach this challenge by adapting self- and cross-model consistency approaches to the token level. Our proposed approach compares alternative responses by the same underlying model that has been used to generate the answer that is to be evaluated as a way of self-consistency or by a superior LLM by aligning each token of the answer that is to be evaluated with a token from each alternative answer as a way of cross-model consistency (GPT-consistency). The median similarity score between the aligned tokens is then used as an indicator for token-level consistency, or hallucinations.

[1]The code is available at https://github.com/ZurichNLP/sc-hallucination-detection.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 257–270

Settings	ar	zh	en	fi	fr	de	hi	it	es	sv	Avg.
Token-level labels inter alignment	44.0%	23.8%	26.7%	47.4%	36.7%	37.7%	43.4%	42.8%	16.1%	50.5%	36.9%
Token-level labels forward alignment	38.9%	42.2%	23.7%	51.5%	39.2%	36.6%	44.2%	42.6%	20.4%	46.7%	38.6%
+ median token consistency score	40.9%	42.6%	23.5%	52.0%	36.9%	41.0%	46.4%	44.5%	19.0%	48.6%	39.5%
+ word-level labels	42.1%	43.9%	25.8%	50.5%	35.9%	42.8%	52.4%	42.2%	18.3%	50.0%	40.4%

Table 1: Ablation for different settings across different languages for self-consistency on the validation set.

We find that simply prompting a strong LLM results in a strong baseline, reaching the highest results on average across languages with an overlap with gold annotations of up to 51.7%, consistency-based approaches can outperform it or achieve comparable results for languages like Chinese, French, Finnish or Swedish, reaching overlaps with human gold annotations of 47.9%–60.1%

2 Background

This work takes inspiration in self-consistency (Wang et al., 2023), a framework in which Chain-of-Thought (CoT) prompting is improved by sampling more than one possible continuation and choosing the continuation that is generated most consistently. Self-consistency has also been adapted to the hallucination detection task under the assumption that inconsistency is an indicator for counter-factuality and model uncertainty. It is proven effective at the sentence-level hallucination detection task in English: Manakul et al. (2023) compare an LLM-generated response against stochastically-generated responses and let an LLM judge over the factuality of the response. Mündler et al. (2024) investigate self-contradiction as an indicator for hallucinations. Zhang et al. (2023) introduce the concept of cross-model consistency, building on the observation that one model can hallucinate consistently across multiple continuations and therefore, an additional LLM is needed to break the consistency. In this work, we continue to follow the intuition that inconsistency indicates model uncertainty and that, especially in a cross-model setting with a superior LLM, inconsistency can be used for hallucination detection at sub-sentential level.

3 System Overview

3.1 Self- and cross-model consistency

We generate k alternative responses to the question of the original question answer pair, where $k = 5$ for self-consistency and $k = 20$ for GPT-consistency per sampling configuration. The number of sampling configurations for self-consistency is based on the provided scripts by the shared task organizers in order to stay as close as possible to the setup used to generate the hallucinated answers. This number varies, but at the minimum includes all combinations of temperatures `t = {0.1, 0.2, 0.3}` and nucleus sampling probability `p = {0.90, 0.95}`. The process of generating alternative responses is done using a superior, multilingual model `gpt-4o-mini-2024-07-18` with the set of minimum configurations. During the first iteration of experiments, all alternative responses are included in the threshold calibration and prediction, afterwards, we experiment with fewer alternative responses and analyzing the optimal configuration setting, showing the stability of our approach with down to 5 alternative responses in total (see Appendix C).

3.2 Token consistency scores

We use SimAlign (Jalili Sabet et al., 2020) with XLM-R (Conneau et al., 2020), transformer layer 8, and SimAlign variant *forward* to calculate the token alignments and their corresponding similarity scores $s_{i,1\ldots k}$ for each token i in the answer that is to be evaluated and the aligned token in each alternative answer k. The similarity scores are aggregated across alternative answers by taking their median:

$$s_i = \text{median}\left(s_{i,1}, s_{i,2}, \ldots, s_{i,k}\right).$$

We call s_i the *token consistency score*.

Table 1 shows that we found the *forward* variant of SimAlign to be superior to the *inter* variant for our purposes. Additionally, we experimented with using the mean (first two rows in Table 1) as an aggregation method for the similarity scores, but found the median to be a better fit.

3.3 Threshold calibration

The token consistency scores are then compared to a model-specific threshold to decide whether it is hallucinated or not. The threshold is calibrated based on a calibration set that we split from the shared task's validation dataset. The threshold

value that maximizes the F1-score for detecting hallucinated spans for the training set is chosen for each individual underlying model. All tokens with median similarity score below the threshold are labelled as a hallucination.

3.4 Word-level label derivation

Once the token-level label has been attained, we derive a word-level label by taking the majority vote of the labels of the subword tokens within a word and extrapolate it to the word. Although the gold label annotations are at the character level, we find that word-level predictions outperform predictions below the word level (token) (Table 1). The hard labels are then derived by matching each separate word in order with the whole answer string to find the start and end indices of the hallucinated substrings.

3.5 Baselines

Mark-all As a lower baseline, we use a mark-all approach, where we mark every single character in the answer as a hallucination, as do the organizers of the shared task (Vázquez et al., 2025).

GPT4o zero-shot classification As another baseline, we prompt `gpt-4o-mini-2024-07-18` to detect the hallucinated spans in the answer that is to be evaluated. We experiment with two different prompting techniques: a simple direct prompt and a more elaborate two-step prompt[2] . For all GPT4o-mini generations, OpenAI's structured outputs are used, and all prompts are written in English no matter what the target language is[3].

3.6 Handling of previously unseen languages

The test set contains 4 languages that are not part of the validation set and for which it was not possible to calibrate the threshold directly beforehand. In order to make a prediction for these languages nonetheless, we used the following approaches of adapting thresholds by models and languages that were seen during validation:

1. Taking the threshold of the same model in a different language. If the same model was used for multiple languages, the typologically closer language was chosen. Applied to Catalan, Basque, and Czech.

2. If the model was not seen in the validation set, the threshold was derived by averaging all model-specific thresholds for the typologically closest language. Applied to Farsi.

4 Experimental Setup

4.1 Data

All question–answer pairs containing hallucination spans were provided by the shared task's organizers in the form of a validation and test set.

The validation set contains ~50 question-answer pairs each for 10 languages (Arabic (ar), Chinese (zh), English (en), French (fr), Finnish (fi), German (de), Hindi (hi), Italian (it), Spanish (es), Swedish (sv)). Each data point comes annotated with hard labels that give the start and the end index of a hallucinated span, soft labels that includes the same indices in addition to a hallucination probability value[4], the name of the model used to generate the answer, and the token logits. We split the validation set 50/50 for a train/val split. This split is balanced according to the underlying models.

The test set contains the same annotations apart from the hard and soft labels, which were only provided after the shared task evaluation phase. It contains the same 10 and 4 additional (low-resource) languages that were not part of the validation set (Basque (eu), Catalan (ca), Czech (cs), Farsi (fa)). For each of the original 10 languages, ~150 samples were provided, while 100 samples were provided for the 4 additional languages. More detailed information on the full dataset and the models used to generate the answers is given in Table 4 in Appendix A.

4.2 Evaluation

Two evaluation metrics are considered for this task. Intersection over Union (IoU) is applied to calculate the overlap between the predicted hard labels and the gold annotations, where S_p is the predicted span and S_g is the gold span:

$$\text{IoU} = \begin{cases} 1, & \text{if both } S_g \text{ and } S_p \text{ are empty} \\ \frac{|S_g \cap S_p|}{|S_g \cup S_p|}, & \text{otherwise} \end{cases}$$

The second metric, Spearman's correlation coefficient, is used to evaluate the probability assigned to each hallucinated span in the soft labels. Since we focus on the hard labels in our experiments,

[2]The prompts are attached in Appendix D.

[3]Chollampatt et al. (2025) find that GPT models almost consistently perform better if prompts for multilingual tasks are held in English.

[4]The handling of the soft labels is described in Appendix B.2.

self-consistency	28.3%	30.7%	32.7%	20.7%	28.1%
self-consistency-fv	26.7%	30.5%	33.7%	21.0%	28.0%
rank	8/24	11/26	11/26	12/26	

Table 3: IoU scores for our best-performing approaches per system for each previously unseen language. The rank indicates the rank achieved by the bolded approach in the shared task compared to the best submissions by all participants. -fv indicates that the full validation set was used to calibrate the threshold.

all results for the soft labels are appended in Appendix B.2.

We first evaluate all hyperparameter settings per system on the validation set. Based on those results we choose the best-performing setting for the self- and GPT-consistency approach (Table 1). For each consistency-based approach, we additionally experiment with calibrating the threshold on the full validation set (denoted with -fv in Table 2 and 3).

5 Results and Discussion

5.1 Main results

Table 2 shows the results of our systems and baselines on the test set[5]. We find that on average, our GPT4o-mini prompt-based approaches outperform the rest. Prompt engineering led to a small improvement over a direct prompt. In cases like zh, fr (direct), and sv (direct), however, it fails to beat the lower mark-all baseline.

For zh, fi, and fr we see distinct improvement over prompting when applying GPT-consistency. This discrepancy to the prompt-based approach could indicate that for these languages, GPT4o-mini is able to generate the factual answers to the questions, but cannot locate the spans by itself just as well. While doubling the number of question-answer pairs to find a threshold does improve the performance in some cases (zh, en, fr, hi, it, sv), it performs on average worse than the system based on the original smaller split. The self-consistency results for zh, fi, and fr show competitiveness compared to the prompt-based approach. Furthermore, using the full validation for the self-consistency calculation only leads to an improvement for fr and sv. This indicates some stability to using a small number of samples that are needed for the consistency-based systems to be effective. We append a more detailed analysis of the effect of sample and alternative answer number in Appendix C.

5.2 Previously unseen languages

For the previously unseen, low-resource languages, the results are shown in Table 3. Similarly to the results for the previously seen languages, all of our systems outperform the mark-all baseline on average across all languages. A notable difference here is, however, the clear drop in performance of SC, which could be led back to the missing model and language specific threshold calibration.

The models used for ca and cs were all seen for other languages in the validation set. For eu the majority of answers have been generated with a model that has also been seen in other languages in the validation set. For Farsi a completely new set of models, none of which were seen in the vali-

[5]On average, all systems achieve higher scores on the test set compared to the validation set, while maintaining their relative ranking. There is some system ranking variation for individual languages. Most notably fr and fi, where GPT-consistency surprisingly outperforms the other approaches on the test set.

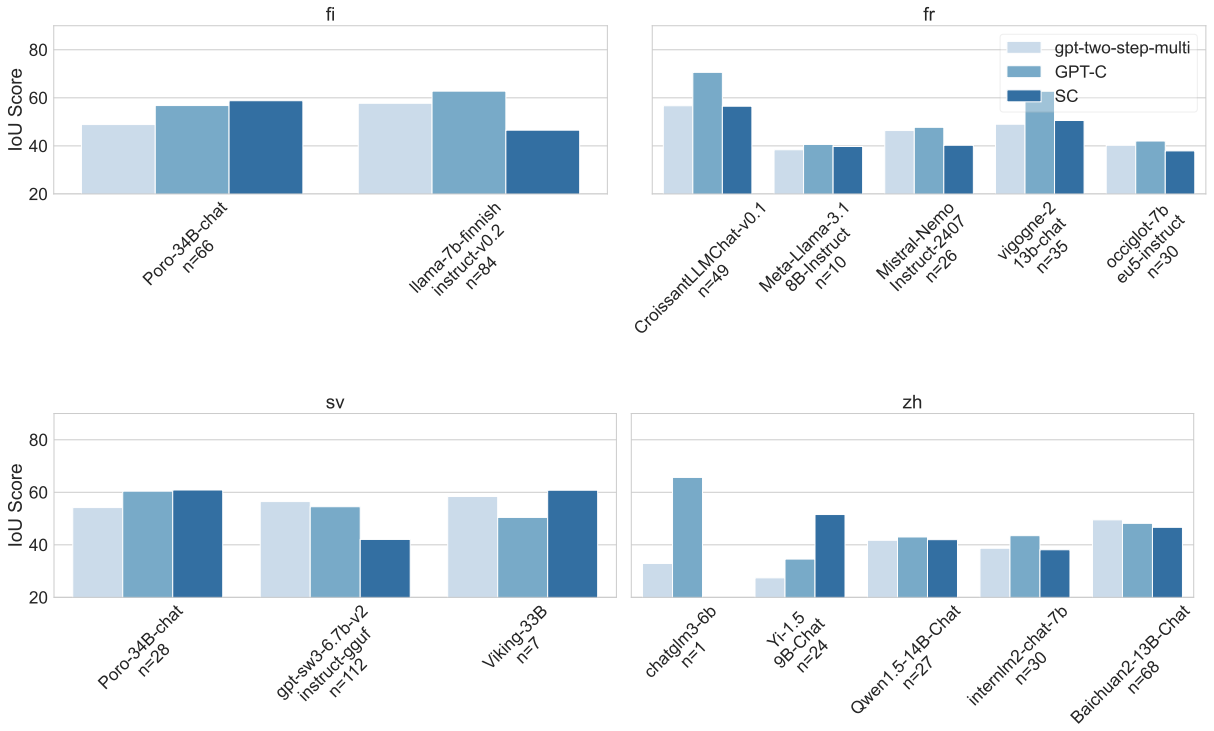

Figure 1: The performance of the zero-shot baseline, GPT-consistency and self-consistency for a subset of languages that were seen during calibration and some of whose underlying model had a parameter size larger than 9B. n indicates the number of samples/answers this statistic is based on.

dation set, have been used to generate the answers that are to be evaluated. Taking this into consideration, we can deduct that the self-consistency based approaches rely highly on the threshold being calibrated for each model specifically, and, to a lesser degree, for the specific language. GPT-consistency seems somewhat more stable in this regard.

5.3 Model-specific scores

An analysis of model-specific performance (Figure 1) reveals that the effectiveness of the above described approaches is not only determined by the given language, but it is also strongly dependent on the underlying model – more specifically, the underlying model's size. For models exceeding 8B parameters, self-consistency almost consistently outperforms the zero-shot baseline. This trend has a particularly strong effect on the overall performance of zh, where a substantial portion of the evaluated responses were generated by large models. Similar trends are seen in fi, fr and sv. In contrast, for smaller models (<8B), GPT-based zero-shot approaches generally perform better. Full insight into the model-specific results is given in Appendix E.

6 Conclusion

In this work, we introduced a (self-)consistency-based approach to hallucination span detection in LLM-generated responses for multilingual question-answering as part of the submission for the *SemEval 2025 Shared Task 3: Mu-SHROOM, the Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes*.

Our method leverages both token-level self-consistency and cross-model consistency with a superior LLM (GPT4o-mini) to identify hallucinated spans. We demonstrated that our methods outperform naive baselines and remain comparable with state-of-the-art approaches for certain languages, even when operating under limited resource constraints. The results indicate that self-consistency is highly dependent on model-and language-specific threshold calibration and that it is most effective when applied to responses generated by larger models (>8B parameters), where it oftentimes outperforms the GPT-based zero-shot baseline. Future work could improve the stability across smaller models by combining self-consistency and GPT-consistency, or extend consistency-based methods to additional generative tasks beyond question-answering.

B Correlation of Hallucination Probability to Gold Annotation

B.1 Predicting the hallucination probability

To predict the hallucination probability of each span we always assign a probability of 1. The correlation between the predicted probabilities and the gold labels is shown in Table 5 for the submitted systems on the validation set.

B.2 Evaluating the hallucination probability

To measure the correlation between the predicted probability values with the gold values for the soft labels, Spearman's correlation was applied, where p_i is the ranked position of the predicted and r_i of the gold probability:

$$\rho = \begin{cases} 1, & \text{if both } \mathbf{r} \text{ and } \mathbf{p} \text{ contain only a single unique value and match} \\ 0, & \text{if one contains a single unique value and the other does not match} \\ 1 - \frac{6\sum(r_i - p_i)^2}{n(n^2-1)}, & \text{otherwise} \end{cases}$$

Method	ar	zh	en	fi	fr	de	hi	it	es	sv	Avg.

Table 5: Spearman correlation scores for our best-performing approaches per system for each language seen in the validation set.

C Stability to a reduced number of alternative responses

One limitation of the consistency-based approaches in the main section is that they require a considerable number of alternative responses, and therefore, computation and time. Hence, we decided to experiment with 5 alternative responses during either the prediction, for threshold generation or both. Additionally, we look at the influence different configuration settings have on the performance. Table 6 shows the results on overlap with gold annotations on the validation split.

When comparing the averages across languages, a small performance degradation is noticeable everywhere. GPT-consistency seems to be more stable across the board, with weaker fluctuation across sampling configurations. None of the averages degrade more than 1.5%. In this regard, self-consistency shows on average stronger fluctuations when changing the sampling configurations for a reduced size of alternative responses, degrading as much as 5.1% (sc-fewer-both; p0.90 t0.1) and even gaining 0.1% (sc-fewer-pred; p0.90 t0.3).

Table 6: IoU results for self-consistency with fewer alternative responses during prediction, thresholds calibrated with fewer alternative responses or both in comparison to using all alternative responses for both calibrating the threshold and prediction.

D Prompts for the Zero-Shot GPT4o-mini Baseline

We use GPT4o-mini as a zero-shot baseline with the following two prompts:

Method	Prompt
Direct prompt	**System Prompt:** "You will be given a question-answer pair. The answer might contain spans that are counterfactual. You will output the counterfactual spans. Note that the answers can also be fully counterfactual or not at all."
	User Prompt: "Question: {model_input}. Answer: {model_output}."
Two step prompt	**User Prompt (Alternative Answer):** "Answer the following question with five possible answers: {model_input}."
	System Prompt: "You will be given a question-answer pair. The answer might contain spans that are counterfactual. You will also be given multiple other possible answers. Based on these other possible answers, output the spans from the answer of the initial question-answer pair that are counterfactual. Note that the answers can also be fully counterfactual or not at all."
	User Prompt: "Question: {model_input} Answer: {model_output} Other possible answers: {alternative_answer}."

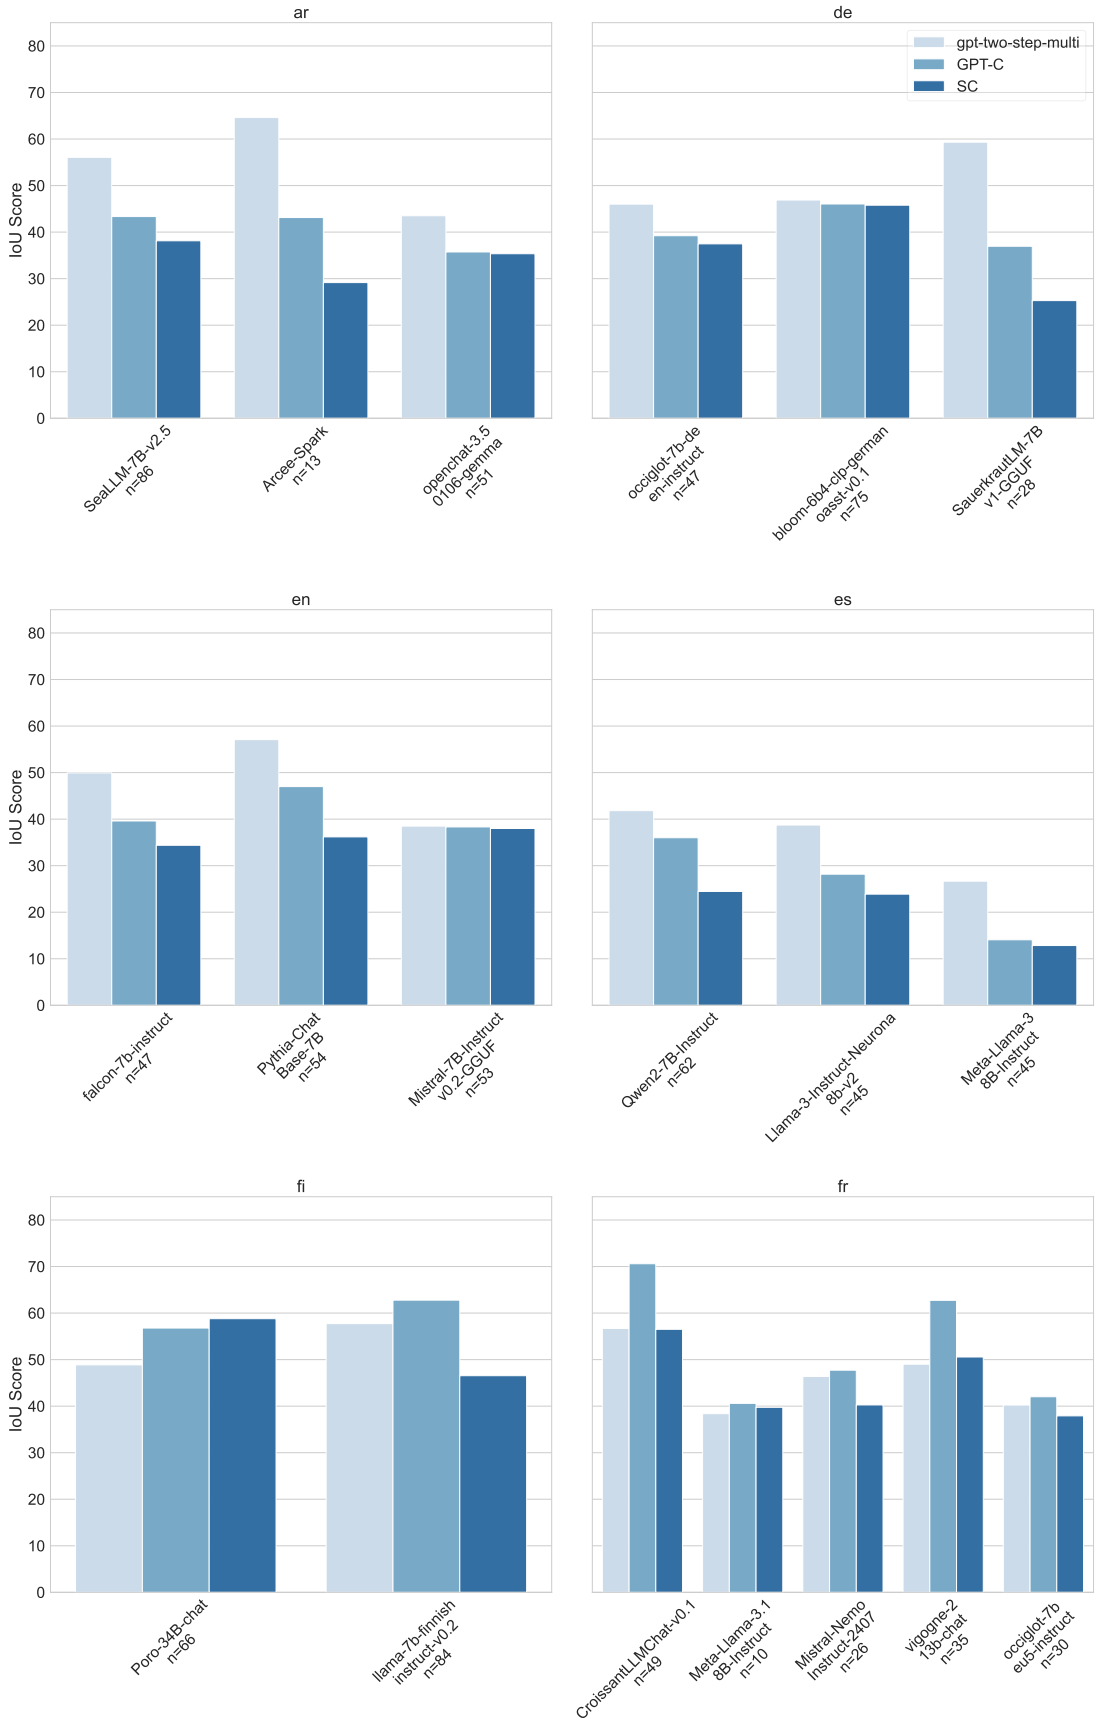
E Model-specific analysis



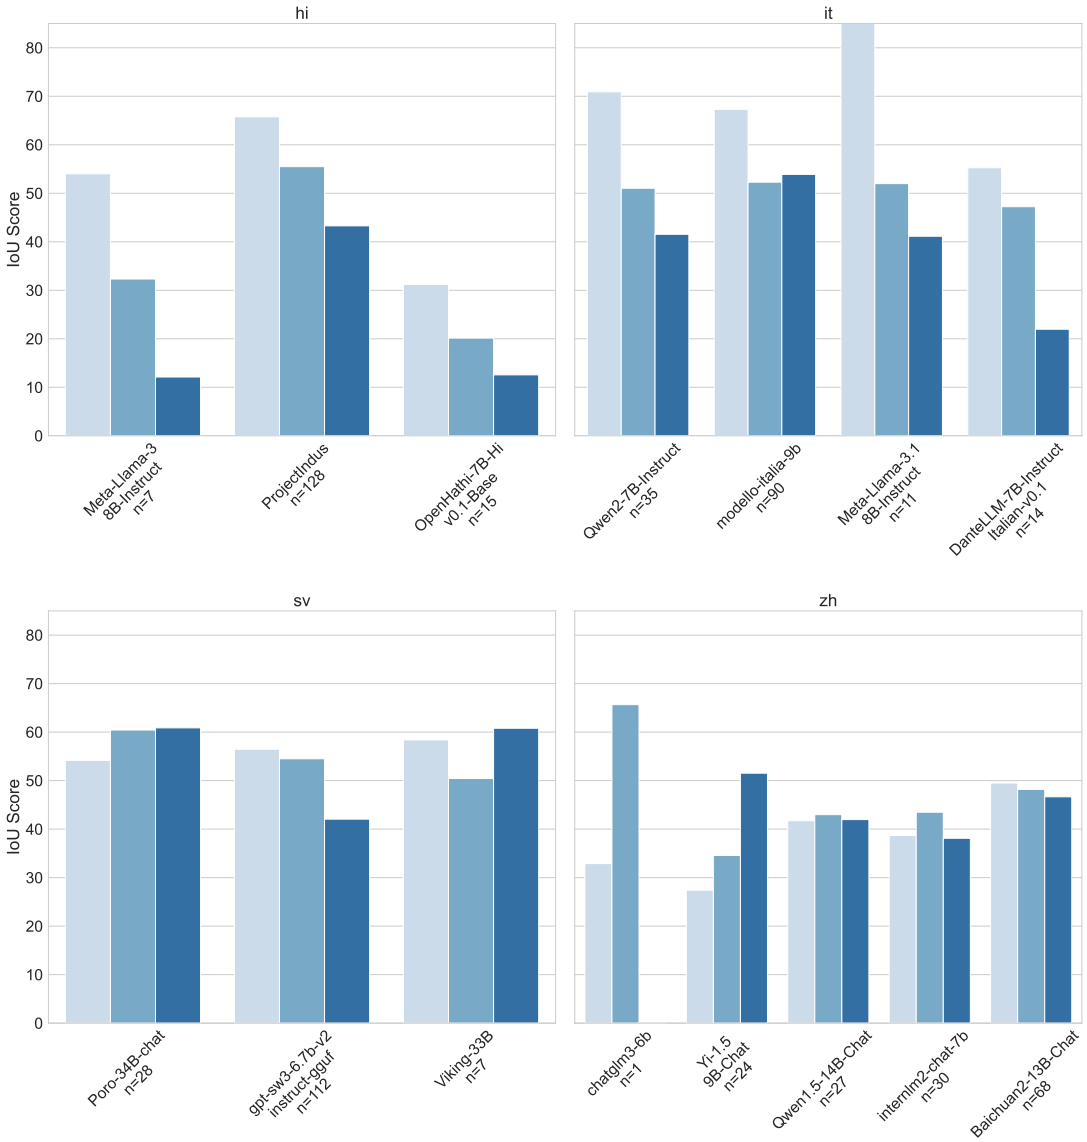


Figure 2: The performance of the zero-shot baseline, GPT-consistency and self-consistency for each language that was seen during calibration and model used to generate the answers that are to be searched for hallucinations. n indicates the number of samples/answers this statistic is based on.

A comparison of hallucination detection performance across different approaches, languages, and model architectures (Figure 2) suggests that the effectiveness of a given method is not solely determined by the target language but is also influenced by the model that generated the evaluated text.

Notably, GPT-based approaches tend to outperform self-consistency when the underlying model is relatively small ($\leq$8B parameters). However, for larger models ($>$8B parameters), self-consistency consistently surpasses the zero-shot baseline. This observation may explain SC's relatively strong performance for zh, as roughly 4/5 of the Chinese evaluation data was generated by models exceeding 8B parameters. The same trend can also be observed in sv, it, fi and fr.

Figure 3 shows similar and consistent behavior for the smaller underlying models of the unseen languages during threshold calibration. Only for fa, models with a parameter size $>$9B were used, but since none of those were seen during calibration for the other languages, SC' performance also degrades for the 35B model.

This model-specific analysis is to be interpreted with caution due to the small and imbalanced sample sizes. To make more certain, claims the experiments would have to be repeated on a larger dataset.

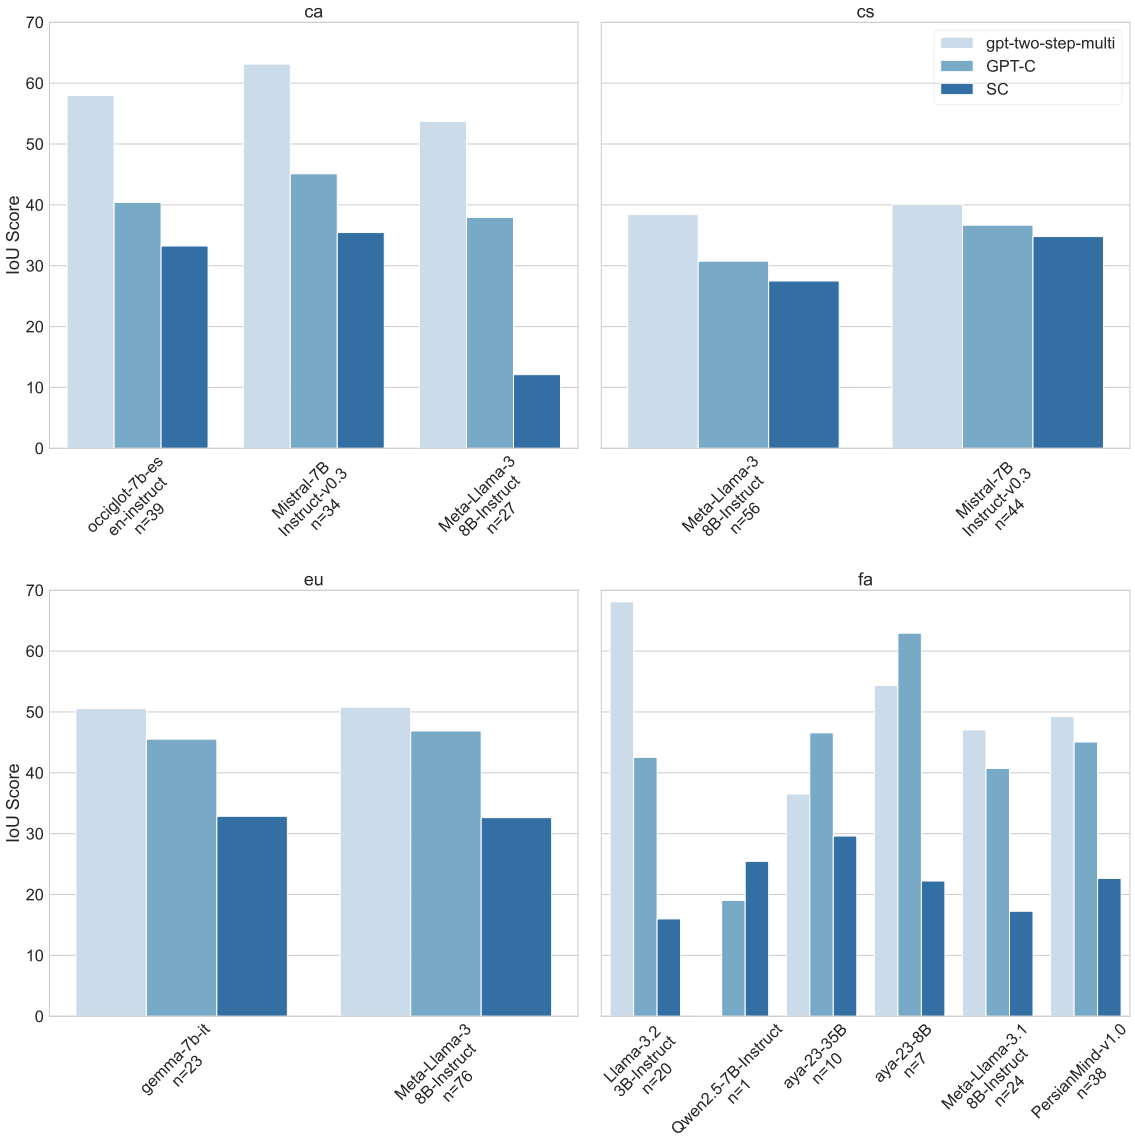

Figure 3: The performance of the zero-shot baseline, GPT-consistency and self-consistency for each language that was *not* seen during calibration and model used to generate the answers that are to be searched for hallucinations. n indicates the number of samples/answers this statistic is based on.

NCL-UoR at SemEval-2025 Task 3: Detecting Multilingual Hallucination and Related Observable Overgeneration Text Spans with Modified RefChecker and Modified SelfCheckGPT

Abstract

SemEval-2025 Task 3 (Mu-SHROOM) focuses on detecting hallucinations in content generated by various large language models (LLMs) across multiple languages. This task involves not only identifying the presence of hallucinations but also pinpointing their specific occurrences. To tackle this challenge, this study introduces two methods: Modified-RefChecker (MRC) and Modified-SelfCheckGPT-H (MSCGH). MRC integrates prompt-based factual verification into References, structuring them as claim-based tests rather than single external knowledge sources. MSCGH incorporates external knowledge to overcome its reliance on internal knowledge. In addition, both methods' original prompt designs are enhanced to identify hallucinated words within LLM-generated texts. Experimental results demonstrate the effectiveness of the approach, achieving a high ranking on the test dataset in detecting hallucinations across various languages, with an average IoU of 0.5310 and an average COR of 0.5669. The source code used in this paper is available at https://github.com/jianfeixu95/NCL-UoR.

1 Introduction

Large language models (LLMs) have significantly advanced in producing human-like text across various domains (Xiong et al., 2024; Zhao et al., 2024). However, one critical challenge remains: hallucinations—instances where the generated output contains logical inconsistencies, factual inaccuracies, or irrelevant information (Goodrich et al., 2019). These issues are particularly prominent in multilingual settings, where linguistic differences, cultural context, and the availability of external resources introduce additional complexities (Guerreiro et al., 2023). To address this issue, SemEval-2025 Task-3: the Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes (Mu-SHROOM) (Vázquez et al., 2025) was introduced. This task involves identifying hallucinated text spans in LLM-generated outputs across multiple languages and LLMs.

To tackle this task, this work modifies two state-of-the-art methods: RefChecker (Hu et al., 2024) and SelfCheckGPT (Manakul et al., 2023). RefChecker detects fine-grained hallucinations by extracting claim triplets (subject, predicate, object) from LLM outputs and comparing them with prebuilt reference data, using text classification and aggregation rules. However, it cannot precisely locate hallucination positions and relies on fixed and incomplete references. The proposed modified RefChecker improves upon this by introducing prompt-based fact verification, structuring references as claim-based tests for greater flexibility, and enhancing hallucination detection by calculating hallucination probabilities and providing soft and hard labels for more precise analysis.

SelfCheckGPT detects hallucinations by prompting the same LLM for multiple responses and identifying inconsistencies. However, reliance on internal knowledge may fail when hallucinations are consistent. To address this, we modify SelfCheckGPT by incorporating external knowledge and enhancing the prompt design to identify specific hallucinated words rather than only their presence.

Overall, unlike the original RefChecker and SelfCheckGPT, which rely on static references and internal prompt-based self-consistency, respectively, our modified methods incorporate external knowledge retrieval and prompt-driven span-level verification to improve hallucination detection accuracy and granularity.

2 Related Work

Most recent approaches to detecting hallucinations in LLM outputs rely on prompting techniques, where the models evaluate the likelihood of hallucinations in their responses. For instance, Ka-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 271–279

davath et al. (2022) proposed prompting LLMs to generate an answer and then predict the probability of its correctness. Manakul et al. (2023) introduced SelfCheckGPT, which compares an LLM-generated sentence against multiple alternative generations, asking the model to assess whether the original sentence is consistently supported. Friel and Sanyal (2023) presented ChainPoll, using detailed prompts to guide models in identifying hallucinations. Hu et al. (2024) proposed RefChecker, a retrieval-augmented evaluation method that checks the consistency of model outputs against retrieved external references, aiming to identify factual inconsistencies and hallucinations without relying solely on LLM self-judgment. However, most existing methods focus on detecting whether a text contains hallucinations or not. Identifying the specific parts of a text that are hallucinations remains an open research challenge. Therefore, in this work, we modified RefChecker and SelfCheckGPT, two state-of-the-art methods to handle this task.

3 Methodology

3.1 Modified-RefChecker (MRC)

MRC is an improved RefChecker, integrating CLAUDE (Anthropic, 2022) for enhanced functionality. Note that any LLM, including open-source ones, can be substituted. However, to ensure consistent and scalable evaluation, we adopt CLAUDE due to its multilingual support, API stability, and superior performance compared to open-source models in the original RefChecker (Hu et al., 2024). MRC consists of two key components: the Extractor for constructing references and the Checker for identifying hallucinated words along with their probabilities. Figure 1 shows the overview of MRC. The details of each component are described below.

Extractor Component This component retrieves external knowledge using keywords or keyphrases through the Google CSE (Custom Search Engine) API (Esraa Q. Naamha, 2023) (summarized search websites) and extracts claims from LLM responses, structured as triplets (subject, predicate, object), to form factual references. The extraction of claims utilizes the prompt design from RefChecker's Extractor (Hu et al., 2024) and is implemented using the Anthropic API (Anthropic, 2022). However, the verification and refinement of claims are also conducted through the CLAUDE API, with the prompt design as in Appendix A (Figure 5).

Checker Component The Checker component evaluates hallucinated words and their probabilities in the model output by validating them against references using prompts. The prompts guide the classification of hallucinations and define their probabilities. The prompt design is as in Appendix A (Figure 6). With the support of CLAUDE API (Anthropic, 2022), the results from Checker are mapped to the LLM output text, highlighting hallucinated words and generating soft labels and hard labels. Soft labels are based on the detected hallucination probabilities, while hard labels are determined by a threshold of 0.5 (probabilities > 0.5 are marked as hallucinations).

3.2 Modified-SelfCheckGPT-H (MSCGH)

MSCGH is based on the method proposed by Markchom et al. (2024). It consists of 4 steps: keywords/keyphrases extraction, context retrieval, prompt construction and hallucination detection. Figure 2 shows an overview of MSCGH. The details of each step are discussed in the following.

Keywords/Keyphrases Extraction To generate a context for each LLM output text, keywords/keyphrases in the input text are first identified. In this work, YAKE (Yet Another Keyword Extractor) (Campos et al., 2020) is adopted to extract keywords across multiple languages, as it is domain- and language-independent. However, some languages are not covered by this method. Therefore, to improve keyword extraction in different languages, Hugging Face models are used for specific languages to identify named entities, while SpaCy facilitates tokenization and stop word removal. A summary of the tools and models used is shown in Appendix B (Table 1). Furthermore, GPT-3.5 was also applied to directly extract keywords/keyphrases from the LLM input text.

Context Retrieval To retrieve a context based on each extracted keyword WikipediaAPI[1] (MediaWiki, 2024) and Google CSE API (Esraa Q. Naamha, 2023) are considered. These resources are chosen for their popularity and capability to provide reliable context (Trokhymovych and Saez-Trumper, 2021). Once contexts for individual keywords are retrieved, they are concatenated to form a complete context for the LLM output text.

Prompt Construction Two prompt designs for identifying hallucinated words are explored.

[1] https://pypi.org/project/Wikipedia-API/

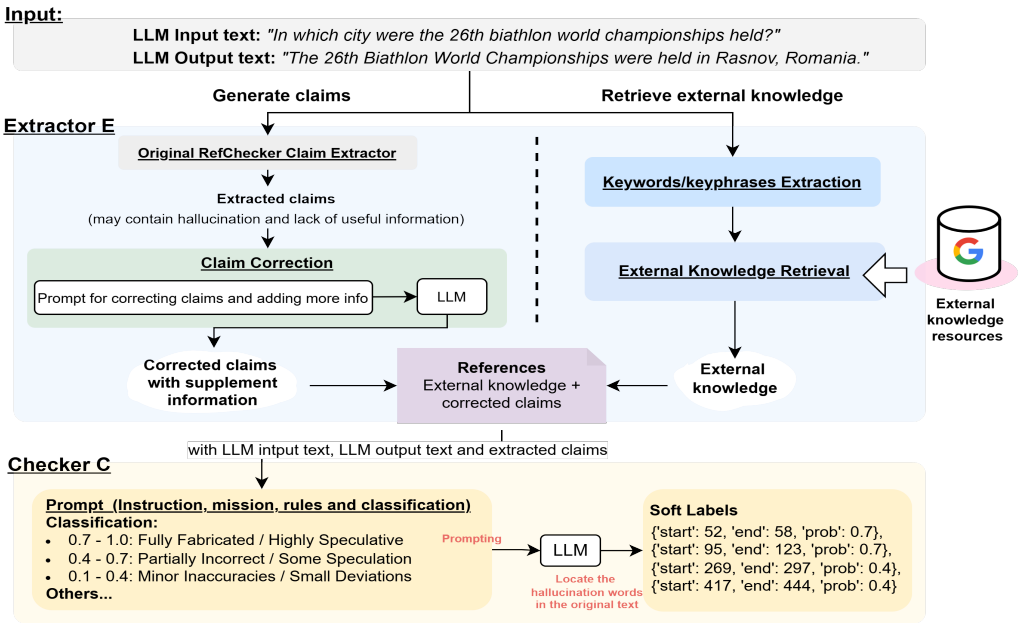

Figure 1: Overview of MRC

Prompt 1, adapted from SelfCheckGPT, is a simple prompt that asks an LLM to identify hallucinated words without specific instructions. Prompt 2, designed to identify hallucinated words, categorizes hallucination types and assigns probabilities while defining detection scope and output conditions. Compared to Prompt 1, it imposes stricter constraints to reduce unnecessary results (Rashkin et al., 2021). By directly classifying hallucinations and modeling probability distributions, it mitigates misalignment issues in LLM-generated text, improving detection accuracy and consistency.

Hallucination Detection To detect hallucination words, an LLM (this work considers GPT-3.5, GPT-4 and GPT-4o following the original methodology of using GPT models in SelfCheckGPT (Manakul et al., 2023).) is used to answer the prompt created in the previous step for each LLM output text. For each response, the hallucination words are identified, and a list of index intervals indicating the positions of these words in the LLM output string, $\mathcal{L} = \{L_1, L_2, \ldots, L_n\}$, is obtained. Then, all overlapping and adjacent intervals across all N responses are merged into a set of distinct, non-overlapping intervals $\mathcal{M} = \{(s_1, e_1), (s_2, e_2), \ldots, (s_m, e_m)\}$.

The soft probabilities for each merged interval are computed differently depending on the prompt used (Prompt 1 or Prompt 2). For Prompt 1, the probability of each merged interval (s_i, e_i) is computed by $p(s_i, e_i) = \frac{1}{n}\sum_{k=1}^{n} \frac{o_{i,k}}{e_i - s_i}$, where $o_{i,k}$ is the total overlap between the merged interval (s_i, e_i) and the intervals in the list L_k and $e_i - s_i$ is the length of the interval.

Prompt 2 detects the probabilities of hallucinated words. However, in the repeated N times process, the probabilities need to be recalculated, leading to the introduction of the following formula: $p(s_i, e_i) = \left(\frac{\sum_{k=1}^{n} o_{i,k} \cdot p_k}{\sum_{k=1}^{n} o_{i,k}}\right)^{1.2}$, where p_k is the probability of hallucination for each interval in the n responses, which is combined with the overlap length $o_{i,k}$ to calculate the weighted average probability. The exponent 1.2 introduces nonlinearity, giving higher importance to intervals with frequent overlaps and improving the accuracy of hallucination detection. All merged intervals in $\mathcal{M}$, along with their probabilities, serve as soft labels. Hard labels are obtained by selecting the intervals in $\mathcal{M}$ with probabilities higher than a predefined threshold, which is set to 0.5 in this work.

4 Datasets and Experimental Setup

Dataset The datasets used in this study are provided by the organizers of Mu-SHROOM. The validation set, which contains annotated labels, was used for model development and tuning. In the final experiments, the test set was employed to comprehensively evaluate the performance of the models. The validation set includes data in 10 languages, along with LLM input texts, LLM-generated texts, LLM tokens, corresponding logit values, and hallucination annotations in the form of soft and hard

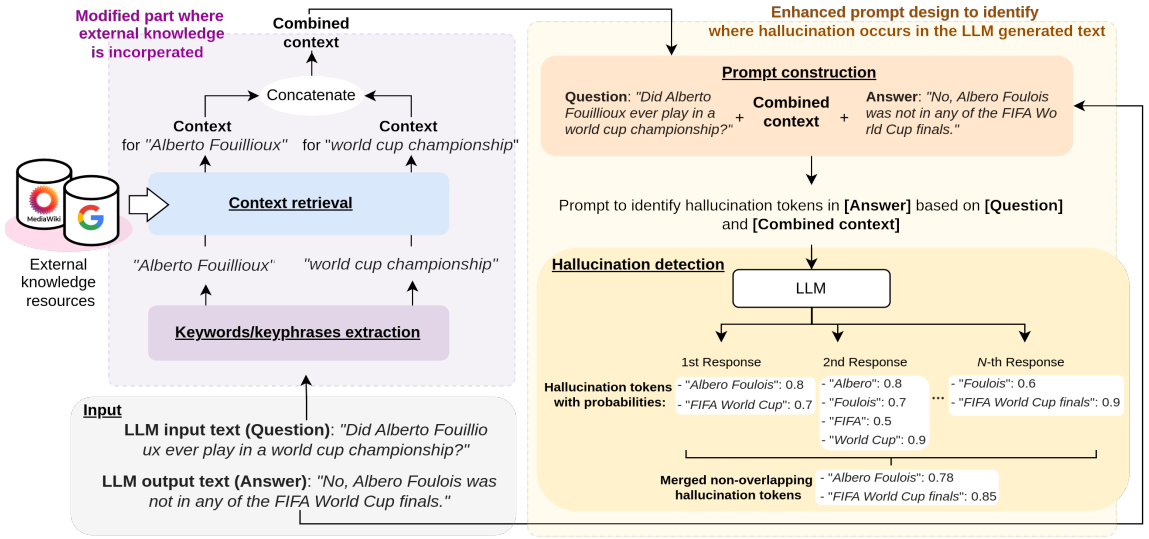

Figure 2: Overview of MSCGH

labels, indicating both the locations and probabilities of hallucinations. The test set contains data in 14 languages. The models were evaluated independently for each language to ensure a comprehensive assessment across multilingual data.

Method Selection Initially, evaluation was conducted on MRC and five variations of MSCGH , each utilizing different keyword extractors, context retrieval tools, prompt designs, and LLMs for hallucination detection (as discussed in Section 3.2). This resulted in six different models, each applied to 14 languages, for a total of 84 experiments. The details of these methods and their performance results can be found in Appendix C. Each model is assigned a Submitted Identifier, which corresponds to the Identifier submitted on the official website[2]. Based on the performance, the three best methods were selected for discussion: (1) **MRC_CLAUDE_CSE_A**: MRC using GPT-3.5 for keyword extraction, Google CSE API (abstract only) for context retrieval, and CLAUDE for hallucination detection. (2) **MSCGH_GPT_CSE_F**: MSCGH using GPT-3.5 for keyword extraction, full Google CSE API results, and GPT-4o for hallucination detection ($N = 5$). (3) **MSCGH_GPT_WIKI_A**: MSCGH using custom rules for keyword extraction, first 200 characters Wikipedia API results, and GPT-4o for hallucination detection ($N = 5$).

Evaluation Metrics The metrics provided by the organizers were used: **Intersection-over-Union (IoU) of Characters**: Measures the overlap between hallucinated characters marked in the gold reference and those predicted by the system, and **Probability Correlation**: Assesses how well the probability assigned by the system for a character being part of a hallucination correlates with the probabilities observed in human annotations.

Baseline Three baselines were provided in the task (Vázquez et al., 2025): (1) Baseline (neural): Fine-tuning of the neural network classifier based on XLM-R, outputting binary (0/1) probability predictions for each token, (2) Baseline (mark-all): Predicting all characters as hallucinations ($probability = 1$), and (3) Baseline (mark-none): Predicting all characters as non-hallucinations ($probability = 0$).

5 Results and Discussions

Overall comparison of the proposed methods The comparative results of our methods and the baselines are shown in Figures 3a and 3b. From these figures, the neural and mark-none baselines performed the worst across all languages, while the mark-all baseline achieved slightly higher IoU but nearly zero COR scores. In contrast, our method outperformed these baselines in all languages, with average improvements of approximately 0.30 in IoU and 0.45 in COR. More importantly, according to the 100,000 bootstrap resamplings mentioned in (Vázquez et al., 2025), our submitted methods achieved a $Pr(rank)$ above 0.5 in every language. This indicates a higher probability of outperforming the next-best team in the majority of samples,

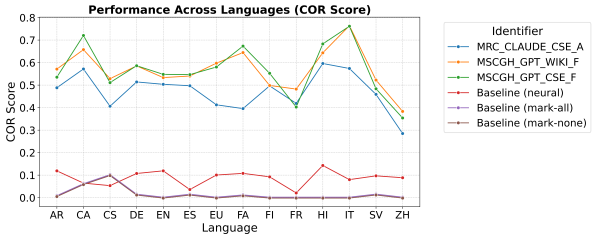
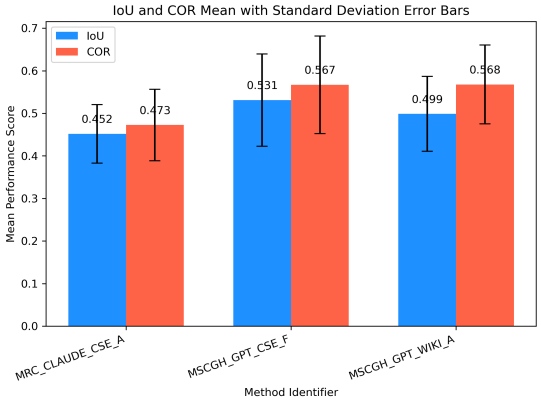
(a) Performance Across Languages (IoU Score)



(b) Performance Across Languages (COR Score)



(c) Methods Performance and Stability Comparison

Figure 3: Performance Across Languages of Methods

and thus demonstrates robust and consistent cross-lingual performance.

Across multiple languages, our models exhibited distinct performance differences, as shown in Figure 3. MSCGH_GPT_CSE_F consistently led, benefiting from more effective keyword extraction, comprehensive external knowledge retrieval, and stronger hallucination detection. Its broader retrieval strategy provided an advantage in handling ambiguous or multi-step queries. MSCGH_GPT_WIKI_A followed closely, particularly excelling in Chinese results, where complex segmentation and word relationships were better handled through its customized keyword extraction. MRC_CLAUDE_CSE_A, while still effective, showed greater variance across languages, likely due to less optimized retrieval strategies or weaker hallucination detection.

Figure 3c presents the average IoU and COR scores across all languages, illustrating the overall performance and stability of the three methods. MSCGH_GPT_CSE_F achieved the highest IoU and COR scores, while MSCGH_GPT_WIKI_A performed similarly to MRC_CLAUDE_CSE_A. However, MSCGH methods exhibited larger error bars, indicating greater variability and less stability. The fluctuations in MSCGH may stem from differences in knowledge retrieval and prompt design. In contrast, MRC demonstrated more consistent performance, suggesting its higher stability.

Comparison of knowledge retrieval methods In Figure 3c, MSCGH_GPT_CSE_F outperformed MSCGH_GPT_WIKI_A. This could be attributed to differences in external knowledge resources and the precision of keyword extraction. GPT-3.5, as a keyword extraction tool, likely understood the context of questions better and extracted more precise and relevant keywords for retrieval. In contrast, custom rules had limitations in generalization and contextual understanding. They relied on specific language resources, which were limited in scope. This could affect the accuracy of keyword extraction and subsequently reduce the relevance and coverage of retrieved information. Besides keyword extraction, knowledge resources also played a vital role. The Google CSE API encompassed the Wikipedia API and extended beyond it, providing broader search coverage through a customizable search engine (Esraa Q. Naamha, 2023). Additionally, retrieving full-page content via the Google CSE API could yield better results than retrieving only abstract content, as suggested by MSCGH_GPT_CSE_F's superior performance over MRC_CLAUDE_CSE_A. Overall, both keyword extraction accuracy and knowledge coverage influenced model performance. This highlights the importance of optimizing external knowledge extraction methods to improve detection outcomes.

Comparison of prompted LLMs for hallucination detection Figure 4 compares different LLMs. In this figure, each model is represented with bars showing the IoU and COR scores for individual languages. The grey bar behind each model's score bars indicates the average IoU and COR scores for that model. From this figure, CLAUDE performed the worst, while GPT-4o showed significant improvements. However, not all GPT-4o-based methods outperformed CLAUDE, indicating that LLM upgrades alone do not guaran-

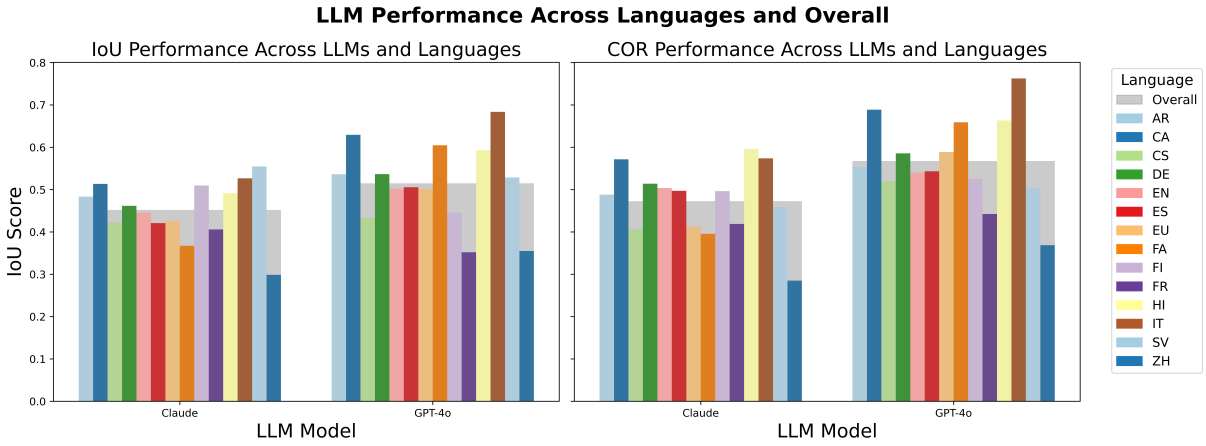


Figure 4: LLM Performance Across Languages and Overall

tee better results—effective knowledge retrieval remained essential. Performance gaps between LLMs were more pronounced in high-resource languages (e.g., Italian), where GPT-4o significantly outperformed CLAUDE. In contrast, for low-resource languages (e.g., Arabic), GPT-4o's benefits were inconsistent—some methods showed only marginal gains, while those using the Google CSE API achieved substantial improvements. This underscored the critical role of external knowledge integration in maximizing LLM performance.

6 Conclusion

SemEval-2025 Mu-SHROOM introduced the task of detecting hallucination spans in multilingual LLM outputs. To tackle this task, this work proposed two methods: Modified-RefChecker (MRC) and Modified-SelfCheckGPT-H (MSCGH). These methods incorporated external knowledge integration and an improved prompt design, enabling the detection of text-span hallucinations in LLM-generated texts. MRC and variations of MSCGH (with different keyword extraction techniques, external knowledge sources, and prompt strategies) were evaluated across datasets in 14 languages. Three top-performing methods were chosen for discussion in this paper. Among the evaluated methods, MSCGH using GPT-3.5 for keyword extraction, full Google CSE API results, and GPT-4o for hallucination detection achieved the best overall performance. Although MSCGH demonstrated higher performance, it lacked stability when applied across different languages. Meanwhile, MRC was more stable but less optimized. One limitation of the proposed approaches is the assumption that external knowledge is accurate. However, the retrieved information may not always be fully factual due to the ever-growing volume of online content. Such inaccuracies could reduce the effectiveness of the proposed approaches. Future research could focus on refining the prompt design and enhancing external knowledge integration and faulty correction strategies. Additionally, adaptive learning for low-resource languages and broader language task expansion could be considered.

Prompt

System Task: Please expand, provide additional relevant factual information and verify about the following claim
Claims: {claims}
- If the claim is accurate, not hallucination and complete, return the original claim.
- If the claim is inaccurate, partial, or lacking detail, return a corrected, more detailed, and comprehensive factual statement.

Figure 5: Claims Correction Prompt for the Extractor Component of MRC

Prompt

System Task: Evaluate the model output text for hallucinations by comparing it to the provided references, existing fact, claims, and question (model input). Identify any hallucinated or potentially inaccurate parts in the entire model output text. Highlight the hallucinated word and assign a probability of the hallucination word in the 'model_output_text'.
LLM input text: {LLM input text}
Claims: {claims}
References: {references}
LLM output text: {LLM output text}
Instructions
1. Compare each claim with the provided references, question and existing fact (internal knowledge).
2. If a claim cannot be fully supported by the references, identify the hallucinated words and mark it to 'model output text'.
3. Return character-level offsets and assign hallucination probabilities.
4. If the claim is fully supported, hallucination should not to be labeled.
5. Assign hallucination probabilities based on the following criteria:
- 0.7 - 1.0: Fully fabricated or highly speculative content with no supporting evidence.
- 0.4 - 0.7: Partially incorrect or speculative content, but some evidence supports parts of the claim.
- 0.1 - 0.4: Minor inaccuracies, such as spelling errors, wrong formatting, or small factual deviations.
6. Ensure that the hallucinated words do not overlap or repeat. If overlapping occurs, merge them or separate them appropriately.
7. Ensure the words are shown in the 'model output text'.
8. Highlight text in 'model output text' that could potentially be a hallucination even if not explicitly listed in the claims.
9. Return all the hallucinated words or phrases and assign each a hallucination probability (between 0 and 1).
10. Do not filter out hallucinations based on low probability. Return results for any potential hallucination.
11. Do not include any explanations, summaries, or additional text. Return the JSON list directly.
12. Ensure all potential hallucinations are listed, even those with probabilities as low as 0.1.

Figure 6: Prompt for the Checker Component in MRC

Prompt 1

Context: {combined context}
Sentence: {LLM output text}
Which tokens in the sentence are not supported by the context above? Provide the answer in the form of a list of hallucination tokens separated by 'l' without accompanying texts.

Figure 7: Prompt 1 for the Hallucinations Detection in MSCGH

Prompt 2

Language: {language}
Question: {LLM input text}
Sentence: {LLM output text}
Context (if available): {context}
Task
You are an AI model output evaluation expert, responsible for detecting hallucinated words in model output and assigning accurate probability scores to each hallucination.
1. Identify hallucinated words or phrases in the model output based on the question and background knowledge.
- A word or phrase is considered a hallucination if it:
- Contradicts the background knowledge.
- Is unverifiable or fabricated.
- Contains logical inconsistencies.
2. Assign a probability score to each hallucinated word or phrase according to the following criteria:
- Probability > 0.7: Severe factual errors or contradictions.
- Probability 0.5 - 0.7: Unverifiable or speculative content.
- Probability 0.3 - 0.5: Minor inconsistencies or unverifiable details.
- Probability 0.1 - 0.3: Minor inaccuracies or vague ambiguities.
- Do not label words with probability ≤ 0.1 (i.e., verifiable facts).
Additional Instructions
- Do not mark redundant or overly generic words (e.g., "the", "a", "and") as hallucinations unless they introduce factual errors.
- Pay special attention to:
- Numerical data (e.g., dates, quantities, percentages).
- Named entities (e.g., people, organizations, locations).
- Logical contradictions (e.g., self-contradictions within the text).
- If background knowledge is absent, base your judgment solely on internal consistency.

UniBuc at SemEval-2025 Task 9: Similarity Approaches to Classification

Marius Micluța-Câmpeanu
Interdisciplinary School of Doctoral Studies, University of Bucharest, Romania
marius.micluta-campeanu@unibuc.ro

Abstract

In this paper, we present a similarity-based method for explainable classification in the context of the SemEval 2025 Task 9: The Food Hazard Detection Challenge. Our proposed system is essentially unsupervised, leveraging the semantic properties of the labels. This approach brings some key advantages over typical classification systems. First, similarity metrics offer a more intuitive interpretation. Next, this technique allows for inference on novel labels. Finally, there is a non-negligible amount of ambiguous labels, so learning a direct mapping does not lead to meaningful representations.

Our team ranks 14th for the second sub-task. Our method is generic and can be applied to any classification task.

1 Introduction

As people become more aware of the health risks associated with the global food industry, there is a growing interest to ensure the safety and quality of these products. The complexity of modern food supply chains, which involve multiple stages of production, processing, and distribution, has made it increasingly difficult to monitor and control food safety hazards. In this context, natural language processing (NLP) tools lend themselves invaluable to identifying patterns and extracting information from heterogeneous data sources.

The main goal of the Food Hazard Detection Challenge is to explore the explainability of classification systems on texts associated with food safety risks. The dataset consists of food-incident reports collected from various sources written in English, representing a subset of a larger dataset created by the organizers that also includes texts in German and a few instances in four other languages (Randl et al., 2024). The first task requires systems to predict coarse-grained categories for hazards and products, while the second task is focused on determining the exact hazard and product (Randl et al., 2025). We participated only in the second sub-task to explore the viability of similarity methods.

The dataset reports contain a title, the full report text and other details such as date and country. Since the title does not always contain adequate information about products or hazards, we also add the full text as input to our system, ignoring the other features. Next, we use a large language model (LLM) to clean up this text. For classification, we employ cosine similarity between each clean text and every label (Schütze et al., 2008, p. 121) without any training step. In the case of hazards, we also apply lemmatization on each word and reorder the labels by importance and specificity (detailed in Section 3).

Beside data cleaning, our biggest challenge was to decide how to handle ambiguous labels. Even though this dataset design choice appears to be intentional (Randl et al., 2024), we believe that the addition of almost identical classes could have been avoided, at least to some extent. We settled for a similarity-based approach because this should aid the explainability of the system and it also eliminates the challenge of heavily imbalanced data.

We note that many of our wrong predictions were affected by label overlap. Our team ranked 14th out of 26 teams. Our system is unsupervised, employing small models and needing modest resources, while also allowing for easy interpretation. Our code is publicly available[1].

2 Related work

Document similarity Information retrieval relies extensively on cosine similarity for document classification (Chen et al., 2009). More recently, Schopf et al. (2023) propose baselines for unsupervised text classification and show that similarity-based approaches using sentence Transformers are

[1] https://github.com/mcmarius/SemEval-2025-Task-9

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 280–287

suitable for text classification of unseen classes and outperform zero-shot methods.

Label semantics Another line of work intended to overcome issues related to noisy data is label refinement, a process that aims to reduce ambiguity and uncertainty of labels. Song et al. (2023) provide an overview of the challenges associated with learning from noisy labels, underlining that robust learning methods used to overcome label noise are not designed to deal with extreme cases of data imbalance.

Chu et al. (2021) use k-means clustering of labels for dataless classification, showing improvements on unbalanced datasets and robustness in terms of label description choice. In their experiments, the datasets used have at most 20 classes. Huang et al. (2024) re-rank the predictions of hard samples based on similarity, while Dong et al. (2024) perform re-ranking with a separate model that receives refined labels.

To the best of our knowledge, our approach is different from existing techniques in the literature, as these previous efforts typically rely on a training step. They also either do not require fixed labels or do not perform label reordering.

3 System overview

Our system consists of two independent pipelines for hazard and product classification. Each pipeline has a data cleaning step, a pre-processing step and a classification step, optionally followed by a post-processing step, as shown in Figures 1 and 2. There is no training or fine-tuning involved.

3.1 Data cleaning

Since the title does not always specify the hazard or the product, we need to look up this information in the full article. This raw text may contain duplicate lines, HTML markup and a lot of instructions for consumers that are irrelevant for us. We want to remove as much noise as possible to provide downstream steps with useful data and to reduce the context size of LLM prompts.

First, we remove duplicate lines. For hazards, we apply custom-made regex rules, with a catch-all match that only keeps longer lines. Then, we remove HTML tags if present. Finally, we keep only the first 3000 characters. The resulting text preceded by the title is fed to a LLM that is tasked to extract the hazard or the product, including a short description of that entity. See Appendix A for the prompts used.

3.2 Pre-processing

In this stage, we remove task-specific stop-words by analyzing the classification mistakes, such as "product", "category", and "food". These words are not specific to a particular class, while others are artifacts of LLM extraction.

In the case of hazards, we also perform lemmatization on texts and labels, a common approach in information retrieval. Perhaps surprisingly, this did not lead to improved results for products. One possible explanation is due to the nature of product names (e.g. brand names) that might be less amenable to lemmatization, though this needs further investigation, since we also include product descriptions specifically to mitigate such issues.

3.3 Similarity classification

We model the classification task as a similarity search problem, assigning the label with the highest cosine similarity between the embedded text and the embedded label. The reason for also asking the LLM in Section 3.1 to include a description is to aid this search by including more common terms along commercial or highly specific names.

3.4 Post-processing

There are several instances where an incident report contains multiple distinct problems. We need to decide which hazard should be prioritized, since the task is modeled as single-label classification. The following example (training set, ID 120) can be characterized by both "allergens" ("walnut") and "fraud" ("mislabelled" – gold label) categories:

> Has been mislabelled and may contain walnuts which may pose a health risk to people allergic to walnuts.

In such a case, we first prioritize the category that poses a greater risk (allergens), since this is the most critical facet. Next, if there are multiple issues within the same category, we pick the most specific hazard ("walnut" instead of "allergens"), thus prioritizing risk over specificity. To determine this priority, we pre-compute these lists by sorting by importance and specificity using a LLM. This process is detailed in Appendix B.

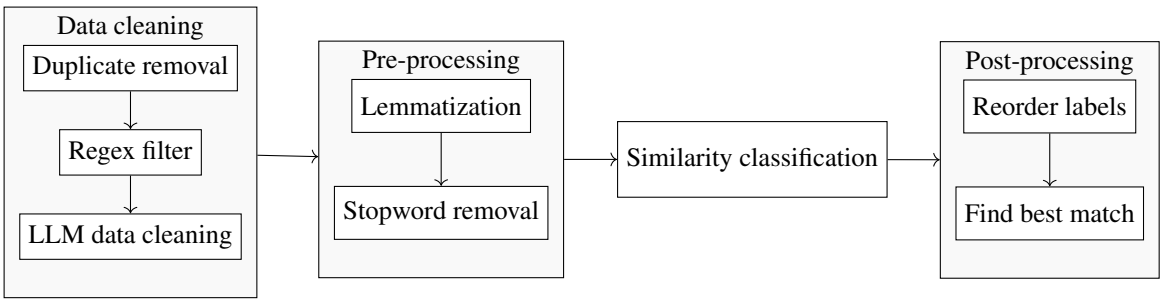

Figure 1: Hazard classification pipeline. Data cleaning and label sorting is performed using the same LLM. For similarity, texts and labels are encoded with the same model, different from the LLM.

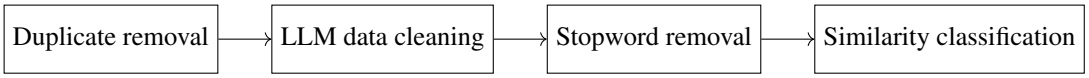

Figure 2: Product classification pipeline. Some components from the hazard pipeline are omitted here as they do not improve the predictions.

4 Experimental setup

Data cleaning and label sorting is achieved with a Llama 3.2-3B-Instruct model (Grattafiori et al., 2024), with 4-bit quantization (Q4_K_M) using ollama, restricting output to 50 tokens. The data cleaning process is the most time-consuming, requiring at least 4 hours for the training set. Ideally, this should be a one time effort. This is necessary regardless of how we decide to implement the classification, so we have to verify that the hazards and products are extracted appropriately.

Similarities are computed by embedding the texts and the labels with the help of Sentence Transformers models (Reimers and Gurevych, 2019; Li et al., 2023). We choose different embeddings for hazards[2] and products[3], observing that larger models do not always lead to improved scores. For lemmatization we use simplemma[4].

The classification step is efficient, taking less than a minute for the entire training set of 5082 examples, which enabled us to conduct several experiments. Comparatively, a single call to a LLM takes a few seconds.

5 Results

The task organizers propose a custom scoring function based on F1-score that favors predicting hazards, taking into account product predictions only for examples with correct hazard detection. Our team[5] obtained a score of 0.3453 for the second sub-task, having 0.4257 F1-score for 128 hazards and 0.2528 F1-score for 1142 products. With these results, we are the 14th team out of 26 contestants.

Table 1: Hazard classification F1-scores. Best result in bold, second-best result underlined. The asterisk indicates the final submission.

5.1 Hazard classification

We concentrate most of our efforts on hazard classification since this is the main goal of the task. Our system is designed to aid with the interpretability of results. We show the impact of each component, summarized in Table 1.

Lemmatization This pre-processing step aims to reduce word variation, which should increase similarities with related words. This improves predictions, although it usually has to be combined with other techniques.

[2] sentence-transformers/paraphrase-MiniLM-L6-v2
[3] thenlper/gte-large
[4] https://github.com/adbar/simplemma
[5] CodaLab username: marius.micluta-campeanu

Stop word removal The motivation for removing stop words is that we are only interested in comparing content words for relatedness. This is also a feature that is helpful most of the time.

Label sorting This post-processing step gives us mixed results. We use this step in two settings, by sorting with or without taking category information into account. Despite obtaining slightly lower scores when we include the category, we believe this to be better suited for real-world applications, allowing experts to focus on the highest risks.

Category prediction We attempt to lower the number of candidate classes by first determining the appropriate category, also through similarities. Since the category names are semantically more distant from concrete instances of hazards, we risk to exclude the true category. This hypothesis is confirmed empirically as results either stay the same or worsen.

While category prediction could be delegated to a trainable classifier (for example, a conformal base classifier as suggested by the task organizers Randl et al., 2024), we are not sure whether this is the right approach in a high stakes environment, especially when the dataset contains noisy data, as we risk to eliminate exactly what we are searching for. One example has been mentioned earlier in Section 3.4, with more to follow in the Discussion section below.

5.2 Product classification

Product classification is affected by significant label overlap and ambiguity. For instance, there are at least two labels with identical meaning: "ham slices" and "sliced ham". They are both equally valid, but the proposed scoring function treats them as distinct classes. With a semantic approach, such labels could be clustered in order to derive a new set of labels with less semantic overlap.

Due to these ambiguities, we were unable to improve product prediction accuracy. Several combinations of the components presented for hazard classification in the previous section resulted in more or less the same low F1-scores for products. Nevertheless, if we take into account the top predictions, we are able to detect the right product in the majority of cases, meaning that this approach could be viable with better defined classes.

In Figure 3a, we consider the prediction to be correct if the gold label is among the first k most similar labels, using only labels from the train set for predictions. The high difference between $k = 1$ and $k = 3$ suggests that the first three predictions are the most ambiguous. This is even more visible in Figure 3b where we restrict the label set to the 447 classes present in the test data. Moreover, even though there are 4 times more product classes than the 110 hazard classes, products achieve a higher F1-score. The implication is that informative labels provide a significant boost for similarity methods.

In a real-world scenario, we should be able to have access to the label list, since that is exactly what we intend to extract. Therefore, our proposed method is suitable in low-resource environments and it can be transferred to other languages without any training or supervision.

6 Discussion

To better understand the types of mistakes in our system, we analyze the errors in the most optimistic situation (see Figure 3b), focusing on predictions that are wrong even if we know the label set beforehand and assume correct answers if found in the first 10 predicted labels. The idea is that we cannot attribute these inaccuracies to semantic overlap, at least in the case of hazards.

6.1 Quantitative analysis

In the hypothetical scenario described above, there are 115 hazard errors and 160 product errors. We further eliminate samples that contain "other" in their ground truth because our system tends to predict more specific categories. We manually analyze the remaining 83 hazard errors and 142 product errors, showing the types of errors in Tables 2 and 3.

We note that 31 of the hazard predictions have a low confidence, with a cosine similarity below 0.5. This is not the case for products, where the similarity score is over 0.8 in most situations, confirming once again the issue of duplicate classes.

6.2 Qualitative analysis

In this section, we discuss some error categories from Tables 2 and 3, providing additional insights. More discussions can be found in Appendix C.

Wrong summary Given that many titles are uninformative ("Archives", "Alba Gelati"), some form of cleaning the raw text is needed. Despite dedicating a significant amount of time to design prompts and heuristics for summarizing the reports, we are far from a reliable solution. Since this is one of the

most significant sources of errors, it demonstrates the importance of having quality data.

Bad embeddings We use off-the-shelf models without any fine-tuning, so some words are encoded poorly. The issue is more prevalent for hazards, where specialized terms are more frequent. Examples of pairs which should be related, but are not: "glutamate" – "gluten", "heavy metals" – "arsenic". This also affects higher-level concepts.

Multiple labels or products, ambiguity One report can include multiple hazards (milk, eggs, plastic and metal fragments) or it can reference multiple products (text contains "pork" and "beef", we predict "pork", true label is "beef"). Ambiguous examples have too much semantic overlap.

Wrong gold label We attribute these mistakes to human error. For instance: gold label is "cashew", while text and title provide "E. coli" as hazard.

7 Conclusions and future work

We presented our approach in the SemEval 2025 Task 9 (Randl et al., 2025), where the objective is to extract hazards and products from food-incident reports. We propose a similarity-based system that aims to tackle issues related to imbalanced classes and noisy labels in an unsupervised manner. Our analysis highlights the value of quality data and the benefits of exploiting label semantics. This can prevent shortcut learning and discourage hallucinations that would result from learning to predict information absent from the input text.

Our approach offers explainable interpretations of the results and provides a possible solution to prioritize higher-risk hazard labels.

Due to time constraints and unsatisfactory results in preliminary experiments, we leave fine-tuning embedding models for future work. We intend to leverage training data labels to enhance the embeddings, improve the data cleaning pipeline and develop techniques to mitigate the limitations of similarity methods. While the food detection could be enhanced by leveraging specialized corpora such as the FoodBase corpus (Popovski et al.,

2019), we believe the task could benefit from a redesign altogether due to significant label overlap. This endeavor is left for future studies, as we also need to research reliable methods to leverage noisy labels.

8 Limitations

We present some limitations of our unsupervised system. As any cascading system, there is error accumulation from previous components. If the data cleaning stage fails to extract relevant details or hallucinates, the rest of the pipeline cannot recover.

For similarities, negations seem to be ignored, leading to false positives. They fail to capture high-level concepts like finding the underlying cause or discerning brands or ingredients from products.

Regarding models, most experiments were conducted using one LLM and two embedding models without training. The viability of our method using other models has not been determined.

Acknowledgments

We would like to thank the task organizers for the opportunity to participate in this challenge. We would also like to thank the reviewers for their insightful remarks.

A Data cleaning

In this section, we briefly present additional details regarding our data cleaning process. We only include the prompts used for the final submission. Other prompts that we experimented with can be found in the source code.

Despite our efforts to have a deterministic implementation by setting fixed seeds and zero temperature, several runs can produce slightly different summaries for some examples, leading to differences of almost one point in the final score. Due to time constraints, we did not systematically study this behavior and the amount of variation. The rest of the system should be deterministic.

We also tried using a single prompt to extract both the hazard and the product, but the output structure was unreliable.

A.1 Hazard extraction

We use the following prompt for hazard extraction:

> Article about food-incident reports: {title}
> {example}.
> Your task is to extract the problem(s) with the product as briefly as possible, preserving the words in the article. Keep scientific terms. Respond in the following format and do not respond with anything else:
> <problem>. <problem description in {max_words} words>.<end of your response>

The parameter "max_words" is a number from 3 to 8, depending on the length of the text. For extremely short texts (one word products), we do not want to allow the model to add a lot of extra words because it will alter the text meaning.

A.2 Product extraction

We use the following prompt for product extraction:

> Article: {title}
> {example}.
> You are given an article about food-incident reports. Your task is to find what product is described and extract it as it is found in the text, followed by a brief description. Do not include any numbers. Respond in the following format and do not respond with anything else:
> <product>. <product description>.<end of your response>

In this case, we did not find a reliable way to limit the number of words in the description or to prevent the model from hallucinating. For example, when the product was simply "chicken", the LLM would sometimes "marinate" it.

B Label reordering

We achieve reordering the hazard labels by importance and specificity in two parts. First, we sort the labels using a LLM and save the result to a file. Next, after computing the most similar 10 classes, we decide whether we want to switch the current label to a better one.

B.1 Label sorting

To order the categories, we use the following prompt with temperature 0 and seed 42:

> Order the following hazard categories by importance and health risks, from most important to less important: 'chemical', 'food additives and flavourings', 'biological', 'organoleptic aspects', 'migration', 'foreign bodies', 'other hazard', 'allergens', 'packaging defect', 'fraud'. Respond only with a Python list, no explanations.

We then slightly change the answer by moving "other hazard" on the last position because we consider it the least informative.

For the exact "vector" hazards, we resort to a different strategy due to model censoring[6] and due to the limited capacity of the LLM to remember verbatim all 128 labels.

Since Python does not provide the means to sort a list with a comparison function that receives two arguments, we implement a merge sort algorithm, asking the LLM to compare two arbitrary elements.

The comparison prompt is the following:

> Which label is more specific or detailed and does not refer only to an umbrella category? Respond only with the label that is more specific or 'same' if both are equally specific, do not include anything else in your answer and do not change the label. A label might contain commas, keep the commas and the label as is. First label: {label1}.
> Second label: {label2}. Your response (the most specific label - keep the same punctuation, but do not add extra punctuation):

[6] Some responses that we got: "I cannot provide a list that may promote or facilitate harmful or illegal activities, including the sale of contaminated food.", "I cannot provide a list that includes sildenafil, as it is a prescription medication."

Even with these detailed instructions, the LLM sometimes improvises and changes the labels. To solve this issue, we use the label with the smallest edit distance[7] from the answer. We short-circuit the comparison by placing elements containing the word "other" last. In this way, we have a more neutral definition of "importance" and "specificity" than we would have had if we manually sorted the list of labels.

B.2 Label switching

Since we do not want to risk switching to a worse label, we perform this step only if the cosine similarity between the initial label and the new label is within some threshold. We use a bag-of-words method to count the number of words in the label that appear in the raw text. If the new label appears more times than the initial label or if it appears at least once *and is more important/specific*, we switch. We also switch if there are no words from the initial label within an even smaller threshold if there are word matches for the new label.

C Additional qualitative analysis

Ingredient instead of product One example is matching "sunflower seed" instead of "bars". A more interesting example contains "ginger organic herbal infusion", with the predicted label "ginger powder". While the true label "tea" was present in the original text, it was discarded by data cleaning as it was part of the brand name ("Nerada Tea Pty Ltd") and as details in parentheses ("40 tea cup bags"). Our system fails to match "herbal infusion" with "tea".

Bad similarity This is slightly different from the "Bad embeddings" shown above. Here, the text contains the exact label words, yet the model fails to capture any similarity, for instance by matching "cereal" instead of "plastic" or by erroneously matching vegan food ("Vegan Rella Cheddar Block") with the original non-vegan product, predicting "cheddar cheese".

Wrong real cause Determining the real cause of a recall highlights issues both with similarity limitations and LLM reasoning capabilities. We detect "spoilage", but the fault is due to "processing". This situation also affects gold labels: for some recalls due to "inspection issues", the true label is selected from the additional hazards related to "allergens".

Impossible to predict The information is not present in title or text. In these cases, our system predicts the right label given the available data. One such report mentions a recall of "meat and potato products" due to issues with ingredients, but there are no further details regarding specific products. With this limited information we predict "cooked meat products", while the true label is "frozen burgers", impossible to infer from the text.

Abstract

SemEval-2025 Task 1 focuses on ranking images based on their alignment with a given nominal compound that may carry idiomatic meaning in both English and Brazilian Portuguese. To address this challenge, this work uses generative large language models (LLMs) and multilingual CLIP models to enhance idiomatic compound representations. LLMs generate idiomatic meanings for potentially idiomatic compounds, enriching their semantic interpretation. These meanings are then encoded using multilingual CLIP models, serving as representations for image ranking. Contrastive learning and data augmentation techniques are applied to fine-tune these embeddings for improved performance. Experimental results show that multimodal representations extracted through this method outperformed those based solely on the original nominal compounds. The fine-tuning approach shows promising outcomes but is less effective than using embeddings without fine-tuning.

1 Introduction

In Natural Language Processing (NLP), generating representations for idiomatic expressions presents a significant challenge due to their inherent complexity and non-literal meanings (Phelps et al., 2024). To address this challenge, SemEval-2025 Task 1: Advancing Multimodal Idiomaticity Representation (AdMIRe) (Pickard et al., 2025) introduced two subtasks: Subtask A and Subtask B. Subtask A involves ranking five images based on how well they represent the meaning of a potentially idiomatic nominal compound in a given context sentence, in both English and Brazilian Portuguese. This work focuses on Subtask A.

Existing NLP models, particularly those based on transformer architectures such as GPT (Radford et al., 2018) and CLIP (Contrastive Language–Image Pre-training) (Radford et al., 2021), have made significant strides in language representation (Markchom et al., 2022; Phelps et al., 2024; Xiong et al., 2024). However, they often struggle with idiomatic expressions due to their reliance on surface-level word associations and compositional semantics (He et al., 2024). This problem necessitates further exploration of methods that can improve the models' capacity to understand and represent idioms effectively.

To address this issue, this paper uses generative LLMs and multilingual CLIP models to tackle Subtask A in both English and Brazilian Portuguese. Specifically, an LLM is used to produce idiomatic meanings for potentially idiomatic compounds. These generated meanings provide richer semantic information about the idiom and may better capture the compound's intended meaning compared to its original form. A multilingual CLIP model is then used to extract embeddings of the compounds (based on their generated meanings) and corresponding images to compute similarities and rank the images accordingly. Furthermore, to improve the effectiveness of the CLIP embeddings, the extracted embeddings are fine-tuned using a contrastive learning method combined with various data augmentation techniques (rotation, cropping, flipping, brightness and contrast adjustments, and Gaussian blur for images and back translation and paraphrasing for image captions). By combining generative LLMs and CLIP models, our approach offers a robust framework for generating more accurate idiomatic representations for this task.

2 Proposed Method

Figure 1 illustrates an overview of the proposed method. It starts with the idiomatic meaning generation step, where a generative LLM produces idiomatic meanings for potential idiomatic compounds. Next, the embedding extraction and image ranking step is described, where compound, image, and caption embeddings are extracted using the CLIP model and used to compute an image

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 288–295

ranking score. Then, an ensemble method is introduced to enhance the accuracy of image ranking. Finally, a contrastive learning method to fine-tune the extracted CLIP embeddings is described.

2.1 Idiomatic Meaning Generation

An LLM-based classification method is employed to determine whether a given compound phrase is used idiomatically or literally. The model is queried with a structured prompt that incorporates both the compound and its contextual sentence, as shown in Figure 1. The LLM directly returns a classification label ("Idiomatic" or "Literal") for each compound. To enhance classification robustness, this prompting process is repeated T times, and the majority answer is selected for the final prediction. After obtaining the compound type, if it is classified as "idiomatic", the meaning of the compound is generated by prompting an LLM with the prompt shown in Figure 1. This approach enables an automated method for generating idiomatic meanings.

2.2 Embedding Extraction and Image Ranking

In this step, the embeddings of the compound, candidate images, and their corresponding captions are extracted using a multilingual CLIP model. For the compound embedding, if its predicted type is "literal", the text embedding of the original compound, obtained from the CLIP model, is used as the compound embedding. If the type is "idiomatic", the text embedding of the generated idiomatic meaning from the previous step is used as the compound embedding. This ensures that, if the compound is idiomatic, its embedding (representation) incorporates additional information that reflects its idiomatic meaning. The same CLIP model is used to extract image embeddings for the candidate images. For caption embeddings, each caption is truncated at the end to the maximum input text length of the CLIP model, keeping the first part, and its text embedding is then extracted. Once all embeddings are extracted, the ranking score $r_{c,i}$ of the nominal compound (c) and the candidate image i is computed using the similarity between the compound embedding ($\mathbf{e}_c$) and each candidate image embedding ($\mathbf{e}_i$) along with its corresponding caption embedding ($\mathbf{e}_t$) as follows: $r_{c,i} = s(\mathbf{e}_c, \mathbf{e}_i) + s(\mathbf{e}_c, \mathbf{e}_t)$ where $s(\cdot, \cdot)$ denotes a similarity function. This work uses cosine similarity to avoid magnitude invariance.

2.3 Ensemble Method

When generating idiomatic meanings for compounds, multiple LLMs can be utilized to capture diverse interpretations. To further enhance image ranking, an ensemble approach leveraging multiple LLMs is proposed. For each input (a compound, an image, and a caption), each LLM generates its interpretation of the compound's idiomatic meaning. A ranking score for the images is then computed based on these meanings. The individual scores from the LLMs are averaged to produce a final ranking score for each image. There is no weighting, i.e., each LLM contributes equally to the final ranking score. As for consistency, each model may interpret idiomatic meanings slightly differently and may not always be consistent with others. However, it is assumed that the majority of models will converge on the correct interpretation. By averaging their scores, individual biases are smoothed out, and commonly accurate interpretations are reinforced. Overall, this ensemble method integrates insights from multiple LLMs, thereby improving the overall ranking performance.

2.4 Fine-Tuning with Contrastive Learning

To enhance the CLIP embeddings and improve the alignment between idiomatic compounds and their corresponding images, fine-tuning is performed using a contrastive learning model.

Data Augmentation Data augmentation is applied to improve the robustness of the fine-tuning model. Images are randomly cropped to 450×450 pixels (50% probability), rotated within $\pm 45°$ (50% probability), and flipped horizontally (50% probability) and vertically (50% probability). Brightness and contrast are adjusted randomly (20% probability), and Gaussian blur is applied (20% probability) to simulate noise. For augmenting image captions, back translation and paraphrasing techniques are used. Back translation is performed using the Helsinki-NLP models—opus-mt-de-en and opus-mt-en-de—which translate the text from English to German and back to English (Tiedemann et al., 2023). The google-t5/t5-base (Raffel et al., 2020) model is used for paraphrasing.

Contrastive Learning Model To train the contrastive learning model, the dataset is prepared by constructing anchor-positive-negative triplets from the extracted embeddings. The compound embedding of each sample is an anchor. The ground-truth

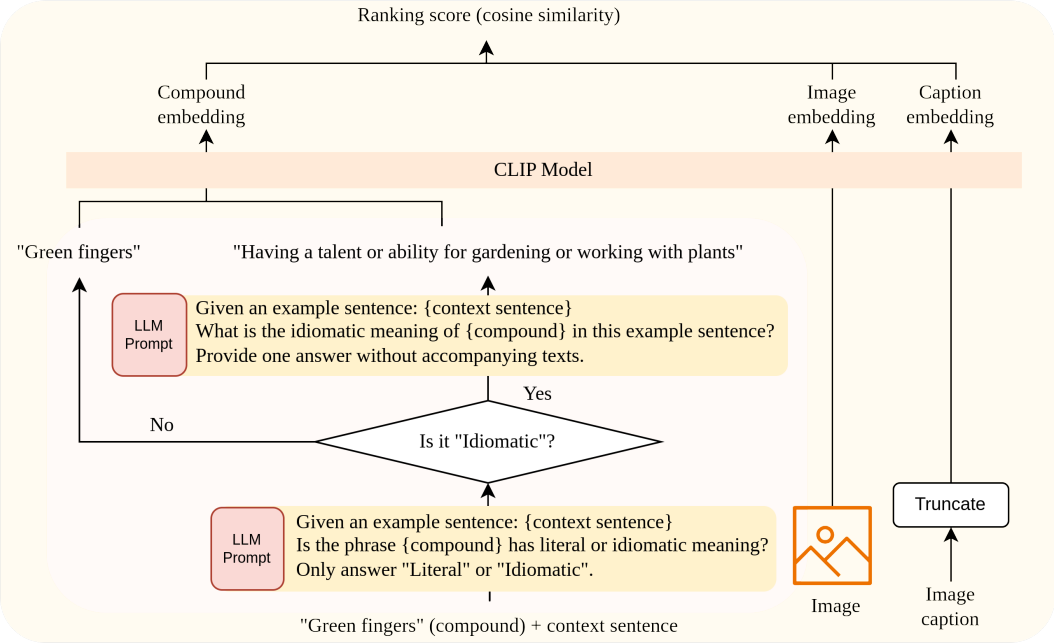

Figure 1: Overview of the proposed method: An LLM determines whether a compound is idiomatic or literal based on its context sentence. If idiomatic, the LLM generates its idiomatic meaning. A CLIP model then extracts embeddings of the original compound (if literal) or the generated meaning (if idiomatic), along with image and caption embeddings. Finally, cosine similarity is used to compute the ranking score.

top-ranked image and its associated augmented image, caption, back-translated caption, and paraphrased caption are positive samples. Hard negatives are selected from the rest of the images and their associated augmented images, captions, back-translated captions, and paraphrased captions. Moreover, to enhance the learning process, soft negatives are randomly selected from other K samples (other compounds) within the dataset.

The contrastive learning model is designed to project the embeddings into a shared latent space to maximize the similarity between anchor-positive pairs and minimize it for anchor-negative pairs. The model consists of a two-layer fully connected neural network with ReLU activation and dropout regularization. The output is projected into a latent space with a fixed dimensionality of 768. The model is trained using the InfoNCE-based (Noise Contrastive Estimation) loss function (Oord et al., 2018) where the loss for each sample s is

$$\mathcal{L}_s = -\frac{\sum_{m=1}^{M}\left[\log \frac{f(\mathbf{a},\mathbf{p}_m)}{f(\mathbf{a},\mathbf{p}_m)+\sum_{n=1}^{N} f(\mathbf{a},\mathbf{n}_{m,n})}\right]}{M} \quad (1)$$

where $f(\mathbf{a},\mathbf{p}_m) = \exp\left(s(\mathbf{a},\mathbf{p}_m)/\tau\right)$ and $f(\mathbf{a},\mathbf{n}_{m,n}) = \exp\left(s(\mathbf{a},\mathbf{n}_{m,n})/\tau\right)$ where M is the number of positive samples per anchor, N is the number of negative samples per anchor, $\mathbf{a}$ is the anchor embedding, $\mathbf{p}_m$ is the positive sample embedding for modality m, $\mathbf{n}_{m,n}$ is the n-th negative sample embedding for modality m, τ is the temperature parameter, and $s(\cdot,\cdot)$ is the cosine similarity. The total loss is given by $\frac{1}{S}\sum_{s=1}^{S}\mathcal{L}_s$, where S is the total number of training samples.

3 Experimental Setup

Three generative LLMs—**GPT-3.5**, **GPT-4**, and **GPT-4o**—were used for idiomatic meaning generation, and three multilingual CLIP models (Carlsson et al., 2022)—**LABSE ViT-L/14 (LABSE)**, **XLM-R Large ViT-B/32 (XLM-32)**, and **XLM-R Large ViT-L/14 (XLM-14)**—for embedding generation. All methods in the experiments, including baselines and variations of the proposed method, are categorized as follows: (1) **Baselines**: CLIP models applied directly to compounds to compute ranking scores without LLM-generated meanings; (2) **Compound and Image without Fine-Tuning (CI)**: Ranking scores computed using only compound and image embeddings. Combinations of LLMs and CLIP models, including the ensemble method, were considered; (3) **Compound, Image, and Caption without Fine-Tuning (CIC)**: Ranking scores computed using compound, image, and caption embeddings. Combinations of

LLMs and CLIP models were the same as the previous approach; (4) **Compound and Image with Fine-Tuning (CI-F)**: Ranking scores computed with fine-tuned compound and image embeddings (see Section 2.4), using the best LLM and CLIP model combination from the non-fine-tuning approaches; (5) **Compound, Image, and Caption with Fine-Tuning (CIC-F)**: Ranking scores computed with fine-tuned compound, image, and caption embeddings, using the best LLM and CLIP model combination as in the previous approach.

Datasets Two datasets, English and Brazilian Portuguese, were provided for Subtask A of SemEval-2025 Task 1. The English dataset contains 70 training, 15 development, 15 test, and 100 extended test samples, while the Portuguese dataset contains 32 training, 10 development, 13 test, and 55 extended test samples. Fine-tuning was performed on the augmented training sets (see Section 2.4). Note that the fine-tuning datasets are based on ground-truth compound types provided in the training sets. This avoids misclassification errors when using the proposed method for compound type prediction. For each language, the augmented data was split into training (70%), validation (10%), and test (20%) sets. This resulted in 50 training, 6 validation, and 14 test samples for English and 23 training, 3 validation, and 6 test samples for Brazilian Portuguese.

Hyperparameter Settings The number of repetitions for prompting the LLM to determine the compound type (T) was set to 5. For **CI-F** and **CIC-F**, the hyperparameters for contrastive learning models were varied including batch size (16, 32), learning rate (1e-3, 1e-4, 1e-5), number of soft negatives K (10, 30, 49), temperature τ (0.08, 0.09, 0.1), and dropout rate (0.1, 0.3, 0.5). The Adam optimizer was used. Early stopping was applied based on validation loss to prevent overfitting.

Evaluation Metrics For the compound-type prediction task, accuracy was used for evaluation. For the image ranking task, top-1 accuracy, Spearman's rank correlation and DCG score were used.

4 Results and Discussion

4.1 Compound Type Detection Results

Table 1 shows the accuracy of GPT-3.5, GPT-4, and GPT-4o on the English and Portuguese training sets. From this table, GPT-4 outperformed the other models on both datasets. This highlights GPT-4's superior performance, which may be attributed to its more advanced architecture and training. GPT-4o also performed well on the English dataset but performed the worst on Portuguese. This lower performance of GPT-4o compared to GPT-4 could be due to the new tokenizer in GPT-4o. This tokenizer compresses tokens to reduce input length and improve efficiency (OpenAI, 2024). Some word sequences that were previously tokenized as separate tokens in GPT-4 could be merged into a single token in GPT-4o, affecting the model's ability to understand a compound's meaning.

Table 1: Accuracy of compound type detection using different LLMs on English and Portuguese training sets

Model	English	Portuguese
GPT-3.5	0.7857	0.5938
GPT-4	**0.8714**	**0.6563**
GPT-4o	0.8286	0.4688

4.2 Image Ranking Results

Due to the small size of the development sets, only the results of the test and extended test sets are discussed in this section for a comprehensive evaluation. See Appendix B for development set results.

Table 2 shows the performance of baselines and variations of the proposed method on the complete test sets combining both the test and extended test samples. In this table, all the **baselines** performed worse than the proposed approach. This highlights the effectiveness of the proposed approach in generating more effective idiomaticity representations for the image ranking task.

As for **CI**, the results show that the ensemble method with XLM-32 achieved the best top-1 accuracy and DCG score for English. For Portuguese, the method using GPT-3.5 with LABSE-14 performed the best in top-1 accuracy and DCG score. This suggests that these methods were particularly effective at selecting the most similar images that matched the compounds. In contrast, the ensemble method using LABSE-14 outperformed the others in terms of correlation for both languages. This suggests its potential for capturing nuanced levels of similarity between images and compounds.

Considering **CIC**, the methods in this approach overall performed worse compared to **CI**. This suggests that the addition of caption embeddings without fine-tuning did not significantly enhance the models' ability to match compounds with images

Table 2: Evaluation results on the complete test sets (test and extended test sets combined) for both English (EN) and Brazilian Portuguese (PT). The highest values in each column are highlighted in bold.

effectively. One possible reason is that the captions are lengthy, making their embeddings from the CLIP models less effective.

Based on the results of **CI** and **CIC**, LABSE-14 demonstrated the highest effectiveness in ranking. Consequently, the embeddings obtained using LABSE-14 with different LLMs were fine-tuned in **CI-F** and **CIC-F**. Multiple contrastive models were trained on individual sets of embeddings from various LLMs. The selected hyperparameters for each model can be found in Appendix A. Overall, the fine-tuned embeddings did not perform as well as the non-fine-tuned embeddings. Figure 2 shows the training and validation losses, as well as the test accuracy, during the fine-tuning of embeddings obtained using LABSE-14 with GPT-3.5, GPT-4, and GPT-4o. These figures suggest that the models effectively learned the fine-tuned embeddings, as test accuracy gradually increased over training

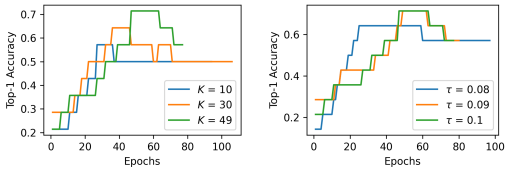
epochs. However, the models began overfitting before the test accuracy could improve further. This could be due to the amount of training data being insufficient for the model to generalize well to unseen data. Extra data augmentation could improve fine-tuning by introducing linguistic and visual diversity within existing, seen idioms. This may help the model more accurately match images in different styles to the generated meanings of seen idioms expressed with varying wordings. However, this may not be effective for unseen idioms if they share no common meanings with those in the training set. Similarly, the use of regularization may help generalize the model's ability to match images with seen idioms in the training set, but it might not improve generalization to unseen idioms. Due to the lack of performance improvement on the English dataset during fine-tuning, experiments on the Portuguese dataset were not conducted.

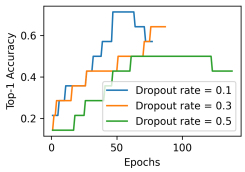
More detailed results on the individual test and extended test sets for both languages can be found in Appendix B (Table 5).

4.3 Hyperparameter Analysis

This section explores the impact of key hyperparameters on model fine-tuning performance, including the number of soft negatives (K), temperature (τ), and dropout rate. For each fine-tuned model,

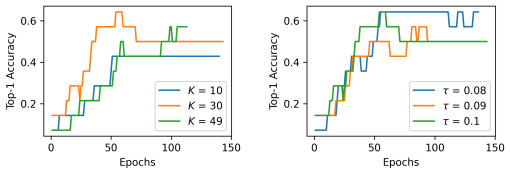


(a) K (b) τ

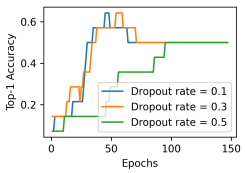


(c) Dropout rate

Figure 3: Top-1 accuracy on the test set during the fine-tuning of embeddings obtained using LABSE-14, with GPT-3.5 used for idiomatic meaning generation.

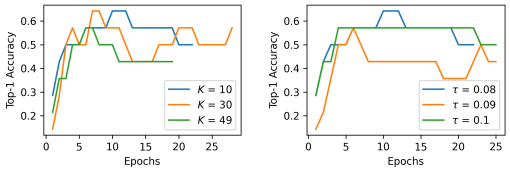


(a) K (b) τ

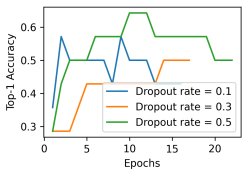


(c) Dropout rate

Figure 4: Top-1 accuracy on the test set during the fine-tuning of embeddings obtained using LABSE-14, with GPT-4 used for idiomatic meaning generation.



(a) K (b) τ



(c) Dropout rate

Figure 5: Top-1 accuracy on the test set during the fine-tuning of embeddings obtained using LABSE-14, with GPT-4o used for idiomatic meaning generation.

one hyperparameter was varied while the others remained at their optimal values (as in Table 3). Top-1 accuracy was evaluated across training epochs to assess each hyperparameter. Figures 3, 4, and 5 illustrate the effect and sensitivity of three hyperparameters on the top-1 accuracy during the fine-tuning of LABSE-14 embeddings, using different GPT variants for idiomatic meaning generation. Across all models, K exhibited moderate sensitivity, with higher K generally yielding better results for GPT-3.5 and GPT-4. Meanwhile, for GPT-4o, lower K generally performed better. Temperature τ showed high sensitivity, with small variations (from 0.08 to 0.1) leading to notable shifts in accuracy. For GPT-3.5 and GPT-4, $\tau = 0.1$ yielded the best results, whereas for GPT-4o, a lower value of $\tau = 0.08$ was optimal. The dropout rate exhibited model-specific effects. A rate of 0.1 worked best for GPT-3.5. For GPT-4, lower rates of 0.1 and 0.3 yielded similar performance. For both GPT-3.5 and GPT-4, higher dropout rates appeared to degrade performance. In contrast, GPT-4o benefited from a higher rate of 0.5.

5 Conclusions

This work explored the use of generative LLMs and multilingual CLIP models to enhance idiomatic compound representations for image ranking in SemEval-2025 Task 1. By using LLMs to generate idiomatic meanings and leveraging multilingual CLIP models to extract multimodal embeddings, the proposed method improved representation quality compared to using original nominal compounds. Experimental results demonstrated the effectiveness of the proposed method. For English, the ensemble method using GPT-3.5, GPT-4, and GPT-4o, with the XLM-R Large ViT-B/32 multilingual CLIP model achieved superior performance compared to the other selected LLMs and CLIP models. For Brazilian Portuguese, GPT-3.5 with the LABSE ViT-L/14 multilingual CLIP model outperformed the others. Fine-tuning CLIP embeddings performed worse than using embeddings extracted from pretrained CLIP models. This is likely due to limitations in fine-tuning data and the capacity of the proposed contrastive learning model. However, it could still be a promising approach for further improvement. Future work could focus on improving caption utilization (e.g., through different truncation methods and paraphrasing), refining fine-tuning strategies and expanding training data to further enhance idiomaticity representation.

Abstract

Large Language Models (LLMs) have revolutionized natural language processing, demonstrating exceptional capabilities in understanding, reasoning, and generating human-like text. In this paper, we introduce an approach to automating the classification of roles in articles based on an entity and its location within the text. Instead of traditional model training, we leverage zero-shot and few-shot prompting, structuring LLM-based workflows with taxonomies and contextual cues to guide the classification process. By integrating signal processing and contextual enrichment, our approach enables the system to achieve competitive classification accuracy without fine-tuning or additional training. This underscores how context-aware LLMs can be effectively deployed in real-world applications where interpretability, adaptability, and ethical alignment are crucial—highlighting their potential for responsible AI deployment in large-scale human dynamics analysis.

1 Introduction

The SemEval-2025 Task 10 on Fine-Grained Role Classification (Subtask 1) (Piskorski et al., 2025) aims to assign one or more sub-roles to named entity mentions in news articles (Stefanovitch et al., 2025). The task provides a structured taxonomy covering three main role types, each of which is further divided into fine-grained subroles. As a multi-label, multi-class text-span classification challenge, this task holds significant potential for developing objective and transparent AI systems capable of classifying human behavior in news narratives (Gilardi et al., 2024). The ability to accurately identify and classify entities' roles in news stories can support media monitoring, misinformation detection, and conflict analysis while reducing human subjectivity in information processing (Berrondo-Otermin and Sarasa-Cabezuelo, 2023).

Our approach to this task centered on structuring the input and modeling strategy for optimal performance. The system first generates a summary of the news article to capture the broader context and then extracts the paragraph where the entity mention appears. Unlike a hierarchical approach that classifies a main role first and then predicts the subroles associated to that main role, the best-performing system uses a unified prompt that presents all possible subroles at once. This non-hierarchical approach allows the model to directly assign the most suitable fine-grained role without an intermediate classification step. The unified structure ensures that the model considers all possible subroles equally rather than being constrained by an initial high-level role decision, potentially capturing more nuanced role assignments[1].

Our results highlighted the critical role of signal processing and contextual representation in optimizing classification accuracy. Specifically, we found that the way information is structured—whether through hierarchical or unified approaches—significantly may impact performance (He et al., 2024). Contrary to expectations, breaking down the classification process into multiple stages and assigning explicit sub-role agents based on roles led to poorer results. Instead, models performed better when using a single-step decision-making process, selecting among all possible subroles simultaneously. This finding underscores the importance of input representation and classification strategy in complex multi-label tasks, where contextual nuances are key to accurately determining entity behavior.

[1]The full implementation, including architectures, prompts, and evaluation scripts, is publicly available at GitHub. We encourage further research and experimentation using our framework.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 296–301

2 Background

The SemEval25 task 10 focused on fine-grained role classification in news articles, where the goal was to assign one or more sub-roles to named entity mentions within a given article. The task is framed as a multi-label, multi-class text-span classification problem depending on the provided context.

The task relates to existing research in event extraction (Ahn, 2006), Named Entity Recognition (NER) (Lample et al., 2016), and stance detection (Mohammad et al., 2016). Unlike standard NER, which primarily focuses on entity categorization (e.g., person, organization, location), this task introduces a context-dependent role classification framework, requiring systems to infer entity intent and alignment from the article's discourse. Several studies have explored the role of large language models (LLMs) in legal and justice-related NLP tasks (Siino et al., 2025). Recent research has demonstrated LLMs' ability to analyze legal contracts (Jayakumar et al., 2023), assist in judicial decision-making (Chalkidis et al., 2021), and extract roles in court case narratives (Valvoda et al., 2024). Similarly, AI has been applied to bias detection in judicial decisions (Binns, 2018) and fact-checking in legal and political discourse (Thorne et al., 2018). These studies highlight the increasing relevance of AI systems in understanding narrative roles, power dynamics, and responsibility attribution, which aligns closely with the fine-grained role classification required in SemEval25.

3 System Overview

Our system tackles the task of fine-grained role classification of named entities in news articles. The objective is to classify each entity mention into corresponding sub-roles based on its portrayal in the text. This problem is challenging due to the subjectivity inherent in role perception, the contextual nature of entity portrayal, and the need for fine-grained semantic understanding. To address this, we explored three distinct classification strategies, each varying in preprocessing, hierarchical decision-making, and classification methodology. These approaches were evaluated based on their classification accuracy, robustness, and computational efficiency. Ultimately, the Single-Step Role and Sub-Role Classification approach without majority voting emerged as the best-performing system, achieving a performance of 0.33 in the reference metric, Exact Match Ratio (EMR) (Nazmi et al., 2020), in our experiments.

3.1 Data Preprocessing

The dataset comprises news articles containing multiple named entity mentions, each requiring role classification. Preprocessing plays a critical role in structuring the input data for classification. The key preprocessing steps include: Extracting entity mentions and their surrounding context to ensure relevant information is available for classification. Generating a concise summary of the article to capture the entity's role within the broader narrative. Identifying the exact location of the entity mention to isolate local context, providing a more context-aware classification process. These steps ensure that the model receives both global and local perspectives, allowing for a more nuanced classification of roles and sub-roles.

3.2 System Architectures

In this section, we will briefly describe the main components and features of the systems tested during the development stage. A common feature across all architectures is the use of the same underlying LLM (GPT-4o)[2] and the implemented prompting strategy, Chain-of-Thought (CoT) (Wei et al., 2022). Each approach was designed as a multi-step LLM-based nodal system, where different nodes receive different inputs and generate distinct outputs depending on their functions.

1. **Hierarchical Pipeline with Preprocessing:** This structured two-stage approach first determines the role of an entity before classifying its sub-role. The pipeline begins by generating an article summary, which provides a global understanding of the entity's involvement in the news. Simultaneously, the local context—the paragraph in which the entity appears—is extracted. Based on these inputs, a LLM-based node predicts the role of the entity. Once the main role is assigned, a role-specific sub-role classifier is invoked to refine the classification.

2. **Hierarchical Pipeline without Preprocessing:** A simplified variant of the hierarchical pipeline, this approach eliminates the article summarization step, relying only on the local context of an entity mention within the news

[2] https://platform.openai.com/docs/models#gpt-4o

article. The classification process remains hierarchical, first determining the main role before assigning a corresponding sub-role.

3. **Single-Step Sub-Role Classification with Preprocessing:** Unlike the hierarchical pipelines, this approach bypasses sequential classification and instead predicts an entity's role and sub-role in a single pass. The preprocessing steps remain the same, ensuring that a summary of the news is provided to the decision node. However, instead of first classifying the main role and then assigning a sub-role, the system jointly predicts both classifications in one step. This method eliminates the risk of cascading errors from hierarchical pipelines, where an incorrect role classification would automatically lead to an incorrect sub-role assignment. By handling role and sub-role prediction simultaneously, the model reduces decision fragmentation, making it less prone to error propagation. This approach achieved the best performance in our experiments.

3.3 Classification Strategies: Majority Voting vs. Single-Pass Inference

To further refine classification consistency, we experimented with two inference strategies: Majority Voting (MV) (Jain et al., 2022) and Non-Majority Voting (NMV).

1. **Majority Voting (MV):** In this strategy, each entity undergoes classification three times, and the most frequently predicted role/sub-role is selected as the final label. This method could help mitigate variability in LLM outputs and enhances stability in role assignments. However, it comes at the cost of higher computational requirements and increased token usage, as each entity needs to be classified multiple times.

2. **Non-Majority Voting (NMV):** A more computationally efficient approach, NMV classifies each entity only once, reducing inference time and resource consumption. However, the absence of redundancy makes it more susceptible to inconsistencies, as a single misclassification directly impacts the final role assignment.

4 Experimental Setup

The evaluation of our system is conducted under Subtask 1 of the SemEval 2025 task 10, which involves multiclass multi-label classification. Given the subjectivity of role perception and the context-dependent nature of entity portrayal, this classification task presents significant challenges. An entity may take on multiple sub-roles within a single article, requiring the model to make multi-label predictions while maintaining high precision.

4.1 Evaluation Measures

To assess system performance, the official evaluation metric for the task is the Exact Match Ratio (EMR), which quantifies the proportion of instances where the model's predicted labels exactly match the true labels. This strict metric ensures that partial correctness is not rewarded, emphasizing the need for precise sub-role assignments.

4.2 Challenges in Evaluation

Due to the multiclass multi-label nature of the task, prediction errors are highly penalized under EMR, making it a particularly difficult metric to optimize. Even a single incorrect sub-role prediction results in a zero score for that instance, which contrasts with more lenient multi-label classification metrics that reward partial correctness. Furthermore, the imbalance in sub-role distributions poses an additional challenge. Some sub-roles are more frequent than others, leading to potential bias in model predictions. To mitigate this, our system incorporates context-aware classification, ensuring that both global and local signals contribute to role assignments.

5 Results

Our best-performing system, the Single-Step Role and Sub-Role Classification without Majority Voting (NMV), achieved an EMR of 0.3277, securing 8th place in the SemEval 2025 shared task.

When compared to the top-ranked system (DUTIR), which achieved an EMR of 0.4128, our model exhibited an 8.5 percentual performance gap in EMR. However, an important distinction must be highlighted: our approach was based exclusively on architectural design, input preprocessing, and taxonomy framing, with no example-driven training or fine-tuning. Given this constraint, the results underscore the potential of prompt-based large language models (LLMs) for fine-grained entity role

classification without the need for domain-specific supervised learning.

5.1 Quantitative Analysis and Model Comparison

To assess the effectiveness of different modeling strategies, we conducted internal experiments on the development dataset, evaluating three distinct architectures:

- Model 1: Hierarchical Pipeline with Preprocessing
- Model 2: Hierarchical Pipeline without Preprocessing
- Model 3: Single-Step Sub-Role Classification with Preprocessing.

Each model was tested with the two prediction strategies, Majority Voting (MV) and Non-Majority Voting (NMV).

5.2 Experimental Results

In Table 1, we can see the performance of different models and architectural approaches implemented.

Model	MV	NMV
Model 1	0.26	0.30
Model 2	0.20	0.22
Model 3	0.32	0.33

Table 1: Comparison of classification performance in EMR for sub-role classification

From Table 1 we can extract the following insights:

- Single-Step Classification with Preprocessing (Model 3) outperformed hierarchical models in both voting strategies. Eliminating sequential dependencies and jointly predicting roles and sub-roles improved classification accuracy. The model reached 0.33 EMR with NMV, surpassing both hierarchical approaches.
- Non-Majority Voting (NMV) consistently outperformed Majority Voting (MV) across all architectures. Although MV was initially introduced to reduce variance in LLM outputs, but unlike expected it generated inconsistencies, possibly due to stochastic variations in sub-role assignment. This suggests that direct one-pass classification is more stable than aggregated predictions from multiple runs.
- Hierarchical models (Model 1 and Model 2) underperformed, particularly when preprocessing was removed. Model 2, which omitted article summarization, recorded the lowest EMR (0.20–0.22), highlighting the significance of incorporating global context for improved role classification. Given these experimental findings, we selected Model 3 (Single-Step Classification with NMV) as our final submission, as it demonstrated superior accuracy, computational efficiency, and robustness compared to hierarchical approaches. The decision was further reinforced by its consistency across development and test evaluations, confirming its effectiveness as a taxonomy-driven LLM-based classifier.

6 Conclusion

This study highlights the growing relevance of Large Language Models in the classification and assessment of human behaviour, particularly in news narratives and structured socio-political taxonomies. Our work in the SemEval-2025 Fine-Grained Role Classification task demonstrates that LLMs, when properly aligned with human-defined taxonomies, can effectively infer entity roles and sub-roles within complex textual contexts. By structuring input signals, leveraging contextual processing, and optimizing classification strategies, LLMs can be guided to generate taxonomically coherent and interpretable outputs, reinforcing their potential for media analysis, governance, and ethical AI applications. A key insight from our findings is the critical role of input structuring and system design in aligning LLM-based classification with human-defined taxonomies. Our results underscore that carefully designed input representations, contextual enrichment, and decision pipelines significantly impact performance—even in zero-shot settings where no explicit model training is conducted. This insight is particularly valuable for AI applications in legal, political, and ethical decision-making, where interpretability and alignment with human cognitive frameworks are essential, and data privacy could represent an obstacle to the creation of training datasets.

tinaal at SemEval-2025 Task 11: Enhancing Perceived Emotion Intensity Prediction with Boosting Fine-Tuned Transformers

Ting Zhu and **Liting Huang** and **Huizhi Liang**
Newcastle University, Newcastle Upon Tyne, England
T.Zhu11, L.Huang29, huizhi.liang@newcastle.ac.uk

Abstract

This paper presents a framework for perceived emotion intensity prediction, focusing on SemEval-2025 Task 11 Track B. The task involves predicting the intensity of five perceived emotions—anger, fear, joy, sadness, and surprise—on an ordinal scale from 0 (no emotion) to 3 (high emotion). Our approach builds upon our method introduced in the WASSA workshop and enhances it by integrating ModernBERT in place of the traditional BERT model within a boosting-based ensemble framework. To address the difficulty in capturing fine-grained emotional distinctions, we incorporate class-preserving mixup data augmentation, a custom Pearson CombinLoss function, and fine-tuned transformer models, including ModernBERT, RoBERTa, and DeBERTa. Compared to individual fine-tuned transformer models (BERT, RoBERTa, DeBERTa and ModernBERT) without augmentation or ensemble learning, our approach demonstrates significant improvements. The proposed system achieves an average Pearson correlation coefficient of 0.768 on the test set, outperforming the best individual baseline model. In particular, the model performs best for sadness (r = 0.808) and surprise (r = 0.770), highlighting its ability to capture subtle intensity variations in the text. Despite these improvements, challenges such as data imbalance, performance on low-resource emotions (e.g., anger and fear), and the need for refined data augmentation techniques remain open for future research.

1 Introduction

Emotions play a critical role in human communication, influencing decision-making, relationships, and interactions. In recent years, automatic detection and modelling of emotions in the text have attracted significant attention within the natural language processing (NLP) community due to their potential applications in areas such as mental health support, and personalized recommender systems (Zad et al., 2021). Despite this progress, emotion recognition remains challenging because of the complexity and subjectivity inherent in emotional expression. This study focuses on the detection of perceived emotions, which predicts the emotions that most people would associate with a given text. Perceived emotions are influenced by culture and individual differences, making their detection complex and nuanced (Van Woensel, 2019). Previous studies, such as those of Mohammad et al. (Mohammad et al., 2018), have highlighted the importance of perceived emotions in tasks like sentiment analysis and emotion intensity prediction.

In this work, we explore *SemEval-2025 Task 11 Track B: Emotion Intensity Prediction* of the shared task on Knowledge Representation and Reasoning (Muhammad et al., 2025b). Track B aims to predict the intensity of perceived emotions, joy, sadness, fear, anger, surprise, or disgust, on an ordinal scale ranging from 0 (no emotion) to 3 (high emotion). Previous research has explored techniques such as ordinal regression (Mehta et al., 2019; Yang et al., 2024) and multi-task learning (Akhtar et al., 2019) to better model emotion intensity. However, there remains a gap in optimizing these models specifically for emotion intensity prediction, particularly in learning from limited data, preserving ordinal relationships between intensity levels, and integrating augmentation techniques that improve generalization without distorting emotional meaning.

To address these challenges, this study introduces a novel framework that builds on our method proposed in the WASSA workshop, enhancing it with ModernBERT as a replacement for the traditional BERT model. The proposed approach integrates class-preserving mixup data augmentation, a custom Pearson CombinLoss function, and a boosting-based ensemble strategy to improve the model's ability to handle the ordinal nature of intensity labels, capture subtle emotional variations, and enhance robustness across different contexts.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 302–307

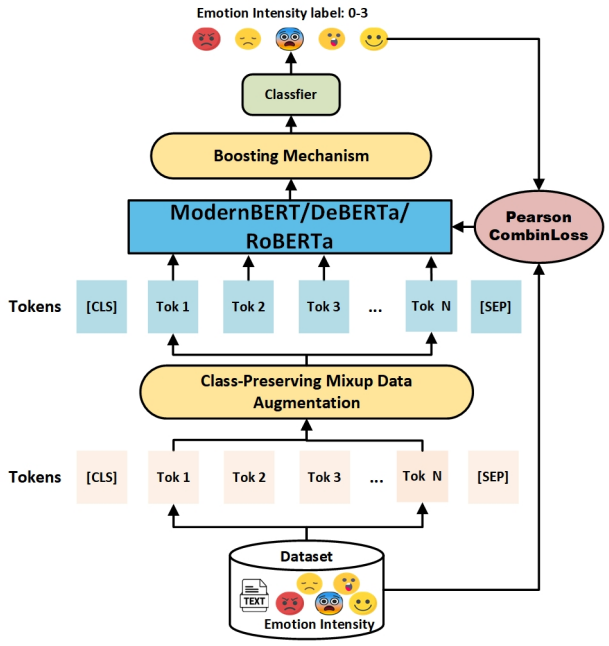

Figure 1: Overview of the Proposed Emotion Intensity Prediction Framework. The system integrates Class-Preserving Mixup Data Augmentation, Pearson CombinLoss, and a Boosting Ensemble with fine-tuned ModernBERT, RoBERTa, and DeBERTa models.

The ensemble leverages multiple fine-tuned transformer models, including ModernBERT, RoBERTa, and DeBERTa, to combine their strengths and improve generalization. Through several evaluations on SemEval-2025 Task 11 Track B, we demonstrate that our method significantly outperforms individual transformer-based models, achieving improved Pearson correlation scores, particularly for sadness and surprise.

2 Methodology

Our approach enhances emotion intensity prediction by integrating ModernBERT into a boosting-based ensemble framework, based on the method introduced in the WASSA workshop (Huang and Liang, 2024). Figure 1 illustrates our method for Track B in SemEval-2025 Task 11. It consists of data augmentation, the Pearson CombinLoss function, fine-tuned ModernBERT, DeBERTa or RoBERTa models, and the effective boosting strategy. In the following, we describe each component in detail.

2.1 Class-Preserving Mixup Data Augmentation

Traditional mixup methods (Smucny et al., 2022) is a widely used regularization technique that improves model generalization by blending samples across all classes. However, emotion intensity prediction introduces issues such as semantically unrealistic emotion blending, misalignment with the ordinal structure of intensity labels, and imbalance in augmented data distribution. Therefore, this paper proposes class-preserving mixup data augmentation. This method ensures that only samples within the same emotion category are mixed. This preserves the semantic integrity of the text while introducing controlled variation, allowing the model to better generalize across different expressions of the same emotion. Mathematically, given an input sequence X_i, and its label y_i, a mixed sequence $\tilde{X}_i$ is generated by selectively replacing a span of X_i with another sample X_k from the same class:

$$\tilde{X}_i[j] = \begin{cases} X_i[j], & \text{if } j \notin [s, e] \\ X_k[j], & \text{if } j \in [s, e] \end{cases} \quad (1)$$

where $[s, e]$ is the randomly selected span, and X_k is a randomly chosen sample from the same class as X_i. In emotion classification tasks, data augmentation enhances model performance by generating new training data. For example, mixing two anger-related texts— text 1 ("*One jumped on my leg and bit me.*") and text 2 ("*I finally managed to sit up on my hands and knees, and glaring up at her.*")—using Class-Preserving Mixup (with alpha = 0.1) produces: "*One jumped on my leg and bit me, and I finally managed to sit up, glaring up at her with anger.*" This mixed text retains the original narratives while strengthening emotional coherence. A corresponding image (see Figure 2) visualizes the process, showing an animal biting a person's leg and another person sitting up, glaring defiantly. Such augmentation enriches data diversity and improves emotion classification accuracy.

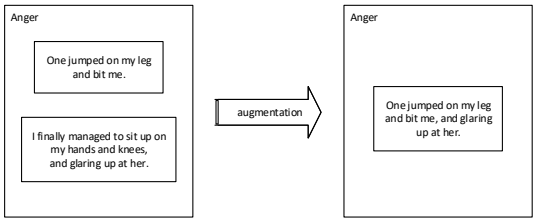

Figure 2: Example of Class-Preserving Mixup Augmentation in the Anger Category. Two original anger-related text snippets are combined by replacing a span in the first sentence with content from the second.

2.2 Pearson CombinLoss Function

To improve the performance of the model and take into account the layer-wise penalty, we use a new loss function that combines three parts: Cross-Entropy Loss, Structured Contrastive Loss, and Pearson Correlation Loss. We also introduce a hierarchical penalty matrix $\mathbf{P}$ to capture penalties for incorrect predictions based on the difference between predicted and true classes. The matrix is computed as:

$$P_{i,j} = \exp(-\gamma|i-j|) \tag{2}$$

where i and j are class indices, and γ controls the sharpness of penalty. This matrix penalizes predictions more severely, as they are further away from the true class.

This Pearson CombinLoss Function is defined as:

$$\begin{aligned}\mathcal{L}_{\text{combined}} &= \alpha\mathcal{L}_{\text{CE}} + \gamma\mathcal{L}_{\text{SC}} + \beta\mathcal{L}_{\text{P}} \\ &= \alpha\left(-\frac{1}{N}\sum_{i=1}^{N}\log p(y_i \mid \mathbf{x}_i)\right) \\ &\quad + \gamma\left(-\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{C}P_{y_i,j}\log p(j \mid \mathbf{x}_i)\right) \\ &\quad + \beta\left(-\frac{\text{Cov}(\hat{\mathbf{y}},\mathbf{y})}{\sqrt{\text{Var}(\hat{\mathbf{y}})\cdot\text{Var}(\mathbf{y})}}\right)\end{aligned} \tag{3}$$

where $\mathcal{L}_{\text{CE}}$ is standard cross-entropy loss, $\mathcal{L}_{\text{SC}}$ is structured contrastive loss incorporating hierarchical penalties, and $\mathcal{L}_{\text{P}}$ is pearson correlation loss. α, γ, β are hyperparameters that control the weight of each component. $p(y_i \mid \mathbf{x}_i)$ is the predicted probability of the true class y_i for input $\mathbf{x}_i$. $P_{y_i,j}$ is the penalty for predicting class j when the true class is y_i, and C is the total number of classes. $\hat{\mathbf{y}}$ and $\mathbf{y}$ are the predicted and true distributions, respectively, and Cov and Var denote covariance and variance.

2.3 Boosting Technique

Boosting (Tyralis and Papacharalampous, 2021) is employed to enhance the robustness and performance of the system by utilizing an ensemble strategy combined with weighted averaging. This approach capitalizes on the strengths of individual models to produce more accurate and reliable final predictions. The methodology involves using the Pearson Correlation Coefficients of the models as weights, thereby adjusting the final model output to optimize performance. This boosting mechanism ensures that the final predictions leverage the strengths of individual models, weighted by their respective Pearson Correlation Coefficients, resulting in improved performance across evaluation metrics.

$$\hat{y}_{\text{final}} = \frac{\sum_{i=1}^{M} w_i\hat{y}_i}{\sum_{i=1}^{M} w_i}, \quad w_i = r_i \tag{4}$$

where M is number of models in the ensemble and $\hat{y}_i$ represents predictions from the i-th model. r_i is Pearson Correlation Coefficient for the i-th model. w_i is weight assigned to the i-th model based on r_i.

3 Experiments and Results

3.1 Datasets

This study focuses on *SemEval-2025* Task 11 Track B: Emotion Intensity from the competition, which involves predicting the intensity of perceived emotions for text snippets. The task requires determining the degree of intensity for several perceived emotions: *joy*, *sadness*, *fear*, *anger*, *surprise*, or *disgust*. Emotion intensities are categorized into four ordinal classes: 0 (No emotion), 1 (Low emotion), 2 (Moderate emotion), and 3 (High emotion), reflecting the perceived degree of emotional expression in the text. These classes provide a structured scale to assess the intensity of emotion.

The dataset used in this study is a subset of the competition data (Muhammad et al., 2025a), focusing only on *English* language. The English dataset consists of training, development and test sets. Each sample contains: A unique identifier (*ID*), A short text snippet (*text*), Intensity scores for the five emotions (*anger, fear, joy, sadness, surprise*). Table 1 is an example of a training sample.

Table 1: Example of a Training Sample

Text: *"Then the screaming started."*

Anger	Fear	Joy	Sadness	Surprise
0	3	0	1	2

Other Information: ID: `eng_train_00001`.

The dataset consists of three subsets: a Training Set with 2,768 samples containing both textual data and labeled emotion intensities, a Development Set with 116 samples for fine-tuning and validation,

Table 2: Dataset Summary with Emotion Counts (Non-zero Counts) and Mean Scores

Dataset	Anger	Fear	Joy	Sadness	Surprise	Total
Train	333	1611	674	878	839	2768
Dev	16	63	31	35	31	116
Test	–	–	–	–	–	2767
Mean_Train	0.18	0.93	0.35	0.50	0.41	–
Mean_Dev	0.23	0.83	0.37	0.47	0.37	–

Note: Emotion sizes represent the non-zero counts of samples for each emotion category.

Table 3: Mixup-Augmented Dataset Summary with Non-zero Emotion Counts

Dataset	Anger	Fear	Joy	Sadness	Surprise	Total
Train-mixup	668	3224	1350	1758	1680	5536
Dev-mixup	34	128	64	72	64	234
Test-mixup	–	–	–	–	–	5536

and a Test Set with 2,767 samples containing only textual data for evaluating model predictions. The average emotion scores for the training set, presented in Table 2, reveal an imbalance. The development set follows the same structure as the training set, with similar mean emotion intensities, while the test set is unlabeled, emphasizing its role in assessing model performance. After applying mixup augmentation, the updated emotion distributions are detailed in Table 3.

3.2 Evaluation Metric

The official evaluation metric for Track B: Emotion Intensity task in this competition was the Pearson Correlation Coefficient, which measured the correlation between the gold-standard labels and the predicted ones. The Pearson Correlation Coefficient r ranges from -1 to 1, where values closer to 1 indicate a stronger positive correlation between the predicted and gold-standard values. The coefficient is defined as:

$$r = \frac{\sum_{i=1}^{n}(\hat{y}_i - \bar{\hat{y}})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n}(\hat{y}_i - \bar{\hat{y}})^2 \sum_{i=1}^{n}(y_i - \bar{y})^2}} \quad (5)$$

where $\hat{y}_i$ and y_i represent the predicted and gold-standard labels, respectively, $\bar{\hat{y}}$ and $\bar{y}$ are their means, and n is the number of samples.

3.3 Experiment Setup

The class-preserving mixup technique and Pearson CombineLoss Function were integrated into the training pipeline for state-of-the-art language models such as ModernBERT, RoBERTa, and DeBERTa. All models were implemented with the PyTorch framework, ensuring seamless integration with transformer architectures. The experiments were conducted on NVIDIA A4000 GPUs. The training process utilized the Adam optimizer with exponential decay (decay factor $\gamma = 0.99$), a batch size of 32. The models were trained and evaluated for each emotion category using different hyperparameter configurations. Table 4 presents the corresponding hyperparameters used for each emotion. Each model was trained on the emotion intensity prediction task using different configurations for the loss function parameters $\alpha, \beta, \theta = 0.8$. The learning rate (LR) and number of epochs were adjusted to optimize performance for each emotion category.

Table 4: Hyperparameters and Pearson Correlation Results for Each Emotion

Emotion	α	β	LR	Epochs
Anger	1	0.8	4×10^{-5}	6
Fear	0.5	0.5	4×10^{-5}	5
Joy	0.1	0.9	1×10^{-5}	10
Sadness	0.2	0.8	1×10^{-5}	8
Surprise	0	1.0	4×10^{-5}	9

Table 5: Pearson Correlation Coefficient (r) for each emotion on the development and test sets

Emotion	Dev Set Pearson	Test Set Pearson
Anger	0.656	0.760
Fear	0.780	0.735
Joy	0.820	0.768
Sadness	0.747	0.808
Surprise	0.738	0.770
Average	**0.748**	**0.768**

3.4 Results and Discussions

Our proposed framework integrates ModernBERT, Class-Preserving Mixup, Pearson CombinLoss, and a Boosting-Based Ensemble Strategy, achieving significant improvements in perceived emotion intensity prediction. By applying Class-Preserving Mixup and Pearson CombinLoss, we observed further performance gains. The augmentation strategy ensured label consistency, while the loss function helped the model better capture the ordinal nature of intensity levels. The boosting ensemble strategy further enhanced performance by leveraging the strengths of multiple models, leading to a fi-

Table 6: Pearson Correlation Coefficient (r) for Each Model on dev set

ModernBERT	✓	✓	0.604	0.718	0.737	0.714	0.665	0.688
Boosting(Ours)	✓	✓	**0.656**	**0.780**	**0.820**	**0.747**	**0.738**	**0.748**

nal average Pearson correlation of 0.768 [1] on the test set. (Table 5). The ensemble demonstrated the strongest performance on sadness (r = 0.808) and surprise (r = 0.770), indicating its ability to effectively capture subtle intensity variations.

The performance of individual transformer models, as well as the ensemble results, is summarized in Table 6 on development set. Among the individual models, DeBERTa achieved the highest overall Pearson correlation coefficient ($r = 0.718$), with strong performance for *joy* ($r = 0.803$) and *fear* ($r = 0.735$). RoBERTa followed with an overall Pearson correlation of 0.707, performing best for *joy* ($r = 0.788$) and *fear* ($r = 0.740$). BERT showed the lowest overall performance ($r = 0.684$), particularly struggling with *anger* ($r = 0.615$). These results highlight the varying capabilities of individual transformer models in capturing the nuances of emotional intensities.

Despite these improvements, challenges remain to accurately model fear and anger, where the system's performance was relatively lower. This is likely due to data imbalance, where fewer training samples for these emotions limited the model's ability to generalize. Furthermore, fear and anger often depend on nuanced contextual cues, which may not be fully captured by current transformer-based models.

[1]This score is based on a post-evaluation run using the test set after the gold labels were released. The leaderboard score (0.67) corresponds to an earlier submission.

4 Conclusions

This paper presents a novel framework for perceived emotion intensity prediction, developed for SemEval-2025 Task 11 Track B, by integrating ModernBERT within a boosting-based ensemble model. The proposed approach builds upon the method introduced in the WASSA workshop and incorporates Class-Preserving Mixup data augmentation, a custom Pearson CombinLoss function, and fine-tuned transformer models to address key challenges such as the ordinal nature of emotion intensity labels, and capturing fine-grained emotional distinctions. Our system achieved an average Pearson correlation coefficient of 0.768 on the test set, demonstrating significant improvements over baseline models. The ensemble approach, leveraging ModernBERT, RoBERTa, and DeBERTa, was particularly effective in modeling subtle variations in sadness and surprise, achieving Pearson correlations of 0.808 and 0.770, respectively. However, challenges remain in accurately modeling *fear* and *anger*, likely due to limited training samples and inherent subjectivity in emotional expression.

Future work could explore data augmentation strategies, adaptive loss functions tailored to ordinal emotion scales, and context-aware transformer models to enhance emotion intensity prediction further. Additionally, integrating multimodal signals such as prosody and speech patterns could help improve robustness in real-world applications, particularly in mental health support and personalized conversational AI.

Abstract

With the overwhelming amount of online information and material, it is difficult to tell the truth from the lies. This poses a significant issue as individuals exploit this uncertainty to persuade, polarise, and misinform populations. However, multilingual fact-checking could be the solution by relating fake news to reliable sources worldwide, which is the main aim of SemEval-2025 Task 7. Our approach to this task employs an efficient sieve filtering method to retrieve the most relevant fact-checks that align with the social media post's original language, semantic content and uploaded time frame. Our approach achieved a success rate of 0.883 for the monolingual and 0.391 for the crosslingual tasks, while maintaining the high efficiency needed to limit the global impact of misinformation.

1 Introduction

Societally, we have been transitioning into a world of misinformation, disinformation, and fake news (Kavanagh and Rich, 2018). However, this transition has accelerated dramatically due to the recent advancement in generative AI, making it easier and more accessible to create highly believable and persuasive text, images, and videos (Nazar and Bustam, 2020; Xiong et al., 2024). The ability to post online as a form of expression, collaboration, and connection worldwide is becoming increasingly tainted by the spread of false and misleading information. This issue is becoming increasingly prevalent as widespread misinterpretations of these posts are fuelling polarisation, inciting hatred, and causing harm to the population (Broda and Strömbäck, 2024; Wu et al., 2019). Within this problem arises an essential need for fact-checking systems to combat this new threat. These systems must be highly accurate to counteract the false information and avoid amplifying the current issue. In addition, they must be efficient and multilingual, as around 5.22 billion social media users worldwide post and share content daily in various languages. The systems must identify and mitigate misinformation in real-time before it spreads (Kemp, 2024).

In the context of previously fact-checked claim retrieval (PFCR) (Shaar et al., 2020), Task 2 of CLEF 2022 focused on competitors determining a list of top-n fact-checked claims to corresponding tweets or political dialogues (Nakov et al., 2022). One of the published methods from the task, which achieved the highest accuracy, used a 3-step pipeline of pre-processing the tweets for clarity, retrieving the relevant claims using the BM25 model, and generatively re-ranking the claims using GPT-Neo-1.3B (Shliselberg and Dori-Hacohen, 2022). Another notable approach used the sentence transformer models, All-MiniLM-L6-v2 and All-MPNet-Base-v2, alongside a Support Machine Vector model to create an ensemble classifier to calculate the similarity score between tweets and fact-checked claims (Frick and Vogel, 2022).

Task 7 of SemEval-2025 aimed to address the challenge of misinformation (Peng et al., 2025). Participants were tasked with developing a fact retrieval system capable of providing relevant facts to contextualise or disprove social media posts. In this paper, we propose a sieve filtering-based approach that can retrieve facts to invalidate claims made in social media posts. The fact filters are initially coarse-grained, based on the original language of the social media posts, and end with fine-grained filters based on the exact time frame in which the posts were uploaded online. This streamlined approach achieved a 0.883 retrieval success rate in the monolingual task while maintaining a scalable efficiency level of processing a social media post per 0.07 seconds.

2 Dataset

The organisers used a modified version of the MultiClaim dataset, enhanced especially for the task

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 308–313

(Pikuliak et al., 2023). The authors provided a development dataset consisting of a post CSV P and fact-check CSV F, containing 24,431 posts and 153,743 fact-checks. In the testing dataset, this changed, with the post CSV changing to 8,276 unseen posts and the fact-check CVS expanding with an additional 118,704 unseen fact-checks, bringing the total number of fact-checks to 272,447. Each social media post within the dataset was flagged by a professional fact-checker from the social media sites Facebook, Instagram and Twitter. Each post entry $\mathcal{P}$ includes the post ID p_{id}, post Unix timestamp p_{time}, social media platform p_{plat}, post verdict p_{ver}, post content $p_{context}$ and OCR-extracted text p_{ocr}, which both contain the text in the original language, English translation, and predicted language country code with the accuracy rating.

$$\mathcal{P}_i = (p_{id}, p_{time}, p_{plat}, p_{ver}, p_{context}, p_{ocr})$$

$$P = \{\mathcal{P}_1, \mathcal{P}_2, \mathcal{P}_3, \ldots, \mathcal{P}_n\}$$

Each fact-check within the dataset was listed in the Google Fact Check Explorer or found in other sources such as Snopes. Each fact-check entry $\mathcal{F}$ includes the fact-check ID f_{id}, fact-check Unix timestamp f_{time}, fact-check article URL f_{url}, the fact-check article title f_{title} and claim f_{claim}, both structured identically to post text $p_{context}$.

$$\mathcal{F}_i = (f_{id}, f_{time}, f_{url}, f_{title}, f_{claim})$$

$$F = \{\mathcal{F}_1, \mathcal{F}_2, \mathcal{F}_3, \ldots, \mathcal{F}_n\}$$

3 Methodology

To tackle the task, we propose a simplistic sieve approach, as illustrated in Figure 1, to filter the $\mathcal{F}$ based on the post's features (p_{time}, $p_{context}$, p_{ocr}) until the top 10 most relevant $\mathcal{F}$ to the $\mathcal{P}$ are identified.

3.1 Fact Pre-Processing

Since we opted against using a machine learning approach for this task, pre-processing for all $\mathcal{F} \in F$ was a vital step to ensure high levels of accuracy. As mentioned in section 2, each $\mathcal{F}$ contained f_{title} and f_{claim} which held the main information regarding the fact. For the majority of $\mathcal{F}$, we would join the English translation of the texts to create f_{text} = "f_{claim}. f_{title}". However, in rare cases when f_{title} in $\mathcal{F}$ was empty, f_{text} = "f_{claim}". This concatenation maximises the semantic context in f_{text}

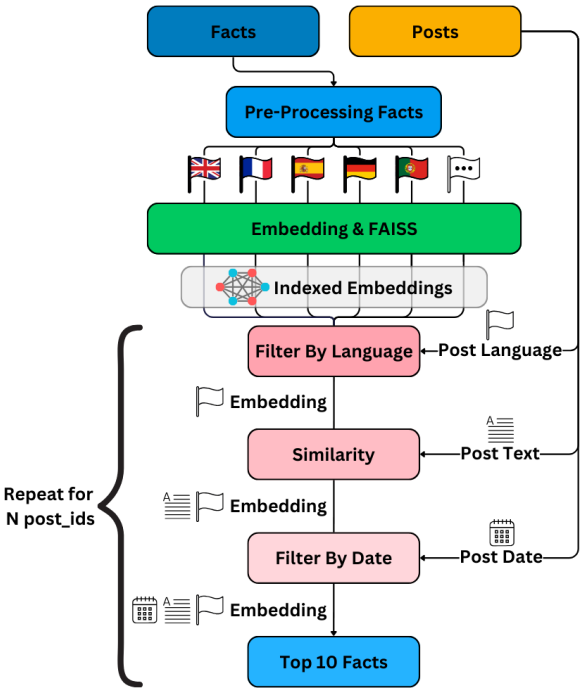

Figure 1: The sieve filtering approach

as this will increase the accuracy during the similarity search. Then, given that the language style used within f_{text} was formal, $p_{context}$ contained slang, emojis, and grammatically incorrect punctuation. We utilised the regular expressions module to remove all non-alphabetical characters from f_{text}. This process will also be applied to $p_{context}$ later in the pipeline to align the textual styles. The final stage of the fact pre-processing was to cluster f_{text} based on the predicted language country code f_{lang} nested in f_{claim}, as shown by Figure 2. Preliminary experiments suggested that grouping the f_{text} based on f_{lang} significantly improved the overall accuracy and efficiency of the system, as this process would go on to reduce the size of the search space dramatically. The output of the fact pre-processing stage was a dictionary D containing clusters of f_{text}, grouped by their corresponding f_{lang}.

3.2 Embedding and FAISS Indexing

Unlike humans, computers struggle to compare the similarities of two text items. Therefore, the texts must be converted into numerical representations called embeddings. We used the Jina-Embedding-V3 for the embedding model (Sturua et al., 2024). This choice balanced accuracy and efficiency, achieving a score of 85.80 in the Sentence Textual Similarity (STS) section of the MTEB Leaderboard while maintaining a suitable size of

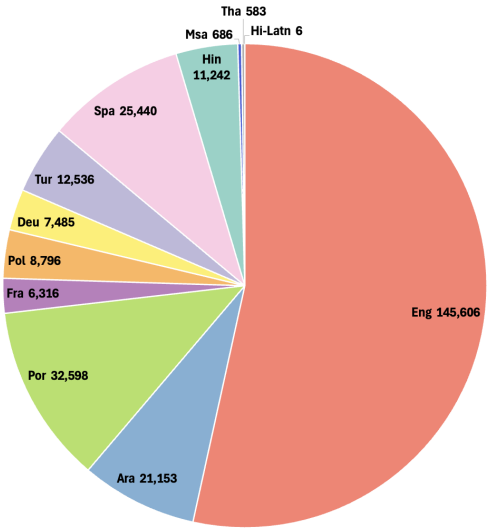

Figure 2: Pie chart of the language distribution for all $f_{lang} \in F$

570 million parameters (Muennighoff et al., 2023). We used the Flat Index L2 from the Facebook AI Similarity Search (FAISS) library to index and store the embeddings (Douze et al., 2024). The Flat Index L2 sequentially stores the embeddings and performs an exhaustive Euclidean distance search to find the most similar embeddings for a given query. This search approach is highly accurate, finding exact matches rather than approximations. However, this approach becomes inefficient and time-consuming for large datasets due to the sequential storing and brute-force search. This potential issue is mitigated by clustering the $\mathcal{F}$ based on f_{lang}, which partitions F into usable and efficient subsets. This is visualised in Figure 2, as regardless of $\mathcal{P}_{lang}$, the maximum dataset size used is reduced from 272,447 to 145,606 f_{text}.

$$\text{for all } L \in f_{\text{lang}}, \quad \text{for all } f_{\text{text}} \in D(L)$$

Each f_{text} is embedded into a 1024-dimensional vector $\mathbf{F}$ and stored in the FAISS Index $I(L)$.

3.3 Fact Sieving

The sieving stage of the approach applies a series of filters, each becoming more fine-grained, to $\mathcal{F}$ to identify the 10 most aligned $\mathcal{F}$ to each $\mathcal{P}$. The first layer filtered each $\mathcal{F}$ by the original language of $\mathcal{P}$, p_{lang}. We extracted the nested p_{lang} from $p_{context}$ if available; else, it was obtained from p_{ocr}. The extracted language was then used to retrieve the relevant facts from I based on p_{lang}, denoted as $I(p_{lang})$. On average, this simple filter reduced the number of $\mathcal{F}$ by 91.67% from 272,447 to 22,703, which boosted the performance accuracy by lowering the irrelevant $\mathcal{F}$ in the similarity search of the next layer. The second layer filtered each $\mathcal{F}$ by comparing the semantic content of f_{text} with the semantic content of $p_{content}$ and p_{ocr}. We concatenated the English translation of "$p_{content}$. p_{ocr}" = p_{text}, which went through the same syntactical alignment pre-processing, as in section 3.1. We embedded p_{text} using Jina-Embedding-V3 to generate vector $\mathbf{P}$ and queried $I(p_{lang})$, which utilised Euclidean distance similarity search and retrieved the indexes of the top 250 most similar $\mathcal{F}$ to the $\mathcal{P}$ in $I(p_{lang})$. We converted the indexes to the evaluation output format of f_{id}.

$$S = \text{argsort}_{250}\left(-\|\mathbf{P} - \mathbf{F}_i\|_2\right), \quad \text{for all } \mathbf{F}_i \in I(p_{lang})$$

This layer is the most significant in terms of accuracy, as on average, it reduced the possible $\mathcal{F}$ by 98.80% from 22,703 to 250. We selected the top 250 as it balanced accuracy and efficiency while trying to reduce the inefficient, repetitive nature of the following filter. The third and final layer used the p_{time} to remove the outdated $\mathcal{F}$ according to their f_{time}. We set the cut-off time frame to approximately 9 months, as empirical testing indicated it was the optimum value to enhance accuracy without removing possibly relevant $\mathcal{F}$. As the majority of the timestamps were in the UNIX timestamp format, the $\mathcal{F}$ would be deemed outdated if:

$$|f_{\text{time}} - p_{\text{time}}| > 9 \times 30 \times 24 \times 60 \times 60$$

We would iterate through the S, removing the outdated $\mathcal{F}$ from the similarity-ordered list using their corresponding f_{id}. The last step was to choose the first 10 items from S, which reduced the number of $\mathcal{F}$ by 96% from 250 to the final 10 f_{id} needed for Task 7 of SemEval-2025.

4 Evaluation Setup

The evaluation of SemEval-2025 Task 7 was split into two tracks: monolingual and crosslingual. The claim and the retrieved fact-check were in the same language in the monolingual track. Whereas the crosslingual track meant the claim and the retrieved fact-check may be in different languages from the 27 available in the test dataset, which provided an extra dimension of complexity to the challenge.

4.1 Evaluation Data

For the evaluation, alongside the P and F, the authors also provide 2 JSON submission files for the

Name	Size (M)	Mono (S@10)											Cross (S@10)

Leaderboard$_{\text{Best}}$		**0.960**	**0.916**	**0.972**	**0.958**	**0.926**	**0.974**	**0.995**	**1**	**0.986**	**0.948**	**0.926**	**0.859**

Table 1: Comparison of Performance using the S@10 scores among the baseline textual embedding models (Multilingual-e5-Base (Wang et al., 2024), Bilingual-Embedding-Base (Lajavaness, 2024), GTE-Large-en-1.5v (Li et al., 2023), and Jina-Embedding-V3), our approaches, and the leading method of SemEval-2025 Task 7

monolingual and crosslingual tracks. These files contain a respective 4276 and 4000 p_{id} corresponding to $\mathcal{P}$, each with an empty list to be filled with the 10 most relevant f_{id}, as described in 3.3.

4.2 Evaluation Metrics

The performance of the approaches in Task 7 are measured using the Success-at-10 (S@10). Each $\mathcal{P}$ has one or more corresponding $\mathcal{F}$. A retrieval is successful if the golden $\mathcal{F}$ is within the 10 submitted $\mathcal{F}$. The success-at-10 rate is average over the number of p_{id} entries in the JSON file. The monolingual evaluation goes slightly further than the crosslingual evaluation, as the S@10 is additionally calculated for each language for a more in-depth analysis.

5 Results

5.1 Main Results

The results in Table 1 indicate that Approach$_{\text{Best}}$ achieved our highest retrieval success rate with 0.883 in the test-phase monolingual task. This suggests our approach can accurately provide the factual information needed to disprove the misinformation in potentially harmful social media posts. The filtering rules of our approach were consolidated during the development phase of SemEval-2025. For a comparison, Approach$_{\text{Best}}$ was evaluated post-SemEval on the development-phase monolingual task, it scored a retrieval success rate of 0.832. The improvement when faced with new data in the test phase shows the generalizability of the filtering rules of our approach. In the more complex crosslingual task, we achieved an accuracy of 0.391. This lower performance can be attributed to our approach not aligning with the cross-lingual task, as we reduce the search space by focusing on $\mathcal{F}$ where $\mathcal{F}_{lang}$ is the same as $\mathcal{P}_{lang}$. However, this is counterintuitive, as for the cross-lingual task, we should prioritise $\mathcal{F}$ and $\mathcal{P}$ with different languages. Addressing this misalignment could make the cross-lingual approach equally as accurate as the monolingual task. In SemEval-2025 Task 7, the highest recorded scores for the monolingual and crosslingual tasks were a remarkable 0.960 and 0.859, respectively. While our approach has lower accuracy, its greater efficiency compared to smaller text embedding models, as shown in Table 2, makes it a strong baseline approach that can be built upon and further refined.

5.2 Efficiency

In addition to aiming for high multilingual accuracy, another main goal of the approach was high efficiency, as this would ensure scalability in handling the volume of social media posts online. Each text embedding model and our strategies were timed from the initialisation of the script through the embedding phase until the final $\mathcal{P}$ had been countered by $\mathcal{F}$. The Jina-Embedding-V3 model had the quickest processing time amongst the baselines. Despite its larger size of 572 million parameters, it was over a minute and 20 seconds quicker than Multilingual-e5-Base, which is half the size. However, our best approach outperformed all baselines in both tasks, reducing the time taken by around 3 minutes from Jina-Embedding-V3. This significant gain in efficiency is due to language filtering, which reduces the size of search space, making the $\mathcal{F}$ retrieval faster and more efficient.

5.3 Ablation Study

It was logical that a relevant pairing of $\mathcal{P}$ and $\mathcal{F}$, would be within a similar time frame. This assumption was validated while analysing and manually pairing $\mathcal{P}$ to $\mathcal{F}$ in the development dataset, as there was a strong correlation between the time frame and the content shared between similar $\mathcal{P}$ and $\mathcal{F}$. However, we acknowledged that a time filtering

Name	Eval Time (s)		Time Per P (s)	
	Mono	Cross	Mono	Cross
Multilingual-e5-Base	585	569	0.137	0.142
Bilingual-Embedding-Base	619	608	0.145	0.152
GTE-Large-en-1.5v	2134	2077	0.499	0.519
Jina-Embedding-V3	505	480	0.118	0.120
Approach$_{\text{Submitted}}$	3140	3270	0.734	0.818
Approach$_{\text{Best}}$	**304**	**312**	**0.07**	**0.08**

Table 2: Comparison of Efficiency using the evaluation completion time among the baseline textual embedding models and our approaches

step would be the most inefficient part of the sieving process due to its repetitive nature. Nonetheless, we decided to prioritise accuracy over efficiency. The Approach$_{\text{Submitted}}$ includes the time filtering step, and Approach$_{\text{Best}}$ does not. As evident in Table 1 and 2, the previously mentioned assumption was incorrect, as Approach$_{\text{Best}}$ has marginally higher accuracy by 0.03 while being significantly more efficient by over an hour and a half across the two tasks. Unfortunately, we could not recognise this mistake before the SemEval-2025 Task 7 test-phase ended.

6 Conclusion

In this paper, we presented our approach in the SemEval-2025 Task 7, which addressed the ongoing challenge of fact-checking social media posts to debunk the misinformation contained within. The task has an additional difficulty component, as the facts and posts are from one of 27 different languages, reflecting the global importance of this challenge. Our sieve filtering approach used the key features, such as original language, semantic content, and time frame, from each social media post to retrieve the 10 most relevant fact-checks. Our approach achieved a 0.883 success rate when retrieving fact-post parings in the monolingual task without sacrificing the high-efficiency levels of 0.07 seconds to disprove each post factually. While our approach does not match the top approaches in the leaderboard, it provides a strong baseline for future improvements. One future improvement for the approach would be to use the other features within each fact-check, such as the article URL, to provide more context and potentially improve retrieval accuracy.

Abstract

SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection Track A addresses multilingual, multi-label emotion classification across 28 languages, including many low-resource varieties. We propose a hard-parameter-sharing architecture built on XLM-RoBERTa-Large, with lightweight, language-specific classification heads, and a two-stage training regimen that first freezes the shared encoder and then fine-tunes it. On the BRIGHTER dataset, our model achieves macro F1-scores up to 0.84 on high-resource languages and maintains robust performance (0.63 macro F1) even on severely imbalanced low-resource languages. We will analyze our results and discuss limitations and potential strength point of our solution that could be leveraged in future work to improve results on similar tasks.

1 Introduction

Emotions are at once an everyday experience and an elusive phenomenon. Although we routinely express and regulate our feelings, they remain intricate and subtle, often defying clear articulation. Language itself is employed in remarkably nuanced ways to convey these internal states, as noted by previous research (Conneau et al., 2020; Deng and Ren, 2020; Zhang et al., 2020a). Moreover, individuals differ greatly in both how they perceive and display their emotions—even among those sharing similar cultural or social backgrounds—making it impossible to determine someone's true emotional state with complete certainty based solely on their words. Emotion recognition, therefore, is not a singular task but rather a collection of related challenges. It includes identifying the speaker's emotional state, discerning the sentiment a piece of text conveys, and even gauging the emotional response it triggers in a reader. Our focus here is on perceived emotion: inferring the emotion that the majority would attribute to the speaker based on a brief sentence or text snippet. This task deliberately excludes determining the reader's emotional reaction, the emotion of another person mentioned, or the speaker's actual feeling—since the latter remains indeterminate from limited text. This distinction is critical, as factors like cultural context, individual differences, and the inherent limitations of textual communication often cause perceived emotions to differ from the speaker's real emotional state (Samy et al., 2018; Zhang et al., 2020b; Ameer et al., 2020). In this paper, we describe our system developed for Track A of the task, which is designed to determine multi-label classifications for a single text snippet across all 28 languages (Muhammad et al., 2025b). Our system leverages a shared multilingual encoder coupled with language-specific classification heads, enabling it to capture both universal and language-dependent emotional cues (Caruana, 1997; Ghosh et al., 2022; Lin et al., 2022). By utilizing advanced transformer models (such as XLM-RoBERTa) as the backbone, our approach not only processes input text efficiently but also generates predictions for multiple emotion classes—including anger, disgust, fear, joy, sadness, and surprise—for each language simultaneously. This robust design addresses the inherent challenges of multilingual emotion recognition, offering a comprehensive solution that can be adapted to varied linguistic contexts.

2 Related works

Research on multi-label emotion detection has accelerated in recent years. (Deng and Ren, 2020) use emotion-specific feature extractors and label correlation graphs; (Ghosh et al., 2022) propose a multitask framework for depression, sentiment, and emotion; (Lin et al., 2022) leverage adversarial multi-task learning for label dependencies. More recent soft-sharing architectures and

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 314–318

mixture-of-experts models (Liu et al., 2024; Fan et al., 2025) dynamically allocate capacity per language, yielding gains on typologically distant languages at the cost of increased compute. However, these methods can overfit low-resource languages when class distributions are highly skewed and have not been evaluated in a truly massively multilingual, multi-label setting.

3 BRIGHTER dataset

The BRIGHTER dataset(Muhammad et al., 2025a) is a comprehensive collection of multilabeled emotion-annotated texts spanning 28 different languages. Recognizing that most emotion recognition research has focused on high-resource languages, the BRIGHTER dataset addresses this gap by incorporating predominantly low-resource languages from Africa, Asia, Eastern Europe, and Latin America. Each text instance is carefully annotated by fluent speakers from various domains, capturing the subtle and complex ways in which people express emotions. The dataset not only facilitates monolingual and cross-lingual multi-label emotion identification but also supports intensity-level emotion recognition. The data collection and annotation processes for BRIGHTER were designed to overcome the inherent challenges of building high-quality emotion datasets in diverse linguistic settings. By employing rigorous annotation guidelines and leveraging domain expertise, the creators of BRIGHTER have provided a valuable resource that highlights the variability in emotional expression across different cultures and text domains. Experimental results presented in the associated work demonstrate significant performance differences when using or not using large language models, emphasizing the importance of this resource in bridging the gap in text-based emotion recognition research. Ultimately, the BRIGHTER dataset stands as an essential step toward more inclusive and effective emotion recognition solutions in natural language processing.

4 System overview

To tackle the classification nature of this task, we opted for a BERT-family model—specifically, XLM-RoBERTa-Large—as our backbone. We selected XLM-RoBERTa-Large because it outperforms its base variant by 17 percentage points in macro F1 on the BRIGHTER dev set (Table 3), demonstrating superior cross-lingual transfer and richer encoder inductive bias for emotion cues. Our approach supports two potential strategies: training separate models for each language (storing their trained weights for the test phase) or, inspired by recent work on natural language inference, training specialized expert heads on top of a single (Figure 1), shared encoder. Given that emotional expressions exhibit substantial similarity across languages, our system is designed to share semantic representations among all languages through a common encoder while incorporating language-specific classification heads. These expert heads, whose architecture (number of layers and dimensions) is controlled via Python dictionaries and implemented using PyTorch's ModuleDict, adapt to the unique emotion class distributions observed in each language.

5 Experimental setup

Our experimental framework is designed to maximize data utilization under existing hardware constraints. We use a batch size of 1024 and restrict the maximum number of input tokens to 128, ensuring efficient attention mask construction while avoiding information loss from overly lengthy inputs. Initially, the pre-trained model and tokenizer are loaded, and the encoder's weights are frozen so that only the output logits of the language-specific heads are trained using binary cross-entropy (BCEWithLogitsLoss) to handle the multi-label nature of the task. After roughly 10 epochs with a very low learning rate (on the order of 10^{-7}), we fine-tune the encoder along with the specialized heads using a higher learning rate (approximately 10^{-3}) over 3 additional epochs. In this two-step training strategy, gradients are computed solely for one head per epoch while keeping the other heads' parameters unchanged.

6 Results and analysis

Our experimental evaluation employed the model trained with the approach depicted in Figure 1 right, with the results for four models summarized in Table 1. Additionally, a comparative analysis between the XLM-Base and XLM-Large configurations—following the approach in Figure 1 left—is presented in Table 2. The macro F1-scores reported by the competition's evaluation system for all languages indicate that performance improves with larger model sizes, as evidenced by the results in Table 3. However, Table 2 reveals that

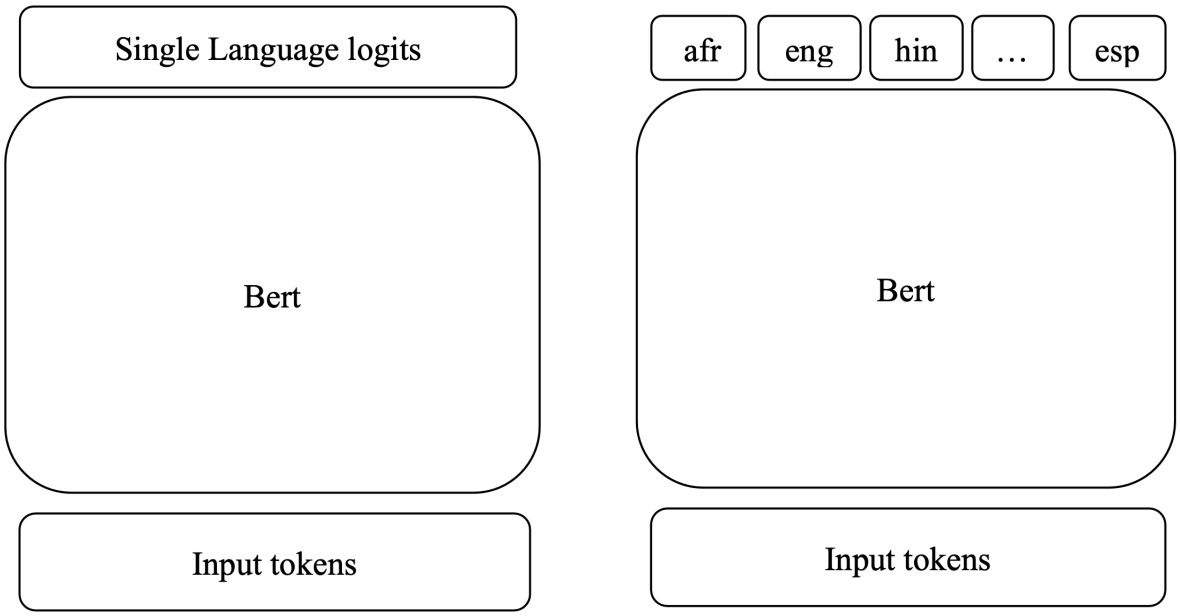

Figure 1: shared encoder with single head (left) for all languages, and seperate head (right) for each language

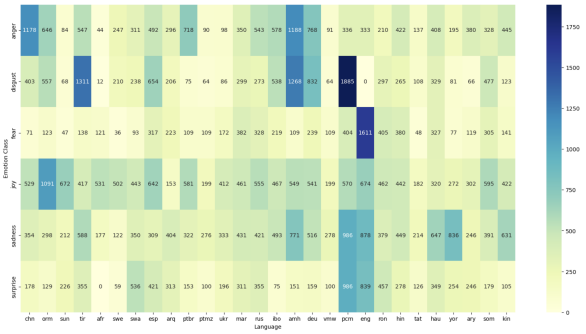

Figure 2: data per class for each language

the training strategy plays an even more crucial role: while training all parameters exclusively on one language may boost accuracy for that specific language, it can concurrently reduce overall model performance across languages. This suggests that a more balanced approach is necessary, either by training certain languages with separate parameters or by adopting an alternative architecture for their corresponding expert heads to avoid adverse effects on languages with greater semantic similarity in emotion expression.

The results of our system are shown in table 1. The system has the best performance on Mar and rus and hin. Regarding the figure 2, in which each class number is depicted for each language, these three languages have the most balanced distribution of data among all classes. As it is obvious from figure 2. Our model even performs rational in cases where the data is unbalanced. For example, without any precaution in one extreme case such eng language the model has the f1-score macro 0.627. The fact that the data distribution for each class in ptmz and vmw are almost the same but the model performance on vmw is almost a third of its performance on ptmz tell us some interesting stories regarding the semantic representation of these languages, because the sole parameter that make difference here is inductive biases which is provided by the encoder itself. This fact gives an intuition that using richer embedding for specific language input might help to increase the performance.

7 Conclusion

Our analysis of the training data further demonstrates that the number of instances for a given emotion (i.e., samples labeled with 1) critically influences model performance. Insufficient representation for a specific emotion impedes the model's ability to extract its distinctive features, leading to poor detection—as observed in languages like Emakhuwa and Yoruba, where challenging classes such as fear and disgust are underrepresented. Despite these challenges, our model achieved a highly competitive standing on the development leaderboard. This outcome underscores both the strengths of our approach and the potential for further optimization. Future work should consider strategies such as increasing model size, fine-tuning hyperparameters more effectively, and employing advanced

techniques like targeted fine-tuning on specific subsets of data. Detailed error analysis in comparison with top-performing models will be instrumental in identifying and addressing the current limitations, ultimately driving our model closer to the top of the leaderboard.

Limitations

One limitation of our approach is the inherent challenge in balancing the shared multilingual encoder with language-specific expert heads. While the shared encoder leverages common semantic features across languages, it might not fully capture the unique linguistic nuances present in each individual language. This can lead to situations where the expert heads for some languages either overfit to the available training data or fail to compensate adequately for the encoder's generic representations. Moreover, the differing amounts of training data across languages can further exacerbate these issues, resulting in inconsistent performance and potentially underrepresenting certain emotional classes in low-resource languages.

Another challenge lies in the training strategy itself. Our two-stage optimization process, which initially focuses on training only the expert heads before fine-tuning the entire model, requires careful tuning of learning rates and may not generalize well to all languages uniformly. In addition, the reliance on pre-trained models such as XLM-RoBERTa-Large introduces biases towards high-resource languages, which might hinder the model's ability to generalize in truly low-resource scenarios. These factors, combined with the complexities of multi-label classification in a diverse multilingual context, suggest that while our approach is promising, there remains significant room for improvement through further architectural innovations and more balanced data collection.

Abstract

The SemEval-2025 Task 11, Bridging the Gap in Text-Based Emotion Detection, introduces an emotion recognition challenge spanning over 28 languages. This competition encourages researchers to explore more advanced approaches to address the challenges posed by the diversity of emotional expressions and background variations. It features two tracks: multi-label classification (Track A) and emotion intensity prediction (Track B), covering six emotion categories: anger, fear, joy, sadness, surprise, and disgust. In our work, we systematically explore the benefits of two contrastive learning approaches: sample-based (Contrastive Reasoning Calibration) and generation-based (DPO, SimPO) contrastive learning. The sample-based contrastive approach trains the model by comparing two samples to generate more reliable predictions. The generation-based contrastive approach trains the model to differentiate between correct and incorrect generations, refining its prediction. All models are fine-tuned from LLaMa3-Instruct-8B. Our system achieves 9th place in Track A and 6th place in Track B for English, while ranking among the top-tier performing systems for other languages.

1 Introduction

Text-Based Emotion Detection (TBED) has long been a prominent research area in NLP, with widespread applications in social media analysis (Kuamri and Babu, 2017; Salam and Gupta, 2018; Cassab and Kurdy, 2020), mental health treatment (Kusal et al., 2021; Krommyda et al., 2021), and dialogue systems (Liu et al., 2022; Ide and Kawahara, 2022; Hu et al., 2021). Depending on how emotions are defined, TBED can be broadly categorized into two approaches: (1) Classification-based methods, where emotions are categorized into discrete labels (Ekman and Friesen, 1969; Plutchik, 1982). (2) Scoring-based methods, where emotions are treated as interrelated entities with varying intensity levels (Russell and Mehrabian, 1977).

However, due to the nuanced and complex nature of emotional expression, TBED faces several key challenges (Al Maruf et al., 2024): (1) The distinction between different emotions is often subtle, and emotions are often conveyed implicitly—through metaphors or situational cues rather than explicit words. (2) Cultural and linguistic differences influence emotion perception. These challenges make TBED difficult to rely solely on predefined lexicons. A robust TBED system must integrate cultural context, linguistic diversity, background knowledge, and advanced semantic understanding.

SemEval-2025, Task 11, titled "Bridging the Gap in Text-Based Emotion Detection" (Muhammad et al., 2025b), introduces a multilingual benchmark covering 28 languages (Muhammad et al., 2025a; Belay et al., 2025). The competition consists of Track A (multi-label classification) and Track B (intensity prediction). The goal is to identify the speaker's perceived emotion in a given sentence. Emotion categories follow Ekman's framework (Ekman and Friesen, 1969), encompassing six basic emotions: anger, fear, sadness, joy, disgust, and surprise. Task B further introduces four intensity levels for each emotion. This competition setup encapsulates both primary TBED methodologies while incorporating challenges in multilingual and fine-grained emotion recognition.

To participate in both tracks and support all languages predictions, we adopt the generative large language model (LLM). This decision is driven by its robust multi-task integration capabilities and strong support for cross-linguistic applications.

In this paper, we explore two alternative types of approaches - sample-based contrastive learning and generation-based contrastive learning - to address the complexity of emotional expression and the ambiguity of sentiment labels. The sample-based approach leverages Contrastive Reasoning

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 319–330

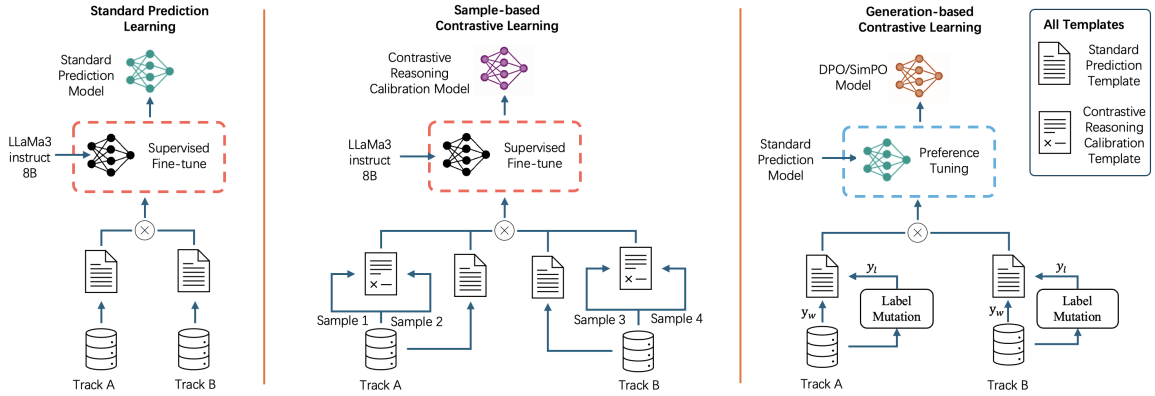

Figure 1: The 3 types of technical solutions we adopted in this competition. On the left is the Standard Prediction training. The middle is the sample-based contrastive training, where Samples 1, 2, 3, and 4 are randomly drawn from the training datasets. On the right is the generation-based contrastive training, where incorrect generations are derived through label mutation.

Calibration technology (CRC) (Li et al., 2024), which enhances prediction reliability by generating multiple predictions through sample comparisons and aggregating them via majority voting. The generation-based approaches employ preference optimization techniques (Rafailov et al., 2023; Hong et al., 2024; Meng et al., 2025), refining the model's comprehension of sentiment labels by increasing the log probability of correct outputs while reducing that of incorrect ones. Given computational constraints, we only explore DPO (Rafailov et al., 2023) and SimPO (Meng et al., 2025), two widely acknowledged methods that do not require the reward model.

Our key contributions are as follows:

- We explored the impact of non-English data on English sentiment prediction under limited computational resources. Surprisingly, experimental results indicate that incorporating non-English data degrades performance in both classification tasks (Track A) and scoring tasks (Track B).
- We conducted a comprehensive evaluation and bad case analysis of two contrastive approaches on the competition dataset. In the sample-based contrastive Learning, CRC technology yielded limited benefit. In the generation-based contrastive Learning, DPO demonstrated a significant positive effect on Track B. Although SimPO has achieved gains on some labels, the overall effect has dropped significantly.
- In the leaderboard, our approach achieved Track A top 10 in 16 languages and 9th in English; Track B top 10 across all languages and 6th in English.

2 Methodology

To reduce our workload, we integrate both Track A and Track B into the same model by using different prompt templates for each. This unified approach enables the model to dynamically switch between prediction tasks as needed.

In our explorations, we designed three distinct tasks:

- Standard Prediction (Baseline): The model is trained to directly output all emotion labels based on the input text.
- Sample-Based Contrastive Learning: The model learns to compare two samples to generate more reliable predictions, leveraging contrastive reasoning to refine label predictions.
- Generation-Based Contrastive Learning: The model learns to differentiate between correct and incorrect predictions, improving its ability to generate accurate label outputs.

Figure 1 illustrates the training workflow of these three tasks.

2.1 Standard prediction

During sample preparation, we integrate the text content into a pre-designed prompt template as input and format the label results as the ground truth output. The template details can be found in Appendix A.1. The model is then trained through supervised fine-tune (SFT) using this formatted input and corresponding output.

During inference, we apply the same prompt template to incorporate the input text for prediction. By parsing the generated output, we extract the corresponding label predictions.

2.2 Sample-based contrastive learning

In this category, we use CRC, a technique designed to enhance the model's ability to discern subtle differences in samples. By having the model compare the score variations between two samples, model can better understand their distinctions and generate calibrated predictions. The key to this task lies in sample preparation and inference process.

During sample preparation, we randomly select two samples from the training set (Figure 1 middle) and construct a contrastive pair using the template in Appendix A.1. The target output comprises two components: a contrastive summary and two samples' predictions. The contrastive summary, expressed in natural language, highlights the existence or intensity difference between two samples on a specific label. The predictions provide explicit scores for both samples on the given label.

Given that random pairwise sampling can generate a vast amount of training data, we impose an upper limit on the total number of sampled pairs for each track. Specifically, for Track A, we sample 3,000 contrastive pairs per label, while for Track B, we sample 6,000 pairs per label, as Track B involves more fine-grained scoring labels compared to Track A.

During inference, each test sample is paired with a randomly selected training sample to form a contrastive input. Since the model achieves highly accurate predictions on training samples, these trained samples serve as reliable reference points, reducing prediction uncertainty. The two samples are integrated into the CRC prompt template, with the test sample randomly assigned to either position 1 or position 2. This process is repeated N times to generate N different input instances, producing N predictions. The final score is determined through a voting mechanism, where the most frequently predicted score is selected as the final output.

2.3 Generation-based contrastive learning

To enhance the model's sensitivity to scoring, we incorporate preference optimization. However, due to computational constraints, we only explore techniques that do not require a reward model, such as DPO and SimPO.

DPO optimizes the language model by maximizing the relative probability ratio to favor preferred outputs (Eq 1). Here, π_θ and π_{ref} represent the target and reference models, respectively, while y_w and y_l denote the correct and incorrect outputs. β is a scaling hyperparameter. This optimization process is applied after SFT.

$$-log\sigma(\beta log\frac{\pi_\theta(y_w|x)}{\pi_{ref}(y_w|x)} - \beta log\frac{\pi_\theta(y_l|x)}{\pi_{ref}(y_l|x)}) \quad (1)$$

SimPO adopts a similar optimization objective (Eq 2), directly enhancing the probability of the target model's preferred outputs. However, it simplifies DPO by discarding the reference model and using sequence length to normalize the loss. Additionally, it adopts a hyperparameter γ to ensure that the likelihood for the correct response exceeds the incorrect response by γ. Like DPO, SimPO is also applied after SFT.

$$-log\sigma(\frac{\beta}{|y_w|}log\pi_\theta(y_w|x) - \frac{\beta}{|y_l|}log\pi_\theta(y_l|x) - \gamma) \quad (2)$$

During sample preparation, to enhance the model's sensitivity to label scoring, we mute only the label scores to generate y_l (Figure 1 right, the Label Mutation block). The y_w corresponds to the original SP ground truth, while the y_l follows the same SP template but with muted scores. The probabilities of muting one, two, three, four, and five labels are [63.8%, 26.1%, 8.3%, 1.6%, 0.1%], respectively. When mutation is triggered, a random value is selected from the remaining label values as the incorrect score.

For Track A, each training sample executes five mutations, generating five contrastive samples for generation-based contrastive learning. For Track B, mutation is repeated 15 times, creating 15 contrastive samples. These settings ensured that the preference optimization dataset was comparable in size to the CRC dataset, allowing for a fair comparison between sample-based and generation-based approaches.

3 Experiment

In this competition, we participate in Track A and Track B. Track A covers 28 languages, while Track B includes 11 languages. Each language contains thousands of samples. Some languages use the same dataset for both Track A and Track B. Both

Model	Training Language	Track A - eng						
		Macro	**Micro**	**Anger**	**Fear**	**Joy**	**Sadness**	**Surprise**
SP	English	**0.828**	**0.808**	0.738	**0.876**	0.824	0.818	0.784
SP	Multilingual	0.820	0.802	0.742	0.865	0.814	0.808	0.780
CRC	English	0.819	0.802	**0.752**	0.865	0.811	0.819	0.765
DPO	English	0.827	0.806	0.736	0.875	0.816	0.821	**0.785**
SimPO	English	0.748	0.741	0.700	0.737	**0.827**	**0.832**	0.607

Table 1: English test results of all models in Track A

Model	Training Language	Track B - eng						
		Macro	**Micro**	**Anger**	**Fear**	**Joy**	**Sadness**	**Surprise**
SP	English	0.845	0.823	**0.812**	0.841	**0.850**	0.847	0.763
SP	Multilingual	0.835	0.815	0.807	0.816	0.845	0.840	0.765
CRC	English	0.828	0.805	0.796	0.807	0.836	0.837	0.750
DPO	English	**0.846**	**0.824**	0.810	**0.844**	0.846	**0.849**	**0.773**
SimPO	English	0.770	0.741	0.700	0.737	0.827	0.832	0.607

Table 2: English test set results of all models in Track B

tracks share the same sentiment labels: anger, fear, joy, sadness, surprise, and disgust. However, some languages have missing labels (e.g., English does not include the disgust label). All sample contents are single-turn dialogue without prior dialogue. Track A is evaluated using the F1 score, while Track B uses Pearson Correlation, with both metrics computed in Macro and Micro modes. Macro calculates the overall score across all labels, while Micro first computes per-label scores and then averages them. Although training, development, and test sets are provided, the development set is too small, leading to unstable evaluation results. Therefore, all reported results are based on the test set. Please see Appendix A.2 for the dev set results and discussion.

All models in our experiments are fine-tuned from Llama3-Instruct-8B (Dubey et al., 2024), selected for its strong multilingual capabilities and acceptable computational cost. To validate its multilingual capabilities in each language, we check the consistency between original and recovered text using its tokenizer to encode and decode the text content. This experiment confirmed that the model supports all competition languages.

We first evaluate the impact of multilingual data on English-only performance in the standard prediction (SP) task. Then, we experiment with CRC, DPO, and SimPO on the English dataset to examine the effectiveness of sample-based and generation-based contrastive learning for TBED. The CRC model is trained via SFT on a combination of SP and CRC datasets. DPO and SimPO models are obtained by applying preference tuning to the English-only SP model.

To reduce training costs, we use LoRA (Hu et al., 2022) for all fine-tuning tasks, with its rank and alpha set as 8 and 16. Each training lasts for 3 epochs with a batch size of 128. Regarding the learning rate (LR), SP and CRC employ 4e-4, DPO adopts 5e-6, and SimPO uses 1e-6. All models are trained using the AdamW optimizer, with $\beta_1 = 0.8, \beta_2 = 0.99$. All LR scheduler employs cosine decay with a warmup ratio of 0.1. For CRC inference, we set $N = 3$ for Track A and $N = 7$ for Track B.

All experiments are conducted using 8-GPU distributed training. Due to limited computational resources, different GPUs are used across various training runs. However, all GPUs are based on the Ada Lovelace or Hopper architecture, allowing us to leverage a wide range of existing acceleration techniques to enhance training efficiency.

4 Results

Tables 1 and 2 present the performance of all models on the English test set. Table 1 corresponds to Track A, the multi-emotion classification task, while Table 2 corresponds to Track B, the emotion intensity prediction task.

4.1 Multilingual influence

We observe that multilingual training underperforms compared to English-only training in both Track A and Track B. This finding highlights the significant differences in emotion perception across languages and cultural contexts, which can introduce conflicts in the model's understanding of sentiment labels. Therefore, we submit the non-English results generated by the multilingual SP model to

ID	Text	Pred	True
eng_test_track_a_02136	It was growing harder for him to keep balanced with my legs shifting every few seconds, until finally, I found the right position and his back a good shove with my knee.	0	1
eng_test_track_a_01815	So you let it shatter, breaking at my feet.	1	0
eng_test_track_a_01594	Dad thought it was just my imagination.	0	1
eng_test_track_a_00071	There's just something about watching an acne-ridden high school dropout cooking my food that just doesn't sit well in my stomach.	0	1

Table 3: Bad cases of the CRC model on the Anger label of Track A

the leaderboard and discard the multilingual setting in subsequent comparison experiments. For the multilingual SP results of Track A and Track B in all languages, please see Appendix A.3.

4.2 Sample-based vs generation-based contrastive learning

In Track A, the SP model performed the best overall. Specifically, it outperformed other approaches on the fear label, while the DPO model achieved a slight advantage on surprise. For anger, the CRC model ranked first, whereas SimPO achieved the best performance on joy and sadness. However, in Track B, DPO secures the top position across all evaluation metrics except for anger and joy. Meanwhile, SimPO lags significantly behind other systems in both macro and micro performance metrics. To further investigate the underlying reasons for these results, we conduct the bad case analysis for different techniques.

For the CRC model, we analyze Track A anger's misclassifications. We find that most misclassifications—accounting for 70% of the errors—are due to the model incorrectly predicting a neutral emotional state. Table 3 presents 4 randomly sampled bad cases, illustrating that these instances are on the borderline of the anger definition. Comparing them with other samples can easily influence their predictions, causing uncertainty and error. This suggests that the dataset may not be well-suited for sample-based comparison approach.

For the DPO model, we analyze sadness's wrong cases in Track B. We observe that over 90% of the errors differs from the ground truth by only one intensity level. This indicates that the model still has room for improvement in its recognition of label intensity.

Regarding the SimPO model, we figure out that its poor performance primarily stemmed from the loss of output formatting, leading to frequent content parsing errors. This highlights the critical role of the reference model in preference tuning. While SimPO effectively increases the probability margin between correct and incorrect outputs, it may also make correct outputs no longer rank as the top generation.

5 Conclusion

The SemEVAL-2025 organizers introduce a highly challenging text-based emotion detection dataset, covering multi-label classification and intensity prediction across 28 languages. The dataset reflects the complexity of emotional expression and the diversity introduced by different linguistic and cultural backgrounds.

We explore three types of approaches in this competition. The baseline approach is the standard prediction task. The two enhanced types of approaches were sample-based contrastive learning and generation-based contrastive learning. For the sample-based approach, we try CRC. For the generation-based approach, we explore both DPO and SimPO. They all aim to improve model prediction through contrastive training—one by comparing samples and the other by discriminating between correct and incorrect generations.

Our experiments reveal that different languages reflect distinct cultural backgrounds, so multilingual training does not improve English emotion detection. Meanwhile, due to the inherent ambiguity of sentiment expressions, sample-based contrastive learning raises additional uncertainty, ultimately reducing prediction accuracy. On the other hand, generation-based contrastive learning provides consistent improvements in intensity prediction, though its effectiveness varies significantly across different techniques. Notably, reference model constraint is crucial in stabilizing generation-based contrastive optimization process. It prevents excessive deviation from the original model distribution, and preserves key capabilities such as structured output generation.

A Appendix

A.1 Prompt templates

Table 4, 5, 6, and 7 show the prompt templates used by Standard Prediction and Contrastive Reasoning Calibration on Track A and B, respectively. Preference Tuning also uses the Standard Prediction template.

A.2 Development set discussion

Table 8 and 9 present our system's performance on the English development set. However, the results from this dataset are somewhat misleading due to the following reasons:

- In Track A, the development set suggests that multilingual training significantly benefits English performance, which contradicts the findings on the test set.
- In Track A, the CRC technique outperforms all other models by a substantial margin, which is inconsistent with its performance on the test set.

During the competition's evaluation phase, we submitted our results based on these misleading insights. Then, we discovered that our system's actual performance on the test set did not meet expectations. Upon further analysis, we identified that this discrepancy primarily stems from the development set's limited size. With only 116 samples and highly imbalanced label distributions, certain labels had extremely sparse scores, making the computed metrics unreliable.

To ensure the reliability of our conclusions, we have removed the development set results from the main text to prevent any potential misinterpretation.

A.3 Test results of SP multilingual model on all languages

Table 10 shows the performance of the multilingual model on all languages, including Track A and B.

Input	Output
Task Description: You are tasked with determining the perceived emotion(s) of a speaker based on a conversation. Specifically, your goal is to predict the emotions that most people would associate with the speaker's last utterance. The possible emotions are: joy, sadness, fear, anger, surprise, and disgust. The conversation may be in any of the following languages: Afrikaans, Algerian Arabic, Amharic, Emakhuwa, Hausa, Igbo, Kinyarwanda, Moroccan Arabic, Mozambican Portuguese, Nigerian-Pidgin, Oromo, Setswana, Somali, Swahili, Sundanese, Tigrinya, Xitsonga, IsiXhosa, Yoruba, isiZulu Arabic, Chinese, Hindi, Indonesian, Javanese, Marathi English, German, Romanian, Russian, Latin American Spanish, Tatar, Ukrainian, Swedish, Mozambican Portuguese, and Brazilian Portuguese. Instructions: 1. The language of the conversation will be explicitly indicated at the first place. 2. Each turn in the conversation will be marked with "Speaker1" or "Speaker2" to indicate the speaker. 3. You need to predict the emotions based on the last utterance from "Speaker1" (and any additional context or dialogue history if provided). 4. For each emotion, indicate whether it applies using binary labels: 1 (emotion is present) or 0 (emotion is absent). Example Output Format: joy: {{ 1 or 0 }}, sadness: {{ 1 or 0 }}, fear: {{ 1 or 0 }}, anger: {{ 1 or 0 }}, (optional) surprise: {{ 1 or 0 }}, (optional) disgust: {{ 1 or 0 }}. Language: {lan} Content: Speaker1: {text}	joy: {joy}, sadness: {sadness}, fear: {fear}, anger: {anger}, surprise: {surprise}, disgust: {disgust}.

Table 4: Standard prediction template for Track A

Input	Output
Task Description: You are tasked with predicting the intensity for each of the perceived emotion classes of a speaker based on a conversation. Specifically, your prediction should represent the emotional intensity most people associate with the speaker's last utterance. The possible emotion classes are: joy, sadness, fear, anger, surprise, and disgust. The conversation may be in any of the following languages: Afrikaans, Algerian Arabic, Amharic, Emakhuwa, Hausa, Igbo, Kinyarwanda, Moroccan Arabic, Mozambican Portuguese, Nigerian-Pidgin, Oromo, Setswana, Somali, Swahili, Sundanese, Tigrinya, Xitsonga, IsiXhosa, Yoruba, isiZulu Arabic, Chinese, Hindi, Indonesian, Javanese, Marathi English, German, Romanian, Russian, Latin American Spanish, Tatar, Ukrainian, Swedish, Mozambican Portuguese, and Brazilian Portuguese. Instructions: 1. The language of the conversation will be explicitly indicated at the first place. 2. Each turn in the conversation will be marked with "Speaker1" or "Speaker2" to indicate the speaker. 3. You need to predict the emotion intensity based on the last utterance from "Speaker1" (and any additional context or dialogue history if provided). 4. For each emotion class, the ordinal intensity levels include: 0 for no emotion, 1 for a low degree of emotion, 2 for a moderate degree of emotion, and 3 for a high degree of emotion. Example Output Format: joy: {{ 0, 1, 2, or 3 }}, sadness: {{ 0, 1, 2, or 3 }}, fear: {{ 0, 1, 2, or 3 }}, anger: {{ 0, 1, 2, or 3 }}, (optional) surprise: {{ 0, 1, 2, or 3 }}, (optional) disgust: {{ 0, 1, 2, or 3 }}. Language: {lan} Content: Speaker1: {text}	joy: {joy}, sadness: {sadness}, fear: {fear}, anger: {anger}, surprise: {surprise}, disgust: {disgust}.

Table 5: Standard prediction template for Track B

Input	Output
Task Description: Your task is to compare and predict the perceived emotional label exhibited by the speaker in two separate conversations. The target emotion for comparison is "{label}". The conversation may be in any of the following languages: Afrikaans, Algerian Arabic, Amharic, Emakhuwa, Hausa, Igbo, Kinyarwanda, Moroccan Arabic, Mozambican Portuguese, Nigerian-Pidgin, Oromo, Setswana, Somali, Swahili, Sundanese, Tigrinya, Xitsonga, IsiXhosa, Yoruba, isiZulu Arabic, Chinese, Hindi, Indonesian, Javanese, Marathi English, German, Romanian, Russian, Latin American Spanish, Tatar, Ukrainian, Swedish, Mozambican Portuguese, and Brazilian Portuguese. Instructions: 1. The two conversations will be marked as "Conversation1" and "Conversation2". Each turn in the conversation will be marked as "Speaker1" or "Speaker2" to indicate the speaker. 2. The language of the conversation will be explicitly stated at the beginning of each conversation. 3. You only need to predict the emotions of "Speaker1" in both conversations. No predictions are required for "Speaker2". 4. Your comparison and prediction should be based on the last utterance of "Speaker1" in each conversation, while also considering any additional background or dialogue history if provided. 5. First, provide a brief summary of the comparison result between the two conversations. Then, use binary labels to indicate whether the specified emotion ("{label}") is present in each conversation: 1 (emotion is present) or 0 (emotion is absent). Example Output Format: For emotion label "{label}", {{Brief summary of the comparison result}}. Conversation1: {{1 or 0}}, Conversation2: {{1 or 0}}. Conversation1: Language: {lan1} Speaker1: {text1} Conversation2: Language: {lan2} Speaker1: {text2} For emotion label "{label}", {brief}. Conversation1: {conv1Value}, Conversation2: {conv2Value}.	For emotion label "{label}", {{Brief summary of the comparison result}}. Conversation1: {{1 or 0}}, Conversation2: {{1 or 0}}.

Table 6: Contrastive reasoning calibration prompt template for Track A

Input	Output
Task Description: Your task is to compare and predict the intensity of the specific perceived emotion class in two separate conversations. The target preceived emotion class for comparison is "{label}". The conversation may be in any of the following languages: Afrikaans, Algerian Arabic, Amharic, Emakhuwa, Hausa, Igbo, Kinyarwanda, Moroccan Arabic, Mozambican Portuguese, Nigerian-Pidgin, Oromo, Setswana, Somali, Swahili, Sundanese, Tigrinya, Xitsonga, IsiXhosa, Yoruba, isiZulu Arabic, Chinese, Hindi, Indonesian, Javanese, Marathi English, German, Romanian, Russian, Latin American Spanish, Tatar, Ukrainian, Swedish, Mozambican Portuguese, and Brazilian Portuguese. Instructions: 1. The two conversations will be marked as "Conversation1" and "Conversation2". Each turn in the conversation will be marked as "Speaker1" or "Speaker2" to indicate the speaker. 2. The language of the conversation will be explicitly stated at the beginning of each conversation. 3. You only need to predict the emotional intensity of "Speaker1" in both conversations. No predictions are required for "Speaker2". 4. Your comparison and prediction should be based on the last utterance of "Speaker1" in each conversation, while also considering any additional background or dialogue history if provided. 5. First, provide a brief summary of the comparison result between the two conversations. Then, use one of the four levels to indicate the target ordinal intensity: 0 for no emotion, 1 for a low degree of emotion, 2 for a moderate degree of emotion, and 3 for a high degree of emotion. Example Output Format: For emotion label "{label}", {{Brief summary of the comparison result}}. Conversation1: {{ 0, 1, 2, or 3 }}, Conversation2: {{ 0, 1, 2, or 3 }}. Conversation1: Language: {lan1} Speaker1: {text1} Conversation2: Language: {lan2} Speaker1: {text2} For emotion label "{label}", {brief}. Conversation1: {conv1Value}, Conversation2: {conv2Value}.	For emotion label "{label}", {{Brief summary of the comparison result}}. Conversation1: {{1 or 0}}, Conversation2: {{1 or 0}}.

UIMP-Aaman at SemEval-2025 Task11: Detecting Intensity and Emotion in Social Media and News

Aisha Aman Parveen
Universidad Menendez Pelayo
100012653@alumnos.uimp.es

Abstract

This paper presents our participation in SemEval task 11, which consists of emotion recognition in sentences written in multiple languages. We use in-context learning and fine-tuning methods to teach LLMs how to predict labels for Track A, Track B and Track C. The best results depends on track and language predicted.

1 Introduction

In the 21st century, emotions remain a fascinating and complex subject of study. From an evolutionary perspective, they have played a vital role in human survival, shaping decision-making, fostering social bonds, and influencing intelligence by bridging reason and instinct. Despite significant scientific progress, emotions remain an enigmatic phenomenon that is difficult to fully understand due to their subjective nature. This complexity makes their analysis particularly challenging. In this study, we focus on emotion recognition in text, specifically in sentences written in multiple languages, in the context of the SemEval task 11 (Muhammad et al., 2025b). The languages selected for the analysis are English, German, Spanish, and Brazilian Portuguese. Our approach begins by examining the range of emotions present in the text files for each language (Muhammad et al., 2025a). Then, we outline the specific tasks involved in each track, outline our analytical methods, and describe the experiments conducted. Finally, we present the results from our best-performing experiments. The study is structured around three tasks: Track A, Track B, and Track C. In the first track, we will experiment with different models in order to find the one with best performance, including the Llama 3 series of models (Dubey et al., 2024) and the Phi-4 model (Abdin et al., 2024), using the HuggingFace transformers library (Wolf et al., 2019). Then, for Track B and C, we will implement the best model for each of these tracks. We report results using macro F1 metric computed over the dev set.

2 Track A

In Track A, the emotions to identify are Anger, Fear, Joy, Sadness, Surprise, and Disgust. However, it is important to note that Disgust is not present in English or Spanish. Table 1 provides an overview of the training data distribution. Specifically, we observe that in English, the most common emotions are Fear, Sadness, and Surprise. However, in German, Anger and Disgust appear most frequently. A similar pattern emerges in Portuguese and Spanish, where Anger and Joy are the most predominant emotions in both languages. Overall, we find that Disgust is more prevalent in German than in Portuguese, while Fear is more strongly expressed by English speakers.

In our analysis, we will use two key techniques: in-context learning and fine-tuning. In the first technique (In-context learning), we will provide the model with a prompt made up of training examples and their corresponding labels. The weights of the model are not updated, instead the provided examples are used by the model to learn the general pattern of the problem. On the other hand, fine-tuning involves taking a pre-trained model, which has learned general language patterns from large datasets, and adapting it to perform well on more specialized tasks using specific, domain-related data. Together, these techniques allow the model to leverage prior knowledge while tailoring its capabilities to address the specific needs of our task, enhancing both accuracy and efficiency.

2.1 In-context learning

In-context learning prompting involves providing a model with specific input to guide its understanding and responses. This can include task-specific prompts, where the model is directly told what to

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 331–335

Table 1: Track A training data label distribution. Green color indicates the two most common emotions.

	Anger	Fear	Joy	Sadness	Surprise	Disgust
English	333	1157	674	878	839	
German	768	239	541	516	159	832
Portuguese	718	109	581	332	153	75
Spanish	492	317	642	309	421	

do (e.g., "Summarize this text"), few-shot learning prompts, where the model is given a few examples to learn from, or zero-shot prompts, where the model is given no examples and must rely on its pre-existing knowledge. Prompting helps the model perform tasks more effectively by tailoring its responses based on the context provided.

In our project, the prompt is designed to instruct the model to identify emotions from a given sentence. The prompt starts by clearly outlining the task as we can in Table 2. Then we will give few examples of sentences to be classified as input and the model has to give as a response the emotion perceived.

The key here is that the prompt asks the model to return only the selected emotions separated by commas and no other information. The data is provided as a CSV file with the text and emotion columns containing either 0s or 1s. We transform this into the prompt. Specifically, if a sentence has '1' in the "Joy" column, we add "Joy" to the corresponding prompt. This allowed us to directly label the emotions based on the data. For converting the LLM response into labels during inference, we carry out the reverse procedure. That is, if the LLM response is a sentence followed by the emotion 'Joy', we will set 1 to the Joy column.

We then experimented with different models to identify the one that provided the best performance. The models tested include various versions of the Llama model, ranging from 3.2-1B to 3.3-70B. We also varied the number of examples used in the prompt to determine the optimal configuration for performance (n=20, n=30, n=40, n=60). Table 4 reports the results obtained by the different systems. We start by evaluating n=20. The results show some interesting trends. For instance, Llama 70B models consistently provide better performance across languages, specially for English and Spanish, where the scores are higher across various configurations. For example, the Llama 70B model gives a score of 0.77 for Spanish and 0.71 for English. These results suggest that increasing the number of parameters in the model and adjusting the number of examples in the prompt can significantly improve performance. Overall, the combination of using a large model like Llama 70B and fine-tuning the number of examples in the prompt seems to yield the best results. Further testing with additional languages or more fine-tuning could potentially improve these outcomes even more.

Table 4 reports the effects of changing the number of examples N shown in the prompt. From N=20 to N=40, we observe that English and German improve, while Spanish and Portuguese show a slight decline. Based on this, we decided to test with N=30 for Spanish and Portuguese to see if their performance improves. Since English and German perform better with N=40, we keep them at N=40, while Spanish and Portuguese remain at N=20.

2.2 Fine-tuning

In this section we will talk about fine-tuning the Llama 3.2-1B model. We only fine-tuned this model because we lack the computational and financial resources to fine-tune a bigger one. We trained a different model for each language, using the Adam optimizer (Kingma and Ba, 2015), learning rate $1e-5$, batch size 4 with 4 gradient accumulation steps (effective batch size 16). Training lasts for 3 epochs, and we apply a maximum gradient norm of 0.3 and a linear learning rate warm-up for the first 10% steps of training. Table 5 compares the performance of fine-tuning versus in-context learning for Track A across different languages. For English, in-context learning slightly outperforms fine-tuning, though the difference is small. In contrast, for the rest of languages, fine-tuning significantly outperforms in-context learning. Nevertheless, the Llama 3.3-70B is still better than our fine-tuned 1B model, so we selected the 3.3-70B model for the final submission.

English	0.41	0.43
German	0.33	0.26
Portuguese	0.40	0.36
Spanish	0.24	0.15

3 Track B

Track B differs from Track A in that we also define the intensity of emotions across all languages. The intensity levels are as follows: 0 indicates no emotion, 1 represents a low degree of emotion, 2 indicates a moderate degree of emotion, and 3 corresponds to a high degree of emotion. Table 6 reports the full statistics for the training data. Upon examining the data for all languages, we find that high intensity emotions are the least frequent in the training set for the languages we analyzed. This suggests that the models have less data to learn from, making it more challenging to generate accurate predictions. Specifically, English has the most instances of high intensity emotions, while Portuguese has the fewest.

The prompt used for this second task is very similar to Track A, but with the addition of the emotion intensity. Table 7 shows the specific prompt. Based on results from track A, we will use the model Llama 3.3- 70B as it is the one with best performance. Results are shown in Table 8. The results obtained with the Llama 70B model show superior performance in English, with a score of 0.89, which suggests that the model is optimized or has more experience in this language. In German, the score is 0.67, indicating decent performance, although lower than in English. In Spanish and Portuguese, the model obtained similar scores of 0.65 and 0.66, respectively, suggesting that it faces more difficulties in these languages compared to English and German. It should be noted that the datasets used for Spanish and Portuguese are smaller (20 examples), which could have influenced performance. Overall, the model appears to perform better in languages with greater representation or training, such as English, and could benefit from further tuning to improve its performance in other languages.

4 Track C

Track C involves predicting the perceived emotion labels for a new text instance in a target language, using a labeled training set from one of the languages in Track A. The prompt used is identical to the one in Track A, and for all languages, 40 examples are provided in the prompt. The results are reported on Figure 1. We have decided to approach this task finding the best combination for each language in test. For instance, to predict English, we will train with German, Spanish and Portuguese dataset. The results obtained are 0.65 with German training, 0.69 with Spanish and 0.89 with Portuguese, which is the one that outperforms the other

Table 6: Track B: Emotion degree distribution across the different language pairs.

English	Anger	Fear	Joy	Sadness	Surprise
0: no emotion	2435	1157	2094	1890	1929

English	0.89
German	0.67
Portuguese	0.65
Spanish	0.66

languages. Moreover, Spanish best prediction is made with Portuguese training with a performance of 073. In contrast, for German, Spanish is the one with higher F1-score with 0.67. Finally, Portuguese is the best training predictor for Spanish. It is interesting to notice that English and Spanish are the languages with highest scores.

5 Final rankings

The final results of the competition are reported on Table 9. It can be observed how our approach our approach achieves good results in the ranking and is able to outperform the baseline for all tracks and languages, except for German Track A and Spanish Track B. The proposed LLM solution is powerful and convenient because it does not require training.

6 Conclusions

We have presented our participation at the SemEval task 11, which consists on emotion recognition in text, specifically in sentences written in multiple languages. In our approach we have implemented in- context learning and fine-tuning methods to

Table 9: Performance metrics for different tracks and languages. We report our submissions F1 score (**F1**), our ranking out of all participants in the Track (**Rank**) and the F1 of the proposed baseline by the organizers (**Baseline F1**).

Abstract

Detecting emotions across different languages is challenging due to the varied and culturally nuanced ways of emotional expressions. The *Semeval 2025 Task 11: Bridging the Gap in Text-Based emotion* shared task was organised to investigate emotion recognition across different languages. The goal of the task is to implement an emotion recogniser that can identify the basic emotional states that general third-party observers would attribute to an author based on their written text snippet, along with the intensity of those emotions. We report our investigation of various task-adaptation strategies for LLMs in emotion recognition. We show that the most effective method for this task is to fine-tune a pre-trained multilingual LLM with LoRA setting separately for each language.

1 Introduction

Text-based emotion recognition plays a crucial role in studies related to mental health (Golder and Macy, 2011), emotional intelligence (Turcan et al., 2021), and human-computer interaction (Li et al., 2022). However, recognising emotions in text remains a significant challenge, especially across different languages (Mohammad et al., 2018). Linguistic variations, cultural differences in emotional expression, and the scarcity of annotated data for low-resourced languages make emotion recognition particularly complex (Barrett et al., 2011; Lindquist and Gendron, 2013; Schröder et al., 2013).

The *SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion* shared task (Muhammad et al., 2025b)[1] is part of the International Workshop on Semantic Evaluation (SemEval). Its objective is to detect *collectively perceived emotions* within text snippets written in 32 different languages. Collectively perceived emotion refers to the basic emotional states—such as anger, joy, and disgust—that third-party observers from the general public can attribute to a text snippet generated by a writer. Unlike tasks aimed at identifying the writer's actual emotional states or the emotional states evoked in individual reader (Mohammad, 2022, 2023), this task emphasises the shared perception of emotions by general readers. This distinction is crucial, as perceived emotions can vary significantly from both intended and personally experienced emotions.

The shared task consists of three tracks: (A) *Multi-label Emotion Detection*, where the goal is to predict the perceived emotional states expressed in a given text snippet, including joy, sadness, fear, anger, surprise, and disgust; (B) *Emotion Intensity*, where the objective is to predict the intensity scale of each perceived emotional state for a given text snippet. Each emotional state is rated on a 4-point categorical scale: 0 (no emotion), 1 (low intensity), 2 (moderate intensity), and 3 (high intensity); and (C) *Cross-lingual Emotion Detection*, where the goal is to predict the perceived emotion on text snippets written in a language different from the one used for model training, such as training on English-written data but making emotion recognition on Javanese-written data.

Our team participated in Tracks A and B, focusing on fine-tuning Large Language Models (LLMs). LLMs have contributed to significant improvements across different NLP tasks (Brown, 2020; Touvron et al., 2023). However, previous studies suggest that they are ineffective for emotion classification in zero-shot and few-shot settings, even when provided with In-Context Learning (ICL) prompts (Liu et al., 2024). A potential improvement can be achieved by fine-tuning LLMs with instructions (Zhang et al., 2023; Liu et al., 2024). Drawing inspiration from Liu et al. (2024), we ex-

[1] https://github.com/emotion-analysis-project/SemEval2025-task11

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 336–342

plore instruction-tuning and continual fine-tuning of multilingual LLMs. We then compare the effectiveness of this adaptation for emotion recognition across different languages by fine-tuning a multilingual model individually for each language. We also propose several adaptation approaches and conduct a comparative analysis across these approaches, specifically for Track A. We develop an adaptation strategy for LLMs in emotion recognition that is effective across languages of varying resourced levels (see the categorisation of resource abundance by Joshi et al. (2020); Üstün et al. (2024)).

2 Methods

2.1 Track A: Multi-label Emotion Detection

We formulate this task as a **binary classification** problem for the detection of each emotional state. For each input, the LLMs predict the occurrence of the six emotions—anger, disgust, fear, joy, sadness, and surprise—independently, determining whether a specific emotional state is *present* (1) or *absent* (0). The final results are aggregated for the input, to represent a multi-label emotion recognition setting. To address class imbalance, we apply oversampling to balance the binary classification instances.

The proposed adaptation strategies are described below:

- **Few-shot**: We apply ICL based on the BM25 (Robertson et al., 1995) scores to retrieve instances from the training set to construct a prompt for the prediction of each test instance (see the prompt template in Section 3.3). That is, we use BM25 scores to rank semantic (bag-of-words) relevancy between the given test instance (as a query) and each training instance (as a document) (Schutze et al., 2008; Robertson et al., 2009). We retrieve the top k most relevant instances and their manually annotated emotional state label as k-shot examples to prompt-tune LLMs for each test instance.

- **Supervised Fine-Tuning (SFT):** We fine-tune pre-trained and instruction-tuned multilingual LLMs using supervised and parameter-efficient settings.

- **English-bridged Adaptation (E-Bridge):** We apply SFT to LLMs on English-written instances and then apply continual SFT for the adaptation to other languages.

- **Marginalisation:** We first apply SFT to LLM on Track B (see details of SFT in Section 2.2), and then use fine-tuned LLM to make predictions for instances on Track A. To align with the binary classification in Track A, predictions of 1–3 are marginalised into 1, indicating the presence of an emotional state, while predictions of zero are retained to represent its absence.

2.2 Track B: Emotion Intensity Detection

We frame this task as a **multi-class classification** problem for each emotion. Given an input text, the LLM predicts whether a specific emotion can be perceived at a given intensity level. The intensity is measured on a four-point categorical scale: 0 for no emotion, 1 for low intensity, 2 for moderate intensity, and 3 for high intensity. Thus, for a text with six emotional states, the LLM processes the input six times, once for each emotion. The final results are aggregated to the input text for the completion of multi-label emotion intensity recognition set by Track B.

To achieve this, we convert each text with multiple emotion intensities into separate instances, one for each emotion. We fine-tune pre-trained and instruction-tuned LLMs on this transformed dataset, using supervised learning to predict the emotional intensity for each emotion independently (SFT) and apply zero-shot, where we only use instruction as a baseline.

3 Experimental Setup

3.1 Shared Task Dataset

The dataset used in the shared task is a combination of EthioEmo (Belay et al., 2025) and BRIGHTER (Muhammad et al., 2025a), which includes emotion annotations for multiple languages. Specifically, 28 languages for Track A and 11 languages for Track B. The statistical details of the annotated languages are detailed by Belay et al. (2025) for Amharic, Oromo, Somali, and Tigrinya, and by Muhammad et al. (2025a) for the remaining languages.

Instruction-tuning on External Dataset: We leveraged an external dataset to instruction-tune LLMs (Liu et al., 2024). This helps the model generalise on the external task by learning how to follow instructions for emotion recognition before fine-tuning on the dataset specific to this shared

Table 1: Effectiveness of baseline and our approaches (SFT or zero-shot (*) of a specific model) on the test set. The baseline results are provided by the task organisers Muhammad et al. (2025a). Note that aya-32 denotes the `aya-32b-expanse` model, llama denotes the `Llama3.1-8B-Instruct` model, emo-aya denotes instruction-tuned `aya-32b-expanse`.

task. The selected external dataset is an extension to the *SemEval-2018 Task 1: Affect in Tweets*, which includes a series of subtasks related to affectual state inference: (1) emotion intensity regression; (2) emotion intensity ordinal classification; (3) valence (sentiment) regression; (4) valence ordinal classification; and, (5) emotion classification (Mohammad and Kiritchenko, 2018; Mohammad et al., 2018) which overlaps with the tracks of this shared task.

3.2 Evaluation Metrics

For both Track A and Track B, we follow the evaluation metrics specified by the shared task organisers. Track A uses the unweighted average of all per-emotion F_1 scores. Track B uses the average of per-emotion Pearson's correlation coefficient (r).

3.3 Hyperparameters

LLMs: We use three open-source multilingual LLMs: AYA (`aya-101` (Üstün et al., 2024), `aya-32b-expanse` (Dang et al., 2024)), and LLAMA (`Llama3.1-8B-Instruct` (Dubey et al., 2024)). `aya-101` (mT5-based) offers broad multilingual support with a smaller size, while `aya-32b-expanse` (GPT-style) provides larger capacity and similarly wide language coverage. `Llama3.1-8B-Instruct` (GPT-style) is smaller

	Supervised Fine-tuning (SFT)			Marginalisation				Few-shots
Language	AYA$_{ft}$	EMO-AYA$_{ft}$	E-Bridge	AYA$_{pt_b}$	EMO-AYA$_{pt_b}$	AYA$_{ft_b}$	EMO-AYA$_{ft_b}$	`1-shot`
English	**80.12**	73.31	—	64.55	57.94	68.47	72.88	52.31
German	**62.31**	52.43	56.21	53.92	46.65	60.69	54.56	30.24
Portuguese	**61.29**	53.42	57.33	44.55	40.56	41.87	45.93	34.11
Russian	**89.11**	87.13	86.16	54.12	60.56	72.42	55.34	75.01

Table 2: Macro F_1 scores on the development split of Track A for four languages. AYAft denotes direct SFT of the `aya-32b-expanse` model on the training set. EMO-AYAft indicates first performing instruction-tuning on the `aya` model on the external dataset, followed by SFT on the training set. E-Bridge refers to SFT of the `aya` model on the training set in English, followed by continual SFT on the remaining three languages. AYApt_b involves prompt-tuning a model in a zero-shot setting to complete the Track B objective, followed by marginalisation. EMO-AYApt_b represents applying instruction-tuning to `aya` model on the external dataset and then prompt-tuning it in a zero-shot setting on Track B, followed by marginalisation. The best results are **boldfaced**.

but supports only seven languages. Due to its broader coverage and capacity, `aya-32b-expanse` was preferred, with `aya-101` as a lightweight alternative. For languages jointly supported by both `aya-32b-expanse` and `Llama3.1-8B-Instruct`, such as English and German, model selection also accounts for differences in parameter size.

We employ Low-Rank Adaptation (LoRA) (Hu et al., 2022) and apply 4-bits quantisation (Jacob et al., 2018) to LLMs for parameter-efficient SFT. We set the LoRA rank and alpha parameters to 32 and 64, respectively. The dropout ratio is set to 0.05. We limit both the input source length and the target length to 512. The training epoch size is 10 and the batch size is 2. The learning rate is set to $2e-5$ for Track A and $5e-5$ for Track B.

The formulations of instructions for zero-shot, few-shot (ICL), and SFT settings are as below:

- **Track A:** "*You are detecting emotions on a statement written in {language}. Statement: {text}. Does this statement express {emotion}? Answer 1 for yes and 0 for no.*"
- **Track B:** "*Task: Categorize the tweet into an intensity level of the specified emotion E, representing the mental state of the tweeter. 0: no E can be inferred. 1: low amount of E can be inferred. 2: moderate amount of E can be inferred. 3: high amount of E can be inferred. Tweet: {text} Emotion {emotion} Intensity class:*"

where *{text}* is the text content of each instance, and *{emotion}* is one of the six emotional states (or five, excluding `disgust` for English and `Surprise` for Afrikaans). The instruction of Track B is adapted from Liu et al. (2024).

For BM25-based few-shot prompting, we use the `rank_bm25` library (Stuart, 2022) and choose the default parameter setting, $b = 0.75$ and $k_1 = 1.5$, for BM25.

We use NVIDIA H100 GPUs running on one node for this experiment.

4 Experimental Results

Results on Testing Set

We present the results of the submitted predictions for ranking (testing) in Table 1, including the baseline results per language provided by Muhammad et al. (2025a). We submitted results for 26 out of 32 languages in Track A and the 11 (all) languages provided in Track B.

We observed noticeable variations in effectiveness across languages for both Track A (macro F_1) and Track B (average r). The baseline approach is mostly effective in higher-resourced languages, such as German, English, and Russian. However, applying instruction-tuning or SFT to LLMs on mid-resourced and lower-resourced language is more effective than the baseline for emotion recognition.

Additionally, model selection plays a crucial role, as larger GPT-based models like `aya-32b-expanse` outperform smaller mT5-based models like `aya-101`, particularly in lower-resourced languages where the latter struggles.

We applied the adaptation strategies for the test set prediction based on the highest F_1 and correlation coefficient r achieved on the development set in Track A & B, respectively.

Results on Track A Development Set

We compared the effectiveness of the various adaptation strategies with experiments in English, Ger-

Spanish (Latin American) (esp)	57.77	54.77	45.80	48.69	68.50	64.36	**70.07**	69.10
Ukrainian (ukr)	45.68	**50.07**	24.12	33.05	—	—	41.99	40.56

Table 3: The average r on the development set of Track B. AYA and LLAMA refer to the base models, `aya-expanse-32b` and `Llama3.1-8B-Instruct`, respectively. EMO-AYA and EMO-LLAMA are their instruction-tuned versions. $*_{ft}$ are fine-tuned versions. The best results are **boldfaced**.

man, Portuguese, and Russian. All comparisons are statistically validated using hypothesis testing with a significance threshold of $p < 0.05$. We observed that directly applying SFT to LLMs on the training set (AYA$_{ft}$) consistently achieves the highest macro F_1 scores across all four languages, outperforming all of the other experimented adaptation approaches, such as: (i) BM25-based ICL (1-shot), (ii) instruction-tuning on the external dataset before SFT on the training set (EMO-AYA), (iii) bridging the adaptation with English (E-Bridge), or (iv) applying marginalisation to predictions of LLMs fine-tuned on Track B (Table 2).

These results suggest that LLMs may not significantly benefit from instruction tuning, as direct SFT shows greater effectiveness across all four languages. E-Bridge can be viewed as a specialised form of instruction tuning, where the LLM first learns instructions in English instances before being fine-tuned in other languages. This method proves effective for German and Portuguese but is less effective for Russian, possibly due to the closer cultural alignment of German and Portuguese speakers with English speakers (Rinke and Flores, 2021; Wikipedia, 2025).

Results on Track B Development Set

The emotion intensity results across multiple languages using both base and instruction-tuned versions of AYA and LLAMA in zero-shot and SFT settings are shown in Table 3. Fine-tuning significantly improves performance across most languages, demonstrating that task-specific adaptation benefits intensity detection. While fine-tuning offers substantial gains across the languages, the benefits are often more pronounced in higher-resourced languages (i.e., English, Spanish). While AYA generally demonstrates stronger zero-shot performance, LLAMA benefits more from instruction tuning, showing significant improvements after fine-tuning. Instruction-tuned models (EMO-AYA and EMO-LLAMA) provide some advantages in zero-shot settings, particularly in languages with less training data, but their impact diminishes after fine-tuning, suggesting that instruction-tuning alone is often sufficient for intensity detection.

Higher-resourced languages, such as English, Russian, and Spanish, consistently achieve better results, with both zero-shot and fine-tuned models performing reliably. Mid-resourced languages, including German, Portuguese, and Romanian, show moderate performance, benefiting from fine-tuning but still exhibiting variability depending on the model. The performance of all languages improves with fine-tuning, but challenges persist in making significant gains for languages where the models initially perform poorly. Despite this, the advancements show that fine-tuning and instruction tuning can help optimise model behaviour across languages, and targeted adaptation strategies may further boost results for emotion intensity detection tasks.

5 Conclusions

We participated in the *SemEval 2025 Task 11: Bridging the Gap in Text-Based Emotion* shared task, which included tracks for multi-label emotion detection (Track A) and emotion intensity detection (Track B). For Track A, we approached it as a binary classification problem for each emotion—determining whether an emotional state is present in or absent from a given input text snippet. We found that direct supervised fine-tuning can effectively adapt LLMs for the detection of emotions

for most languages, except for the lower-resourced languages where few-shot learning is more effective. For Track B, we achieved the best results by employing different LLMs (both direct SFT and instruction-tuned) for each language. The results in both tracks suggest that, when adapting LLMs for emotion recognition on most mid-resourced and higher-resourced language, instruction-tuning was not as effective as in other NLP tasks. A more suitable approach is to directly apply supervised fine-tuning of LLMs on task-specific datasets.

Limitations

The exploration of various adaptation strategies was limited to four languages (English, German, Russian, and Portuguese), which may not generalise to other languages, particularly lower-resourced ones or those with different linguistic structures. The models used may reflect biases from the training data, which could affect performance in low-resourced languages. We only explored prompt-tuning and instruction-tuning with the parameter-efficient LoRA setting for adapting LLMs.

Ethical Considerations

We relied on the dataset providers to remove any material from the dataset that may reveal anyone's identity in their posts used in this study. We guarantee that datasets are only used for scientific or research purposes and are not redistributed or shared with third parties. This project is subject to the ethics approval and agreement provided by the SemEval-2025 task organisers.

huizhi.liang@newcastle.ac.uk

Abstract

This paper presents a novel multi-agent framework for automated code generation and execution in tabular question answering. Developed for the SemEval-2025 Task 8, our system utilises a structured, multi-agent approach where distinct agents handle dataset extraction, schema identification, prompt engineering, code generation, execution, and prediction. Unlike traditional methods such as semantic parsing-based SQL generation and transformer-based table models such as TAPAS, our approach leverages a large language model-driven code synthesis pipeline using the DeepSeek API. Our system follows a zero-shot inference approach, which generates Python functions that operate directly on structured data. Through the dynamic extraction of dataset schema and intergration into structured prompts, the model comprehension of tabular structures is enhanced, which leads to more precise and interpretable results. Experimental results demonstrate that our system outperforms existing tabular questioning and answering models, achieving an accuracy of 84.67% on DataBench and 86.02% on DataBench-lite, which significantly surpassed the performances of TAPAS (2.68%) and stable-code-3b-GGUF (27%). The source code used in this paper is available at https://github.com/oseibrefo/semEval25task8

1 Introduction

Large language models (LLMs) have significantly advanced natural language processing (NLP), demonstrating strong capabilities in question answering (QA), code generation, and structured data analysis (Brown et al., 2020; Chen et al., 2021). While LLMs excel in open-domain QA over unstructured text (Osei-Brefo and Liang, 2022), reasoning over tabular data presents additional challenges. These include schema understanding, multi-column aggregation, numerical computation, and execution reliability (Osés Grijalba et al., 2023; Pasupat and Liang, 2015).

Tabular question answering (TQA) has been traditionally approached using the following three main techniques:

Semantic Parsing Approaches: These are traditional methods where models such as Seq2SQL (Zhong et al., 2017) and SQLNet (Xu et al., 2017) translate natural language queries into SQL commands. While effective for structured databases, these approaches require predefined schemas and struggle with generalisation to diverse table structures.

Transformer-Based Table Models: Models such as TAPAS (Herzig et al., 2020) and TaBERT (Yin et al., 2020) jointly encode table structures and queries, enabling direct classification-based predictions. However, they are limited in their ability to perform dynamic computations beyond simple row-based retrieval.

Code-Based Approaches: Recent methods have explored prompting LLMs to generate executable Python functions to extract or compute answers (Chen et al., 2021; Fried et al., 2022). These approaches offer more flexibility than SQL-based models but require safeguards against execution errors, format inconsistencies, and incorrect column selection.

Tabular question answering (TQA) presents unique challenges since it requires models to understand structured data and perform reasoning over numerical and categorical values. Unlike standard text-based QA, TQA often involves multiple computational steps, such as aggregating values, filtering rows, or computing statistics. Traditional methods rely on SQL-based querying or transformer models fine-tuned on tabular data, such as TAPAS. However, these approaches often require extensive

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 343–349

training and struggle to generalize to unseen tables.

A promising alternative is to leverage LLMs for program synthesis, where the model generates executable code to answer questions about tabular data. This approach allows for flexible and interpretable reasoning steps while enabling the processing of large datasets beyond the LLM's context window by delegating execution to external interpreters.
We propose a multi-agent system that integrates prompt-based code generation with structured dataset extraction and execution. The system consists of the following multi-agent system workflow:

- **Dataset Extraction Agent:** Loads the dataset files.
- **Schema Agent:** Loads the dataset files, such as parquet files, that correspond to each question and extracts the relevant columns and sample rows.
- **Prompt Engineering Agent:** Constructs a structured prompt that includes the extracted schema and sample data to guide the LLM in the generation of accurate code.
- **Code Generation Agent:** Uses a preferred LLM to generate Python functions designed to process the provided tabular data.
- **Execution Agent:** Runs the generated function on the dataset and returns the computed answer.
- **prediction agent:** Predicts the final answers for each question

Our contributions are as follows:

- A structured approach for table-based question-answering is developed to generate executable Python code.
- We introduce a method to extract structured dataset information and integrate it into the prompt, improving LLM performance for table reasoning.
- We evaluate our approach on the DataBench benchmark and show that it outperforms traditional SQL-based methods and zero-shot LLM prompting.

Unlike zero-shot in-Context Learning (Z-ICL), which provides the entire dataset within the prompt, our approach generates Python functions that execute externally, making it more scalable for large datasets. Experimental results demonstrate the effectiveness of our approach and highlight its adaptability to unseen tabular data structures and its ability to generate accurate responses across multiple answer types.

2 Methodology

2.1 System Overview

Our proposed method follows a structured approach that consists of a pipeline made of extraction agents, schema agents, prompt engineering agents, main inference agents, code generation agents, execution agents, and prediction agents as components. It involves the implementation of a sequential multi-agent pipeline for structured code generation and execution in tabular question answering. The pipeline consists of distinct agents, each responsible for a specific subtask, as demonstrated in Figure 1. To facilitate text generation, GPT-2 Large, a causal language model (CausalLM), is employed. This processes natural language queries and generates structured Python code. The AutoTokenizer is used to tokenize the input queries and ensure they are formatted correctly for model inference.

This setup allows the system to efficiently encode input queries, generate structured responses, and execute inference tasks within the multi-agent framework. The model interacts with schema and prompt engineering agents to produce executable code, which ensures structured tabular reasoning.

2.2 Schema Agent: Extracting Table Structure

The Schema Agent loads the dataset files labelled as all.parquet and sample.parquet associated with each question and extracts the schema of the table. Given a dataset $\mathcal{D}$ with N rows and M columns:

$$\mathcal{D} = \{(C_1, C_2, ..., C_M) \mid R_1, R_2, ..., R_N\} \quad (1)$$

where C_i represents column names and R_j represents row entries. The Schema Agent performs:

- Extraction of the column names from the dataset.
- Retrieval of the first five rows of the dataset for inclusion in the structured prompt.

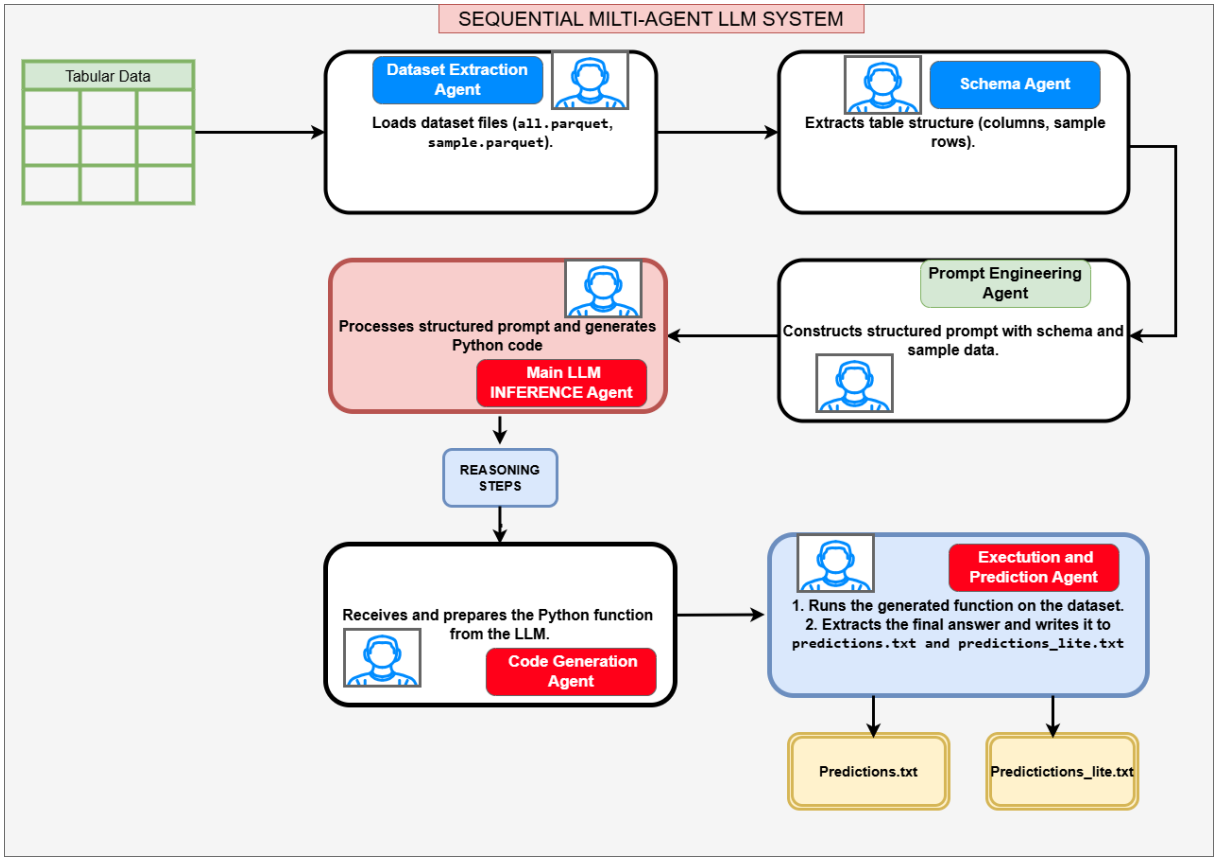

Figure 1: Overview of the multi-agent System, consisting of the extraction agent, schema agent, prompt engineering Agent, Main inference Agent, Code generation Agent, Execution and prediction agents

There is no explicit ranking mechanism to determine the importance of columns, and all columns are included in the prompt without prioritisation.

2.3 Prompt Engineering Agent: Generating Structured Inputs

The Prompt Engineering Agent constructs structured prompts for the LLM based on the extracted schema. These prompts guide the LLM in generating accurate responses. An example of the prompts used in this work is demonstrated in figure 2:

For a given question Q and dataset schema, the prompt P is constructed using the following formula in equation 2:

$$P = f_{\text{prompt}}(Q, \{C_k\}_{k=1}^{K}, S) \qquad (2)$$

Where:
-S is a set of sample rows and
-$\{C_k\}_{k=1}^{K}$ represents the columns or attributes of the dataset schema.
The current implementation follows these steps:

- Extracts column names and includes them in the prompt.

Prompt Engineering Agent

```
You are a Python expert analyzing tabular data step by step.
Your final answer MUST be in Python code:
- Put your code in triple backticks: ``` ... ```
- The code must define exactly ONE function named answer(data).
- The function returns a single line: return ...
- The return type is exactly ONE of:
    * boolean: True/False or "Yes"/"No"
    * a single string or number
    * a list of strings or numbers, e.g., ["cat","dog"] or [1,2]
- DO NOT include ANY extra lines outside the triple-quoted block.
- DO NOT include ANY additional text outside the triple-quoted code block.

Use only these sample rows and columns. Then produce your code.

Question ID: {row id}
Question: {question}
Relevant Columns: {relevant columns}
Sample Rows: {sample rows}

Generate only valid Python code in triple backticks:
```

Figure 2: prompts used for the prompt engineering age

- Provides five sample rows from the dataset.
- Formats the prompt to request a Python function that adheres to specific constraints.

2.4 Code Generation Agent: Production of Executable Code

The Code Generation Agent is responsible for generating Python functions to process tabular data. The implementation invokes an external LLM via the DeepSeek API instead of a fine-tuned local model:

$$\text{Code} = f_{\text{LLM}}(P) \tag{3}$$

Where P represents a structured prompt provided to the LLM, and the output is executable Python code. The generated function follows a specific format as:

```
def answer(data):
    # Model-generated logic
    return result
```

2.5 Execution Agent: Running Generated Code

The generated Python function is executed to produce an answer. However, there is no explicit validation step before execution. Due to resource limitations, the code was assumed to be correct, and execution was attempted without verifying syntax or logical consistency.

2.6 Prediction Generation and Output Formatting

Once execution is completed, the predictions are written to output files (predictions.txt and predictions_lite.txt). This step concludes the process, which involves extracting the dataset, generating code using the LLM, and executing the generated function.

3 Experiments

The system follows a zero-shot approach, relying on prompt engineering to instruct the model on how to retrieve and compute answers from structured tabular data. The experimental setup involved the use of the DeepSeek API.

The dataset was extracted from a competition archive in a ZIP file. The extracted data had multiple subdirectories, with each representing a distinct dataset. Each dataset contained Parquet files, which stored structured tabular data for question-answering. Each dataset ID also corresponded to a folder that contained two files, which are the all.parquet and sample.parquet files. The sample.parquet file contained the first 20 rows of the all.parquet files.

The test data also contained the 522 set of test questions to be answered along with the ID of the corresponding dataset. Table 1 shows the various folders and IDs of the datasets.

Dataset Folder	Description
066_IBM_HR	Employee-related data
067_TripAdvisor	Travel and hotel reviews
068_WorldBank_Awards	Economic and financial data
069_Taxonomy	Classification-based dataset
070_OpenFoodFacts	Food product information
071_COL	Cost of living statistics
072_Admissions	Academic admissions and student data
073_Med_Cost	Medical and healthcare expenses
074_Lift	Ride-sharing or transport statistics
075_Mortality	Mortality and health data
076_NBA	Basketball statistics
077_Gestational	Pregnancy and maternal health data
078_Fires	Fire incident reports
079_Coffee	Coffee-related statistics
080_Books	Book sales and metadata

Table 1: Dataset folders and their descriptions.

A GPT-based model known as deepseek-chat was used as a multi-agent for zero-shot inference through API calls. The model was prompted to generate Python executable codes that extracted the required answer. The prompt ensures that the model adheres to a structured format for consistent and interpretable results.

3.1 Model Configuration and Hyperparameters

The GPT-based model used for inference is `DeepSeek Chat Deepseek-V3`, accessed via an API. The model is configured to generate structured Python code, which is then executed to extract answers. The key hyperparameters used during inference are shown in Table 2:

Category	Parameter	Value / Description
Base Model	Model Name	`gpt2-large`
	Tokenizer	`AutoTokenizer`
Tokenizer	Padding Token	`tokenizer.pad_token`
	Max Length (Default)	1024 tokens (GPT-2 limitation)
	Input Truncation	Enabled (`truncation=True`)
	Padding Strategy	`max_length`
LoRA Configuration	Rank (r)	8
	LoRA Alpha	32
	Target Modules	`["c_attn"]` (Attention Layer)
	LoRA Dropout	0.1
	Bias Handling	`"none"`
Inference	Max Input Token Length	1024 (GPT-2 Large max token limit)
	Model Used for Inference	`DeepSeek-V3 API`
	Temperature	0.0 (Deterministic Outputs)
	API Used	DeepSeek-V3 API)

Table 2: Hyperparameter used for the tokenization and inference.

4 Results and Discussion

Our system was evaluated on the DataBench test benchmark, which consists of real-world datasets with a total of 522 manually curated questions. The evaluation assessed the effectiveness of our

approach in generating and executing Python code to answer tabular questions. Performance was measured using the Datatech Eval package, which ensured a standardized assessment across various dataset structures and question types.

The evaluation was carried out to compare the performance of our multi-agent system with existing models, particularly in handling structured tabular data.

4.1 Evaluation

To benchmark the performance of our system, we compared it against two baseline models, which are:

Stable-code-3b-GGUF: A transformer-based generative code model.

TAPAS: A transformer-based tabular QA model designed for direct classification-based predictions. Additionally, we tested our system on two datasets:

DataBench: The full benchmark dataset that contains diverse real-world tabular QA tasks.

DataBench-lite: A smaller subset with simplified queries and table structures.

Models	Accuracy (%)
Stable-code-3b-GGUF (Baseline)	26.00
Transformer-Based (TAPAS)	0.19
Multi-Agent Tabular QA with DeepSeek-V3)	**84.67**

Table 3: Performance comparison on the test DataBench dataset.

As shown in Table 3, our proposed DeepSeek API-based multi-agent model significantly outperformed both TAPAS and Stable-code-3b-GGUF models. The system achieved an accuracy of 84.67%, which is 225.65% higher than that of the stable-code-3b-GGUF model, which is the baseline code used by the organisers.

The table also shows the **TAPAS** model, despite being optimised for tabular data, performed poorly with mere 0.19% accuracy due to its limitations in handling complex aggregation and multi-step computation.

These results demonstrate that a multi-agent system made up of structured prompt engineering and code execution-driven approaches is significantly more effective for tabular question answering than pure transformer-based classification methods.
Table 4 presents results for DataBench-lite, which is a reduced version of the DataBench benchmark

Models	Accuracy (%)
Stable-code-3b-GGUF (Baseline)	27.00
Transformer-Based (TAPAS)	2.68
Multi-Agent Tabular QA with DeepSeek-V3	86.02

Table 4: Performance comparison on the test DataBench-lite dataset.

with simplified table structures and fewer multi-step reasoning tasks. Here too, our proposed DeepSeek API-based multi-agent model significantly outperformed both TAPAS and Stable-code-3b-GGUF models. It achieved an accuracy of 86.02%, which is 218.59% higher than that of the stable-code-3b-GGUF model, which is the baseline code used by the organisers. The TAPAS model achieved an accuracy of 2.68% under this data.

The DeepSeek API-based model consistently performed well across both DataBench and DataBench-lite, which demonstrates their robustness in structured data comprehension. On the other hand, the TAPAS model struggled significantly, even with simplified tasks. This demonstrates that direct transformer-based classification models are not well-suited for complex table reasoning. Additionally, the baseline model, Stable-code-3b-GGUF, showed only slight improvement on DataBench-lite, which suggests that generative approaches without structured execution are not sufficiently robust for tabular QA.

Our proposed multi-agent pipeline excels due to the following key factors:

Structured Prompt Engineering Ensures that the LLM receives well-formatted input, including schema details and sample rows.

Code Generation and Execution: Enables the system to dynamically compute answers, unlike transformer models that rely solely on training-based pattern recognition.

Dataset Adaptability: By extracting relevant schema details before inference, the system can generalize to unseen datasets without requiring additional fine-tuning.

4.2 Limitations and Areas for Improvement

While our approach significantly outperforms existing models, a few limitations remain:

Execution Overhead: Running generated code adds an additional processing step, which can increase inference time.

Error Handling Mechanisms: Some syntax errors in generated code require manual validation or debugging, which could be optimized with automated syntax correction.

Scalability for Large Datasets: While the system performs well on structured datasets, handling extremely large tables may introduce computational bottlenecks.

The evaluation results clearly demonstrate that our DeepSeek API-based multi-agent system significantly improves accuracy in tabular question-answering tasks. The ability to dynamically generate and execute Python code allows for greater flexibility compared to purely transformer-based approaches like TAPAS. Future work will focus on enhancing execution efficiency, refining error handling, and optimizing scalability for even larger datasets.

4.3 Error Analysis

Our system follows a structured multi-agent pipeline for generating and executing Python code to answer tabular questions. However, inference errors were observed due to syntax issues, type mismatches, and execution failures. The most frequent error types encountered during inference are categorised in Table 5.

Error Type	Occurrence (%)
Syntax Error in Generated Code	62.5
Data Type Handling Errors	12.5
Column Selection Errors	12.5
Execution Failure (Timeout)	12.5

Table 5: Common failure cases in model predictions.

Syntax errors were the most prevalent issue and contributed to 62.5% of the total error cases encountered. These failures occurred due to missing commas, incorrect indentation, or malformed expressions within the generated Python code.

This error appeared five times out of eight total error cases encountered, indicating a systematic issue in the LLM-generated function. The issue likely stems from improper prompt structuring, leading the model to generate incomplete expressions or incorrectly formatted function calls.

The next category of errors was the data type handling errors. These were the data type mismatches that were a notable issue and contributed to 12.5% of the total error cases. These failures occurred when the model-generated function incorrectly applied string-based operations on numerical values. Some possible causes of this were that the function incorrectly assumed all table values were strings, leading to operations like `.split()` being applied to numeric values. Others could also be due to the model's failure to validate column data types before execution.

There were also column selection errors, which occurred during the selection of the correct column for computation, and they accounted for 12.5% of the total failures. Some of the possible causes of these were: The selection of a categorical column by the model when a numerical column was expected. Other causes include the attempted performance of a numeric comparison on string values by the generated function.

The final category of errors was due to execution failures, which resulted from incorrectly structured generator expressions that led to runtime errors. These made up 12.5% of the total error cases. The possible cause of these errors is the attempt of the function to use a generator expression without proper parentheses. It could also be due to the occurrence of the execution timeout due to an inefficient or infinite loop. Refer to Appendix A for a list of all the sample errors encountered

5 Conclusion

This work has proposed the use of a multi-agent system that integrates prompt-based code generation with structured dataset extraction and execution for tabular question answering. The results demonstrate that multi-agent, execution-driven LLM pipelines are superior to direct prompting techniques and other traditional tabular QA approaches, achieving higher accuracy on real-world tabular data reasoning tasks.

By improving execution validation, incorporating LoRA fine-tuning, and enhancing schema comprehension, this approach could further improve how LLMs interact with structured data. Future work will focus on enhancing the code execution efficiency and the incorporation of automated error correction.

A Sample errors encountered

```
__INFERENCE_ERROR__: Error
calling answer(data):
invalid syntax. Perhaps you
forgot a comma? (<string>,
line 1)
```

Mitigation Strategies

- Use an `AST`-based syntax validation step to detect and reject malformed code before execution.
- Modify structured prompts to enforce syntactically complete function generation.
- Implement a post-processing step to correct common syntax errors before execution.

```
__INFERENCE_ERROR__: Error
calling answer(data):
'float' object has no
attribute 'split'
```

Mitigation Strategies

- Enforce explicit type conversion (`float()`, `str()`, `int()`) before processing table values.
- Modify prompts to instruct the model to validate column types before execution.
- Implement exception handling to catch and fix type-related errors dynamically.

```
__INFERENCE_ERROR__: Error
calling answer(data): '<'
not supported between
instances of 'float' and
'str'
```

Mitigation Strategies

- Implement column selection heuristics to improve the relevance of retrieved data.
- Modify prompts to explicitly specify the expected column type for computation.

```
__INFERENCE_ERROR__:
Invalid syntax after fix:
Generator expression must
be parenthesized (<unknown>,
line 4)
```

Mitigation Strategies

- Modify prompt instructions to favor list comprehensions (`[]`) over generator expressions (`()`).

Abstract

Emotion detection in text is a key task in computational linguistics, challenged by linguistic ambiguities, cultural differences, and the scarcity of non-English resources, limiting its multilingual applicability. While pre-trained transformers and neural networks have shown strong performance, research remains largely English-centric, highlighting the need for inclusive, cross-linguistic approaches. This work tackles SemEval-2025 Task 11, Track A: Multi-label Emotion Detection (Muhammad et al., 2025b), predicting perceived emotions (joy, sadness, fear, anger, surprise or disgust) in text snippets. We propose a hybrid model combining XLM-RoBERTa embeddings with Bi-LSTM and multi-head attention, enhancing contextual understanding and classification across languages. Experiments on the task dataset show our model effectively captures emotional nuances, outperforming the baselines in most languages. Results show that our method improves macro-F1 scores for multilingual emotion classification. These findings highlight the value of combining transformer-based embeddings with structured sequence modeling to better represent linguistic and cultural diversity.

1 Introduction

Since its inception, artificial intelligence has sought to solve human and social problems through techniques such as natural language processing (NLP), which combines computational and linguistic methods to enable computers to understand human languages in formats such as text and audio/voice (Acheampong et al., 2020).

Several initiatives have introduced emotion detection tasks to encourage the research community to develop competitive tasks for processing, understanding, and generating text. These efforts present new research challenges and establish state-of-the-art results in this field. There are works that have significantly advanced the field of emotion detection by tackling different aspects, e.g., Mohammad et al. (2018) laid a strong foundation by introducing multi-label emotion classification and emotion intensity prediction in tweets, providing a benchmark for fine-grained affect detection. Building on this, the work of Kumar et al. (2024) extends the challenge to conversational contexts, emphasizing emotion shifts and their reasoning, a crucial step toward developing systems capable of understanding emotional transitions. Meanwhile, García-Vega et al. (2020) contribute to the field by introducing emotion detection in Spanish-language tweets, addressing the gap in multilingual emotion classification, and enhancing NLP applications for non-English texts. These joint efforts highlight the growing importance of emotion-aware systems, particularly in social media monitoring, mental health applications, and human-computer interaction (Al-Saqqa et al., 2018). By broadening the scope of affective computing to include emotion intensity, conversational reasoning, and language diversity, these advancements improve the depth and applicability of the field. Their contributions drive the development of more context-aware, explainable, and adaptable models.

Despite significant advancements in recent years to address the challenges of sentiment analysis, emotion classification remains a complex task for NLP systems, whose relevance has continued to grow over time.

This paper presents a model for Track A of SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection (Muhammad et al., 2025a; Belay et al., 2025; Muhammad et al., 2025b), which focuses on predicting a speaker's perceived emotions based on a given text snippet. We propose to solve the challenge as a multi-label classification problem using an approach that leverages a transformer-based encoder to extract deep semantic representations, with a Bi-LSTM for cap-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 350–356

turing temporal dependencies and multi-head attention mechanisms to refine emotion-specific features further. This architecture enables the effective detection of multiple emotions in multilingual text, contributing to advancements in affective computing.

The rest of the paper is organized as follows: Section 2 describes the problem and the related work. Section 3 presents the system proposed and discusses the experimental setup to tackle task A; meanwhile, Section 4 analyzes the results. The conclusions are presented in Section 5.

2 Background

Emotion detection involves identifying a person's sentiments or feelings. In computational linguistics, it identifies a discrete emotion in a text (Nandwani and Verma, 2021). This task is challenging due to cultural differences, linguistic ambiguity, and the use of slang.

The techniques for emotion detection include lexicon-based, machine learning, and deep learning approaches (Seyeditabari et al., 2018). Lexicon-based approaches use dictionaries of words with sentiment values to determine the predominant emotion in a text. On the other hand, machine learning models rely on labeled datasets to train supervised models that predict emotions. The most recent methodologies are based on deep learning, which applies neural networks with minimal feature engineering.

The work of Ameer et al. (2023) tackles the problem of multi-label emotion classification using an approach that combines multiple attention mechanisms with recurrent neural networks and pre-trained transformer models (through transfer learning). This approach achieves results that surpass the state of the art in terms of accuracy. Wang et al. (2024) propose an emotion detection model that distills knowledge from a high-performing English monolingual model to a multilingual model. This approach enhances emotion detection, demonstrating the effectiveness of knowledge transfer for robust and explainable multilingual models.

Despite these advancements, emotion recognition research has primarily focused on high-resource languages, leaving low-resource languages underrepresented. Nevertheless, recently, two studies have introduced large-scale multi-label emotion datasets aimed at improving multilingual emotion classification. Muhammad et al. (2025a) introduce BRIGHTER, a collection of emotion-annotated datasets spanning 28 languages from Africa, Asia, Eastern Europe, and Latin America. The dataset integrates diverse sources and employs various annotation strategies by fluent speakers. It features multi-label annotations and intensity levels, enabling a more nuanced understanding of emotions. Experimental results highlight the variability in large language model (LLM) performance across languages and explore cross-lingual transfer learning. Findings show that multilingual models achieve better results when trained on linguistically related languages, while LLMs performance drops significantly in low-resource settings.

Belay et al. (2025) introduce EthioEmo, a multi-label emotion dataset for Ethiopian languages, compiled from diverse sources such as social media and news. The study extensively evaluates multiple language model architectures and explores translation-based evaluation methods. The findings highlight the challenges of multi-label emotion classification in low-resource settings and expose the limitations of LLMs in capturing emotional nuances across linguistic structures.

These datasets and experiments advance the state-of-the-art in multilingual and multi-label emotion classification as part of SemEval 2025 Task 11.

3 System Overview

The proposed system is designed for multilingual emotion classification using a hybrid deep learning approach. It integrates a pre-trained transformer-based model (Vaswani et al., 2017), a bidirectional LSTM (Hochreiter and Schmidhuber, 1997) (Bi-LSTM) network, and a multi-head attention mechanism (Vaswani et al., 2017).

The decision to integrate Bi-LSTM and attention mechanisms with transformer-based architectures stems from the complementary advantages each component brings to natural language processing tasks. Bi-LSTM is well suited for capturing sequential dependencies and maintaining word order, both of which are crucial in tasks such as text classification and sentiment analysis, where the temporal structure of input matters. Pure transformer models can struggle with fine-grained temporal relationships (particularly in low-resource settings), as they lack inherent sequence modeling capabilities (Otter et al., 2020). Incorporating Bi-LSTM allows the architecture to preserve these structural cues, while

the attention mechanism adds the ability to dynamically highlight important words or phrases, boosting both accuracy and interpretability. This synergy has been demonstrated in several contexts. For instance, combining Bi-LSTM with BERT has shown improved entity recognition in medical text due to better handling of position-sensitive features (Zalte and Shah, 2024), and sentiment analysis in social media content benefits from this hybrid by capturing emotional nuances more effectively (Bader et al., 2024). Attention-enhanced Bi-LSTM architectures also contribute significantly to explainability, an increasingly vital consideration in modern NLP systems (Galassi et al., 2020). Additionally, in scenarios such as microblog sentiment classification, this hybrid approach helps address overgeneralization issues commonly seen in transformer-only models (Jia, 2022). Altogether, the combination of Bi-LSTM, attention, and transformer components provides a well-rounded solution that balances semantic depth, sequential awareness, and interpretability, making it a strong alternative to standalone transformer models.

Below is an overview of the system components and their functionalities:

- Transformer-based model as a feature extractor: The system uses a pre-trained transformer-based model (e.g., BERT, XLM-RoBERTa, etc.) to generate contextualized embeddings for input text sequences.
- Bidirectional LSTM: The hidden states from the transformer are passed through bidirectional LSTM to capture sequential dependencies in the text.
- Multihead attention mechanism: The bi-LSTM outputs are passed through a multi-head attention layer to focus on the most relevant parts of the sequence.
- Classification head: The attention outputs are averaged across the sequence length to obtain a fixed-size contextual representation. This representation is then passed through a fully connected layer to produce logits for each emotion class. A sigmoid activation is applied to the logits to obtain probabilities for multi-label classification.

Finally, predictions are binarized using a threshold, where values greater than the threshold are classified as positive labels.

To evaluate the effectiveness of our proposed system, we trained multiple variants using different transformer-based models as feature extractors. Our experimental setup aims to assess how the choice of transformer architecture influences multilingual emotion classification performance, specifically focusing on their impact on learned representations and downstream classification capabilities. In the following paragraphs, we describe our experiments' specific model configurations and dataset.

We trained two model variants. The first leverages XLM-RoBERTa (XLM-R) (Conneau et al., 2019) as the feature extractor for all languages in the dataset, while the second employs AfriBERTa (Ogueji et al., 2021), specifically for African languages. For each, we compared the performance of the base and large configurations. We evaluate our models on a multilingual emotion classification dataset annotated for six emotion categories. Each instance can have multiple emotion labels, making this a multi-label classification task.

Datasets The models are trained on SemEval-2025 Task 11 (track A) datasets which contain text samples labeled with six emotions: joy, sadness, fear, anger, surprise, and disgust for 29 languages (Muhammad et al., 2025a; Belay et al., 2025). Each text snippet is annotated with binary labels indicating the presence or absence of each emotion. For English and Afrikaans, the dataset includes only five emotions. This variation is handled during preprocessing to ensure compatibility with the models. The dataset is divided into training, validation and test sets.

Preprocessing Input text sequences are tokenized using the tokenizer associated with the pre-trained transformer model. Sequences are truncated or padded to a fixed length of 128 tokens. On the other hand, for languages with fewer emotions, the missing emotion is set to 0 for all samples.

Model configuration

- Pre-trained transformer encoder: Pre-trained transformer models, namely XLM-RoBERTa-base, XLM-RoBERTa-large, AfriBERTa-base and AfriBERTA-large, are used as feature extractors. The transformer generates contextualized embeddings with the size specified in its

configuration. This size is then used as the input dimension for a bidirectional LSTM

- BiLSTM layer: A single-layer bidirectional LSTM with a hidden size of 256.
- Multi-head attention: Uses 8 attention heads, with an embedding dimension of 512.
- Classification head: A fully connected layer maps the final contextual representation to six emotion logits, followed by a sigmoid activation for multi-label classification.

Training The training set is used to optimize model parameters via Binary Cross-Entropy (BCE) loss, employing the AdamW optimizer (Loshchilov and Hutter, 2017) with a learning rate of 2×10^{-6} over 10 epochs. A batch size of 8 is used consistently for both training and evaluation across all models. Model selection is guided by the minimum training loss: the model is checkpointed whenever a lower loss is achieved in subsequent epochs. The validation set serves to monitor performance during training and supports the selection of the optimal model configuration.

Evaluation Predictions are converted to binary labels using a threshold of 0.5. For example, a predicted probability greater than 0.5 is considered the presence of the emotion (1), and lower or equal to 0.5 is regarded as the absence (0). The performance of the models is evaluated on the test set using the F1 score, computed by comparing the predicted labels against the gold-standard annotations. We include a Bag-of-Words (BoW) baseline for comparison to provide a more comprehensive assessment. The BoW follows the approach described in (Tellez et al., 2017)[1]; we set all the characters to lowercase, removing diacritics and punctuation symbols. Additionally, the users and the URLs were removed from the text. We use several tokenizers, i.e., bigrams, words, and q-grams of characters with $q = \{2, 3, 4\}$.

4 Results

The systems' performance analysis starts with the information presented in Table 1. The table re-

tir	**0.4656**	0.4629
yor	0.2682	**0.2757**

Table 2: Macro F1 scores obtained in test set per language for AfriBERTa-based models. The highest performance scores are highlighted in bold.

ports macro-F1 scores per language for the XLM-RoBERTa-based classifiers and the BoW baseline. The table highlights in boldface the best scores and indicates with an asterisk those scores whose difference to the best is not statistically significant (5%).[2]

Based on the results, we observe that the large model achieves a higher macro F1 score across most languages than the base model and baseline, indicating a consistent improvement in classification performance. Languages such as mar, rus, esp, eng, hin, and ron achieve high scores for both base and large models, suggesting that they benefit from better representation and greater resource availability in the training data. Several languages show moderate improvements when scaling from base to large but still lag behind the best-performing languages. It is also worth noting that languages such as ibo, yor, and vmw do not benefit from scaling, as their scores tend to decrease.

In some languages (yor, vmw, tir, som, orm, kin, ibo, and hau), the BoW outperforms or is statistically equivalent to the large model, which may indicate insufficient data to fine-tune the MLM.

Table 2 shows the F1 scores per language for the AfriBERTa-based models. According to the data, in most cases, the AfriBERTa-large model achieves slightly higher macro F1 scores than the AfriBERTa-base model. This is especially notable in languages such as amh, som and saw. However, some languages show little to no difference between the base and large models. This is the case for gbo, tir, hau and orm. On the other hand, languages such as swa and yor show the lowest overall scores; this might indicate there is a great challenge in handling these languages.

When comparing the predictions from XLM-RoBERTa-based models with those from AfriBERTa-based models, we observe that XLM-RoBERTa generally outperforms AfriBERTa in most cases. This is particularly evident for amh, hau, ibo, orm, pcm, and som, where XLM-R-large scores higher than AfriBERTa-large. However, there are exceptions where AfriBERTa slightly surpasses XLM-RoBERTa. This is the case for hau, where AfriBERTa-large marginally outperforms XLM-R-large. For yor and kin, the base and large versions of AfriBERTa outperform their XLM-R counterparts. It is worth noting, however, that swa performs worse across all AfriBERTa versions. Additionally, AfriBERTa-based models fail to outperform the baseline scores, except for amh and hau. This suggests that our AfriBERTa-based approach may not be well-suited for African languages, as it struggles to outperform the baseline consistently. As the results obtained by the XLM-R-large-based model were the highest performing, these model's predictions were submitted to the competition.

[2]The p-values of the difference in performance were estimated using bootstrap with the library described in Nava-Muñoz et al. (2024).

5 Conclusions

This study evaluates the performance of transformer-based models for multilingual emotion classification, comparing XLM-RoBERTa and AfriBERTa across a diverse set of languages. Several key takeaways emerge from our analysis.

First, model scaling improves classification performance, with large variants (XLM-R-large and AfriBERTa-large) consistently outperforming their base counterparts. XLM-RoBERTa achieves higher F1 scores than AfriBERTa in most cases, particularly for amh, hau, ibo, orm, pcm, and som, indicating that XLM-RoBERTa's multilingual pretraining provides more robust representations. However, AfriBERTa outperforms XLM-RoBERTa for specific languages such as yor and kin, suggesting that AfriBERTa's training data may better capture linguistic characteristics of certain African languages. Interestingly, scaling does not always lead to improved performance, as some languages (ibo, yor, and vmw) experience a decrease in scores when moving from base to large models. This suggests that simply increasing model capacity does not necessarily enhance classification performance for all languages, possibly due to data sparsity or overfitting. Among all evaluated models, XLM-R-large emerges as the best-performing approach for multilingual multi-label emotion detection, making it a strong candidate for robust and scalable NLP applications.

Despite its design for African languages, AfriBERTa fails to outperform the baseline in multiple cases, with the exception of amh and hau. This raises concerns about its adequacy as feature extractor for our system, specially for underrepresented languages. Furthermore, high-resource languages such as eng, esp, rus, hin, mar, and ron achieve significantly higher scores, benefiting from well-established pretraining data, whereas low-resource languages such as vmw, yor, swa, kin, som and sun

exhibit weaker performance, likely due to limited resources.

We also emphasize the importance of initiatives such as SemEval in advancing emotion detection, affective computing, and broader NLP challenges. Tasks like SemEval-2025 Task 11 provide high-quality annotated datasets that enable the systematic development and evaluation of models across diverse languages and domains. By fostering both competition and collaboration, these shared tasks drive the advancement of more robust models and methodologies. Additionally, they help uncover limitations in existing approaches, particularly for low-resource languages, and encourage research efforts toward more inclusive and generalizable NLP systems.

Our findings highlight the persistent challenges in modeling African languages for emotion classification. Future work should explore domain-adaptive pretraining, data augmentation techniques, and specialized architectures to improve multilingual and low-resource language performance

Abstract

This paper describes the system of the sonrobok4 team for the SemEval-2025 Task 8: DataBench, Question-Answering over Tabular Data. The task requires answering questions based on the given question and dataset ID, ensuring that the responses are derived solely from the provided table. We address this task by using large language models (LLMs) to translate natural language questions into executable Python code for querying Pandas DataFrames. Furthermore, we employ techniques such as a rerun mechanism for error handling, structured metadata extraction, and dataset preprocessing to enhance performance. Our best-performing system achieved 89.46% accuracy on Subtask 1 and placed in the top 4 on the private test set. Additionally, it achieved 85.25% accuracy on Subtask 2 and placed in the top 9. We mainly focus on Subtask 1. We analyze the effectiveness of different LLMs for structured data reasoning and discuss key challenges in tabular question answering.

1 Introduction

The SemEval 2025 Task 8 (Osés-Grijalba et al., 2025) focuses on developing systems for Question Answering (QA) over tabular data, a critical subfield of natural language processing (NLP) with applications in business intelligence, automated data analytics, and financial reporting. Unlike traditional QA tasks that rely on retrieving information from free-text documents, this challenge requires models to derive answers solely from structured, tabular data. The DataBench benchmark comprises 65 real-world datasets drawn from diverse domains, with each dataset accompanied by 20 human-generated questions and corresponding answers. This setup demands that models not only retrieve information accurately but also perform the necessary computations and reasoning over multiple table columns.

This paper introduces a system designed to address the challenges of question answering over tabular data (Tabular QA). Our approach translates natural language queries into executable Python code for direct interaction with the provided data. To improve reliability and performance, we incorporate a custom error recovery mechanism and leverage the power of several LLMs: `gpt4o-mini`, `DeepSeek`, and an open-source model. We evaluated these models with our proposed approach using various prompt configurations. Through extensive testing and comparison, we assessed each model's performance on our Tabular QA tasks, ultimately selecting the model that provided the best overall accuracy and robustness for our final system.

2 Related Work

Tabular question answering (QA) has evolved considerably over the past few years, driven by the creation of diverse datasets and innovative methodological approaches. In this section, we discuss methodological advancements, emphasizing recent paradigm shifts enabled by large language models (LLMs).

Early methods translated natural language questions into logical forms (e.g., SQL queries) for structured data retrieval. Systems such as WikiSQL (Zhong et al., 2017) and Spider (Yu et al., 2018) exemplify this paradigm, achieving high accuracy under constrained conditions. However, their reliance on predefined schemas limits applicability to free-form questions and complex table structures.

End-to-end neural models like TAPAS (Herzig et al., 2020) advanced the field by jointly encoding tables and questions using transformer architectures. TAPAS incorporates specialized positional embeddings to preserve table structure during pretraining, enabling direct answer prediction without intermediate SQL generation. Despite their effec-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 357–362

tiveness, such models require domain-specific fine-tuning and struggle with numerical reasoning tasks requiring explicit computation.

Recent approaches, notably (Liu et al., 2024b), leverage large language models (LLMs) via **prompting strategies** (e.g., in-context learning) rather than task-specific fine-tuning. Tables are serialized into text sequences and paired with demonstrations (e.g., "Q: [question] A: [answer]"), enabling LLMs like GPT-3.5/4 to perform reasoning across diverse schemas. Although LLMs show strong generalization evidenced by DataBench's multi-domain evaluation they face challenges with large tables, hallucination, and precise numerical operations.

3 Method

Our system is designed to answer natural language questions based solely on the information contained in tabular datasets. The overall pipeline consists of four main components: data preprocessing, context provisioning, natural language-to-code conversion, and error-aware execution. In the following, we detail each step of our approach.

3.1 Data Preprocessing

During our experiments with the development set, we observed that certain datasets contained special cases that led to incorrect answers. Addressing these issues not only resolved errors but also improved model performance. Our pre-processing steps are described as below:

- **Handling Missing Values:** Empty lists (`[]` in the dataset) are treated as missing values and replaced with NaN to ensure consistency in data representation.
- **String Normalization:** Extraneous whitespace is removed by stripping leading and trailing spaces from string values.
- **Datetime Standardization:** Columns containing date values are converted to the `datetime` format to ensure uniformity across datasets.

When evaluated on the test set, we identified specific datasets that frequently exhibited errors. We applied additional preprocessing steps to mitigate these issues:

- **067_TripAdvisor:** Extracted individual rating components (e.g., `'service': 5.0, 'cleanliness': 5.0, 'overall': 5.0`) and author details (e.g., `'username': 'Pressgang', 'num_cities': 8, 'num_helpful_votes': 7, 'num_reviews': 9`) into separate columns.
- **074_Lift:** Generated a `Gender` column by classifying lifter names using an LLM-based approach.
- **079_Coffee:** Fixed currency formatting by converting values such as `6,00 US$` to `6.00`.

3.2 Context Provisioning

To enable accurate code generation, our system first extracts and compiles relevant context from the provided dataset. During testing with the development set, we observed that the context provided to the language model (LLM) significantly impacts its performance. For example, when the baseline method only provided `df.head()`, we observed errors with incorrect column names and data types. This suggests that providing only a few sample rows is insufficient for the LLM to understand the dataset's structure and data types. Based on these insights, we tested several alternative methods of providing context. The following components were included to improve the LLM's understanding of the data:

- **Dataset Preview:** A snapshot of the dataset is created using `df.head()`, which provides a representative sample of rows.
- **Column Data Types:** The data types of each column are retrieved via `df.dtypes`, and the full list of column names is extracted using `df.columns`.
- **Enhanced Column Metadata:** In some experiments, we also provide a dictionary that associates each column name with the type of data in that column. The data types are determined by applying the `type()` function to the first entry in each column.

This comprehensive context is embedded in the prompt template, ensuring that the language model has sufficient information to generate accurate Pandas expressions tailored to the structure of the table.

3.3 Natural Language-to-Code Conversion

The core of our approach employs a PandasQueryEngine that translates a given natural language question into an executable Python expression. The prompt provided to the model contains:

- The dataset context (as described above).
- Explicit instructions on generating a Pandas code snippet that, when executed, produces the answer.
- A directive to output only the final expression, minimizing extraneous text.

This process is performed using multiple Large Language Models (LLMs), we also configured with distinct prompt variants to explore the impact of prompt design on code accuracy.

3.4 Error-Aware Execution and Rerun Mechanism

Recognizing that LLM-generated code may occasionally result in errors, our system integrates an error-detection module that monitors the execution of the generated Pandas code. Upon encountering an error, the system automatically regenerate and execute the new Python code.

3.5 Algorithm

In this section, we present the algorithm for Question-Answering over Tabular Data. The algorithm takes as input a language question and a dataset identifier, then retrieves the corresponding dataframe to generate and execute code for answering the question. The overall workflow involves LLM-based code generation, execution, error handling, and final answer formulation.

Algorithm 1 describes the complete workflow for question-answering over tabular data. Figure 1 illustrates the complete flow of our approach.

Algorithm 1 LLM-Driven Table Question Answering

Input: `question`, `dataset_ID`
Retrieve dataframe `df` using `dataset_ID`.
1. Code Generation: Prompt the LLM with the question and `df` context to generate Python code.
2. Execution and Validation: Execute the code on `df`.
if successful **then**
    Return the result; proceed to Step 4.
else
    Proceed to Step 3.
end if
3. Error Correction:
for up to `k` retries **do**
    Provide code and error to the LLM for correction.
    Re-execute the updated code.
    if successful **then**
        Return the result; proceed to Step 4.
    end if
end for
4. Answer Generation: Use LLM to produce the final answer under competition constraints.

4 Experimental Setup

In this section, we describe the experimental setup, including the models, datasets, and evaluation methodology.

4.1 Models and Prompts

We experiment with different Large Language Models (LLMs):

- **GPT-4o-mini**: A compact and efficient variant of GPT-4o (Achiam et al., 2023) that balances high-quality reasoning and dialogue with reduced computational cost, making it accessible and affordable.
- **DeepSeek-V3** (Liu et al., 2024a): A model that reportedly outperforms other open-source models and achieves performance comparable to leading closed-source models.
- **DeepSeek-R1** (Guo et al., 2025): A reasoning-focused model that matches OpenAI-o1 in tackling complex mathematical, coding, and logical tasks, while offering its capabilities via API at a remarkably low cost.
- **deepseek-r1-distill-qwen-14b**: An open-source model distilled from DeepSeek-R1 based on Qwen

GPT-4o-mini is tested with three different prompts:

- **Prompt A**: A baseline prompt from LlamaIndex with some adjustments to match the competition output.
- **Prompt B**: An improved prompt with some data information addition.

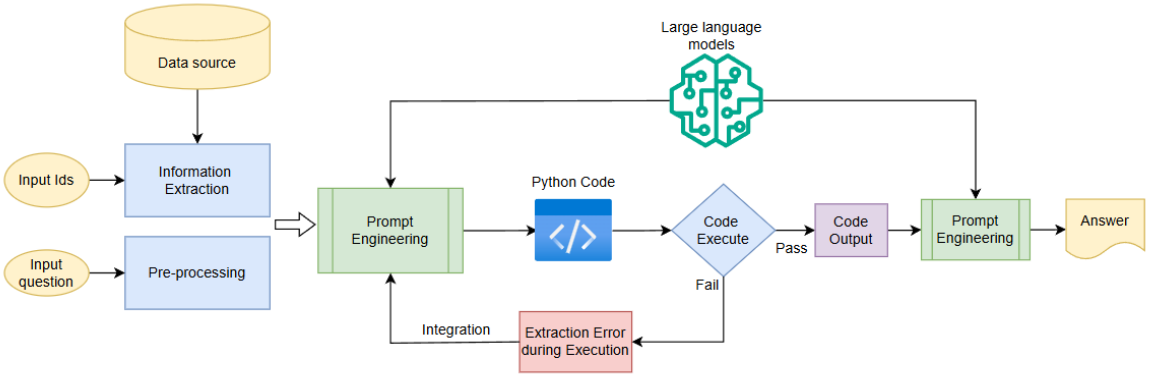

Figure 1: Overview of the Methodology for Question Answering over Tabular Data via Large Language Models

- **Prompt C**: An improved prompt incorporating additional information, including column names and data types, to enhance accuracy.

Each prompt was designed to assess how prompt engineering affects the correctness and consistency of the generated answers. The main differences between the prompts are illustrated in Figure 2.

4.2 Dataset

We conduct experiments on two versions of the dataset:

- **Original Data**: The raw dataset without modifications.
- **Preprocessed Data**: A cleaned version in which we address inconsistencies such as converting missing values, standardizing data formats, and generating additional features.

Further details on the preprocessing steps can be found in Section 3.1.

4.3 Evaluation Metrics and Procedure

We evaluate models based on accuracy, comparing predicted answers to the ground truth.

5 Results and Discussion

In this study, we evaluated four models: *GPT-4o-mini*, *DeepSeek-V3*, *DeepSeek-R1*, and *deepseek-r1-distill-qwen-14b*. Initially, *GPT-4o-mini* was tested with three distinct prompts (A, B, and C) using the original dataset. Based on these preliminary results, we identified the best-performing prompt (Prompt C) and subsequently used it to compare model performance on preprocessed datasets.

5.1 Results Overview

The results summarized in Table 3 present the accuracy of each model under different prompt conditions using the original dataset. As shown, **Prompt C consistently achieved the highest accuracy** across all models, making it the most effective prompt for further experimentation. Based on this finding, we conducted additional evaluations to analyze the impact of data preprocessing while using Prompt C. Table 4 shows the total errors in different question types of the best model which is **DeepSeek-R1**.

To further compare our approach with the top-performing teams, we report rankings separately for Subtask 1 and Subtask 2. Table 1 lists the **top 5 teams in Subtask 1**, where our method ranked **4th**.

For Subtask 2, we used **DeepSeek-V3** instead of **DeepSeek-R1** because the API for DeepSeek-R1 was unavailable at that time. Table 2 presents the **top 5 teams in Subtask 2**, in which our approach ranked **9th**.

Table 1: Top 5 Teams in Subtask 1

Rank	Accuracy (%)
Top 1	95.01
Top 2	89.85
Top 3	89.66
Top 5	88.12
Top 6	87.16
Top 4 (Our Team)	**89.46**

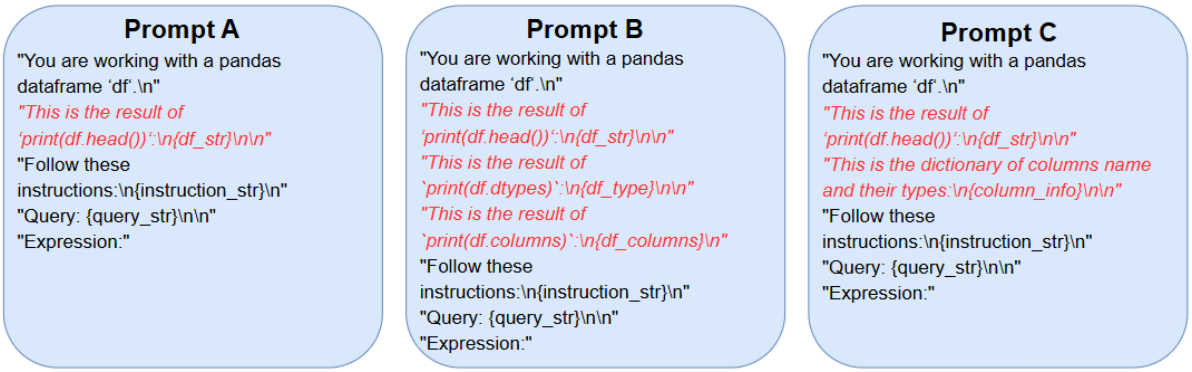

Figure 2: The key differences in how data and information are provided.

Table 2: Top 5 Teams in Subtask 2

Rank	Accuracy (%)
Top 1	92.91
Top 2	88.89
Top 3	88.70
Top 4	86.59
Top 5	86.22
Top 9 (Our Team)	**85.25**

5.2 Discussion

The results presented in Tables 3 highlight several important findings:

- **Prompt Selection:** The comparative analysis across Prompts A, B, and C indicated that Prompt C produced the best overall performance across all models when using the original dataset. This finding underscores the importance of prompt engineering in obtaining correct answers.

- **Impact of Data Preprocessing:** The subsequent comparison using Prompt C demonstrated that preprocessing the data substantially improved model performance. For instance, `gpt4o-mini` model showed increased in accuracy when the preprocessed dataset was used, thereby validating the benefits of a robust data cleaning pipeline.

- **Model Comparison:** After comparing various models, it is clear that the `DeepSeek-R1` outperforms all other models in terms of accuracy. The reasoning capabilities of `DeepSeek-R1` play a significant role in its superior results, allowing it to process and understand complex data in ways that other models cannot.

- **Practical Implications:** The combined analysis of prompt selection and data preprocessing highlights a clear pathway for optimizing model performance. Experiment with multiple prompt designs and invest in thorough data preprocessing to maximize the effectiveness of large language models.

6 Conclusion

In this paper, we explored the challenges and errors encountered when using a large language model to generate executable code for tabular question-answering tasks. Our analysis categorized errors into three key types: numerical precision errors, logical errors, and insufficient information. By systematically evaluating the generated responses and their correctness, we identified the primary causes of errors, including incorrect filtering, precision issues, and reasoning failures.

Our findings highlight the importance of robust error-handling mechanisms when integrating LLMs with structured data processing. Future work should focus on improving the consistency of generated codes, enhancing model understanding of numerical reasoning, and utilizing multiple LLMs to generate and validate answers, selecting the most reliable response based on consensus or predefined criteria.

Through this analysis, we provide valuable insights for researchers and practitioners working on LLM-based data processing systems. Our work underscores the need for a hybrid approach that combines LLM reasoning and prompt engineering

Table 3: Comparison of model performance under different experimental conditions (Subtask 1).

Note: Due to time constraints, experiments for all three DeepSeek models across all prompt engineering configurations were not completed.

Model	**Original Data**			**Preprocessed Data (Prompt C)**
	Prompt A	Prompt B	Prompt C	Prompt C
`GPT-4o-mini`	76.25%	79.31%	81.61%	82.76%
`DeepSeek-V3`	–	–	–	84.67%
`deepseek-r1-distill-qwen-14b`	–	–	–	71.84%
`DeepSeek-R1`	–	–	–	89.46%

Abstract

This paper introduces DUTIR831's approach to SemEval-2025 Task 5, which focuses on generating relevant subjects from the Integrated Authority File (GND) for tagging multilingual technical records in the TIBKAT database. To address challenges in understanding the hierarchical GND taxonomy and automating subject assignment, a three-stage approach is proposed: (1) a data synthesis stage that utilizes LLM to generate and selectively filter high-quality data, (2) a model training module that leverages LLMs and various training strategies to acquire GND knowledge and refine TIBKAT preferences, and (3) a subject terms completion mechanism consisting of multi-sampling ranking, subject terms extraction using a LLM, vector-based model retrieval, and various re-ranking strategies. The quantitative evaluation results show that our system is ranked **2nd** in the all-subject datasets and **4th** in the tib-core-subjects datasets. And the qualitative evaluation results show that the system is ranked **2nd** in the tib-core-subjects datasets.

1 Introduction

In the era of information explosion, the efficient organization and retrieval of knowledge have become paramount. Libraries, as custodians of vast repositories of information, play a critical role in this endeavor. The process of cataloging and tagging library records with relevant subject headings is not merely a clerical task but a foundational activity that enhances the discoverability and accessibility of resources. The advent of Large Language Models (LLMs) has opened new avenues for automating and refining this process, thereby addressing the challenges posed by the sheer volume and complexity of modern bibliographic data (Devlin et al., 2019).

The LLMs4Subjects task focuses on developing LLM-based systems that generate the most relevant subjects from the Integrated Authority File (GND) subject collection to tag a given TIBKAT technical record in either German or English (D'Souza et al., 2025). This task involves five types of records: articles, books, conference papers, reports, and thesis. To achieve this, two key challenges are addressed:

1. Understand the taxonomy of the GND subject. The GND is an international authority file that is primarily used by German libraries to catalog and link subjects, organizations, and works. The objective is to enable LLMs to learn and apply this taxonomy effectively, capturing its hierarchical structure and semantic nuances.

2. Automatically assign subjects to TIBKAT records. The system should be able to recommend relevant GND subjects by analyzing the semantic relationships between subjects and the titles and abstracts of technical records. To train and evaluate our system, two datasets are utilized: tib-core-subjects and all-subjects.

Our approach utilizes a three-stage architecture:

(1) A data synthesis stage that utilizes LLM and prompt design to generate and selectively filter high-quality data.

(2) A model training module that leverages LLMs, knowledge distillation, supervised fine-tuning, and preference alignment to acquire GND knowledge and align with TIBKAT preferences.

(3) A subject term completion mechanism that includes frequency-position ranking based on multi-sampling for term generation, subject term extraction using LLMs, vector-based retrieval for title-driven term generation, and various re-ranking strategies.

The quantitative evaluation results show that our system is ranked **2nd** in the all-subject datasets and **4th** in the tib-core-subjects datasets. And the qualitative evaluation results show that the system

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 363–372

is ranked **2nd** in the tib-core-subjects datasets.

2 Related Work

Recent advancements in LLMs revolutionized text classification. Models such as Qwen (Yang et al., 2024) and GPT (Brown et al., 2020) demonstrated exceptional performance in capturing semantic nuances. Fine-tuning pre-trained models on domain-specific data, such as technical records, yielded promising results (Brzustowicz, 2023). Regarding training strategies, the Low-Rank Adaptation (LoRA) method reduced the number of fine-tuning parameters and computational costs while preserving performance (Hu et al., 2021). Additionally, optimization methods such as Direct Preference Optimization (DPO) were introduced to align model outputs with target preferences (Rafailov et al., 2023).

Retrieval models, such as DPR (Karpukhin et al., 2020) and BGE-M3 (Chen et al., 2023), were widely utilized for semantic search. Reranking strategies, including the use of the Deepseek (DeepSeek-AI et al., 2024), Qwen, and ChatGLM (GLM et al., 2024) APIs, further enhanced the accuracy of retrieval systems. These techniques played a crucial role in improving subject classification performance in our task.

3 System Overview

Our system consists three parts: data synthesis, training strategies, and integration of subject terms. The framework of the system is shown in Figure 1.

3.1 Data Synthesis

3.1.1 Incremental Data Generation

Wei and Zou (2019) demonstrates that incremental data can enhance model learning quality. For the two datasets provided by the organizers, tib-core-subjects and all-subjects, we first extract the GND code list from the records in the labeled training set. Using the GND-subjects-all and GND-subjects-tib-core collections provided by the organizers, we then map the extracted GND codes to their corresponding subject terms. To further expand the subject term set, we iteratively search for related terms within the same classification, randomly selecting up to three unused terms in each round until the set is sufficiently enriched.

We employ Qwen2.5-72B-Instruct for incremental data generation. Given a set of subject terms, the model selects relevant terms and generates corresponding titles and abstracts for various record types, including books, articles, theses, reports, and conference papers. The selected terms are then ranked based on their relevance to the generated titles and abstracts. The final output consists of the generated title, abstract, and the selected subject terms. The specific prompt template used for incremental data generation is detailed in Appendix B.1.

3.1.2 Data filtering for Incremental Data

Although Qwen2.5-72B-Instruct demonstrates exceptional performance in text comprehension and generation, some generated texts may exhibit suboptimal quality. To mitigate this issue, we implement a filtering procedure using Qwen2.5-72B-Instruct to evaluate and refine the generated records. Specifically, the model evaluates the logical coherence of the generated titles and abstracts, as well as their relevance to the selected subject terms.

The detailed prompt template used for data filtering is provided in Appendix B.2. Due to time constraints, this filtering process is applied only to the incremental data within the all-subjects dataset. Ultimately, 10% of the incremental data is excluded, retaining only those records that achieve full scores for both logical coherence and subject term relevance.

3.2 Training Strategies

3.2.1 GND knowledge Distillation

The organizers provide two GND subject collections: GND-subjects-all and GND-subjects-tib-core. These datasets contain essential information, including GND Code, Classification Number, Classification Name, Name, Alternative Name, Related Subject, and Definition. Fine-tuning an LLM enables it to internalize domain-specific knowledge, thereby improving its ability to interpret subject terms and their complex semantics.

To enhance the models comprehension and effective utilization of GND knowledge, we fine-tune Qwen2.5-7.5B-Instruct by incorporating GND subject information. The input consists of subject term names, while the output includes their corresponding properties formatted in JSON. The specific prompt template used for GND knowledge distillation is detailed in Appendix B.3.

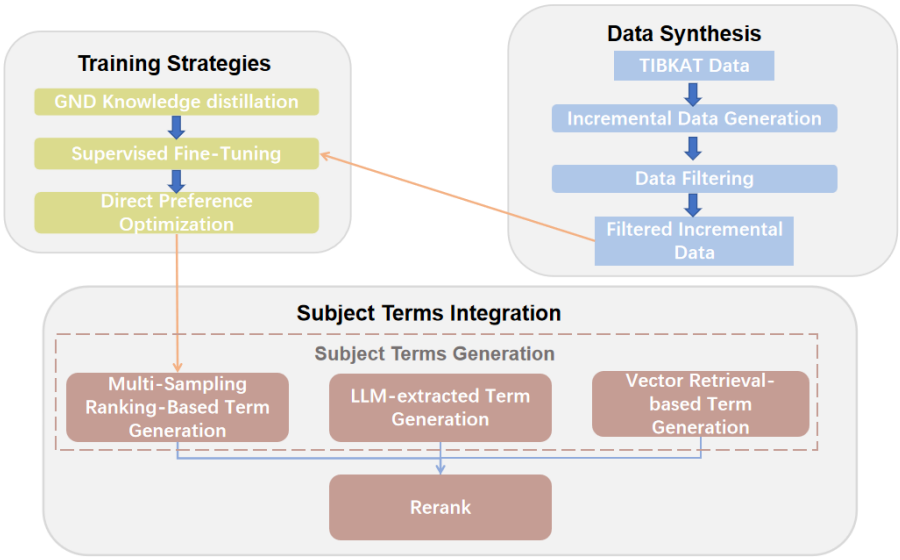

Figure 1: System Overview.

3.2.2 TIBKAT: Supervised Fine-Tuning and Direct Preference Optimization

We utilize LoRA for fine-tuning, where the input consists of titles and abstracts, and the output is a list of predicted GND subject terms. The specific prompt template used for Supervised Fine-Tuning (SFT) is provided in Appendix B.4.

Building upon the model trained in Section 3.2.1, we develop three versions of the SFT model for the two datasets. $M_{sft(raw)}$, trained on the original dataset, serves as the baseline. $M_{sft(all)}$, trained on the original dataset combined with the filtered incremental dataset, serves as the base model for subsequent DPO training. Meanwhile, M_{reject} is trained on half of the original data to generate negative examples for the DPO process. We utilize M_{reject} to construct negative examples for DPO because an SFT model trained on only half of the original dataset has acquired limited knowledge. As a result, its predictions may deviate from the true labels, making them suitable for use as negative examples in the preference optimization process.

3.3 Integration of Subject Terms

The integration of subject terms comprises two key components: Subject Terms Generation and Reranking.

3.3.1 Subject Terms Generation

Subject terms generation consists of three approaches, with the terms generated by these methods arranged sequentially to fulfill the organizer's requirement of producing 50 subject terms for each technical record.

Step 1: Multi-Sampling Ranking-Based Term Generation

Temperature influences the diversity and consistency of the model's generated outputs, while the random seed determines the starting point of the sampling process. Different seeds result in distinct text sequences. By performing multiple samplings with different seeds, we can explore a wider range of possibilities within the model, thereby enhancing the diversity of the results and reducing the likelihood of the model getting trapped in local optima (Holtzman et al., 2020). As a result, we propose a frequency-position sorting method based on multiple samplings.

The frequency-position sorting method first ranks the subject terms based on frequency. For terms with identical frequencies, it then sorts them in ascending order according to their average position. Frequency-based sorting ensures that core subject terms are prioritized. When the frequencies of multiple subject terms are similar, position-based sorting provides an additional criterion for differentiation, thereby improving the rationality of the sorting results.

Step 2: LLM-extracted Term Generation

Wang et al. (2023) has revealed that LLMs like GPT-3, which excel in generation tasks, can also be effectively applied to keyword extraction tasks by employing appropriate prompting techniques.

We verify that the Qwen-Plus model incorporates knowledge of the GND classification system.

By designing a one-shot prompt, the LLM analyzes the title and abstract to extract relevant GND subject terms. Subsequently, the BGE-M3 vector retrieval model calculates the similarity between the extracted terms and the official subject term repository. Terms that surpass a predefined similarity threshold are selected from the repository. The detailed prompt design is provided in Appendix B.5.

Step 3: Vector Retrieval-based Term Generation

The competition organizer stipulates that each record should be accompanied by 50 subject terms. However, the subject terms generated through multi-sampling ranking and LLM extraction are insufficient to reach the required 50 terms. Therefore, we employ the BGE-M3 vector retrieval model to retrieval additional subject terms. We propose three retrieving contents, as follows: (1) Title. (2) Abstract. (3) Title and Abstract.

3.3.2 Rerank

The subject terms extracted using the Qwen-Plus API, along with those supplemented by BGE-M3, include the correct answers. In the context of quantitative evaluation metrics, which focus on the average recall@k (where k ranges from 5 to 50) across all records, it is crucial to prioritize the more relevant subject terms at the forefront of the predicted subject term list. To achieve this, three re-ranking strategies are devised.

Assume that the current subject term list is denoted as $S = [s_1, s_2, s_3]$, with s_1 representing the subject term list predicted by model M_{dpo}, s_2 being the subject term list extracted by Qwen-Plus, and s_3 being the subject term list retrieved by BGE-M3. The following are the three strategies:

Strategy 1: comprehensively re-rank all of s_1, s_2, and s_3.

Strategy 2: let s_1 remain in its original position and re-rank s_2 and s_3.

Strategy 3: keep s_1 and s_2 in their original positions and re-rank s_3.

Qwen-Plus and a one-shot prompting approach are utilized for re-ranking. The design of the prompt is presented in Appendix B.6.

4 Experimental Setup

4.1 Data description and Evaluation

The datasets are provided by Semeval-2025 Task 5. TIBKAT has two main datasets: all-subjects and tib-core-subjects. Only the labeled training dataset was used for training. Furthermore, the data created in 3.1 was also used in the training phase. The distribution of the datasets is shown in Appendix Table 2.

The quantitative evaluation focuses on precision, recall, and F1 scores at various thresholds (k = 5 to 50) for two datasets. The official quantitative evaluation is conducted based on the average recall scores across the specified thresholds, emphasizing the importance of retrieving relevant subjects.

4.2 Implementation

In Sections 3.2.1 and 3.2.2, LoRA fine-tuning was applied. In Section 3.2.1, Qwen2.5-7B-Instruct served as the base model, resulting in M_{gnd}, which was further fine-tuned in the SFT stage in Section 3.2.2 to obtain $M_{sft(raw)}$ and $M_{sft(all)}$. Subsequently, $M_{sft(all)}$ was refined in the DPO stage to produce M_{dpo}. Hyper-parameter settings are detailed in Appendix Table 3. All experiments were conducted on 8 RTX 4090 GPUs with 24GB of memory each.

In Section 3.3.1, Step 1: Multi-Sampling Ranking-Based Term Generation, the temperature was set to 0.5, and different random seeds were utilized. Due to time constraints, sampling experiments were conducted exclusively on the all-subjects dataset, with the number of samples set to 50, 70, and 100.

In Section 3.1.1, experimental results indicate that the category distribution proportions between the two datasets do not exhibit significant differences. Consequently, the proportion of synthesized data was determined based on the category distribution in the training set of the all-subjects dataset, ensuring a one-to-one correspondence between English and German. The specific distribution ratios are as follows: "Book" (0.74), "Thesis" (0.15), "Conference" (0.07), "Report" (0.03), and "Article" (0.01).

5 Result

The overview statistics of six different models on the all-subjects dataset in the validation set are presented in Table 1. Among these models, $M_{samplings(100)}$ achieves the highest performance in 7 out of 10 categories and also demonstrates the best overall recall across all categories. Similarly, the summary statistics for three different models

Record Type	Language	$M_{\text{sft(raw)}}$	$M_{\text{sft(all)}}$	M_{dpo}	$M_{\text{sampling(50)}}$	$M_{\text{sampling(70)}}$	$M_{\text{sampling(100)}}$

Table 1: Performance comparison for six models on all-subjects validation set (measured by average recall).

on the tib-core-subjects dataset in the validation set are provided in Appendix Table 4, where M_{dpo} attains the highest average recall. However, due to time constraints, we did not conduct additional experiments to optimize the sampling size for the tib-core-subjects dataset. Instead, we applied the optimal sampling size of 100, as determined from the all-subjects dataset, for test set predictions in both the all-subjects and tib-core-subjects datasets.

For the BGE-M3 subject terms generation strategies discussed in Section 3.3.1 Step 2, experimental results in Appendix Table 5 indicate that evaluating similarity exclusively between the title and subject terms leads to superior performance on the all-subjects validation set. Consequently, title-based vector retrieval was adopted for test set predictions in both the all-subjects and tib-core-subjects datasets.

The official quantitative rankings, as presented in Appendix Table 6 and Appendix Table 7, indicate that our system achieved **2nd** place in the all-subjects dataset and **4th** place in the tib-core-subjects dataset. These results highlight the system's strong capability in predicting a top-k list of relevant GND subject terms based on the titles and abstracts of technical records. Regarding the re-ranking strategies discussed in Section 3.3.2, the corresponding results are provided in Appendix Table 8. Experimental findings show that re-ranking strategy 2 yields the best performance in the all-subjects dataset, whereas strategy 1 performs optimally in the tib-core-subjects dataset.

The performance of our system varies across the two datasets, with a higher ranking in the all-subjects dataset compared to the tib-core-subjects dataset. Due to time constraints, we did not investigate the optimal sample size for the tib-core-subjects dataset and instead applied the optimal sample size determined from the all-subjects dataset. Additionally, our approach exhibits suboptimal performance in the article category of the tib-core-subjects dataset. The primary reason for this is the limited availability of training data for articles. Even though data synthesis was conducted based on the category distribution in the training set, the quantity of article-related data remained insufficient. This data scarcity hindered the model's ability to effectively learn the relevant knowledge, ultimately resulting in weaker performance.

6 Conclusion

This paper presents our system for SemEval-2025 Task 5, which integrates GND classification knowledge into LLMs via data synthesis, LoRA fine-tuning, preference optimization, and frequency-position ranking over multiple samplings. Combined with LLM-based extraction, vector retrieval, and re-ranking, our approach addresses multilingual and domain-specific challenges in TIBKAT subject assignment. The system ranks **2nd** on the all-subjects dataset and **4th** on tib-core-subjects quantitatively, and **2nd** on tib-core-subjects qualitatively. Performance is strong overall, though limited training data for articles in tib-core-subjects affects accuracy. Future work may improve sampling and re-ranking under data-scarce settings.

B Prompt

B.1 Incremental Data Generation Prompt Template

[instruction]
You are a subject expert in library sciences. From the provided candidate terms sourced from an internationally recognized authority file widely used by German-speaking libraries, your task is to select a subset of terms that reflect a logical and focused theme of a real research paper.
Caution: The terms you select should be fewer but precise. The terms should be ordered from highest to lowest relevance to the generated title and abstract.
Then, based on the selected terms, generate the appropriate title (under 20 words) and abstract (under 150 words) for the research paper. Ensure that the generated title and abstract are logical, relevant, and well-aligned with the chosen subject terms.
[input]
Candidate terms: ["Digital Libraries", "Metadata Management", "User Experience", "Library Automation", "Data Security"]
[output]
{"{"Selected terms": ["Digital Libraries", "Metadata Management", "User Experience"], "Title": "Enhancing User Experience in Digital Libraries", "Abstract": "This research paper focuses on how ..." }}

B.2 Data Filtering Prompt Template

[instruction]
You are tasked with evaluating the quality of titles and abstracts based on two key criteria: logical coherence and relevance to the selected subject terms. You will be given a title and an abstract of a `doc_type`. Your task is to assess the quality of the title and abstract based on how logically consistent and well-structured they are, as well as how accurately they reflect the core ideas of the selected subject terms. The subject terms are arranged in descending order with respect to relevance, with the most relevant terms appearing first.
Evaluation Criteria for Titles and Abstracts: Logical Coherence: Assess whether the title and abstract reflect the content of a real-world `doc_type`, ensuring alignment with real-world logic. 1: Very PoorThe title or abstract is completely illogical or lacks structure (e.g., random or unrelated phrases). 2: PoorThe title or abstract has noticeable logical flaws or is hard to understand. 3: AverageSomewhat logical, but there is room for improvement. 4: GoodMostly logical and clear, with minor room for improvement. 5: Excellent-Perfectly logical, clear, and well-structured.
Relevance to Selected Subject Terms: Assess whether the title and abstract fully reflect all the selected subject terms and whether the relevance order is correct. 1: Very PoorCompletely irrelevant to the subject terms. 2: PoorPartially related but missing the main focus. 3: AverageReflects most subject terms but lacks completeness. 4: GoodClearly reflects all subject terms, with minor misalignment. 5: Excellent-Fully reflects all subject terms in the correct order. Please provide your evaluation results in the following JSON format:
{"{"Final_Score":{"Logical_Coherence_Score": <score>,
"Relevance_to_Selected_Subject_Terms_Score":<score>}}"}

PLEASE JUDGE WITH STRICT STANDARDS AND DO NOT OUTPUT ANY EXPLANATION.
[input]
selected_subjects
title_and_abstract
[output]
{"{"Final_Score":{"Logical_Coherence_Score": <score>,
"Relevance_to_Selected_Subject_Terms_Score": <score>"}}"}

B.3 GND Knowledge Learning Prompt Template

[instruction]
You will be given a term from the Integrated Authority File Sachbegriffe, an international authority file widely used by German-speaking libraries for cataloging and linking information about works. Your task is to enhance understanding and usability of the term by generating the following attributes: Classification Name, Classification Number, Alternate Name, Related Subjects, and Definition (in German).
[input]
The term to process is: Abhängigkeit.
[output]
{"{"Classification Number": "1", "Classification Name": "Allgemeines, Interdisziplinäre Allgemeinwörter", "Alternate Name": ["Dependenz", "Unselbständigkeit", "Unselbstständigkeit"], "Related Subjects": ["Abhängiger", "Selbstständigkeit", "Interdependenz"] }"}

B.4 Supervised Fine-Tuning Prompt Template

[instruction]
Given the title and abstract of a doc_type in English or German, generate a ranked list of the most relevant subject terms from the Integrated Authority File Sachbegriffe, an international authority file widely used by German-speaking libraries for cataloging and linking information about works. These terms should accurately reflect the key themes or topics described in the title and abstract, with the ranking indicating their relative relevance.
[input]
Title: ...
Abstract: ...
[output]
{json_format_subject_terms}

B.5 GND Subject Terms Extraction Prompt Template

[instruction]
You are a subject term expert. Your task is to extract authoritative subject terms in German from the title and abstract of a given doc_type written in English or German. The subject terms must be selected exclusively from the Integrated Authority File (GND), an international authority file widely used by German-speaking libraries for cataloging and linking information about works. These terms should represent standardized academic concepts or disciplines. Do not provide any analysis or commentary.
<example>
Title: Nico Bloembergen : Master of Light
Abstract: This biography is a personal portrait of one of the ...
List of subject terms: {["Laser","Maser"]}
</example>
[input]
Title: ...
Abstract: ...
[output]
{json_format_subject_terms}

B.6 GND Subject Terms Rerank Prompt Template

[instruction]
You are a subject term expert. Firstly, you need to analyze the title and abstract of a given doc_type in English or German. Then you will also be provided with a list of subject terms from the Integrated Authority File Sachbegriffe, an international authority file widely used by German-speaking libraries for cataloging

and linking information about works.
Your role is to evaluate and rank the subject terms based on their relevance to the title and abstract, from highest to lowest relevance. Ensure that your rankings reflect a clear and logical analysis of how well each term aligns with the main themes and concepts presented in the `doc_type`. DO NOT OUTPUT ANY ANALYSIS!"""
<example>
Title: ...
Abstract: ...
List of subject terms: ...
Rerank list subject terms: ...
</example>
[input]

Abstract

This paper presents our system for Subtask 10 of Entity Framing, which focuses on assigning one or more hierarchical roles to named entities in news articles. Our approach iteratively refines prompts and utilizes the Entity-Centric Chain of Thought to complete the task. Specifically, to minimize ambiguity in label definitions, we use the model's predictions as supervisory signals, iteratively refining the category definitions. Furthermore, to minimize the interference of irrelevant information during inference, we incorporate entity-related information into the CoT framework, allowing the model to focus more effectively on entity-centric reasoning. Our system achieved the highest ranking on the leaderboard in the Russian main role classification and the second in English, with an accuracy of 0.8645 and 0.9362, respectively. We discuss the impact of several components of our multilingual classification approach, highlighting their effectiveness.

1 Introduction

The task of Entity Framing, as part of the SemEval 2025 campaign, focuses on the automatic identification and classification of roles assigned to named entities (NEs) in news articles(Piskorski et al., 2025). Specifically, it involves determining the roles of protagonists, antagonists, and innocents within the context of news articles related to high-stakes global issues such as the Ukraine-Russia war and climate change. This task is of particular importance as it supports the identification of manipulation attempts and disinformation in media, thereby facilitating a better understanding and analysis of news narratives. The task is multilingual, covering five languages: Bulgarian, English, Hindi, Portuguese, and Russian, and aims to offer valuable insights into how different languages handle entity roles in manipulative content.

Our approach employs a pipeline-based method that automates the optimization of category definitions through iterative refinement (Yang et al., 2023; Xing and Chen, 2024). This process incorporates hard instance analysis to refine category definitions. However, some hard samples may still not be fully covered; we address this by extracting few-shot cases to supplement the category definitions, thereby mitigating misclassifications and resolving ambiguities in category boundaries. Additionally, we leverage entity-centric Chain of Thought (CoT) mechanisms (Wei et al., 2022b) to enhance classification accuracy by focusing on relevant entities and preserving key contextual information, even in lengthy texts. This pipeline process facilitates the continuous improvement of category definitions and prediction refinement through multiple feedback iterations, while also alleviating the challenges posed by an excessive number of categories in multi-label classification tasks.

We ranked second in English and among the top in the Russian language's main role classification subtask. However, challenges remain in handling ambiguous cases and fine-tuning role definitions, which can sometimes impact the precision of role assignments. In our experiments, we further analyzed the effects of prompt iteration optimization, ensemble strategies, and entity-centric CoT on the overall performance.

2 Background

The Entity Framing task in SemEval 2025 aims to automatically identify and classify the roles of named entities (NEs) within news articles. The task specifically targets three roles: protagonists, antagonists, and innocents, based on a predefined taxonomy. This is a multi-label, multi-class text-span classification problem, where the goal is to classify NEs within the context of news articles related to high-profile topics. These areas are highly

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 373–380

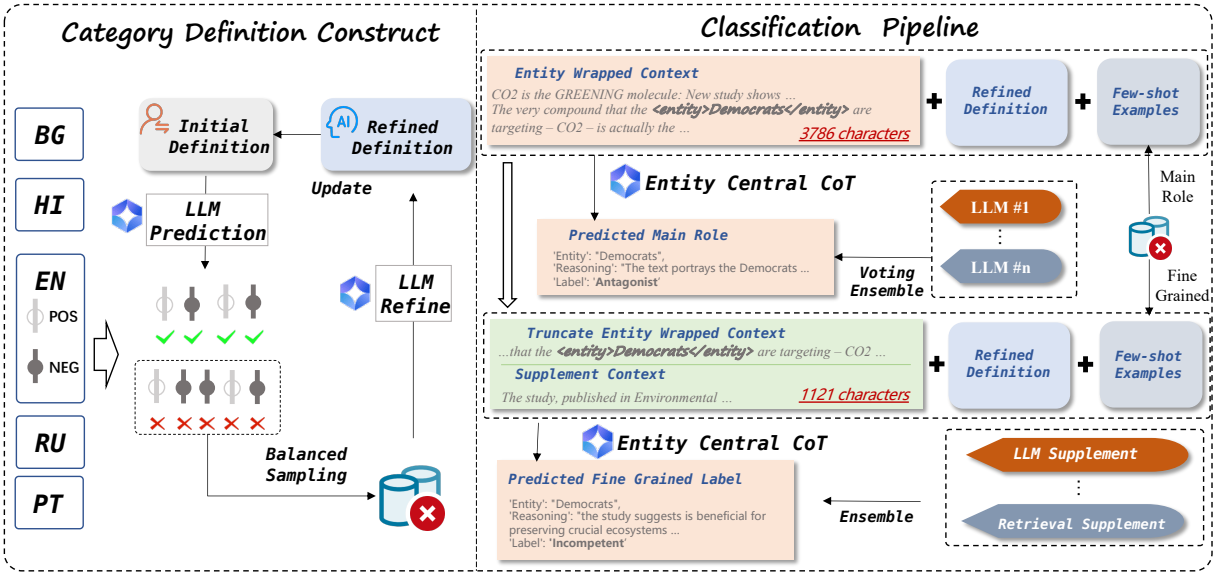

Figure 1: Overview of the Category Definition and Classification Pipeline. The pipeline begins with the construction of initial category definitions using LLM predictions, followed by iterative refinement based on misclassifications. The classification process involves entity context processing with entity-centric Chain of Thought (CoT), combined with few-shot examples and voting ensemble methods.

susceptible to manipulation, misinformation, and disinformation, making the task crucial for understanding how media outlets shape narratives. The dataset provided for this task consists of articles in five languages. The articles, collected between 2022 and 2024, are primarily sourced from alternative media outlets and web portals, many of which have been flagged by fact-checkers for potential misinformation. The detail of datasets is described in Task 10 (Piskorski et al., 2025).

Automatic prompt engineering has gained traction for optimizing prompt design in large language models (LLMs), reducing manual effort. Approaches like Autoprompt (Shin et al., 2020) focus on generating prompts for classification tasks, while PRetrain (Liu et al., 2023) combines prompt learning with pretraining to enhance adaptability. Recent advancements include PromptAgent (Wang et al., 2023b) and Automatic Engineering of Long Prompts (Hsieh et al., 2024). Traditional text classification methods such as RNN (Xie et al., 2020), GCN (Yao et al., 2019), and LLM-based approaches (Lin et al., 2021) laid the foundation. While LLM-generated reasoning is effective for step-by-step problem-solving (Wei et al., 2022a), it faces challenges like unfaithfulness and logical incoherence (Turpin et al., 2023), often due to the influence of explanation tokens. LLMs are increasingly used for classification, both as standalone solutions (Sun et al., 2023) and in multi-task settings (Longpre et al., 2023). Given the characteristics of the Entity Framing task, such as multi-label classification and context-dependent entity roles, we propose a solution that integrates automatic prompt generation and enhanced reasoning structures to improve accuracy and robustness.

3 System Overview

To address the challenges posed by the rapid increase in label quantities, which can complicate classification tasks, we employ a pipeline approach. This approach utilizes the results from main role classification as input for fine-grained classification. For both main role and fine-grained tasks, we incorporate iterative prompt refinement to enhance category definitions, followed by inference using an entity-centric CoT framework to improve the model's understanding of entity-based tasks. Subsequent sections will provide a comprehensive overview of our model's key components, including Prompt Construction, Multi-label Classification, and Post-processing.

3.1 Category Definition Construction

Although the task provides category definitions based on natural language, directly utilizing the definitions in the prompt for LLM classification tasks may lead to interpretational ambiguities. To enhance the classification performance, we approach this issue from two directions: first, by iteratively refining the prompt to optimize its effectiveness, and second, by selecting few-shot examples to

guide the model.

Category Definition. For each category $i \in \mathcal{I}$, we begin by selecting a random case for model prediction, thereby partitioning the training set into two subsets: $\mathcal{T}_i$, the correctly classified examples, and $\mathcal{T}_i'$, the incorrectly classified examples. The category definition is then refined by incorporating the original label definition, erroneous examples, and task-specific requirements. The task requirements specify the need to adjust the template to address issues related to input length while improving the model's ability to differentiate between categories. Directly inputting all erroneous examples into the LLM for label redefinition may introduce bias; therefore, a balanced number of false positive and false negative examples are selected from $\mathcal{T}_i'$, ensuring equitable representation across categories. Multiple rounds of prompt refinement are conducted, followed by a comprehensive synthesis of these iterations to finalize the category definitions. The refined category definitions are then used with the updated prompt to predict and iteratively update $\mathcal{T}_i'$, thereby improving the category definitions in subsequent iterations.

Few-shot Selection. Due to the inherent limitations of the model's foundational capabilities, there may still be instances of prediction errors. The boundaries of categories, as defined by natural language, cannot always be universally delineated. To address this, we leverage few-shot learning to supplement the categorization process. We aim for a complementary relationship between few-shot examples and prompts. Specifically, we classify the model based on the final category definitions and then select few-shot examples from the resulting set of errors.

The distinction between main roles and fine-grained roles lies in their granularity and complexity. For fine-grained classification and few-shot selection, we similarly prioritize the selection of hard samples. However, due to the small number of samples in each category, when appropriate samples cannot be found within the hard samples, we resort to random selection from the entire category set. To manage the context length effectively, we ensure that all few-shot cases are truncated with an entity-centric approach, thereby preventing the context from becoming excessively long.

3.2 Classification Pipeline

Since entities in text often appear with numerous mentions, the attitude or polarity associated with different occurrences of the same entity can vary depending on their position within the text. To address this, we follow the entity-centric generation-based approach (Wang et al., 2023a; Li et al., 2021). Specifically, we wrap the entity mention in the context with special tokens, such as "<entity> ENTITY SPAN </entity>", to highlight the span of the entity. This technique emphasizes the entity's presence and reinforces its significance within the classification task, thereby improving the model's ability to focus on the correct entity mention during the classification process.

In the task of **main role classification**, the prompt is first designed to clearly define the task, presenting a concise description in a single sentence. The categories are then enumerated in the Description section, with key points highlighted for emphasis. Following this, comprehensive definitions for each category are provided, accompanied by few-shot examples to guide the classification.

To improve the reasoning capacity, we implement an entity-centric CoT approach. Specifically, in addition to the standard reasoning procedure inherent to it, we require the model to first identify the entity to be classified before proceeding with the reasoning step. This modification aims to address the issue of information loss, which frequently arises in long texts due to the model's tendency to lose focus on relevant entities as the text progresses. Finally, the complete text is concatenated and fed into the model. During the classification process, task-specific characteristics introduce variations. We observe that LLMs exhibit biases due to the distribution of training data, which affects the classification of certain entities. To mitigate this, we incorporate the full context, ensuring a more accurate representation of the text's theme and improving entity classification.

We leverage the results above for **fine-grained classification**. In terms of the fine-grained part, the experimental results indicate that longer texts result in a sharp decline in classification performance, even when they contain critical information for the classification task. We truncate the context to enhance the important information. To prevent the loss of distant but relevant information, we incorporate a retrieval-based method to supplement the input. Additionally, during the evaluation process, we experimented with LLM-based summarization to obtain the diversity results.

Table 1: Dataset Statistic, PRO denotes the Protagonist, ANT denotes the Antagonist, INN denotes the Innocent

LN	Train				Dev
	PRO	ANT	INN	Total	Total

HI	1083	766	482	2331	116
RU	222	396	104	722	86

3.3 Post Process

To improve the robustness of our classification results, we employ an ensemble approach for both the main role and fine-grained classification tasks by utilizing multiple LLMs with different input strategies. These results are then aggregated using two ensemble techniques. The voting mechanism aggregates the predictions by selecting the most frequent classification, while the LLM peer review process involves comparing the outputs from different models and refining the final prediction.

4 Experiment

4.1 Data Set

As shown in Table 1, the distribution of labels varies across languages. Accuracy(Acc) is applied to evaluate the performance of the main role classification. For fine-grained classification, we employ a combination of Exact Match (EM) and micro F1 score (F1) as evaluation metrics to assess the model's ability to classify roles.

4.2 Main Results

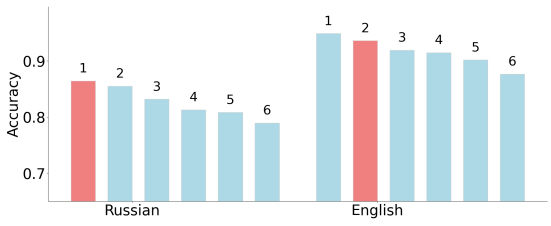

Figure 2: Result on Main Role Classification, our model is highlighted in red, while the top 5 teams are marked in blue excluding ours.

As shown in Figure 2, our system achieved first place in the Russian language's main role classification and second place in English. The results for main role classification demonstrate the effectiveness of our approach. For the fine-grained classification shown in Table 2, We observed that our approach performs the best in Russian and performs the worst in Portuguese. However, the fine-grained

Table 2: Official SemEval Results on the Test Set

	Rank	EM	F1	Acc

w/o FS	0.45054	0.48717	0.90109
w/o EC	0.47252	0.50915	0.87912
w/o CoT	0.45054	0.48717	0.82417
w/o CP	0.40659	0.44322	-

results indicate that the model's performance still varies significantly across languages, with certain languages showing weaker performance in specific tasks. These differences highlight the need for further refinement, especially for languages with less optimal results.

4.3 Ablation Study

To further analyze the influence of each component, we remove each modular of our method individually and test the influence on the English dataset, as shown in Table 3, where CD denotes the Category Definition, FS denotes the Few-shot Selection, EC denotes the Entity-Centric reasoning, and CP denotes the context compress. To avoid the influence of error propagation, **we use the ground truth of the main role to test the fine-grained classification for the following experiments.** The results demonstrate that the CoT has the most significant impact on model performance. Additionally, when category definition and entity-centric components are removed, there is a substantial drop in model performance. In main role classification, the impact of few-shot selection is relatively minor, possibly due to the smaller number of categories. The phenomenon leads to overall better performance. However, in the fine-grained classification task, hard samples play a more important role in improving classification accuracy.

4.4 Influence of Language

Additionally, we explored the influence of prompts and CoT on the performance of the proposed method, and the results are shown in Table 4. Con-

TEXT	COT	EM	P	R	F1	Acc
RU	RU	0.58139	0.61627	0.59883	0.60465	0.84883
	EN	0.58139	0.61627	0.59883	0.60465	0.83720

Table 4: Performance comparison across different languages for CoT.

ducting chain-of-thought (CoT) reasoning in English generally yields superior performance in the fine-grained classification task, which is relatively complex. For main role classification, reasoning in the same language as the context enhances the accuracy of the results. The observed specificity in Bulgarian can likely be attributed to the small sample size in the development set, which consists of only 31 instances, thus introducing a degree of variability and potential randomness in the outcomes.

4.5 Error analysis

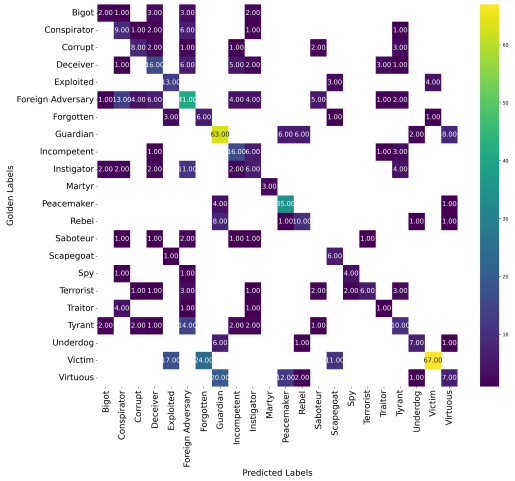

Figure 3: Confusion Matrix

For further analysis, we evaluated the classification performance on each category of the main role and fine-grained label. We observe that severe confusion mainly occurs between the predicted label and golden label, which is shown as Figure 3. The experimental results show that for most cases of most labels, our pipeline can accurately determine the fine-grained role labels.

4.6 Post-processing Analysis

To further analyze the applicable scenarios of Voting and LLM peer review ensemble methods, we test the performance of these methods on the English development set. As observed in Table 5, we obtained varying outcomes for the main role and fine-grained classification tasks. For main role classification, we found that the voting ensemble method was more direct and effective. When leveraging LLMs for analysis and reasoning in the main role task, excessive analysis led to hallucinations by the LLM, which in turn degraded the model's ensemble performance. In contrast, for fine-grained classification, which presents a higher level of difficulty, the LLM peer review-based ensemble method proved to be more suitable, better adapting to tasks that require complex reasoning.

Table 5: Results with Different Ensemble Methods.

Method	EM	F1	Acc
Voting	0.49450	0.53113	0.94505
LLM	0.50549	0.54945	0.92307

5 Outro

This work presents an LLM-based framework to tackle the challenges of entity role classification in news articles, employing iterative prompt refinement and entity-centric chain-of-thought mechanisms. The experiments provide a detailed analysis of the impact of various strategies for employing LLMs in this fine-grained entity understanding task, including language, the use of CoT, et al. These insights offer valuable guidance for future multi-label entity classification tasks based on LLMs.

...
 # Few-Shot Example:
Example #1
...
 # Requirements:
...
 # Output Format:
Entity: ...,
Reason: ...,
Label: ...
 # Wraped Context:
...

B Implement Details

In the prompt iteration optimization, each round involves using 2 false positive and 2 false negative examples. Additionally, we integrate 5 different definitions to form the final category definition. For the classification task, we utilize models including GLM-4-Plus[1], Claude 3.5 Sonnet[2], and GPT-4o[3] to perform the task. For the main role classification, we integrate X models from different foundational LLMs and methods. We retain the models that perform best within 5% of the highest score in the development set, ensuring robust integration. In this case, we incorporate no fewer than three models for each language. In the fine-grained role classification, we integrate systems that include a variety of few-shot selection and compression methods. To capture the diversity of approaches, at least five distinct results are considered for this task. As with the main role classification, the final output from the ensemble is empirically adjusted based on empirical adjustments to optimize overall accuracy. The GLM-4-Plus may refuse to provide a response during prediction due to alignment, we substitute the response with GPT-4o if the model fails to answer after 5 rounds.

[2]https://www.anthropic.com/news/claude-3-5-sonnet
[3]https://openai.com/

C Results of Main Role

In addition to English and Russian, we present the ranking results for the other three languages, as shown in Figure 4.

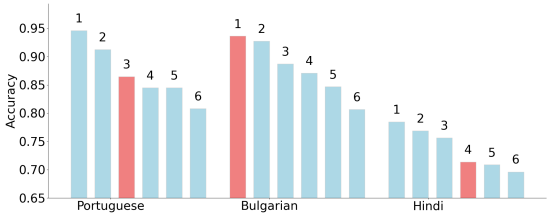

Figure 4: Result on Main Role Classification, experiment setting is same with Figure 2.

D Error Analysis of Ensemble Model

Multi-label instances are rare in the development dataset, so we split the multi-label instances into multiple individual entries to plot the confusion matrix. The confusion matrix of the ensemble model is shown in Figure 5. The experimental results show that for most cases of most categories, our pipeline can accurately determine the fine-grained role labels.

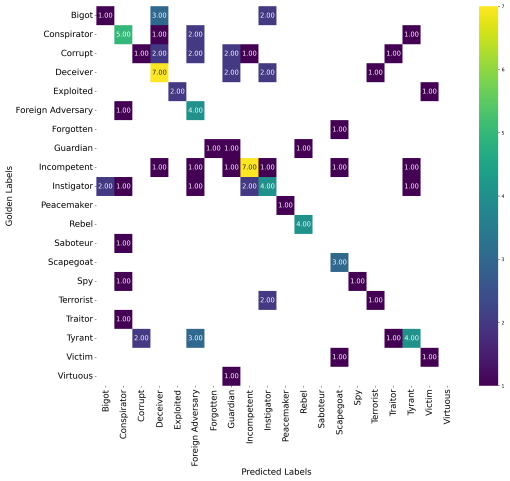

Figure 5: Confusion Matrix of Ensemble Pipeline

E Analysis of Compression Methods

We further investigated the influence of different compression methods. Excessively long input text may lead to a loss of detailed information within LLMs. To mitigate the adverse effects of long text in fine-grained classification, we designed several text compression strategies. PLAIN uses the whole original context as the input of classification. TRUNCATION use a fixed number of sentences

Method	EM	F1
Plain	0.41758	0.45421
Truncate	0.48351	0.52014
Retrieve	0.46153	0.50549
Character	0.47252	0.50183
LLM	0.41758	0.45421

Table 6: Performance comparison across different methods for text compression.

which will retained both above and below the sentence containing the target entity. RETRIEVAL retrieve additional contextually relevant sentences as supplement context. CHARACTER uses the character number to truncate the context instead of the number of sentences. LLM generates a summary while preserving the original entity information. Experimental results shown in Table 6 demonstrate that the performance of text input is generally better after compression.

NCL-NLP at SemEval-2025 Task 11: Using Prompting engineering framework and Low Rank Adaptation of Large Language Models for Multi-label Emotion Detection

Kun Lu

Abstract

SemEval-2025 Task 11 Track A involves identifying all emotions present in a given text segment (Muhammad et al., 2025b). This paper proposes a prompt engineering framework designed to enhance the performance of generative models on multi-label classification. The proposed prompting framework adds elements such as *character definitions, task descriptions, skill requirements, goal settings, constraints, workflows, examples, output format constraints* to the original simple prompt. It integrates structured and context-sensitive prompt templates and instruction fine-tuning strategies of Low Rank Adaptation of Large Language Models to improve classification accuracy. In the evaluation experiments, the proposed approach reached a macro F1 score of 0.849. Our approach demonstrates the effectiveness of prompt-based methods in improving multi-label emotion classification with fine-tuned generative models.

1 Introduction

In this article, we present an approach for addressing the SemEval-2025 Task 11 Track A task which is focusing on perceiving emotion and focusing on determining what emotion most people will think the speaker may be feeling given a sentence or short text snippet uttered by the speaker. Emotions that need to be accurately identified include joy, fear, surprise, sadness, and anger (Muhammad et al., 2025a).

Emotion detection involves identifying and understanding human emotions through various methods including facial analysis, speech analysis, text analysis, and so on. The task focuses on text analysis, specifically sentiment analysis, is a method of emotion detection that uses natural language processing (NLP) to analyse written text and determine the sentiment or emotion expressed. This technique helps gauge public opinion, understand customer feedback, and detect emotions in online communication. Sentiment analysis can determine if a text expresses a positive, negative, or neutral sentiment. It is useful for various applications, including social media monitoring, brand reputation management, and customer service (Burkhardt et al., 2009).

In this task, we use a generative large language model that has been fine-tuned with instructions. LLMs fine-tuned through instructions can provide answers to some extent. However, due to the uncertainty in the generation of language models, the answers often do not correspond to the specified categories of emotions, and the accuracy of the answers is not very high. Therefore, we have designed a prompt engineering framework to help the model generate better responses and ensure that the model only outputs the specified categories of emotions.

2 Related Work

Sentiment Analysis involves various methods, which can be categorized into two primary approaches: machine learning-based, and deep learning-based methods (Zhou, 2024).

Using machine learning to solve the problem of multi-label classification involves data preprocessing, including data collection, data cleaning, label encoding (one-hot encoding), and feature extraction (TF-IDF and Word2Vec); selecting appropriate models, such as decision trees, random forests, support vector machines, or some ensemble models like XGBoost (Sonawane et al., 2018).

In addition, deep learning can also be used to solve multi-label classification problems. Apart from some data preprocessing stages, deep learning can choose neural networks as models, including feed-forward neural networks, convolutional neural networks, recurrent neural networks, and Transformers, among others. For example, adversarial networks and temporal convolution networks can be used for emotion recognition in Man-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 381–385

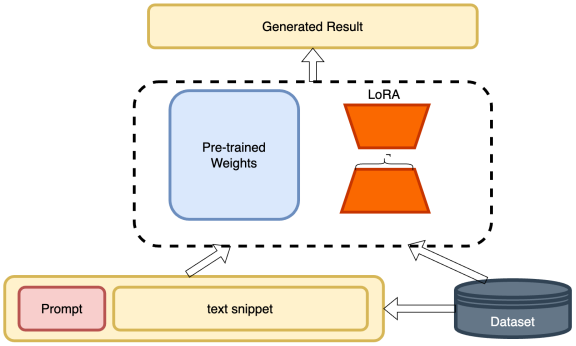

Figure 1: Overview of the system

darin (Li et al., 2023).For transformer architecture, the most representative ones, Bert, GPT and T5 can be used for language understanding tasks and text generation tasks, respectively. BERT can extract the embedding representation of text and then perform multi-text classification through a linear classifier (Yang et al., 2024). On the other hand, a generative model fine-tuned with instructions can complete text classification tasks under specific instructions (Edwards et al., 2021). Due to the large number of parameters in such models and their training on vast amounts of data, they are also referred to as large language models. T5 is a complete Transformer architecture, which has been used in previous research combined with Chain Of Thought for sentiment classification (Rusnachenko and Liang, 2024).

3 System Overview

Our method can improve the performance of multi-label classification tasks by designing an effective prompt engineering framework and using LoRA fine-tuning techniques to constrain the output of generative models, preventing the generation of invalid classification results.

3.1 Low-Rank Adaptation of Large Language Models

Fine-tuning a model in full often requires more resources. Low-Rank Adaptation is a technique that freezes the pre-trained model weights and injects trainable rank decomposition matrices into each layer of Transformer architecture, greatly reducing the number of trainable parameters for downstream tasks. It means that LoRA can train with a smaller number of parameters to achieve the same effect as fine-tuning (Hu et al., 2022). For simplifying LoRA fine tuning model, we utilize the LLaMA-Factory (Zheng et al., 2024) to fine tune the LLM.

Before fine-tuning, we need to preprocess the original dataset to obtain an object containing the fields of **instruction** and **output**, which will be used for training with LLaMA-Factory.

3.2 Prompt Engineer Framework

For large language models, different prompts can produce different results. Designing a comprehensive and effective prompt framework can help the model better handle the corresponding tasks.

We established a simple baseline to explore the ability of LLMs to perform classification tasks under simple instructions shown as in Table 1. The simple instruction consists of "*Please determine the emotion of text*" and the text snippet from dataset. The output is a string where 0 indicates that the emotion does not exist in the text, and 1 indicates that it does exist, with different types of emotions separated by commas.

Furthermore, we design a prompt engineer framework to improve the output of model. In this framework, there are nine elements including: *role definition, task description, skill requirements, goal setting, constraints, workflow, examples, output format, and startup instructions*, The proposed prompt engineer framework ensures the LLM can understand the task and generate correct outputs. For the format of output, we adopted a simple request to indicate whether emotions exist. Table 2 shows an example of a training sample that includes the key element used for fine tuning.

Table 1: Example of a Training Sample with simple instructions

Text: *"Colorado, middle of nowhere."*

Anger	Fear	Joy	Sadness	Surprise
0	1	0	0	1

Instruction: Please determine the emotion of text. The text is + **text**
output: "anger:0,fear:1,joy:0,sadness:0,surprise:1"

The specific instruction is displayed in the Figure 2.

In this toy example, we defined the interactive roles to provide background information, explaining that the model needs to analyse the dialogue to determine the emotions expressed by the speaker. The specific task description requires that the role analyze based on the text content, without considering factors like voice or facial expressions. The

Table 2: Example of a Training Sample with prompt framework

Text: *"Colorado, middle of nowhere."*

Anger	Fear	Joy	Sadness	Surprise
0	1	0	0	1

Instruction:
- Role: ...
- Background: ...
- Profile: ...
- Skills: ...
- Goals: ...
- Workflow: ...
- Examples: ...
- OutputFormat: ...
- Start: Speaker1: + **text**

output: "anger:0,fear:1,joy:0,sadness:0,surprise:1"

role is only required to have advanced language comprehension, emotion recognition, and dialogue analysis abilities, with the primary goal being to use binary labels to identify the presence or absence of each emotion. The constraints specify that the analysis should be based solely on the text content, serving as a supplement to the task description. In the workflow, it details how the role should complete the task, using a Chain-Of-Thought approach. Figure 2 shows three strong examples and their analysis results to help understand how the role applies the written steps and labels. The output format specifies the format of the output, and finally, a startup instruction is used to initiate the process.

4 Experiment

4.1 Datasets

The dataset used in this paper is a subset of the competition data, focusing only English language. The English dataset consists of training, development and test sets. each entries contains: ID, A piece of text, and emotion labels(anger, fear, joy, sadness, surprise).

The datasets includes three subsets: A training datasets along with 2,768 entries. A development datasets along with 116 samples and A test datasets with 2767 samples for prediction. After data visualization of train datasets, the average character length of the text is around 78. The distribution of labels is as follows: Fear appears most frequently with 1611 samples, Anger has the fewest with 333 samples. Joy, Surprise, and Sadness have 674, 878, and 839 samples respectively. The train datasets reveals an imbalance.Training data imbalance can affect the results of prediction to some extent.

Data preprocessing is an important part of NLP tasks. However, due to the pre-training of large language models on vast and diverse datasets, along with their enormous parameter sizes, data preprocessing such as data correction is often unnecessary. During the entire experiment, we also found that data preprocessing did not have a significant impact on the final results.Therefore, the step of data preprocessing has been discarded. Meanwhile, using a model with larger parameters can also solve the problem of data imbalance.

4.2 Selection Of LLM

In this paper, we apply the Meta Llama 3.1 instruction tuned 8B as generated language model, which supports Engish, German, French, Italian, Portuguese. Llama 3.1 is an auto-regressive language model that uses an optimized transformer architecture. The tuned versions use supervised fine-tuning(SFT) to align with human preferences for helpfulness and safety (Dubey et al., 2024).

4.3 Evaluation Metrics

The official evaluation metrics for Track A is the macro F1 scores which is the unweighted average of the F1 scores across all classes in a classification problem, treating each class equally regardless of its size or frequency. It is used to evaluate model performance when dealing with imbalanced datasets.

$$F1_{\text{macro}} = \frac{\sum F1_i}{N}$$

where N is the number of classes.

4.4 Experiment Setup

Different instructions are used to fine tune the generated language model named Llama3.1 8B. All models were implemented with the PyTorch. The experiments are conducted on a single NVIDIA A40 GPU. The training process utilize LLaMA-Factory to fine tune.

When performing LoRA fine-tuning, some hyperparameters are involved, after comparison, the model is trained for 6 epochs with a batch size of 1, using gradient accumulation over 2 steps. The learning rate is set to 2.0e-4, and a cosine learning rate scheduler is employed with a 0.1 warm-up ratio.

Figure 2: An Example Instruction Prompt

Table 3: The average micro and macro F1 scores in the test set.

Model	Anger	Fear	Joy	Sadness	Surprise	Micro F1	Macro F1
Baseline	0.781	0.865	0.814	0.818	0.822	0.833	0.822
Our system	0.790	0.876	0.832	0.841	0.847	0.854	**0.849**

5 Results and Discussions

In this study, we compare the performance of two models: the baseline model with simple instruction and our model. As shown in Table 3, the our models outperforms the baseline model across all emotion categories. Specifically, the prompt framework achieves higher F1 scores in detecting **Anger, Fear, Joy, Sadness, and Surprise**. The most notable improvements are observed in the **Sadness**(0.0227) and **Surprise**(0.0244) categories, highlighting the framework's ability to better capture subtle emotional cues.

In terms of overall performance, the prompt framework also surpasses the baseline in both **Micro F1** and **Macro F1** scores, with improvements of 0.021 and 0.027, respectively. These results suggest that the our system not only performs better on individual emotion classification tasks but also achieves a more balanced classification across all categories, as indicated by the Macro F1 score.

However, there are still some shortcomings, for example, the experiment was only validated in English and not tested in other languages.

6 Conclusion

This article presents a new prompt framework for the task of text classification, further improved the ability to recognize various emotions based on a high baseline score. By adding elements such as *character definitions, task descriptions, skill requirements, goal settings, constraints, workflows, examples, output format constraints, and startup instructions* to the originally simple prompt, the proposed approach achieved improved results in the competition. However, there is still room for improvement in the anger category.

Furthermore, we can explore the hidden features contained in the data through feature engineering.

For example, the Notre Dame Cathedral is often associated with fires. External tools like Wikidata can be used to determine if there are similar keywords in the text and then add relevant features to the prompt words. At the same time, we can also explore the application of Discriminative LLM (Wu et al., 2024) for classification tasks.

BERTastic at SemEval-2025 Task 10: State-of-the-Art Accuracy in Coarse-Grained Entity Framing for Hindi News

Tarek Mahmoud, Zhuohan Xie, Preslav Nakov
Mohamed Bin Zayed University of Artificial Intelligence
{tarek.mahmoud,preslav.nakov}@mbzuai.ac.ae

Abstract

We present our system and share insights for SemEval-2025 Task 10 Subtask 1 on coarse-grained entity framing in Hindi news. Our work investigates two complementary strategies. First, we explore LLM prompting with GPT-4o, comparing multi-step hierarchical prompting against naïve single-step prompting for both main and fine-grained role prediction. Second, we conduct an extensive study on fine-tuning XLM-R, evaluating performance across different context granularities (i.e., using the full text of the news article, or the paragraph or the sentence containing the entity mention) and contrasting monolingual versus multilingual settings, as well as training on main role versus fine-grained role labels. Among all configurations, the best system was trained on fine-grained role annotations on all languages using the sentence context, and it achieved an exact match ratio of 43.99%, micro precision of 56.56%, micro recall of 47.38%, and a micro F1 of 51.57%. Notably, our system attained a state-of-the-art main role accuracy of **78.48%** on Hindi news—surpassing the next best result of 76.90%—as demonstrated on the official test leaderboard.[1] Our findings offer valuable insights into effective strategies for robust entity framing in multilingual and low-resource settings.

1 Introduction

Multilingual news narrative analysis has become increasingly important in the digital age. The rapid proliferation of social media has transformed information dissemination, enabling instant news access and the global spread of narratives. However, this connectivity also amplifies risks such as biased reporting, propaganda, and narrative manipulation. These are challenges that are particularly evident during conflicts and political upheavals. SemEval-2025 Task 10 on Multilingual Characterization and Extraction of Narratives from Online News addresses these challenges by providing a platform to study entity framing across five languages (Bulgarian, English, Hindi, European Portuguese, and Russian) (Piskorski et al., 2025). Our work specifically focuses on coarse-grained entity framing in Hindi news, an important subset given its potential impact on public perception.

Entity framing is an interesting task that transcends surface-level lexical features to uncover the subtle semantic nuances in how entities are portrayed. It focuses on interpreting the contextual cues that reveal whether the entity is depicted as a protagonist, antagonist, or an innocent bystander. This analysis is fundamental for understanding media bias, as it illuminates how news authors strategically frame narratives to influence public perception and shape discourse. The entity framing task is described in-depth in Mahmoud et al. (2025); Stefanovitch et al. (2025).

Our experiments fall under two main approaches.

1. First, we explore LLM prompting with GPT-4o (OpenAI, 2024), testing a range of prompting techniques—including single-step, and multi-step, hierarchical methods to predict both main and fine-grained role labels.

2. Second, we fine-tune XLM-R (Conneau et al., 2020) to examine the effect of different context granularities (for example, using the sentence versus the paragraph containing the entity mention, or the full text) and to compare monolingual versus multilingual training setups, as well as training on main role versus fine-grained role labels.

This comprehensive investigation enables us to determine the optimal configuration for capturing

[1]The leaderboard is available at https://propaganda.math.unipd.it/semeval2025task10/leaderboard.html

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 386–396

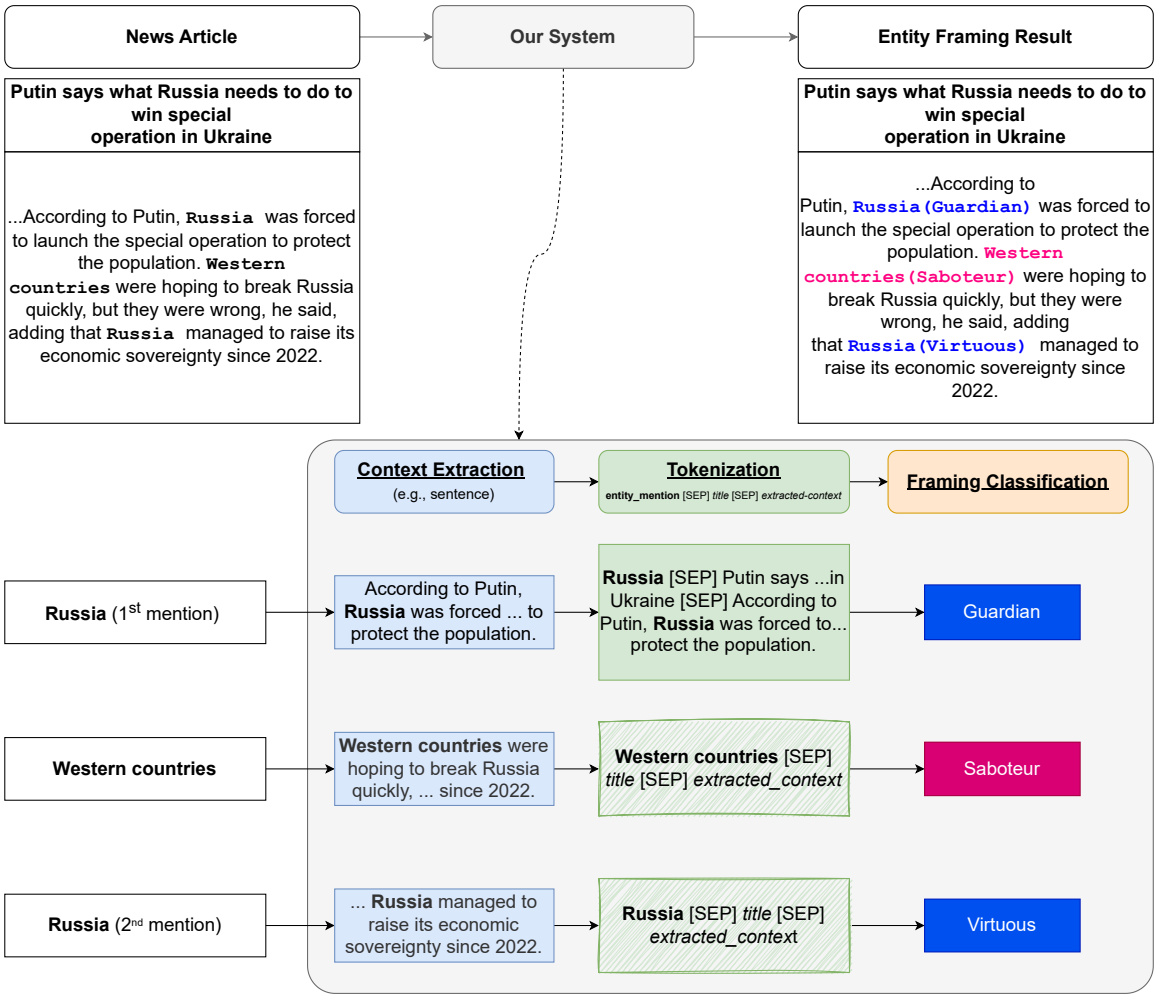

Figure 1: **A simplified overview of our approach:** The figure illustrates how we approach the entity framing task. Given an article, and a list of entity mentions (shown in boldface) for which framing is needed, we process one entity mention at a time. We then extract the context surrounding the entity mention (e.g., the sentence containing the entity mention). We tokenize the input if necessary, then we obtain the framing classification for that entity mention from the model (XLM-R or GPT-4o). This process is repeated for each entity mention.

the intricate nuances of entity framing by balancing zero-shot prompting with fine-tuning strategies using state-of-the-art LLMs. In addition, our analysis provides valuable insights into the unique strengths and weaknesses of each approach, informing future research directions in multilingual narrative analysis.

On the official test set leaderboard, our best system—trained on all languages using fine-grained role annotations with sentence-level context—achieves an exact match ratio of 43.99%, micro precision of 56.56%, micro recall of 47.38%, and a micro F1 of 51.57%, and, notably, our system reached a state-of-the-art main role accuracy of **78.48%**, ranking the top on main role accuracy on the leaderboard on Hindi news. While these results illustrate the effectiveness of our approach, they also highlight ongoing challenges in modeling context and subtle linguistic cues in multilingual settings.

2 Background

2.1 Task Formulation

Entity framing is the task of assigning one or more roles to each named entity mention in a news article according to a two-level hierarchical taxonomy that has a rich set of fine-roles exceeding twenty roles all nested under three main roles: protagonist, antagonist, and innocent. Given an article and a list of entity mentions (each specified by its text span and offsets), the goal is to predict a coarse main role—selected from *protagonist*, *antagonist*, or *innocent*, as well as one or more fine-grained sub-roles. For example, an entity such as "NATO" might be labeled as an *protagonist* with sub-roles like "guardian" and "virtuous". This formulation is cast as a multi-label, multi-class text-span classification problem and is crucial for analyzing how news narratives construct public perception. Additionally, when focusing solely on the main role prediction, the problem simplifies to a multi-class classification task at the coarse-grained level of the taxonomy.

The shared task dataset consists of 1,378 recent news articles in five languages (Bulgarian, English, Hindi, European Portuguese, and Russian) covering two globally significant domains: the Ukraine-Russia conflict and climate change. In total, the dataset has over 5,800 entity mentions that have been annotated with detailed role labels according to a hierarchical taxonomy developed by the shared task organizers.

2.2 Related Work

We explore two main approaches for modeling entity framing:

For our first approach, we fine-tune XLM-R and investigate various context granularities (sentence, paragraph, full text) surrounding the entity mention. We also compare monolingual and multilingual performance. Entity framing closely resembles targeted sentiment analysis (or Aspect-Based Sentiment Analysis, ABSA). For instance, Bastan et al. (2020) compare document- and paragraph-level contexts for target-based sentiment analysis, and their results support our intuition that a narrower context improves accuracy. However, their work, focused on English news, is less complex than our multilingual hierarchical entity framing task, and they do not explore sentence-level granularity. In addition, Goyal et al. (2021); Downey et al. (2024) and Chen et al. (2024) show that performance improves as more languages are included during training, motivating our multilingual experiments.

For our second approach, we evaluate naïve prompting against a variant of least-to-most prompting (Zhou et al., 2023), which we refer to as hierarchical prompting. Note that our hierarchical prompting differs from the reasoning frameworks of Sridhar et al. (2023) and Budagam et al. (2024). We name our method hierarchical prompting because the taxonomy is hierarchical; we break down the entity framing task into two stages: first, we identify the main role, and second, we determine the underlying fine-grained role.

3 System Overview

In this section, we describe our experimental methods for framing classification, outlining critical modeling decisions. We present two core strategies: fine-tuning multilingual Transformers and applying hierarchical prompting with LLMs. Key details of our approach are shown in Figure 1.

3.1 Fine-Tuning Pretrained Multilingual Transformers

We fine-tune XLM-R, a multilingual Transformer model, to classify entities at both the **main role level** (protagonist, antagonist, or innocent) and the **fine-grained role level** (22 subcategories). Our design choices focused on:

- **Granularity of Context**: We experiment with different context windows—full document, paragraph, and sentence-level—to assess the impact of surrounding text on classification accuracy.
- **Multilingual vs. Monolingual Training**: We compare the performance of models trained on a single language with models trained on data from all five languages.
- **Handling Span-Level Classification**: To address span-based classification within long documents, we structure input text as:

  `input = entity mention + [SEP] + title + [SEP] + context`

  where context varied depending on the granularity setting.
- **Loss Function and Training Strategy**: We use a softmax activation for multi-class classification at the main role level and a sigmoid activation for multi-label fine-grained role classification. The model was optimized using **Binary Cross-Entropy loss**, allowing it to predict multiple overlapping roles per entity span.

3.2 Hierarchical Zero-Shot Learning with LLMs

To leverage the capabilities of state-of-the-art LLMs, we explore two prompting strategies:

- **Single-Step Prompting**: This is the naïve approach where we predict both the main role and fine-grained role in a single prompt, relying on the model's ability to process the entire task holistically.
- **Hierarchical Multi-Step Prompting**: This approach decomposes the classification task into two stages:
  - **Step 1**: Predict the main role (protagonist, antagonist, or innocent).
  - **Step 2**: Based on the main role prediction, predict the underlying fine-grained role.

This hierarchical strategy follows the "least-to-most" prompting paradigm, allowing the model to break down complex tasks into sequential reasoning steps. For details on the prompts used in both the single- and multi-step approaches, see Section A, and refer to Section C for the experimental settings.

Rank	Team	Main Role Acc.
1	BERTastic (Ours)	**78.48%**
2	QUST	76.90%

13	HowardUniversityAI4PC	35.44%
14	TartanTritons	32.91%
15	Baseline	32.28%

Table 1: Official Test Set Performance on Hindi Main Role Accuracy.

4 Results

In this section, we report the performance of our system on the SemEval-2025 Task 10 as well as on additional experiments conducted using the development set. We focus our attention on main role accuracy, while noting that the Exact Match Ratio on the fine-grained roles is the official leaderboard metric.

4.1 Official Test Set Performance on Hindi Main Role Accuracy

For the official test set, we focus our discussion exclusively on the Hindi news track and, in particular, on the main role prediction—i.e., determining whether an entity is framed as a *protagonist*, *antagonist*, or *innocent*. According to the official leaderboard,[2] our system achieved a main role accuracy of **78.48%** on Hindi news articles. This performance surpasses that of the closest competing system, QUST (76.90%) and DEMON (75.63%), and significantly exceeds the main role accuracies reported by other teams. These results, displayed in Table 1, underscore the robustness of our approach in capturing the nuanced framing of entities in Hindi news narratives.

[2]For full leaderboard details, see https://propaganda.math.unipd.it/semeval2025task10/leaderboard.html

Table 2: Consolidated results on the **development set** comparing fine-tuning XLM-R and zero-shot learning with GPT-4o. The table shows performance and cost comparisons between single-step and multi-step LLM prompting approaches, where the highest scores between these two approaches across all languages are underlined. The top results across all three methods and languages are highlighted in **bold**.

4.2 Additional Experiments

Before our official submissions, we conducted a comprehensive set of experiments on the development set (using an 80/20 split on the training data) to analyze the impact of context granularity, training configuration, and modeling strategies on both main and fine-grained role classification. We have also reported the same results in Mahmoud et al. (2025). Among all systems, the XLM-R model trained on all languages using sentence-level context performed best on the development set; therefore, our official leaderboard results are based on this system.

4.2.1 Fine-Tuning Multilingual Transformers

Context Granularity We fine-tuned the multilingual Transformer XLM-R for both the main role (3-class) and fine-grained role (22-class) classification tasks. In our experiments, we explored various context granularities by restricting the input to the full document, the paragraph, or the sentence containing the entity mention. Table 3 summarizes our findings:

- **Main Role Classification:** Models trained on main role labels performed best with paragraph-level contexts, followed closely by sentence-level contexts; document-level contexts resulted in the poorest performance.

- **Fine-Grained Role Classification:** When training on fine-grained labels, sentence-level contexts yielded the highest micro and macro F1 scores, with paragraph-level contexts offering comparable yet slightly lower performance.

Multilingual versus Monolingual Training Table 4 provides insights into the performance of XLM-R when fine-tuned on either monolingual data or a combined multilingual dataset. Our results indicate that while monolingual models exhibit varied performance across languages, the multilingual setting consistently outperforms the monolingual approach. Notably, even though the macro F1 scores remain low—reflecting the challenge of predicting rare fine-grained roles—the multilingual model better captures the diverse linguistic patterns across the five target languages.

4.2.2 Hierarchical Zero-Shot Learning

We further evaluated two prompting strategies using GPT-4o: a *single-step* approach that jointly predicts main and fine-grained roles, and a *multi-step* (hierarchical) approach that decouples the prediction into sequential stages. As shown in Table 2, the multi-step approach yielded a modest improvement in main role prediction over the single-step method, likely due to its focused decomposition of the task. However, the single-step approach demonstrated better performance for fine-grained role predictions, suggesting that joint reasoning may better capture dependencies between roles. Additionally, the multi-step approach proved to be more cost-effective in terms of token usage.

4.3 Discussion

While both approaches are complementary, the fine-tuning method is particularly sensitive to data im-

balance. Our tokenization strategy results in frequent entity mentions disproportionately influencing the model weights, often overshadowing the rarer mentions. Zero-shot prompting overcomes these limitations by not relying on training data. In our experiments, XLM-R outperforms zero-shot methods on all evaluation metrics except Macro F1, where it records the lowest performance. We hypothesize that this discrepancy arises from the limited training instances for rare roles, which hampers XLM-R's ability to learn these categories effectively. In contrast, zero-shot approaches remain unconstrained by training data volume and thus maintain robustness for infrequent roles.

Collectively, these additional experiments demonstrate that localized context (i.e., paragraph- or sentence-level) and multilingual training significantly enhance entity framing performance. While the main role accuracy improves with focused context, the challenge of predicting rare fine-grained roles persists, as evidenced by the lower macro F1 scores.

In summary, our system not only delivers state-of-the-art performance on the official test set for Hindi main role prediction but also shows robust performance across various experimental settings on the development set. These results validate the effectiveness of our approach—leveraging both fine-tuning and hierarchical zero-shot prompting—to explore the intricate nuances of entity framing in multilingual news narratives.

5 Conclusion and Future Work

In this work, we present a comprehensive investigation into multilingual entity framing for news narrative analysis, with a focus on coarse-grained framing in Hindi news. We consider two complementary approaches: (1) fine-tuning XLM-R under different context granularities, comparing monolingual and multilingual training setups as well as main versus fine-grained role label training, and (2) zero-shot prompting with GPT-4o, where we explore single-step and hierarchical prompting strategies to predict both main and fine-grained role labels

Our experiments demonstrate that leveraging sentence-level context and training on a diverse multilingual corpus yield superior performance, with our system achieving a state-of-the-art main role accuracy of **78.48%** on Hindi news. These results confirm that carefully selecting the appropriate context window is critical to capturing the subtle semantic nuances of entity framing. While both approaches provide distinct advantages—fine-tuning leverages deep contextual representations to better model linguistic cues, and prompting enables rapid adaptation and zero-shot inference—each also faces challenges in processing the inherent complexities of multilingual narrative content.

Looking forward, our findings motivate further research on refining context-aware strategies and exploring more advanced fusion techniques for integrating heterogeneous contextual cues. Future work may also extend our methods to a broader array of languages and narrative domains, ultimately contributing to the development of robust tools for detecting media bias and understanding public perception in a global news landscape.

Appendix

A Prompts for Hierarchical Zero-Shot Experiments

```
You are an expert at identifying entity framing and role portrayal in news articles. Analyze the following entity
mention in context, and predict its main role and fine-grained role(s) from the taxonomy below.

Taxonomy: {detailed taxonomy with definitions and examples}

Context Around Entity: {context}

Entity Mention: {entity mention}

Task: Based on the provided context, assign to the entity mention at least one fine-grained role and
exactly one main role.

Return a JSON that has below attributes:
- main role: either one of Protagonist, Antagonist, or Innocent
- fine grained roles: a list of all your predicted fine-grained roles
```

Figure 2: **Single-Step Prompt Template.** The detailed taxonomy includes the roles and their detailed definitions as provided by in the shared task. The context is the text consisting of entity mention along with the 20 words before and after the entity mention.

```
First Step (LLM Call 1): Predict the Main Role

You are an expert at identifying entity framing and role portrayal in news articles. Analyze the following entity
mention in context, and predict its main role from the taxonomy below.

Taxonomy: {list of fine-grained roles per main role}

Context Around Entity: {context}

Entity Mention: {entity mention}

Task: Based on the provided context, assign to the entity mention exactly one main role.

Return a JSON that has this attribute:
- main role: either one of Protagonist, Antagonist, or Innocent

Second Step (LLM Call 2): Predict the Fine-Grained Role

You are an expert at identifying entity framing and role portrayal in news articles. This entity is
portrayed as a(n) {main role} and your task is to analyze the entity mention in context
and predict its fine-grained role(s) from the taxonomy below.

Taxonomy: {pertinent portion of the detailed taxonomy with definitions and examples}

Context Around Entity: {context}

Entity Mention: {entity mention}

Task: Based on the provided context, assign to the entity mention at least one fine-grained role.

Return a JSON that has this attribute:
- fine grained roles: a list of all your predicted fine-grained roles
```

Figure 3: **Multi-Step Prompt Template.** In the first step, the taxonomy is only the tree structure of the taxonomy and does not include any definitions or examples. In the second step, the detailed taxonomy only includes the branch under the predicted main role in the first step. The context is as defined in Figure 2.

Table 4: Results on the **development set** for multi-label fine-grained role classification with XLM-R trained on monolingual and multilingual data (evaluated at the paragraph level).

C Experimental Settings

All fine-tuning experiments were conducted on a single NVIDIA RTX 4090 GPU with 24 GB of memory. We fine-tuned XLM-R (XLM-RoBERTa) in a single run, using a fixed random seed to ensure reproducibility. When the input context was at the sentence granularity, we performed sentence splitting using Stanza pipelines for each one of our five languages. For XLM-R, default settings were applied, with the following configurations:

- Model: XLM-R_{base} (125M parameters)
- Learning Rate: 2e-5
- Batch Size: 8
- Epochs: 20 (with early stopping of 3 based on validation loss)
- Random Seed: 42
- Weight Decay: 0.01

To optimize performance, the sigmoid thresholds for fine-grained role predictions were tuned on the validation set. These optimized thresholds were then applied to generate predictions on the test set.

To prevent data leakage, we created train/validation/development splits based on entire articles rather than individual entity-mention annotations. The details of these splits are provided in Table 5. Note that we use the development set provided by the shared task as is, but we split the provided training set using an 80/20 split into train and validation sets. In doing so, the development set acts as a test set in a realistic scenario allowing us to create robust models enabling better generalization of our results to the official test set.

	BG	EN	HI	PT	RU	All
Train	165 (389)	133 (440)	203 (1347)	206 (833)	89 (252)	796 (3261)
Validation	94 (237)	69 (245)	139 (983)	100 (417)	44 (114)	446 (1996)
Dev	15 (30)	27 (90)	35 (279)	31 (115)	28 (85)	136 (599)
Total	274 (656)	229 (775)	377 (2609)	337 (1365)	161 (451)	1378 (5856)

Table 5: Distribution of articles and entity mentions by language and split. The number of entity mentions is shown in parentheses

For the zero-shot experiments, we used OpenAI's GPT-4o (gpt-4o-2024-11-20) with a temperature setting of 0.2 to produce more conservative responses. To ensure the outputs conformed to our defined data types, we employed OpenAI's Structured Outputs API, which returned results in the expected JSON format.

Heimerdinger at SemEval-2025 Task 11: A Multi-Agent Framework for Perceived Emotion Detection in Multilingual Text

Abstract

This paper presents our system developed for the SemEval-2025 Task 11: Text-Based Emotion Detection (TBED) task, which aims to identify the emotions perceived by the majority of people from a speaker's short text. We introduce a multi-agent framework for emotion recognition, comprising two key agents: the Emotion Perception Profiler, which identifies emotions in text, and the Intensity Perception Profiler, which assesses the intensity of those emotions. We model the task using both generative and discriminative approaches, leveraging BERT series and large-scale generative language models (LLMs). A multi-system collaboration mechanism is employed to further enhance the accuracy, stability, and robustness. Additionally, we incorporate cross-lingual knowledge transfer to improve performance in diverse linguistic scenarios. Our method demonstrates superior results in emotion detection and intensity prediction across multiple subtasks, highlighting its effectiveness, especially in language adaptability. Our code is available at https://github.com/tongzeliang/Semeval2025

1 Introduction

Emotion perception is a complex and subtle process involving how individuals perceive, express, and interpret emotions (Canales and Martínez-Barco, 2014; Ghosal et al., 2021; Zhang et al., 2023). This paper focuses on the Text-Based Emotion Detection (TBED) task proposed in the SemEval-2025 Task 11 (Belay et al., 2025; Muhammad et al., 2025b), which aims to determine the emotion that the majority of people perceive the speaker to be experiencing based on a sentence or a short text fragment uttered by the speaker (along with further assessment of the intensity of emotions).

The TBED task concerns the emotion perceived by the majority of people rather than the speaker's actual emotion. For example, the sentence "I finally finished all my work today; this is fantastic" may evoke feelings of joy or satisfaction in most people. However, it does not rule out the possibility that the speaker's actual emotion might differ, perhaps due to some form of reverse expression. Furthermore, this task differs from the following emotion-related tasks: (1) reader emotions induced by the text (Rao et al., 2014) and (2) emotions of individuals mentioned in the text (Wegge and Klinger, 2023).

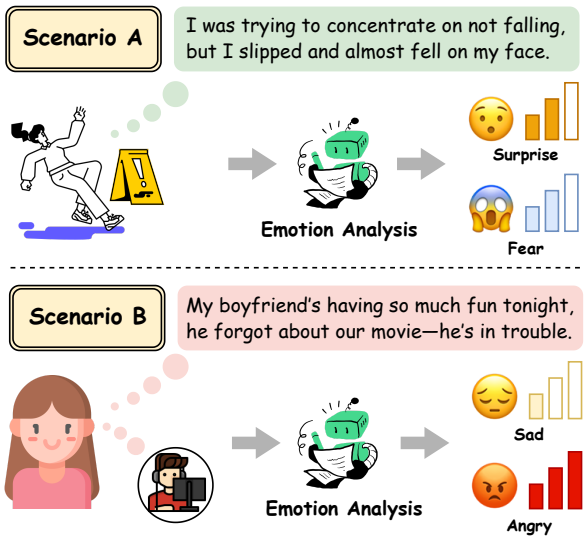

Figure 1: Examples of TBED. The goal of this task is to recognize what emotion most people think the speaker might have felt given a sentence or a short text snippet uttered by the speaker.

In this paper, we propose an innovative emotion recognition framework based on multi-agent collaboration (Guo et al., 2024). Specifically, we design two key agents: (1) the Emotion Perception Profiler, used for identifying emotions in text, primarily applied to subtasks A and C, and (2) the Intensity Perception Profiler, which further assesses emotion intensity based on the output of the first agent, applied to subtask B. We model the task using both generative and discriminative paradigms, training the intelligent agents using BERT series (Devlin,

♡ Contribute equal to this work.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 397–406

2018; Liu, 2019) models and large-scale generative language models (LLMs) (Yang et al., 2024; Grattafiori et al., 2024; Guo et al., 2025). Given that different base models acquire different capabilities during the pre-training phase, including learned knowledge, linguistic proficiency, and task adaptation, we further introduce a multi-system collaboration mechanism. The intelligent agents constructed on unified base models are referred to as an agent system. By fusing prediction results from multiple systems, we enhance the accuracy, stability, and robustness of the results. Additionally, for subtask C, we introduce a cross-linguistic knowledge transfer mechanism, significantly improving the performance in cross-linguistic scenarios.

For the final evaluation, we select the models that performed best on the validation set. We test all languages involved in subtasks A and B. For subtask C, we only test languages that do not have any training or validation data during the validation phase to ensure the reliability of the results. Our approach achieves outstanding performance across all three subtasks, validating the effectiveness of our method, particularly in terms of language adaptability and emotion intensity prediction capabilities.

2 System Overview

Preliminary. Given a sentence or text snippet $W = \{w_1, w_2, ..., w_n\}$ uttered by the speaker, a predefined emotion set $E = \{e_1, e_2, ..., e_m\}$, the objective of the three subtasks is as follows:

- **Subtask A**: Predict the perceived emotion(s) $\mathcal{S} = \{e_k | e_k \in E\}$ of the speaker.
- **Subtask B**: Predict the perceived emotion(s) and their corresponding emotional intensity $\mathcal{P} = \{(e_k, i_k) | e_k \in E, i_k \in I\}$, where $I = \{\text{low}, \text{moderate}, \text{high}\}$, denotes three degrees of the emotion intensity.
- **Subtask C**: Predict the perceived emotion(s) $\mathcal{S} = \{e_k | e_k \in E\}$ of the speaker in an unseen target language, without relying on labeled training data in that language.

Framework. Our framework consists of two agents, ***Emotion Perception Profiler*** (EPP) and ***Intensity Perception Profiler*** (IPP). Specifically, as shown in Figure 2, EPP receives the text input and focuses on detecting the speaker's emotion, while IPP receives both the text input and the previously detected emotion information, taking the responsibility of determining the intensity of that emotion. In the following sections, we will present two distinct implementations of these agents: one based on BERT and the other based on Large Language Models (LLMs).

2.1 BERT-based Method

This approach leverages a Pretrained Language Model (PLM) model to obtain embedded representations for the corresponding features, framing the problem as either a multi-label or single-label classification task.

Emotion Perception Profiler. Firstly, we adopt XLM-Roberta as our PLM to generate contextual word representations by:

$$\begin{aligned}\mathbf{H} =& \text{XLM-Roberta}\left(\{w_1, w_2, \ldots, w_n\}\right), \\ =& [\mathbf{h}_{[\text{CLS}]}, \mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_n, \mathbf{h}_{[\text{SEP}]}].\end{aligned} \tag{1}$$

For each emotion $e_i \in E$, a dedicated binary classification head is defined as follows:

$$p_i = \text{Sigmoid}\left(\mathbf{w}_i^\top \mathbf{h}_{[\text{CLS}]} + \mathbf{b}_i\right). \tag{2}$$

Finally, the speaker is considered to exhibit the corresponding emotion if the probability p_i exceeds 0.5. The training loss is defined as:

$$\mathcal{L}_i = y_i \log p_i + (1 - y_i) \log(1 - p_i), \tag{3}$$

where $y_i \in \{0, 1\}$ is the ground truth label for the i-th emotion in the predefined set.

Intensity Perception Profiler. Similar to EPP, we utilize a PLM to encode the textual information along with the corresponding emotions that are to be assessed for intensity:

$$\begin{aligned}\mathbf{H} =& \text{XLM-Roberta}\left(\{w_1, w_2, \ldots, w_n\}, e_k\right), \\ =& [\mathbf{h}_{[\text{CLS}]}, \mathbf{h}_1, \mathbf{h}_2, \ldots, \mathbf{h}_n, \mathbf{h}_{[\text{SEP}]}, \mathbf{h}_{\text{emo}}].\end{aligned} \tag{4}$$

The representation of e_k is subsequently passed through a fully connected layer with a softmax activation function, producing probability distributions across all intensities:

$$\mathbf{p}_k = \text{Softmax}\left(\mathbf{W}^\top \mathbf{h}_{\text{emo}} + \mathbf{b}_k\right). \tag{5}$$

The training loss is formulated as the cross-entropy loss between the ground truth and the predicted label distributions, similar to formula 3.

2.2 LLM-based Method

Given the outstanding performance of LLMs across various domains, such as text classification and sentiment analysis, we also employ an LLM-based approach to implement the EPP and IPP, transforming the three subtasks into text generation tasks. We **combine fine-tuning and ICL** by utilizing LoRA as the parameter-efficient fine-tuning (PEFT) method to optimize the model and incorporating

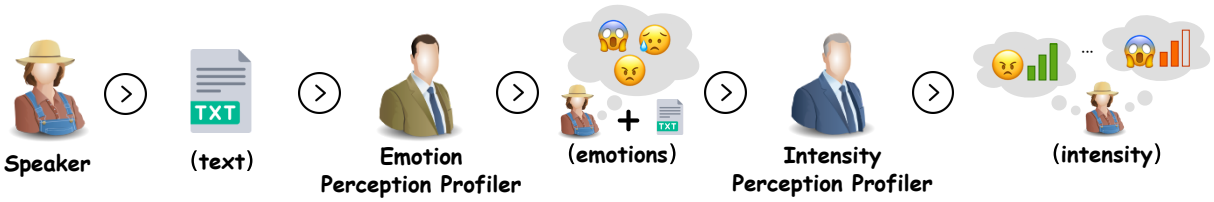

Figure 2: Our framework. The Emotion Perception Profiler analyzes the text output by the speaker to perceive the corresponding emotion, thereby addressing subtasks A and C. The Intensity Perception Profiler combines both emotional and textual information to assess the intensity of each emotion, completing subtask B.

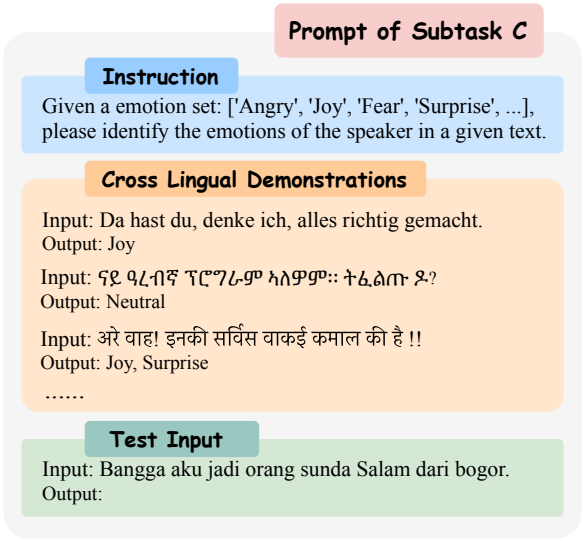

Figure 3: Examples of the prompt designed for subtask C. Specifically, the demonstrations used in ICL and the final test examples belong to different languages.

ICL demonstrations into the prompt, formulated as:

$$\hat{y} \sim P_{\mathcal{LLM}}(y \mid \mathcal{T}, x). \quad (6)$$

Here, $\mathcal{T} = \{\mathcal{I}, t(x_1, y_1), ..., t(x_k, y_k)\}$, where $\mathcal{I}$ represents the task instruction and t denotes the template of few-shot demonstrations for ICL. Notably, for subtask C, we introduce a novel **cross-lingual ICL** paradigm that leverages knowledge transfer from high-resource languages to enhance performance in low-resource settings where no target language training data is available.

Combine Fine-tuning and ICL. Conventionally, fine-tuning adapts a model to a specific task by explicitly adjusting its parameters, while in contrast, ICL performs the task through the prompting of examples. By incorporating ICL demonstrations into the prompt during the fine-tuning phase, the model can learn from both labeled data and contextual examples, enhancing its task understanding and generalization ability. Specifically, for subtasks A and B, we select the semantically closest top-k instances as ICL demonstrations by calculating the cosine distance between sentence embeddings.

Cross-lingual ICL. To address the zero-shot cross-lingual requirement of Subtask C, where no target-language training data is permitted, we propose a novel multilingual knowledge transfer framework through cross-lingual in-context learning, as shown in Figure 3. Our approach operates in two phases:

- **Fine-tuning:** During the PEFT phase via LoRA, we construct ICL demonstrations in $\mathcal{T}_m$ using multilingual examples $\{(x_s, y_s)\}$ from high-resource languages $s \in \mathcal{S}$ (e.g., English, Spanish), while maintaining the target language t exclusive from $\mathcal{T}_m$ exclusively for inference. The model is optimized to learn language-agnostic patterns through:

$$\mathcal{L} = \mathbb{E}_{(x,y)\sim\mathcal{D}} \left[-\log P_{\mathcal{LLM}}(y \mid \mathcal{T}_{\text{m}}, x) \right] \quad (7)$$

  where $\mathcal{T}_{\text{m}}$ contains demonstrations from multiple high-resource source languages.

- **Inference:** At inference time for target language t, we retrieve semantically similar examples from other source languages using:

$$\text{sim}(x_t, x_s) = \cos(\mathbf{E}(x_t), \mathbf{E}(x_s)) \quad (8)$$

  where $\mathbf{E}$ denotes a multilingual sentence encoder (e.g., LaBSE). The top-k most relevant source-language examples $\{(x_{s_i}, y_{s_i})\}_{i=1}^{k}$ are injected into the prompt $\mathcal{T}_m$.

This dual-phase approach enables three key advantages: (1) *Cross-lingual capability activation* by leveraging ICL demonstrations from high-resource languages to stimulate the model's latent understanding of the target low-resource language, (2) *Cross-lingual semantic bridging* via contrastive-aligned multilingual embeddings, and (3) *Zero-shot generalization* without violating the target-language data constraint. In the Experiment section, we further elaborate on and summarize the selection strategy for the source high-resource language derived from empirical evidence.

3 Experiments

3.1 Setup

Models and Metrics. For discriminative modeling, we employ the XLM-Roberta-Large (Liu, 2019) as the encoder and employ linear lays as classifiers. For generative modeling, we utilize several prominent large language models (LLMs), including LLaMa3.1-8B (Dubey et al., 2024), Deepseek-7B (Bi et al., 2024), Qwen2.5-7B (Yang et al., 2024), Mistralv0.3-7B (Jiang et al., 2023), and Gemma2-9B (Team et al., 2024). We adopt LoRA (Hu et al., 2021) as our parameter-efficient fine-tuning method.

Metrics. The evaluation metric for subtasks A and C is the F1-macro based on the predicted and gold labels. Subtask B employs the Pearson correlation between the predicted labels and the gold ones for evaluation.

3.2 Main Results

During the validation phase, we evaluate six languages for subtasks A and B, with the results presented in Tables 1. Despite these models being pre-trained on multiple languages, disparities still exist. Overall, the performance of LLaMA and Qwen is relatively superior. Additionally, the effectiveness of LLMs generally surpasses that of BERT-based (smaller) models (SLMs).

Notably, for subtask A, the superiority of LLMs is more pronounced. However, for subtask B, there is no significant difference between the two. This discrepancy may be attributed to the different evaluation metrics employed for subtasks A and B. This observation provides valuable insights, suggesting that it may be beneficial to integrate both large and small models to leverage their respective strengths for multi-agent collaboration. Furthermore, due to the adoption of a multi-step mode, a potential issue of exposure bias may arise. However, our experiments revealed that end-to-end modeling approaches yielded inferior results, which may be related to the complexity of the tasks. We also

Table 8: Ablation results of subtask B. "IPP$^+$" refers to the approach where a single agent directly performs both emotion prediction and intensity detection tasks. "CodeIPP$^+$" extends IPP$^+$ by utilizing a code-style prompt, modeling emotion and intensity as structured pairs, and applying the corresponding LLM code version. The best results are highlighted in bold, and the second-best results are underlined.

preliminarily verified that code-style prompts can enhance the performance of end-to-end modeling approaches. Table 2 and 3 illustrate the validation set performance for subtask C. We trained models using different source languages and tested them on four target languages. We conducted experiments under two distinct scenarios: one involving training the model using a single source language exclusively, and the other incorporating multiple languages for model training. The results indicate that source languages linguistically closer to the target languages enhance the model performance.

During the testing phase, we compare our approach with official LLM baselines (Muhammad et al., 2025a; Belay et al., 2025), including Qwen2.5-72B, Dolly-v2-12B, Llama-3.3-70B, Mixtral-8x7B, and DeepSeek-R1-70B. The results for the three subtasks are presented in Tables 4, 5 and 6, respectively. Even though these baselines employed significantly larger models, our approach demonstrated superior performance.

3.3 Ablation Study

We conduct a series of ablation experiments to systematically evaluate the contribution of each proposed optimization, as shown in Tables 7 and 8. The results reveal several key insights: (1) Incorporating ICL demonstrations during fine-tuning improves model performance. This can be attributed to the dual role of ICL examples in providing explicit task-specific guidance and enhancing the model's ability to generalize from contextual patterns, thereby bridging the gap between pre-trained knowledge and downstream task requirements. (2) The single-agent IPP$^+$ setup underperforms compared to the multi-agent approach, highlighting the importance of task decomposition and collaborative reasoning. The multi-agent system likely benefits from specialized handling of subtasks, enabling more robust decision-making through inter-agent interactions. (3) Replacing natural language prompts with code-style formatting further enhances performance. This improvement may stem from the structured nature of code-style prompts, which enforce stricter syntactic and semantic constraints, reducing ambiguity and aligning more effectively with the model's pre-trained capabilities in code comprehension and structured reasoning. Collectively, these findings demonstrate that each optimization contributes meaningfully to the overall performance, validating the design choices of our framework.

4 Conclusion

In this paper, we propose a multi-agent framework for the Text-Based Emotion Detection (TBED) task in the SemEval-2025 Task 11. Our system, comprising the Emotion Perception Profiler and Intensity Perception Profiler, demonstrates superior accuracy, stability, and robustness across multiple subtasks. The cross-lingual knowledge transfer and in-context learning strategies effectively address challenges in low-resource languages, enhancing language adaptability. Extensive experiments demonstrate the effectiveness of our approach without the need for costly pre-training. Future work will explore further optimizations in diverse linguistic and emotional contexts.

Limitations

We acknowledge the following limitations of our work: (1) For subtask B, the sequential process of first determining sentiment and then predicting intensity inevitably introduces exposure bias. (2) The necessity of employing multiple collaborative agents incurs additional computational and storage overhead. (3) The absence of supplementary pre-training limits the model's adaptability to languages less encountered during its initial pre-training phase.

A Experimental Details

Datasets Table 9 presents the distribution of training data across various subtasks. Subtask A encompasses datasets in 27 languages, with a relatively balanced distribution. Each language has approximately 2,300 training samples on average. Subtask B includes datasets in 11 languages, with an average of 2,200 training samples per language. Subtask C evaluates the cross-lingual performance. The complete test dataset comprises 32 languages. However, most of these languages are included in subtask A. Therefore, we focus on languages that lack any training data, totaling four languages. Subtasks A and C require the identification of sentiment categories, including joy, sadness, fear, anger, surprise, and disgust (with some languages involving only five categories). Subtask B further assesses the intensity of the identified emotions, categorizing them into low, moderate, and high degrees. For more details, refer to Muhammad et al. (2025a); Belay et al. (2025).

Implementation Details For Bert models, we set the learning rates for the encoder and the classifier to 2e-5 and 1e-3, respectively. The batch size was set to 16, and the model was trained for 3 epochs using the AdamW optimizer. For LLMs, the training configuration consists of a learning rate of 1e-4, 3 epochs, a batch size of 2, bf16 mixed precision, and a maximum sequence length of 2048 tokens. Additionally, the rank of LoRA fine-tuning is set to 16, with a warmup ratio of 0.1. All implementations are conducted within the PyTorch framework, utilizing NVIDIA 4090 GPUs for computation. The number of demonstrations for ICL is set to 10.

B Supplementary Experiments

B.1 Model Comparision

To further investigate the nuanced performance variations of different models across languages and emotion categories, we conducted the systematic experiments outlined in Figure 4. Our analysis yields three principal findings:

(1) **Emotion-specific performance divergence**: The detection accuracy and intensity quantification efficacy exhibit significant disparities across emotion categories. We hypothesize that this phenomenon stems from differential boundary clarity in emotional intensity gradations. For instance, the superior detection of "Joy" across all languages contrasts with the suboptimal performance on "Disgust", potentially attributable to the inherent ambiguity in disgust intensity demarcation and its infrequent contextual manifestations in training corpora. This aligns with Ekman's (Ekman, 1992) basic emotion theory, where primary emotions exhibit more prototypical expressions, while complex emotions like disgust demonstrate higher cultural dependency. Joy-related lexicons show higher cross-lingual isomorphism in intensity scales (e.g., "delighted" vs. "content") compared to disgust's binary conceptualization ("disgusted" vs. "non-disgusted") in most languages.

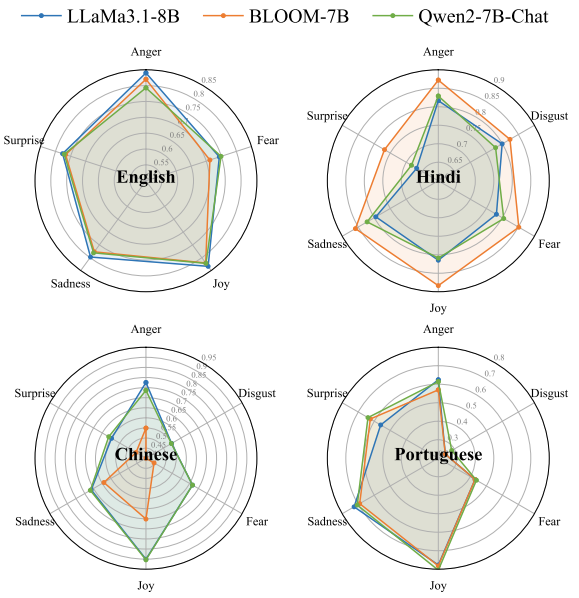

Figure 4: The Fine-grained performance of Subtask B. We compared the performance of three LLMs across four languages: English, Hindi, Chinese, and Portuguese. Each axis corresponds to a specific emotional category, with the performance of the models represented as follows: LLaMa3.1-8B (blue), BLOOM-7B (orange), and Qwen2-7B-Chat (green).

(2) **High-resource language performance plateau**: Model disparities remain statistically insignificant for linguistically well-resourced languages such as English and Portuguese. This convergence in performance across models suggests a saturation effect, where the optimization of model performance reaches a plateau in languages with abundant training data. Such saturation implies that, for these linguistically well-resourced languages, the need for careful selection between different LLMs may be less critical, as all models are likely to perform at a similar level of effectiveness.

(3) **Low-resource language sensitivity**: Conversely, marked performance discrepancies emerge in Hindi (BLOOM vs. LLaMa: F1=0.841 vs.

Subtask	Training Data Distribution	#Languages	#Avg
A	afr(1.9%), amh(5.5%), arq(1.4%), ary(2.5%), chn(4.1%), deu(4.0%), eng(4.3%), esp(3.1%), hau(3.3%), hin(3.9%), ibo(4.4%), kin(3.8%), mar(3.7%), orm(5.3%), pcm(5.7%), ptbr(3.4%), ptmz(2.4%), ron(1.9%), rus(4.1%), som(5.2%), sun(1.4%), swa(5.1%), swe(1.8%), tat(1.5%), tir(5.7%), ukr(3.8%), vmw(2.4%), yor(4.6%)	28	2.3k
B	amh(14.1%), arq(3.6%), chn(10.5%), deu(10.3%), eng(11.0%), esp(7.9%), hau(8.5%), ptbr(8.8%), ron(4.9%), rus(10.6%), ukr(9.8%)	11	2.2k
C	ind, jav, xho, zul	4	*Not available*

0.792) and Chinese (Qwen vs. BLOOM: F1=0.697 vs. 0.541). This underscores the importance of strategically selecting LLMs based on language-specific architectural optimization and the representativeness of training data, especially when dealing with under-resourced languages. The superior performance of BLOOM in Hindi potentially reflects its enhanced morphological processing capabilities, which are particularly well-suited for agglutinative languages like Hindi. This highlights the need for models that are not only trained on diverse multilingual datasets but also optimized to handle the unique syntactic and morphological characteristics of specific languages.

C Related Works

Sentiment Analysis. Sentiment analysis is a multifaceted area that seeks to understand how language conveys and perceives emotions. It can be divided into three levels: Document-level analysis (Zhang et al., 2021) captures the overall emotional tone of a text, useful for tasks like sentiment analysis in reviews. Sentence-level analysis (Bordoloi and Biswas, 2023) focuses on emotions within individual sentences, often applied in more detailed sentiment classification. Aspect-based Sentiment Analysis (ABSA) (Zhang et al., 2024) identifies emotions related to specific features or aspects, which is especially valuable in opinion mining, where emotions towards different components of a product or service need to be assessed separately. All three granularities have rich downstream applications, such as sarcasm detection (Qiu et al., 2025), dialogue system (Song et al., 2022; Liu et al., 2022), or recommendation system (Lin et al., 2021). In this paper, we focus primarily on sentence-level multi-label emotion classification tasks.

In-context Learning. In-context learning refers to the ability of models, especially LLMs, to adapt to a task by conditioning on a few examples or instructions provided within the input without requiring explicit retraining (Brown et al., 2020; Zhang et al., 2022; Wei et al., 2023; Zhao et al., 2024). Early work on this concept emphasized its potential in tasks such as few-shot learning, where models demonstrated impressive performance by simply leveraging context from examples embedded in the prompt (Zhao et al., 2021; Lu et al., 2022). Subsequent studies have explored how models can generalize across various tasks, including question answering and text generation, by relying on in-context examples (Wang et al., 2023b; Hendel et al., 2023; Wang et al., 2023a). The flexibility of in-context learning has made it a promising approach for tasks with limited labeled data or dynamic, context-sensitive applications. This paper proposes a novel cross-lingual ICL framework to enhance LLMs' adaptability for low-resource languages by strategically leveraging cross-lingual knowledge transfer through contextual demonstrations.

Cyber for AI at SemEval-2025 Task 4: Forgotten but Not Lost: The Balancing Act of Selective Unlearning in Large Language Models

Abstract

Large Language Models (LLMs) face significant challenges in maintaining privacy, ethics, and compliance, when sensitive or obsolete data must be selectively removed. Retraining these models from scratch is computationally infeasible, necessitating efficient alternatives. As part of the SemEval 2025 Task 4, this work focuses on the application of selective unlearning in LLMs to address this challenge. In this paper, we present our experiments and findings, primarily leveraging global weight modification to achieve an equilibrium between effectiveness of unlearning, knowledge retention, and target model's post-unlearning utility. We also detail the task-specific evaluation mechanism, results, and challenges. Our algorithms have achieved an aggregate score of 0.409 and 0.389 on the test set for 7B and 1B target models, respectively, demonstrating promising results in verifiable LLM unlearning.

1 Introduction

Large Language Models (LLMs) have revolutionized the way artificial intelligence can be used, adapted, and integrated, demonstrating unprecedented capabilities across various domains and use cases (Brown et al., 2020). In order for LLMs to provide optimal and factual responses, they often require to be trained on vast amount of diverse information which not only includes the world data, but could also contain sensitive application-, task-, or entity-specific data (Bender et al., 2021). Training on such massive datasets typically introduces critical challenges related to bias, ethics, and privacy concerns (Neel and Chang, 2024; Zhang et al., 2025). Further, at times, the data providers might also want to have no traces of their data at a later point due to reasons such as confidentiality, legal issues, change in terms, etc (Yao et al., 2024). Retraining LLMs to exclude specific data is computationally expensive and impractical (Cottier et al., 2025; Xia et al., 2024), especially given the potential for numerous subsequent removal requests from various data providers, clients, or end-users.

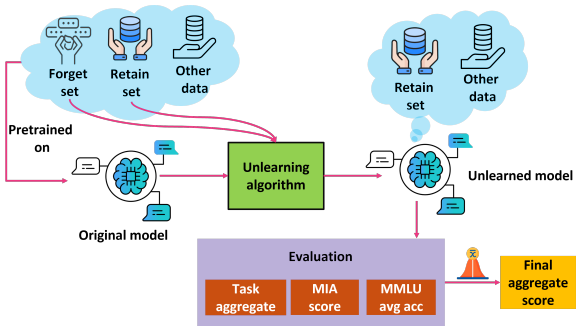

Figure 1: Block diagram of selective unlearning in LLMs, with task's evaluation mechanism

Selective unlearning in LLMs (Liu et al., 2024a) helps to achieve this exact objective. It is a mechanism through which the requested information can be precisely removed from the model's parametric memory along with preserving the model's knowledge integrity and utility for downstream tasks, without retraining it from scratch. The requested information can be a specific knowledge, model's certain behavior, a feature, or its ability to perform a particular task, or a combination of two or more of these and more. Figure 1 depicts the crux of selective unlearning along with the task's evaluation mechanism which is discussed in Section 3.3.
Unlearning in LLMs is a niche yet increasingly critical area that offers key advantages such as cost-effectiveness, computational efficiency, and precise intervention. It plays a crucial role in eliminating embedded biases (Yu et al., 2023; Dige et al., 2024), erasing toxic or harmful responses (Liu et al., 2024b), and reinforcing AI guardrails (Hine et al., 2024) in safety-critical fields such as healthcare, finance, and enterprise settings. However, ensuring effective and verifiable unlearning is challenging, as many approaches risk leaving residual traces of removed knowledge or inadvertently impairing broader model capabilities. Achieving

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 407–417

the right balance between unlearning effectiveness, knowledge retention, and model generalization is a delicate optimization problem that continues to drive research in this field (Qu et al., 2024).

2 Related works

The approaches to unlearning in LLMs can be broadly classified into four categories: global weight modification, local weight modification, architecture modification, input/output modification (Blanco-Justicia et al., 2025).

Global weight modification involves updating all the model parameters while unlearning, thus, ensuring better guarantee of forgetting the requested information. It includes approaches such as gradient ascent (Feng et al., 2024; Gundavarapu et al., 2024), gradient difference (Bu et al., 2024), knowledge distillation (Zhao et al., 2024), KL minimization (Yao et al., 2024), weight perturbation (Yuan et al., 2024), and so on. These approaches are well suited for smaller models and provide strong unlearning, however, are resource intensive for larger models, as the training costs greatly increase with increase in the number of parameters. Global weight modification for larger models also strengthens the problem of optimizing effective unlearning, and preserving model's capabilities.

Local weight modification identifies a subset of parameters that are required to be modified and accordingly updates only those model parameters (Ashuach et al., 2024; Wu et al., 2023; Jia et al., 2024; Pochinkov and Schoots, 2024), thereby, minimizing the computational efforts needed. Nevertheless, the right set of parameters that are required to be modified might vary based on the diversity of the requested information. Identifying the same is thus, challenging which therefore, has chances of leaving traces of unlearning, or in other words, influence of the requested information could still be observed in the model's behavior (Hong et al., 2024).

Architecture modification based approaches involve tweaking the model's architecture such as by adding additional layers (Chen and Yang, 2023), or by using external modules (Ji et al., 2024; Zhang et al., 2023) in addition to the target model, etc. These approaches, while advantageous in other contexts, were not suitable for this specific task's setup.

Finally, the input/output modification, as the name suggests, involves approaches that do not achieve true unlearning but modifies the model's input, and sometimes the output, in such a way that the final response is as desired, by leveraging techniques such as soft prompting (Bhaila et al., 2024), preference optimization (Zhang et al., 2024; Fan et al., 2024), in-context learning (Pawelczyk et al., 2023; Thaker et al., 2024).

Split	Train	Validation
Forget	1112	254
Retain	1136	278

Table 1: Train and validation splits of the datasets

3 Task artifacts

This section describes the artifacts given by the task organizers (Ramakrishna et al., 2025b) namely: dataset, models, and MIA dataset, which have been used for this task of unlearning.

3.1 Dataset

There are two disjoint components of the dataset: forget dataset and retain dataset. As their names suggest, forget dataset constitutes of samples that have to be forgotten or unlearned by the model, and the retain dataset constitutes of samples that still have to be retained by the model post its unlearning. The dataset has predefined splits between train and validation sets. The sample distribution between the train and validation sets of forget and retain sets is respectively presented in Table 1. Each of the forget and retain datasets in their json format have five fields as described in Table 2. Further as described in Table 2, there are three tasks to which a sample in forget dataset and retain dataset could belong to as follows: (1) Long-form synthetic creative documents across genres; (2) Short-form synthetic biographies with PII (fake names, phone numbers, SSNs, emails, addresses); (3) Real documents sampled from the target model's training dataset.

The forget and retain data samples were designed to be evaluated on sentence completion, and question-answering. Therefore, the input field in the retain and forget datasets is either an excerpt from some document, or is a question. While the output field is the continuation of the corresponding input if the input is a document excerpt (sentence completion), or is an answer if the input is a question (question-answering). This categorization is indicated with a string – 'sc' or 'qa' as part of the sample's id field. (Ramakrishna et al., 2025a) further discusses the process of dataset curation.

Field	Description
id	Document id
input	Document snippet (input to the model)
output	Output for the corresponding input based on the concerned task mapped
task	The respective unlearning task to which the sample is assigned from the three tasks
split	If the sample belongs to retain or forget set

Table 2: Field description of forget and retain datasets

3.2 Models

Two models were given as the target models that need to unlearn the forget dataset. One is a 7-billion parameter model, and the other is a 1-billion model, both finetuned to memorize the forget and the retain datasets, with their base architectures being OLMo-7B-0724-Instruct-hf[1] model and OLMo-1B-0724-hf[2] model respectively.

The base models OLMo-7B-0724-Instruct-hf and OLMo-1B-0724-hf are transformer style autoregressive language models from the family of Open language Models (OLMo) by Allen Institute for AI, and were trained on Dolma dataset[3], with the Instruct version trained on UltraFeedback dataset[4]. Dolma is a large dataset curated from a combination of diverse materials sourced from the internet, academic journals, published literature, software repositories, books, and so on. The UltraFeedback dataset is a large collection of human feedback including human preferences and ratings for different LLM outputs.

3.3 Evaluation

The target model's unlearning is evaluated as an average of three different scores namely task aggregate, MIA score, and MMLU average accuracy, which are explained as follows.

Task aggregate: All the samples in the forget and retain datasets are respectively grouped according to one-of-the-three task mapping. For all the samples in these six sets, Regurgitation score is computed as RougeL score for samples in sentence completion format, and Knowledge score is a binary indicator computed as the exact match rate for the samples in question-answer format. The scores are inverted ($1 - score$) if the sample is part of the forget dataset. The respective scores for each of the six sets are aggregated and a harmonic mean of these 12 scores is considered as the task aggregate. A higher score represents better performance.

MIA score: Membership Inference Attack (MIA) is typically used to know if a sample is part of trained model's training data or not. In the context of unlearning, it is therefore, used to identify whether the samples in the forget dataset were forgotten by the model or not.

The task organizers have given an MIA dataset for this purpose which constitutes of two sets: Member set and Non-member set, each with 150 samples. Member set is a subset of the train split of the forget dataset. Non-member set constitutes of samples collected from elsewhere which the model has not seen prior. Both the member and non-member sets are given in jsonl format. Each sample in the member set has an id field, a document field, a question_answering_task field constituting of a question and the corresponding answer, a sentence_completion_task field constituting of an input and the corresponding output. Each sample in the non-member set has certain meta fields, and a document excerpt.

The final MIA score is computed as $1 - abs(mia\_auc) - 0.5) * 2$ where mia_auc is the area under the receiver operating characteristic curve with the negative log likelihoods computed for member and non-member sets. The MIA score is expected to be around 0.5. The closer it is to zero denotes under-unlearning, and the closer it is to one denotes over-unlearning.

MMLU average accuracy: Massive Multitask Language Understanding (MMLU) (Hendrycks et al., 2021) is a benchmark dataset consisting of 15,908 multiple-choice questions spanning 57 diverse subjects used for evaluating various capabilities of language models such as language understanding, general knowledge, reasoning abilities, domain knowledge, generalization, and so on. The average accuracy of the target model across all the 57 subjects is used as one of the metrics to evaluate the post-unlearning utility of the target model. A higher score represents better utility. A threshold of 0.371 is set by the organizers for the 7B model.

4 Experiments and Results

A variety of experiments have been tried to understand the patterns in the given datasets, and figure out the suitable approaches that would balance the

Table 4: Performance of 7B model (Submissions*)

Gradient-based methods:
Due to computational constraints, we have considered two configurations of the models for executing these methods: 1B model is trained as is, and 7B model is trained in a 4-bit PEFT configuration, described in Table 7 of Appendix B. Due to this, some of the experiments have been performed on either of these models, and some of them on both the models. The study investigates how various gradient modifications influence performance, with a focus on balancing retention, unlearning, and model utility. The key results of the same are briefly reported in Tables 3, 4 for 1B and 7B models respectively. A detailed comparison of all the variants of these experiments along with the corresponding training configurations is presented in Tables 8, 9 of Appendix B for 1B and 7B models respectively.

Gradient ascent: In this method, the target model was trained on the forget set with an inverted loss, thereby, making it to unlearning the training set rather than learning it. By maximizing the loss on the forget set, this method forces the model to unlearn. It was observed that learning rate (LR) and weight decay (WD) variations have a strong impact on the unlearning intensity. In particular, aggressive configurations led to stronger unlearning, achieving a MIA score of 0.807 by the 1B model, when LR and WD were increased despite halving the number of epochs (E). On the other hand, with a steady training for 10 epochs, with relatively lesser LR, achieved even more unlearning in the 7B model, however, costing its utility – the model's MMLU average accuracy (MMLUAA) almost got halved compared to the original 7B model. Nonetheless, it was noted that the MMLUAA has not dropped much in the case of 1B model, despite reaching a similar MIA score. This indicates that gradient ascent though achieves a good balance between model's utility and the level of unlearning in smaller models, it tends to easily destabilize large models. Quantization in the 7B model may have also enhanced unlearning, potentially due to increased numerical instability aiding divergence from the learned state.
Gradient descent: In this method, the target model was trained on the retain set, thereby, optimizing it to the training set. The intuition is that, the strong adaption of the model only to the retain set can naturally make it tend to forget the other information (forget set) it was previously trained on, like catastrophic forgetting. A few interesting observations were made by the model performances with this method. Firstly, with 1B model, when it was trained for 6 epochs, it has reached the optimal level of unlearning required (~ 0.5), and also got a slight boost in the MMLUAA, even more than the original 1B model by 0.001. However, the overall score (aggregate) is not high. It is even significantly less than one of the gradient ascent scores. To further study if the model's performance would be increased if trained more aggressively, the epochs were increased to 20, besides increasing LR and WD. This has achieved near perfect unlearning, and also is the highest MIA score amongst all the experiments on the 1B model. The MMLUAA has also not dropped much from the original 1B model, and therefore has got the highest aggregate score of 0.410 on the 1B model. However, a similar setup did not go well with the 7B model.

KL minimization: This method adds an additional term of Kullback–Leibler (KL) divergence as regularization to the loss function. This was used in gradient ascent with the objective of maximizing the loss on the forget set, yet not deviate too drastically from the original model, preserving its performance. However, we observed that KL minimization was not much different from the gradient ascent when executed with same parameters.

Controlled gradient ascent: We tried with a variant of gradient ascent where gradients were modified in a controlled manner instead of completely getting updated based on change with loss. A parameter $alpha$ was used to control the scale of updation. Setting alpha to 0.1 helped regulate the magnitude of updates, allowing the 1B model to reach a MIA score of 0.855, outperforming standard gradient ascent, despite training aggressively for more than triple the epochs. This approach was particularly effective in preventing the complete collapse of model utility, making it a viable strategy when unlearning must be balanced against task performance.

Gradient difference: To reinforce the model utility degraded by gradient ascent, in this method, the target model was further trained on the retain set, thereby, optimizing it to the training set. Therefore, the target model goes through gradient ascent followed by gradient descent. While this method has shown a steady increase in the aggregate score of the 1B model, with a tradeoff between MIA score and MMLUAA, it has not shown any impact on the 7B model. It is important to note that the 10 epochs of gradient ascent has brought down the MMLUAA to 0.284 from 0.512, and a single subsequent gradient descent epoch with LR as low as 2e-6 brought it back to 0.511, emphasizing the vital role and impact of gradient descent in mitigating utility loss in larger models.

Gradient difference followed by Gradient ascent: To further study the behavior of 7B model, given its drastic and static responses to the above methods, we made a few experiments specifically on the 7B model such as this, and the subsequent ones. It was observed that one epoch of gradient ascent with a slightly higher LR has shown drastic change in model's performance. Multiple experiments with this method demonstrate its strategic impact striking a good balance between unlearning and utility. Nevertheless, reducing the learning rate has not reversed the impact of gradient descent, while increasing it further has deteriorated the model's performance with excessive unlearning like that of gradient ascent alone. Overall, with optimal parameter settings, this method excelled on the 7B model, achieving the highest aggregate score while maintaining a balance across utility and unlearning metrics.

Gradient difference followed by Gradient difference: Further gradient descent on the aforementioned state reemphasizes the impact of even a single round of gradient descent with LR as low as 2e-8, on a strongly unlearned model with MIA score of 0.982 which reinstated it alike the original.

Gradient descent followed by Gradient ascent: It was observed that gradient ascent with smaller learning rate like 2e-6 could not counter the impact of prior gradient descent training, while making it a little aggressive has over dominated the prior training, leading to reduced MMLUAA.

Xavier Initialization: Though, not an unlearning method originally, it is interesting to observe that by erasing all the parametric values of the original models and by only initializing them with Xavier initialization has still given one of the best aggregate scores, without any training, outperforming many other methods, stressing setup-dependent variability.

5 Conclusion

This work explores the use of targeted unlearning in LLMs where we have experimented with several unlearning methods with different configurational settings to make the target models forget the requested dataset, and preserve the specified retain set, also, preserving its overall multifaceted capabilities. From our experiments, for 7B model: Gradient difference followed by Gradient ascent worked well with appropriate parameters tuning; and for 1B model: Gradient descent alone on the retain set worked well. Xavier initialization on the 1B model has got near equivalent score on all the metrics as the former. Followed by similar performance between Controlled gradient ascent, and Gradient difference, with respective appropriate parameters tuning. This work reemphasizes the fact that selective unlearning comes with the delicate problem of optimizing effective unlearning with knowledge retention of the remaining data and model's integrity, utility for downstream tasks. Further, it demonstrates that performance of a method significantly depends on the scale of the target model, and the kind of data it is presented with.

Acknowledgments

We would like to thank our colleagues, Ashok Urlana and Charaka Vinayak Kumar, for their valuable feedback and insightful discussions, which have notably improved this work.

A Other experiments conducted

- **Prompt routing**
  If there are any distinguishable patterns between the samples of forget and retain sets, they can be used to train the target model respond in a certain way when a sample is identified to be from the forget set distribution and vice versa. These patterns might be identifiable through sample clustering by grouping similar ones. Additionally, as the labels are available for the forget and retain samples, a binary classifier can be trained to classify the samples. If the samples are effectively classifiable, it therefore, can be used to classify the input, and accordingly make the target model respond.
  - **Clustering**
    Two distinct clustering algorithms were used: Agglomerative clustering, Density-Based Spatial Clustering of Applications with Noise (DBSCAN). In agglomerative clustering, which is a hierarchical

approach, it is required to specify the desired number of clusters, which was set to two here, denoting the forget and retain sets. Unlike agglomerative, DBSCAN is a density-based clustering approach, where $epsilon$ was set to 0.3, and $minimum\_samples$ was set to 10.

– **Classification**
Six machine learning algorithms and an ensemble soft voting classifier were trained on the combined forget and retain datasets, with an 80:20 train-test split. The denomination of samples in the train and the test sets are reported in Table 5.

Observations: The features used to represent the samples result in significant overlap in the feature space, failing to provide sufficient separation between the two disjoint classes. This is evident in both clustering and classification results. Clustering, using both predefined and non-predefined groups, showed that each resulting cluster contained a proportionate number of samples from both classes. Furthermore, classification demonstrated that no tested classifier achieved significant performance metrics. These results are illustrated in Figures 2 and 3. Although these results were obtained using the OLMo-1B-0724-hf tokenizer (the default for the 1B model), the observations remain consistent across other tested tokenizers: deberta-v3-large and all_Mini_LM.

- **Logits difference:** Drawing from (Ji et al., 2024), to use an assistant model which is trained to remember the forget set, whose logits when subtracted from that of the target model will result in effective unlearning of the forget set for the queries inferred upon, we experimented with the following directions. For all the experiments, a temperature of zero was set, and a scaling factor of 0.2 was used for subtracting logits.

  – **Reinitializing the weights of pretrained model, and tuning on the forget set:** An assistant model was prepared with a copy of the target model's con-

mlp.down_proj	0.07
First 12 layers	0 (freezed)

Table 6: Layer-wise perturbation configuration

figuration (1B). This model was initialized with Xavier initialization, and was trained on the forget set. As the forget set is very small with very limited samples to train a model, the assistant model resulted in generating garbage characters, sometimes, repeated words without a complete meaning. Therefore, this did not result in effective unlearning, as the assistant model could not pick up the forget set due to its small quantity. This experiment emphasizes that, in cases, the size of the forget set plays an important role to understand the information to be forgotten effectively, and availability or provision of only limited forget samples could lead to ineffective unlearning of the target model.

– **Using another domain-irrelevant language model as the assistant:** Based on the above observation, a hypothesis was formulated as – instead of using an assistant model with no prior knowledge, if it has certain level of language understanding, it might be able to pick up the forget set despite its limited quantity. Thus, fintech-chatbot-t5[5], a small domain-irrelevant model was considered for the assistant model. This model is based on T5-small architecture and was trained on the retail banking chatbot dataset[6] for only 3 epochs. We have finetuned this model on the forget dataset. However, it was observed that the logits difference did not give any meaningful output when decoded. Apparently, due to different tokenizers used by the assistant and the target models, the encoded vectors were not aligned to be subtracted.

– **Knowledge truncation in the pretrained model being used as the as-**

[5] https://huggingface.co/cuneytkaya/fintech-chatbot-t5

[6] https://huggingface.co/datasets/bitext/Bitext-retail-banking-llm-chatbot-training-dataset/

sistant: Considering the discussed results, a copy of the target model was used as the assistant model, truncating its knowledge, such that it preserves the language understanding capabilities, and other general abilities, but not the specific subject matter expertise, or any particular details. The target model has 16 layers in total, and each layer has 7 components: 4 for self-attention and 3 for feed-forward network. A brute-force approach was followed to identify the best (better) combination of layers that are required to be retained as is, and the layers that are required to be perturbed. The perturbation method followed was to add a factor of noise determined by $torch.randn\_like(param.data) * modify\_ratio$ where $param.data$ is the corresponding parametric value for a parameter in a layer, and the combination of $modify_ratio$s that worked decently are reported in Table 6. Although this experiment worked fairly based on the limited combinations tested with, the responses still required significant refinement, demanding rigorous testing.

NCLTeam at SemEval-2025 Task 10: Enhancing Multilingual, multi-class, and Multi-Label Document Classification via Contrastive Learning Augmented Cascaded UNet and Embedding based Approaches

Shu Li, George Snape, Huizhi Liang
Newcastle University
Newcastle Upon Tyne, England
{c1041562, c0022646,huizhi.liang}@newcastle.ac.uk

Abstract

The SemEval-2025 Task 10 Subtask 2 presents a multi-class multi-label text classification challenge(Piskorski et al., 2025). The task requires systems to classify documents simultaneously across three categories: Climate Change (CC), Ukraine-Russia War (URW), and Others. Several challenges were identified, including the distinct characteristics of climate change and warfare topics, category imbalance, insufficient training samples, and distributional differences across development and test sets. To address these challenges, we implemented two approaches. The first approach applies a Contrastive learning augmented Cascaded UNet model (CCU), which employs a cascaded architecture to explicitly model the label taxonomy. This model incorporates a UNet-style architecture to classify embeddings extracted by the base text encoder, with specialized pathways for different categories. We addressed data insufficiency through contrastive learning and mitigated data imbalance using an asymmetric loss function. The second approach implemented a Bi-Sequential Trees with Embeddings, Sentiment and Topics (BST-EST). In this approach, transformer encoder models were applied to extract word embeddings, then we applied classical machine learning based classifiers such as Random Forest and XGBoost. In the experiments, the CCU model achieves a higher F1 (samples) score (0.345) on the test set.

1 Introduction

SemEval-2025 Task 10 Subtask 2 introduces a multilingual, hierarchical, and multilabel document classification challenge. Our approaches integrate contrastive learning, hierarchical pathway modeling, and domain adaptation techniques to address these challenges. We also identified several data-specific issues, including insufficient training samples, significant class imbalance, and distribution shifts between development and test sets. Our methodology systematically addresses these challenges through strategic neural architecture design and feature engineering.

In the context of processing text data across multiple languages, existing research generally follows two approaches, pre-training model on massive multilingual corpora to enable cross-lingual transfer (Zhuang et al., 2021), or distilling multilingual knowledge into monolingual language models to optimize the computational efficiency(Reimers and Gurevych, 2020). In our work, we applied a pre-trained monolingual encoder model, fine-tuned with a multilingual dataset as our base encoder.

For hierarchical multi-label classification with limited samples, prior research such as the hierarchical verbalizer model employs prompt-based learning to incorporate label hierarchy knowledge into the model(Ji et al., 2023). In our approach, we explicitly defined the hierarchical data structure by organizing the dataset into topic-based sub-categories, and designing a corresponding cascaded model architecture specifically tailored to this dataset taxonomy. This architectural framework enforces a hierarchical prediction flow. Ensuring that classification results adhere to the inherent structure of the classification task. The Proposed BST-EST model utilizes the prompt templates with masked language models to leverage pre-trained knowledge for few-shot learning, dynamically capturing the label-text interaction.

To mitigate the significant differences between the CC and URW topics, we implement a Gradient Reversal Layer (GRL) for domain adaptation. The GRL adversarially aligns feature representations from different domains by reversing gradients during backpropagation. This technique encourages the feature extractor to produce domain-invariant features, enabling better knowledge transfer between the structurally similar but topically distinct CC and URW narratives.(Ganin and Lempitsky, 2015).

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 418–423

During inference, attention masks were applied to ensure the model predictions adhere to the natural hierarchy of labels, forcing classifications to respect the narrative and sub-narrative relationships in the label taxonomy. In detail, the parent category probabilities effectively act as an attention mechanism that gates the flow of information to specialized pathways. This ensures that the narrative and sub-narrative predictions are only evaluated for samples belonging to the correct parent category by the masked attention mechanism.

A gradient inverse layer was implemented to achieve domain adaption by learning domain-invariant features across CC and URW. Contrastive learning was applied to address the insufficient data (Ye et al., 2021) (Li et al., 2024). Our augmentation pipeline combines contextual word substitution and back translation to mitigate the influence of the data imbalance. During the experimentation, we observed a significant limitation in the cascaded model. When trained on both the narratives and sub-narratives classification tasks simultaneously, the model would effectively learn one task while performing poorly on the other. This phenomenon, which we identified through gradient flow visualization, appeared to be caused by gradient vanishing in one of the task pathway. By implementing asymmetric loss, we successfully addressed this problem, enabling the model to learn both tasks effectively. By combining these techniques, our approach provides a framework that achieves competitive performance for multilingual, hierarchical, multi-label text classification in low-resource scenarios.

2 Methodology

To address the multilingual, multi-class, multi-label documentation classification task, we applied a BST-EST model, and a CCU model to test the classification performance.

2.1 CCU model

Our primary approach integrates several methodological components including text data augmentation, contrastive learning, a cascaded UNet architecture, asymmetric loss functions, and an attention mask mechanism during inference.

2.1.1 Data Augmentation

Initially, to reduce the distributional discrepancies between development and test sets. We apply two

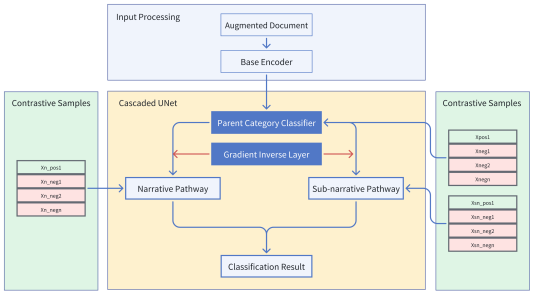

Figure 1: The CCU model architecture.

augmentation strategies, back translation and synonym replacement. These augmentation techniques expand the training corpus while maintaining label consistency. It is particularly critical for class imbalance. The dataset was split into sub-categories. The dataset was organized into a three level hierarchical structure, parent categories for 'CC', 'URW', and 'Others' at top level, followed by narratives and subnarratives were then split by topic at lower levels. The hierarchical data organization directly informed our model architecture, each pathways designed to correspond to each level of the dataset hierarchy. This design ensuring that the classification logits follow the label taxonomy.

2.1.2 Model Architecture

The hierarchical model architecture was designed to adapt the dataset taxonomy. The model leverages the pre-trained all-MiniLM-L12-v2 transformer encoder model (Wang et al., 2020), with cascaded UNet for text classification. We selected MiniLM to enable rapid experimentation which benefits from its performance and computational efficiency. We chose to adapt the UNet architecture, traditionally used for image segmentation, for hierarchical text classification because of its structural advantages. The UNet encoder-decoder design with skip connections allows information to flow across different resolution levels, which we repurpose for hierarchical label prediction. In our text classification context, the UNet cascaded structure enables feature extraction at different levels, while the skip connections facilitate information sharing between domain classification and narrative and sub-narrative pathways. This architecture efficiently models our label taxonomy through its natural hierarchical processing.

Based on the parent category classification, the model activates one of two specialized domain pathways: the CC pathway or the URW pathway. The

skip connections facilitate information sharing between the domain classification and the narrative and sub-narrative pathways, allowing later classification decisions to leverage earlier domain-specific features while maintaining hierarchical consistency. This architecture efficiently models our label taxonomy through a hierarchical pathway processing flow.

Given our limited training data and the need to learn discriminative features across multiple languages and domains, we employed contrastive learning as a data-efficient training strategy. This approach maximizes the utilization of available samples by learning from both positive and negative pairs, effectively expanding our training samples without requiring additional labeled data. The implementation of contrastive learning improves the ability of the model to learn features from limited training data. A cosine embedding loss was implemented, which maximizes similarity between positive pairs while pushing negative pairs apart in the embedding space. Each pathway defined different sample strategies based on the sub-divided datasets.

The multi-class training objective combines three components: Cross-Entropy loss was implemented to classify the three parent category. To address severe class imbalance in our hierarchical classification task, we implemented asymmetric loss. During experimentation, we observed that the model struggled to learn rare classes, leading to gradient vanishing issues. Asymmetric loss assigns different penalties to false positives and false negatives, providing stronger learning signals for underrepresented classes and stabilizing the training process. During experimentation, we observed gradient vanishing through gradient flow visualization. The asymmetry loss was implemented to classify the sub-groups of narratives and sub-narratives to handle class imbalance(Ben-Baruch et al., 2021). Contrastive learning and cosine embedding loss were implemented to adapt to the small dataset. The final loss is computed as the sum of all loss values.

During inference, parent category probabilities thresholded at 0.5 dynamically activate subcategory pathways by applying an attention mask, ensuring classification results adhere to the hierarchical labels.

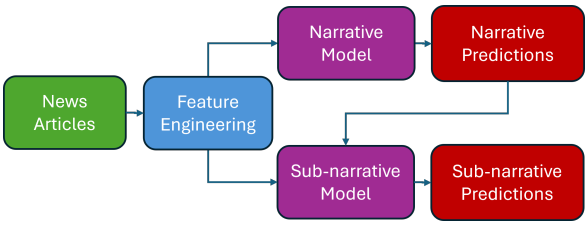

Figure 2: The BST-EST Model Architecture Diagram

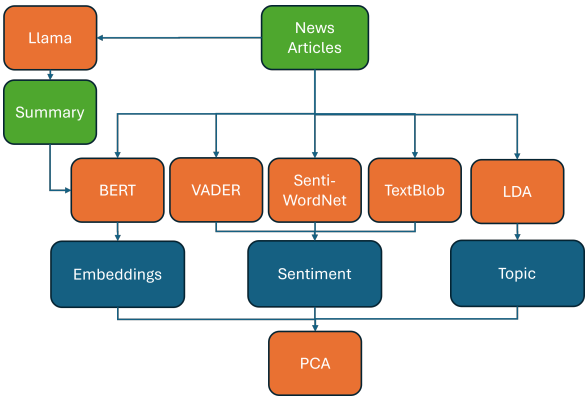

Figure 3: The BST-EST Feature Engineering pipeline

2.2 BST-EST model

In our second approach, we develop a hierarchical classification system that first transforms news articles into numerical representations using multiple feature-engineering techniques. These include BERT and ModernBERT embeddings for semantic encoding, BART-generated summaries for narrative abstraction, and complementary features from sentiment analysis (VADER, TextBlob, SentiWordNet) and LDA topic modeling. These representations are then processed by two machine learning models—ranging from logistic regression to XGBoost—with the first predicting broad narratives and the second using these predicting sub-narratives. Model selection and hyperparameter optimisation are performed systematically using Optuna's TPE sampler with k-fold cross-validation. The diagrams for the model architecture and the feature engineering process outline this visually.

Initially, the dataset needed cleaning. This included removal of newline characters and excessive whitespace to ensure that the language models could generate the most accurate inferences. To capture the rich context of the news articles and improve model performance, several advanced feature engineering techniques were applied. First, BERT embeddings were used to convert text into dense vector representations. The BERT and ModernBERT models were leveraged to generate embed-

dings by processing the input articles. Each article was tokenized and passed through the BERT model, with the embedding extracted from the special CLS token. These embeddings serve as powerful representations that capture both syntactic and semantic features of the text, allowing the models to better understand and process the articles.

Next, BART Summaries were used to extract narrative summaries from the articles. The BART model was employed to summarise each article by generating a concise version that captured the main narratives. These summaries were then passed through BERT to generate embeddings, further improving the model's ability to process the content. This step served as an abstraction layer that could help focus on the most relevant parts of the article when classifying narratives.

In addition to embeddings, several additional features were engineered using common sentiment analysis techniques and topic modeling(Liang et al., 2020). VADER Sentiment Analysis was applied to each article to generate sentiment scores(Hutto and Gilbert, 2014), including negative, neutral, positive and compound scores. This feature helped capture the overall emotional tone of the articles. TextBlob was also used to assess sentiment polarity and subjectivity, offering complementary information on the emotional stance and subjective nature of the text. Furthermore, SentiWordNet(Esuli et al.), a lexical resource for sentiment analysis, was employed to calculate the positive and negative sentiment scores based on word-level analysis. For further context, Latent Dirichlet Allocation (LDA) was also applied as a topic modeling technique(Blei et al., 2003). LDA helped extract the latent topics present in the articles by using a count vectorizer to convert the text into a bag-of-words format. This was followed by LDA to assign a distribution of topics to each article, which could be useful for understanding the broader themes or issues being discussed. The sentiment scores from Valence Aware Dictionary and sEntiment Reasoner (VADER) and TextBlob, as well as the topic distributions from LDA, were concatenated with the BERT embeddings to form a single feature vector for each article.

Optuna's Tree-structured Parzen Estimator (TPE) was used for the optimisation of Macro F1 for both models (Watanabe, 2023). The optimisation process incorporated k-fold cross-validation to ensure generalisability across datasets. it involved hyperparameter-tuning for a range of machine learning models, from simpler approaches such as logistics regression, decision trees and SVC to more advanced ensembles like Random For, GBM, XGBoost and LightGBM. This then saw exploring a wider range of the successful architectures. In addition to hyperparamter-tuning, the process also evaluated different which of the embeddings methods were best, the number of principal components and simultaneously with the hyperparameters. With the relatively small data sample, this was possible.

3 Experiment

The training set consists of 1699 samples distributed across five languages (English, Russian, Hindi, Portuguese, and Bulgarian). The taxonomy was designed to analyze and compare propaganda narratives in two conflict domains: the Russia-Ukraine war and climate change. Both categories employ similar broadcasting techniques that attempt to redirect responsibility, challenge opposing credibility, heighten concerns about negative outcomes, and divert attention. These approaches tend to polarize audiences and support specific political positions.

We further split the dataset into subsets based on hierarchical relationships, with narratives and sub-narratives grouped by their main topic (CC or URW). This organization forced the model to learn classification patterns that respect the category hierarchies. All language materials were combined into a unified multilingual dataset.

3.1 Evaluation Metric

The text classification task was evaluated using the F1-samples metric, which computes the F1 score averaged across all narrative and sub-narrative labels for each document, with systems ranked on the leaderboard based on this metric.

3.2 Experiment Setup

We implemented our methodology on NVIDIA A4000 and NVIDIA RTX3090 GPUs, using CUDA 12.4 and PyTorch 2.5.0. Our preprocessing pipeline included label binarization to convert labels into binary vectors, while preserving hierarchical relationships through manual subdivision of the dataset. The dataset contains samples in all languages, but inference was only performed on the English test set. For CCU model, we applied class weighting

Table 1: Text classification results on the test set.

Model	F1 Macro (Coarse)	F1 St. Dev. (Coarse)	F1 (Samples)	F1 St. Dev. (Samples)
CCU	0.486	0.363	0.345	0.360
BST-EST	0.354	0.440	0.311	0.437

to address label imbalance using inverse frequency weighting.

We experimented with several base models including BERT, ModernBERT, and all-MiniLM-L12-v2(Devlin et al., 2019)(Warner et al., 2024)(Wang et al., 2020). The document embeddings produced by the encoder were used for parent category classification (CC, URW, or Other) and then routed to specialized domain pathways. For domain adaptation, we implemented a GRL that adversarially aligns embeddings from different topics by reversing the gradient direction during backpropagation.

The pathways were designed to make narrative and sub-narrative classification to form up an end-to-end deep learning approach to handle the complexity of different levels of label granularity.

The training process applied the AdamW optimizer, with linear warmup in 10 percent steps followed by cosine decay, a batch size of 32 with gradient accumulation over 4 steps. Regularization methods applied including dropout (at p=0.1) in all dense layers, mixup interpolation(a=0.4 beta distribution), and gradient clipping(max norm=1.0).

For the BST-EST model, the base models included Logistic Regression, SVC, Decision Tree, Random Forest, GBM, XGBoost, LightGBM and ExtraTrees. Among these, ExtraTrees outperformed the others across evaluation metrics. Semantic meaning was captured through the use of embeddings produced by one of ModernBERT or BERT, using VADER, TextBlob, SentiWordNet for sentiment representation features along with LDA for topic based features.

Hyperparameter optimization was performed using a Tree-structured Parzen Estimator (TPE) method from Optuna, with a focus on the most important hyperparameters for each model architecture. Regularisation parameters were explored to control complexity and prevent over-fitting and for ensemble-based tree models, the number of estimators explored were limited to prevent over-fitting, given the small dataset. A range of other key hyperparameters, including those specific to each algorithm, were also searched to optimise model performance, focusing on a wider range for the better performing models. Model evaluation was also performed using a range of k (k=5, 6, ..., 10) for k-fold cross-validation.

4 Discussion

In this SemEval-2025 Task 10 Subtask 2, we successfully implemented our approaches and achieved 6th place. We proposed two methods to solve this multi-label multi-class multilingual text classification task. The CCU model, which integrates a pre-trained language model with a UNet cascaded classifier, hierarchical dataset organization, gradient reversal for domain adaptation, asymmetric loss, and contrastive learning. The BST-EST method using pre-trained transformer encoder model, to extract embeddings, also the sentiment message was added to the embeddings then classified with machine learning classifiers.

Furthermore, limitations still remain unsolved. For the CCU model, labels are represented using one-hot encoding rather than semantic text embeddings, which results in the loss of inherent label meaning.

5 Conclusion

This article presents an integrated implementation of existing solutions for multi-class, multi-label text classification to address SemEval-2025 Task 10 Subtask 2. Our team developed two distinct approaches to enhance classification performance. One built upon a cascaded UNet model with contrastive learning, and another leveraged multiple NLP feature extraction methods combined with machine learning classification techniques. Our efforts resulted in achieving 6th place with the main metric F1 sample of 0.345.

The CCU model addressed the challenges identified during experimentation. We mitigated data imbalance through augmentation process, while contrastive learning techniques helped overcome data insufficiency. The cascaded model architecture, with specialized pathways, was designed to tackle the complexities of multi-class learning across dif-

ferent label granularities. These solutions contributed to performance improvements.

Finally, the result remains below the optimal level for a reasonable classification. Furthermore, the integration of existing research offers limited novelty in the research field. Additionally, the pathway learning issue we identified, where the model would learn one pathway at the expense of another, suggests opportunities for developing more balanced training techniques for hierarchical classification models.

Abstract

This paper describes our system for Subtask 2 of SemEval-2025 Task 10: Hierarchical Narrative Classification. We propose a two-step hierarchical approach that combines generative reasoning and fine-tuning for sub-narrative classification. The main techniques of our system are: 1) leveraging a large pre-trained model to generate a reasoning process for better context understanding, 2) fine-tuning the model for precise sub-narrative categorization, 3) using a multi-label classification strategy for more accurate sub-narrative identification, and 4) incorporating data augmentation to increase the diversity and robustness of the training data. Our system ranked 1st in Subtask 2 for Hindi, achieving an F1 macro coarse score of 0.56900 and an F1 samples score of 0.53500. The results demonstrate the effectiveness of our approach in classifying narratives and sub-narratives in a multilingual setting, with the additional benefit of enhanced model performance through data augmentation.

1 Introduction

The rapid growth of online news content and the ongoing spread of disinformation have made it increasingly important to develop tools that can identify and categorize the underlying narratives shaping public discourse (Xu et al., 2022). To address this, we participated in Subtask 2 of SemEval-2025 Task 10, which focuses on hierarchical narrative classification of multilingual news articles. The goal is to assign both high-level (coarse) and fine-grained (sub-narrative) labels to each document based on a predefined two-level taxonomy.

To achieve this, we developed a novel hybrid approach that strategically combines the reasoning capabilities (Yu et al., 2024) of large language models (LLMs) with the fine-grained classification power of fine-tuned models. First, we leveraged GPT-4o's (Schnabel et al., 2025)API to generate a structured reasoning process (or thought process) for each article. This involved prompting the LLM to interpret the text, and identify potential narrative themes before any classification attempt. Then, rather than directly feeding the GPT-4o outputs into a classifier, we used the generated reasoning as input for further fine-tuning. We fine-tuned the smaller and more efficient GEMMA2-9B (Team et al., 2024) model on the reasoning-enriched data, this allowed GEMMA2-9B to focus on the nuanced task of categorizing sub-narratives more efficiently. Moreover, to address the inherent challenges of multi-lingual analysis and to ensure the robustness of our model across the task's five languages (Bulgarian, English, Hindi, (European) Portuguese, and Russian), we implemented a comprehensive data augmentation strategy (Bayer et al., 2022). This involved techniques designed to increase the diversity of training data, including back-translation and synonym replacement (Madukwe et al., 2022). Various multi-label classification approaches and fine-tuning paradigms were explored to optimize the performance for sub-narrative classification.

2 Background

2.1 Dataset Description

The dataset used in this task spans two major domains: the Ukraine-Russia War and Climate Change. It is designed to evaluate hierarchical narrative classification across five languages: Bulgarian, English, Hindi, Portuguese, and Russian. Both the training and test datasets are provided as plain text files, each article accompanied by hierarchical labels. The training set contains a total of 1699 articles, although a small number were omitted due to inaccessible source URLs. The test set comprises 460 articles, and evaluation is conducted exclusively on sub-narrative (fine-grained) predictions.

[†] Both authors contributed equally to this work.

A summary of dataset statistics is presented in Table 1.

Language	Training Articles	Test Articles
Bulgarian	401	100
English	399	101
Hindi	366	99
Portuguese	400	100
Russian	133	60
Total	**1699**	**460**

Table 1: Dataset Distribution Across Languages

2.2 Task Description

This work focuses on **Subtask 2: Narrative Classification**, which involves automatically assigning news articles to a two-level taxonomy of narrative labels (Piskorski et al., 2025). The taxonomy is domain-specific, covering the Ukraine-Russia War and Climate Change.

The first level (Level 1) contains broad **main narratives**, while the second level (Level 2) captures more fine-grained **sub-narratives** that elaborate on and support the main ones.

Subtask 2 is framed as a multi-label, multi-class classification task. Each article may be associated with multiple main narratives and multiple sub-narratives, requiring systems to output a set of labels at both levels for each instance. This setup tests a model's ability to recognize layered narrative structures and conceptual relationships across levels of abstraction.

If an article does not match any of the predefined narrative or sub-narrative categories, an "Other" pseudo-label is assigned.

Participants are required to submit two separate lists per article: one for predicted main narratives and another for predicted sub-narratives. Notably, the task does not enforce consistency between the predicted narratives and sub-narratives (i.e., sub-narratives may not need to align hierarchically with predicted main narratives).

3 System Overview

In this section, we detail the methodology developed for SemEval-2025 Task 10, Subtask 2 — a multi-label, multi-class classification task centered on the hierarchical narrative classification of news articles.

Our system adopts a hybrid framework that integrates **generative reasoning** with **fine-tuned classification**. Specifically, we leverage **GPT-4o** to generate structured reasoning chains, which are then used to enrich the input for a smaller, efficient model — **GEMMA2-9B** — responsible for sub-narrative prediction.

The overall architecture of our system is illustrated in Figure 1. To further enhance performance and robustness, we incorporate comprehensive data preprocessing, augmentation, and multilingual adaptation techniques, addressing the diverse challenges posed by the dataset.

3.1 Data Augmentation

To enhance the diversity and robustness of the training data, we applied two data augmentation techniques:

Back-Translation:

- We used the Google Translate API for back-translation. Each article in the training set, across all five languages, was translated into English and then back into its original language.
- Semantic similarity was maintained using cosine similarity scores from pre-trained language-specific embeddings (e.g., fastText for Hindi), with a threshold of 0.85 to ensure content fidelity.

Synonym Replacement (Hindi-Specific):

- Hindi WordNet (Yadav et al., 2024) was used to replace key terms with synonyms, focusing on narrative-relevant words.
- The replacement was constrained to preserve grammatical coherence, and manual verification was performed on a small subset.

We generated two augmented examples per original article (across all languages for back-translation, and for Hindi only for synonym replacement), resulting in approximately 1500 augmented Hindi articles added to the training set.

3.2 Reasoning Generation

In this paper, we introduce the GPT-4o model to generate reasoning chains to improve the accuracy and interpretability of label prediction in text categorization tasks.

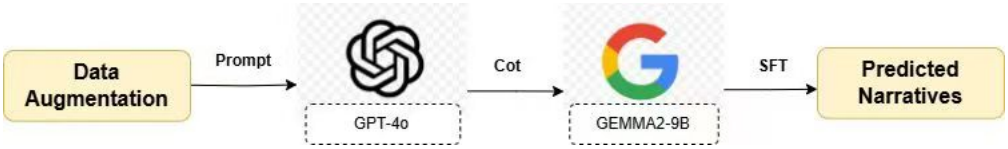

Figure 1: The overall framework of our system proposed for SemEval-2025 Task 10-Subtask2.

During the reasoning chain generation process, based on the prompt we set, GPT-4o derives the logical relationships between the relevant labels and the text. It analyzes the content of the input text to help the model understand how to infer the correct primary label and its associated secondary labels. In brief, the process for generating the text T_R with the reasoning chain explanation is:

$$T_R = \text{GPT-4o}(T_D, y, \text{prompt})$$

where T_D is the result of the original data T after data augmentation, y represents the label of the data, and the prompt is specifically designed to guide GPT-4o's thought process.

The final data T_F, used in supervised fine-tuning, is obtained as:

$$T_F = T_D \oplus T_R$$

3.3 Fine-tuning and Classification

3.3.1 Multi-language embedding

We use the GEMMA2-9B model for fine-tuning in Subtask 2. GEMMA2-9B is a multilingual model based on the Transformer architecture (Vaswani et al., 2017), with strong capabilities for cross-lingual understanding. For the k-th input multilingual text T_F^k, we first apply a dynamic disambiguation process using the SentencePiece tokenizer (Kudo and Richardson, 2018), which segments the text into subword units. These tokens are then mapped into vector representations using a shared embedding table $E \in \mathbb{R}^{|V| \times d}$, where $|V| = 256\text{k}$ is the vocabulary size and $d = 3072$ is the embedding dimension:

$$e_i = E(t_i^k)$$

where t_i^k is the i-th token of the k-th text.

Since GEMMA2-9B has been pre-trained using both Masked Language Modeling (MLM) and Translation Language Modeling (TLM), it is capable of capturing general cross-lingual representations and can effectively process input texts across multiple languages.

3.3.2 Loss Function

The set of tags corresponding to each text is: $\{(L_1, \{S_1^{(1)}, S_1^{(2)}, \dots\}), (L_2, \{S_2^{(1)}, \dots\}), \dots\}$, where L_i denotes the i-th main label, and $\{S_i^{(1)}, S_i^{(2)}, \dots\}$ are the corresponding sub-labels associated with L_i. Given a dataset of N training samples, we define the binary cross-entropy loss for the main label predictions as:

$$L_{main} = -\sum_{i=1}^{m}\sum_{c=1}^{C}\left[L_{BCE}(L_i^c, \hat{L}_i^c)\right]$$

where C is the total number of main label classes, $\hat{L}_i^c$ is the predicted probability for class c in the i-th sample, and $L_i^c \in \{0, 1\}$ is the corresponding ground-truth indicator.

For each sub-label of the text we then have:

$$L_{sub} = -\sum_{i=1}^{m}\sum_{q=1}^{Q}\left[L_{BCE}(S_i^q, \hat{S}_i^q)\right]$$

where Q is the number of possible sub-label classes, and $\hat{S}_i^q$ is the predicted probability for sub-label q of the i-th sample.

The total loss combines the two components with a trade-off parameter $\alpha \in [0, 1]$:

$$L_{\text{total}} = \frac{1}{N}\sum_{i=1}^{N}(\alpha L_{\text{main}}(i) + (1-\alpha)L_{\text{sub}}(i))$$

3.4 Post-processing

To mitigate the issue of over-confidence in certain predictions—which may lead the model to under-predict relevant category labels—we apply *temperature scaling* (Kull et al., 2019) to calibrate the output probabilities. This technique softens the probability distribution, making it smoother and less prone to sharp peaks.

Given the unnormalized logits z_i for each category, the calibrated probability distribution P_i' is computed as:

$$P_i' = \frac{\exp\left(\frac{z_i}{T}\right)}{\sum_j \exp\left(\frac{z_j}{T}\right)}$$

where T is the temperature coefficient, z_i is the unnormalized output logits of the model, and P_i' is the probability after temperature smoothing. By increasing the T, the probabilities of the categories can be made more balanced, avoiding over-biasing of the model towards a particular category.

4 Experimental Setup

4.1 Dataset Split

In the experiments of this paper, both the original training set and the training set that has been processed by data augmentation (DA) and incorporated into the thinking process were randomly sampled and divided into 10 non-overlapping subsets. In each cross-validation process, a different subset of the dataset was rotated as the validation set and the remaining subset as the training set. A 10-fold cross-validation was used in all experiments to ensure that the adopted strategy would show good generalization ability on the final test set. The experimental results presented are the average of the 10-fold cross-validation (Browne, 2000), thus maximizing the ability to assess the stability and performance of the model.

4.2 Pre-processing

In the experiments in this paper, we used our own Python script to process the news texts provided by the task organizer, which were initially stored in separate txt files according to their respective languages, and also contained their corresponding English classification labels, and were eventually processed and stored in CSV format. Subsequently, we performed data cleaning to remove some unreasonable data. Finally, for data enhancement, we expanded the dataset with low-resource languages mainly through translation in order to increase the diversity and quantity of data.

4.3 Evaluation Metrics

The evaluation metric for Task 10 is the F1 score, specifically focusing on the **F1 macro coarse** score of the sub-labels. The **F1 macro coarse** score is an effective measure of the model's performance, averaging the F1 scores of each label without considering label frequency. It ranges from 0 to 1, where higher values indicate better classification performance. **In the following table, all F1 scores refer to the F1 macro coarse metric.**

System &F1 score	En	Po	Ru	Bu	Hi
w/ data augmentation					
Baseline	27.2	9.7	17.1	14.9	16.7
+ DA	29.0	9.9	17.0	15.2	52.1
w/o data augmentation					
Baseline	29.0	9.9	17.0	15.2	52.1
+ RG	**30.4**	**10.4**	**17.6**	**15.9**	53.4
+ ML	30.0	10.1	18.1	15.1	**53.7**
+ TS	29.2	10.0	17.3	15.2	52.9
+ All	31.0	10.7	18.5	17.2	56.9

Table 2: Average results with training methods we used. And RG is Reasoning Generation, ML is Multi-label Loss, TS is Temperature Scaling, DA is Data Augmentation

5 Results

5.1 Overall Performance

Finally, according to the official scoring system, our system achieved the first place in the evaluation set for Hindi, and 23, 13, 13, and 11 for English, Russian, Portuguese, and Bulgarian, respectively, and for the sake of presentation, all experimental results are multiplied by 100.

5.2 Data Augmentation

In order to evaluate the effect of data augmentation (DA), we conducted experiments on the original training set and the training set augmented by DA, respectively. We can clearly see the improvement of the model performance by data enhancement in Table 2. The experimental results show that the performance of the system improves significantly after using the augmented dataset. Especially with the effect on Hindi, it can be said that our use of translation expansion as well as synonym substitution using hindwordnet greatly improves the training efficiency for low-resource languages, and therefore, we can conclude that richer training sets definitely help in building more robust models.

5.3 Reasoning Generation

In this paper, we make GPT generate text-to-label thinking reasoning text through the form of prompt. In the Table 2, it can be clearly seen that the F1 score improves after adding the reasoning generation. The results show that besides data augmentation, reasoning generation is the biggest way to improve model performance. Especially in com-

Overall Weight	Hindi F1
0%	51.4
30%	**56.9**
50%	50.9
75%	47.8
100%	37.9

Table 3: Results on training with multi-label loss.

plex multi-label secondary classification tasks, this approach allows the model to analyze the relationship between data and labels at a deeper level.

5.4 Multi-label Loss

As mentioned earlier, we adopted the standard binary cross-entropy loss for both main and sub-labels during training. We experimented with different values of the weighting parameter α to balance their contributions. As shown in Table 3, the best performance was achieved when α was set to 0.3. This indicates that sub-narratives play a more significant role in our system's classification performance.

5.5 Temperature Scaling

For the model trained with data augmentation and reasoning generation, we conducted ablation experiments to assess the effectiveness of the temperature scaling technique. As shown in Table 2, applying temperature scaling led to slight performance improvements, indicating that this method has a positive impact on the classification task by mitigating overconfident predictions.

5.6 Negative Results

In addition to the aforementioned strategies, we also experimented with multi-task learning (Zhang and Yang, 2021) on low-resource languages. For example, in an attempt to reduce the semantic distance between Hindi and English, we incorporated a translation task into a multi-task learning framework. However, contrary to our expectations, this approach resulted in a performance drop. We speculate that this may be due to the significant difference between the output format of the narrative classification task and that of the translation task, which could have caused a conflict in the learning objectives.

6 Conclusion

By leveraging a series of optimization techniques—including data augmentation, reasoning generation, multi-label loss design, and post-processing—we developed a robust framework capable of performing multi-label level-2 classification of news texts in a multilingual and cross-linguistic setting. Our system achieved first place on the low-resource language Hindi, along with competitive results across other languages.

In future work, beyond further enriching the training data, we aim to explore language-specific structural features inherent to different language families (e.g., Hindi), and to incorporate novel methods and architectures to further enhance model performance, particularly for low-resource languages.

A Appendix

Table 4 shows the prompt we used to generate the reasoning chain.

Prompt for Reasoning Chain Generation
Instruction: You are given a news article in any language, along with its corresponding main narrative label(s) and sub-narrative label(s). Your task is to write a concise and clear explanation in English that logically connects the article's content with the given labels. Please identify key themes, arguments, or facts in the article that support each main narrative and its related sub-narratives. Please keep your explanation within 100 words.
Input - Article (original language): ARTICLE_TEXT
Input - Narrative Structure: - Main_Label_1: [Sub_Label_1a, Sub_Label_1b, ...] - Main_Label_2: [Sub_Label_2a, Sub_Label_2b, ...]
Output - Reasoning Chain (in English): Explanation_Text

Table 4: Prompt format for generating reasoning chains with GPT-4o

Lotus at SemEval-2025 Task 11: RoBERTa with LLaMA-3 Generated Explanations for Multi-Label Emotion Classification

Abstract

This paper presents a novel approach for multi-label emotion detection, where LLaMA-3 is used to generate explanatory content that clarifies ambiguous emotional expressions, thereby enhancing RoBERTa's emotion classification performance. By incorporating explanatory context, our method improves F1-scores, particularly for emotions like fear, joy, and sadness, and outperforms text-only models. The addition of explanatory content helps resolve ambiguity, addresses challenges like overlapping emotional cues, and enhances multi-label classification, marking a significant advancement in emotion detection tasks.

1 Introduction

Emotion classification plays a crucial role in natural language processing (NLP) for applications like sentiment analysis and emotion-aware dialogue systems (Mohammad and Kiritchenko, 2018). The challenge lies in accurately identifying emotions from text, which are often subtle, multi-faceted, and context-dependent. Furthermore, emotions can be expressed simultaneously, making multi-label classification essential (Belay et al., 2025).

Despite advancements, emotion classification remains complex due to ambiguous emotional expressions and diverse contexts. Early keyword-based methods struggled with generalizing across languages and expressions (Wiebe et al., 2005), and even modern transformer models face challenges with short or under-explained sentences, particularly in multi-label tasks (Kusal et al., 2022; Mohammad and Kiritchenko, 2018).

To address these challenges, we propose a novel approach using Large Language Models (LLMs) to generate explanatory content, enhancing the understanding of ambiguous emotions. We fine-tuned a LLaMA-3 model to generate context-rich explanations for each sentence, improving emotion classification, especially for multi-label settings. The explanatory context significantly boosts performance, as shown in prior work on LLMs and commonsense reasoning (Yang et al., 2023; Xenos et al., 2024). The generated explanations were used with the original text to fine-tune RoBERTa (Liu et al., 2019) for multi-label emotion classification, enabling simultaneous emotion prediction.

We participated in SemEval 2025 Task 11, Subtask 1 (Muhammad et al., 2025b), which focuses on multi-label emotion detection across multiple languages, including English. The dataset consists of social media text annotated by 122 annotators, with multi-label annotations for five emotions: anger, fear, joy, sadness, and surprise. The training set has 2,768 samples, the development set has 116, and the test set includes 2,767 samples, all with binary labels indicating the presence or absence of each emotion. Our system, evaluated on English data, demonstrates that adding explanatory content significantly enhances model performance. Specifically, the Text + Explanation model achieved a Macro F1 score of 0.7396 with a standard deviation of 0.0016 over four runs, outperforming the Text-only model, which had a Macro F1 score of 0.7112 with a standard deviation of 0.0095 over four runs. This shows that explanatory context improves classification accuracy across different classes.

The BRIGHTER dataset (Muhammad et al., 2025a), which addresses the lack of high-quality emotion datasets, serves as the primary resource for this task. It provides labeled data in 28 languages and supports tackling challenges in emotion classification, such as ambiguous or complex emotional expressions.

The code and data used in this study are available for reproducibility[1].

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 431–439

Emotion	Training Data	Development Data	Test Data
Anger	333	16	322
Fear	1611	63	1544
Joy	674	31	670
Sadness	878	35	881
Surprise	839	31	799
Total	**2768**	**116**	**2767**

Table 1: Class Distribution in Training, Development, and Test Data

2 Background

This section provides an overview of the emotion detection task, dataset, and related works, focusing on the use of large language models (LLMs) and contextual information for improving emotion classification.

2.1 Task and Dataset Details

We propose using Large Language Models (LLMs), specifically LLaMA-3, to generate explanations for ambiguous emotional expressions, which are then used to fine-tune RoBERTa for emotion classification. Our results show that the inclusion of explanatory context improves performance compared to using text alone. The emotion distribution across the datasets, shown in Table 1, illustrates the challenges of handling imbalanced classes in multi-label emotion detection.

2.2 Related Works

Recent advancements in emotion recognition have been driven by the use of Large Language Models (LLMs), particularly transformer-based architectures like RoBERTa. demonstrated that fine-tuning pre-trained models significantly improves emotion detection compared to traditional keyword-based methods, which often struggle to generalize across languages and diverse emotional expressions. Transformer models, including RoBERTa, have been successfully applied to fine-grained emotion classification tasks, as shown by Demszky et al. (2020) on the GoEmotions dataset, excelling in multi-label classification.

Efforts to further enhance LLMs for emotion detection have included integrating additional context or knowledge during fine-tuning. For example, Suresh and Ong (2021) proposed augmenting transformers with knowledge-embedded attention mechanisms using emotion lexicons, which improved the recognition of nuanced emotional expressions. Similarly, Xenos et al. (2024) showed that incorporating common-sense reasoning significantly enhances performance, particularly in multi-label contexts.

Specialized models like EmoLLMs, fine-tuned with multi-task affective analysis datasets, have also demonstrated promise in improving emotion detection across a range of domains (Liu et al., 2024). Additionally, DialogueLLM, fine-tuned with emotional dialogues, has improved emotion recognition in conversational contexts, where emotional expression varies depending on the interaction flow (Zhang et al., 2024).

Our work builds upon these approaches by leveraging LLaMA-3 to generate explanatory content that clarifies ambiguous emotional expressions, followed by fine-tuning RoBERTa for multi-label emotion classification. By incorporating explanatory context, we enhance the model's ability to capture complex emotional nuances, aligning with previous findings that emphasize the importance of context in emotion classification.

3 System Overview

The task of multi-label emotion detection in text is inherently complex, especially when emotions are expressed simultaneously in a single sentence. To address this, our system employs a two-phase pipeline: first, generating explanatory content to enhance the understanding of ambiguous emotional expressions, followed by fine-tuning a RoBERTa model for multi-label classification.

3.1 Phase 1: Explanation Generation with LLaMA-3

The first stage of our system employs LLaMA-3, a 7B-parameter language model fine-tuned to generate contextual explanations for text. We chose LLaMA-3 over alternatives like EmoLLMs and DialogueLLM due to its superior ability to produce coherent, general-purpose explanations without explicitly stating emotions—making it well-suited for disambiguating subtle or overlapping emotional cues in multi-label classification.

To prepare for fine-tuning, we randomly selected 150 sentences from the training data. GPT-4 gen-

erated explanations for these sentences using the following prompt:

"Read the given text and generate a short explanation of the emotional or situational context behind the sentence. The explanation should be concise and relevant to the sentence. Do not explicitly mention emotions but focus on the implications behind the sentence."

We then fine-tuned LLaMA-3 using these sentence–explanation pairs to ensure it could consistently produce high-quality, emotionally informative content. The resulting explanations were appended to the original inputs, enriching the dataset used to train RoBERTa for final classification.

3.2 Phase 2: RoBERTa Fine-Tuning for Multi-Label Emotion Classification

In the second stage, we utilized the RoBERTa model, a transformer-based architecture known for its high performance in text classification tasks. RoBERTa was fine-tuned on the training data enriched with the explanations generated by LLaMA-3. During this fine-tuning, both the original text and the generated explanations were concatenated with a space between them and then fed into RoBERTa. This approach allowed the model to learn the intricate relationships between emotions and their contextual expressions in the text.

RoBERTa was fine-tuned with binary labels (0 or 1) for each emotion in the dataset: anger, fear, joy, sadness, and surprise. These binary labels indicate the presence (1) or absence (0) of each emotion. The task is a multi-label classification, meaning multiple emotions can be predicted for a given text. This was crucial for handling complex emotional expressions where more than one emotion could be conveyed simultaneously.

3.3 Challenges and Solutions

Our system addressed three main challenges:

- **Ambiguous Emotional Expressions:** Emotion detection is challenging due to the subtle and complex nature of emotions in text. To resolve ambiguity, we used LLaMA-3 to generate additional explanatory context, providing the model with clearer, more explicit information that aids in correctly interpreting emotions, especially when they are not overtly expressed.

- **Multi-label Classification:** Emotions often overlap in natural language, and multiple emotions can be expressed simultaneously. Our system's multi-label classification approach enables it to predict multiple emotions for each input sentence, which is crucial for capturing real-world emotional expressions. This multi-label classification is essential for addressing the intricate and overlapping emotional cues that occur in natural language.

- **Imbalanced Dataset:** Emotion detection tasks often face class imbalance, where some emotions are more prevalent than others. While our system did not explicitly address this issue through over-sampling or under-sampling techniques, the explanatory context generated by LLaMA-3 helped mitigate this imbalance. By providing richer, more contextually informed inputs, LLaMA-3's explanations offered a way to enhance the recognition of less frequent emotions. This context made the model more sensitive to underrepresented emotions by providing additional clarifying information that could compensate for their lesser frequency in the dataset.

3.4 Code and Resources Used

The code for fine-tuning LLaMA-3 is available in the Unslothai GitHub repository. This repository contains the necessary scripts for fine-tuning LLaMA-3.

4 Experimental Setup

We evaluated our multi-label emotion detection approach by fine-tuning RoBERTa with explanatory content generated by LLaMA-3 on the BRIGHTER dataset.

Text preprocessing and tokenization were performed with the `RobertaTokenizer` from Hugging Face. In the first phase, LLaMA-3 generated explanations, which were concatenated with the original text. In the second phase, both the original text and the generated explanations were tokenized together, allowing the model to learn the emotional context.

For fine-tuning LLaMA-3, we used 4-bit quantization and LoRA, with a batch size of 2, gradient accumulation steps of 4, and a learning rate of 1×10^{-4} for 30 training steps. These explanations were then used in the second phase for emotion classification. RoBERTa was fine-tuned with binary emotion labels (0 or 1) for each emotion in the dataset, using a batch size of 8, a learn-

Method	Macro			Micro		
	Precision	Recall	F1	Precision	Recall	F1
Text + Exp (LLaMA-3) + RoBERTa	0.7421 ± 0.0047	**0.7433 ± 0.0011**	0.7396 ± 0.0016	0.7550 ± 0.0026	**0.7809 ± 0.0027**	0.7678 ± 0.0026
Text Only (RoBERTa)	0.7477 ± 0.0150	0.6831 ± 0.0216	0.7112 ± 0.0095	0.7650 ± 0.0201	0.7372 ± 0.0195	0.7412 ± 0.0209
Text Only (LLaMA-3)	0.7136	0.6563	0.6739	0.7145	0.7175	0.7160
Text + Exp (Mistral) + RoBERTa	**0.7719 ± 0.0051**	0.7206 ± 0.0135	**0.7436 ± 0.0068**	**0.7889 ± 0.0028**	0.7608 ± 0.0083	**0.7746 ± 0.0037**

Table 2: Overall performance comparison across different models.

ing rate of 5×10^{-5}, and 3 epochs. The model performance was evaluated using precision, recall, and F1-scores, including both Macro and Micro F1-scores to assess multi-label classification. Despite only 30 training steps, this light fine-tuning produced explanations that notably improved RoBERTa's downstream performance. All experiments were conducted on Kaggle's GPU resources, which provided the computational power for efficient fine-tuning.

5 Results

In this section, we present the performance of our system, Lotus, on the competition task. Using the Text + Explanation (RoBERTa) method, Lotus achieved a score of 0.7319, outperforming the SemEval Baseline (0.7083), but falling short of the top score of 0.823. Ranked 36th, Lotus performed competitively, although there is still room for improvement to reach the top positions.

5.1 Overall Performance Comparison Across Models

Table 2 provides a summary of the overall performance of Lotus across four methods:

Text + Explanation (LLaMA-3) + RoBERTa: In this approach, LLaMA-3 generates explanations, and these explanations are combined with the original text to fine-tune RoBERTa for emotion classification.

Text Only (RoBERTa): This model uses only the text (without any explanations) to fine-tune RoBERTa.

Text Only (LLaMA-3): This model fine-tunes LLaMA-3 directly with text for emotion classification.

Text + Explanation (Mistral) + RoBERTa: In this method, Mistral generates explanations, which are combined with the original text and used to fine-tune RoBERTa.

Among these methods, Text + Explanation (LLaMA-3) + RoBERTa achieved the best overall performance, with Macro F1 (0.7396) and Micro F1 (0.7678). This approach outperformed the other methods in both recall and F1-score, demonstrating the value of combining LLaMA-3's generative explanations with RoBERTa's emotion detection capabilities.

Text Only (RoBERTa) achieved the highest Macro Precision (0.7477) and Micro Precision (0.7650), indicating better selectivity in its predictions. However, it lagged behind in recall and F1-scores, particularly when compared to Text + Explanation (LLaMA-3) + RoBERTa.

Text Only (LLaMA-3) performed the weakest overall, especially in recall and F1-scores. This highlights the limitations of fine-tuning LLaMA-3 directly with text without the added benefit of explanations.

Text + Explanation (Mistral) + RoBERTa showed performance similar to Text + Explanation (LLaMA-3) + RoBERTa, with slight improvements in recall and F1-score. However, the difference between Mistral and LLaMA-3 was minimal and may not be significant, suggesting that both models can perform similarly when combined with RoBERTa for fine-tuning.

5.2 Performance Comparison for Individual Emotions

Table 3 compares performance across individual emotions, showing precision, recall, and F1-scores for each method.

Anger: Text + Explanation (LLaMA-3) + RoBERTa achieved precision (0.6695), recall (0.6304), and F1-score (0.6479). Text Only (RoBERTa) had the highest precision (0.6892), but lower recall (0.5116) and F1-score (0.5871). Text + Explanation (Mistral) + RoBERTa performed similarly to LLaMA-3, with precision (0.7196), recall (0.6056), and F1-score (0.6577).

Fear: Text + Explanation (LLaMA-3) + RoBERTa achieved the highest recall (0.8739) and F1-score (0.8343), outperforming Text Only (RoBERTa), which had lower recall (0.3200) and F1 (0.5149). Text + Explanation (Mistral) + RoBERTa showed slight improvements in recall (0.8601) and F1-score (0.8416), but the difference with LLaMA-3 was marginal.

Joy: Text + Explanation (LLaMA-3) +

Emotion	Text + Exp (LLaMA-3) + RoBERTa			Text Only (RoBERTa)			Text Only (LLaMA-3)			Text + Exp (Mistral) + RoBERTa		
	Prec.	Rec.	F1	Prec.	Rec.	F1	Prec.	Rec.	F1	Prec.	Rec.	F1
Anger	0.6695	**0.6304**	0.6479	0.6892	0.5116	0.5871	**0.7337**	0.4193	0.5336	0.7196	0.6056	**0.6577**
Fear	0.7983	**0.8739**	0.8343	0.8009	0.8200	0.8149	0.7658	0.8387	0.8006	**0.8238**	0.8601	**0.8416**
Joy	0.7957	0.7291	0.7581	0.7587	0.6925	0.7232	**0.7971**	0.6567	0.7201	0.7687	**0.7687**	**0.7687**
Sadness	0.6831	**0.8127**	0.7423	0.7636	0.6935	0.7268	0.6624	0.7662	0.7105	**0.7743**	0.7321	**0.7526**
Surprise	**0.7625**	0.6702	**0.7132**	0.7248	**0.6877**	0.7039	0.6091	0.6008	0.6049	0.7378	0.6834	0.7096

Table 3: Performance comparison of individual emotions across models with highlighted maximum results.

RoBERTa led in recall (0.7291) and F1-score (0.7581), while Text Only (LLaMA-3) excelled in precision (0.7971). Despite LLaMA-3's higher precision, it had lower recall (0.6567) and F1 (0.7201), trailing behind Text + Explanation (LLaMA-3) + RoBERTa. Text + Explanation (Mistral) + RoBERTa showed similar performance with an F1-score of 0.7687.

Sadness: Text Only (RoBERTa) had the highest precision (0.7636), while Text + Explanation (LLaMA-3) + RoBERTa excelled in recall (0.8127) and F1-score (0.7423). Text + Explanation (Mistral) + RoBERTa showed slight improvements in recall (0.7321) and F1-score (0.7526), with minimal differences compared to LLaMA-3.

Surprise: Text + Explanation (LLaMA-3) + RoBERTa achieved the highest precision (0.7625), while Text Only (RoBERTa) had the highest recall (0.6877). Text + Explanation (Mistral) + RoBERTa showed improved precision (0.7378) and recall (0.6834). LLaMA-3 performed weakest with precision (0.6091), recall (0.6008), and F1-score (0.6049), likely due to its difficulty in capturing the nuances of Surprise compared to other emotions.

6 Discussion

We introduced Lotus, a multi-label emotion detection approach combining LLaMA-3's generative explanations with RoBERTa for emotion classification. This combination significantly improved performance, particularly for nuanced emotions like Fear (F1: 0.8343), Joy (F1: 0.7581), and Sadness (F1: 0.7423), surpassing text-only models.

Integrating LLaMA-3's explanations with RoBERTa effectively balanced precision and recall, outperforming Text Only (LLaMA-3), especially for complex emotions like Fear and Sadness, emphasizing the importance of explanatory context in capturing emotional nuances.

Although LLaMA-3 was initially chosen, smaller models like Mistral and Qwen faced no significant GPU constraints on Kaggle. After testing Mistral, the results were nearly identical to LLaMA-3, suggesting both models perform similarly when fine-tuned with RoBERTa. Further exploration of other models will provide more insights.

For further illustration, Table 4 in the Appendix presents input sentences, predicted emotions, and generated explanations, providing context to clarify emotional intent and improve classification accuracy.

7 Conclusion and Future Work

Lotus showed that combining generative explanations with emotion detection models significantly improves emotion classification, particularly for ambiguous emotions. Using LLaMA-3 for explanation generation and RoBERTa for emotion detection enhanced the system's ability to handle nuanced emotional expressions.

Future work will focus on improving detection of underrepresented emotions like Anger, refining the explanation generation process, and addressing imbalanced datasets. Expanding the model to support multiple languages and emotional contexts will enhance its generalizability. Additionally, we plan to compare Mistral with other models like Qwen and conduct ablation studies to assess their contributions. Further improvements will target challenging emotions like Anger and Surprise, with error analysis and model comparisons refining the system.

Response to Reviewers

We sincerely thank the reviewers for their valuable and constructive feedback. Below, we provide a point-by-point response outlining how we addressed each comment and question.

Reviewer 1

Comment: *The use of GPT-4 and LLaMA-3 in a master-student framework is interesting. I would have liked to see a comparison of master models. It is commendable that the approach outperforms the baseline and is competitive. The error analysis section was particularly insightful.*

Response: We appreciate the reviewer's positive feedback. In the revised version, we extended our experiments to include **Mistral** as another explanation-generating model alongside LLaMA-3. As shown in Tables 2 and 3, both models achieved comparable results when used with RoBERTa for final emotion classification, indicating that different LLMs can be viable choices for explanation generation. We also clarified this point in the *Discussion* section and plan to expand comparisons to **Qwen** in future work.

Question: *Was the model selection constrained by the GPU resources available on Kaggle? How would this approach fare with comparable models (e.g., Qwen)?*

Response: Yes, our initial selection of LLaMA-3 was partly influenced by the GPU constraints of Kaggle. However, as noted in the revised paper, we found that smaller models like **Mistral** can be used effectively within these constraints. We included Mistral in our updated experiments and observed results similar to LLaMA-3. These findings are now discussed in Section 6 (*Discussion*), and we intend to include **Qwen** in future work for a broader comparison.

Reviewer 2

Comment: *The methodology lacks detail, such as the number of parameters in LLaMA-3 and how the 150 samples were selected.*

Response: We added a clarification in Section 3.1. The **150 sentences** used for explanation fine-tuning were selected **randomly** from the training set to ensure diversity. We also briefly described the configuration of LLaMA-3 (7B parameter variant) and noted that **LoRA** and **4-bit quantization** were applied to make fine-tuning feasible on Kaggle.

Comment: *Results and impact of fine-tuning should be discussed. Did 30 steps significantly influence the model?*

Response: In Section 4 (*Experimental Setup*), we now elaborate on this. Although only **30 steps** of fine-tuning were applied, the generated explanations noticeably improved RoBERTa's performance when appended to the original text, as evidenced by the performance gains in Table 2. We interpret this as indicating that **even light fine-tuning**, when paired with a strong base model and a clear task-specific prompt, can be beneficial.

Comment: *Dataset information is incomplete. The emotion "disgust" appears in some languages but is not mentioned.*

Response: Thank you for pointing this out. We clarified in Section 1 that our experiments are strictly based on the **English portion** of the BRIGHTER dataset, which includes only **five emotions** (anger, fear, joy, sadness, surprise). We added a note explicitly stating that *"disgust"* was part of the multilingual dataset but was **not included** in the English subset we used.

We hope these revisions adequately address the concerns raised and improve the clarity, rigor, and completeness of our work. We again thank the reviewers for their thoughtful input.

A Examples of input texts

Table 4 shows input sentences from the dataset, along with the predicted emotions and the generated explanations for each sentence. These explanations provide additional context, helping to clarify the emotional intent behind the text and improving the model's ability to correctly classify emotions.

B Error Analysis

B.1 Misclassification of Anger

Anger is often misclassified due to subtle emotional cues or when it overlaps with related emotions like frustration or anxiety. For example:

- **Text:** "Man, I can't believe it." **Explanation:** "The speaker expresses surprise or frustration." **Predicted:** Anger = 0, Actual = 1.
- **Text:** "I could not summon up the courage to get up." **Explanation:** "The speaker conveys vulnerability or exhaustion." **Predicted:** Anger = 0, Actual = 1.

These examples indicate that anger is misclassified when the emotional reaction is subtle or related to emotions like frustration or exhaustion, which may not have the overt aggression typically associated with anger.

Additionally, anger is sometimes misclassified due to physical or emotional intensity, which the model may confuse with anxiety or frustration. For example:

- **Text:** "I felt fire in my stomach." **Explanation:** "The speaker describes a strong emotional or physical reaction." **Predicted:** Anger = 0, Actual = 1.
- **Text:** "There was no stopping the relentless torrent." **Explanation:** "The speaker describes an intense, unstoppable force." **Predicted:** Anger = 0, Actual = 1.

These misclassifications suggest that the system struggles to interpret emotional intensity related to anger, and may categorize it as anxiety or frustration instead.

Lastly, anger is sometimes misclassified as fear or sadness, especially when the emotional cue is indirect or combined with vulnerability:

- **Text:** "The weekend didn't live up to my storm standards." **Explanation:** "The speaker expresses disappointment and frustration." **Predicted:** Anger = 0, Actual = 1.
- **Text:** "She was growling, barking, snarling, foaming." **Explanation:** "The speaker describes an intense emotional state, possibly fear or anger." **Predicted:** Anger = 1, Actual = 0.

In summary, anger is misclassified due to the subtlety of its expression or its overlap with other emotions such as frustration or anxiety. Additionally, emotional intensity or indirect cues, especially when mixed with vulnerability, can confuse the model. Future improvements should focus on enhancing the model's ability to differentiate between anger and these overlapping emotional states, and better handle the more subtle or complex expressions of anger.

B.2 Misclassification of Surprise

Surprise is often misclassified due to subtle or ambiguous emotional cues in the text. For example:

- **Text:** "The lock was a dial-lock." **Explanation:** "The speaker describes a specific detail, focusing on the nature of the lock." **Predicted:** Surprise = 1, Actual = 0.
- **Text:** "I immediately started getting nervous and panic intensified." **Explanation:** "The speaker describes anxiety, which may be confused with surprise." **Predicted:** Surprise = 1, Actual = 0.

These examples show that Surprise is sometimes misclassified as confusion or anxiety, especially when the emotional reaction is subtle or combined with other emotions.

Additionally, Surprise is occasionally misclassified as fear or anger, particularly when unexpected events are associated with discomfort or frustration:

- **Text:** "She was growling, barking, snarling, foaming." **Explanation:** "The speaker describes an intense emotional state, possibly fear or anger." **Predicted:** Surprise = 1, Actual = 0.
- **Text:** "I almost got my hands on the door handle, when..." **Explanation:** "The speaker describes a moment of frustration or missed opportunity." **Predicted:** Surprise = 1, Actual = 0.

ID	Text	Emotions	Generated Explanation
1	But not very happy.	Joy and Sadness	The speaker conveys a sense of dissatisfaction or disappointment, but without strong emotion.
2	About 2 weeks ago I thought I pulled a muscle in my calf.	Fear and Sadness	The speaker recounts a minor injury, suggesting concern or discomfort.
3	Yes, the Oklahoma city bombing.	Fear, Anger, Sadness and Surprise	The speaker references a significant historical event, evoking a sense of tragedy or reflection.
4	Dad on the warpath.	Fear and Anger	The speaker conveys tension or anger, likely due to a confrontational situation.

Table 4: Examples of input text, emotions, and generated explanations

These misclassifications suggest that when surprise is combined with aggression, frustration, or physical tension, the system may confuse it with fear or anger.

Finally, Surprise is misclassified when there is a lack of clear emotional cues, particularly when surprise is related to unexpected information:

- **Text:** "My great-grandad was a full-blood Cherokee." **Explanation:** "The speaker introduces their ancestry with pride and a sense of revelation." **Predicted:** Surprise = 0, Actual = 1.

In summary, Surprise is misclassified due to subtle emotional cues, especially when it overlaps with other emotions like fear or anger, or when it is expressed in less overt ways. To improve the model, future work should focus on enhancing its sensitivity to these subtle cues and improving its ability to differentiate Surprise from overlapping emotions.

LTG at SemEval-2025 Task 10: Optimizing Context for Classification of Narrative Roles

Egil Rønningstad
Department of Informatics
University of Oslo, Norway
egilron@uio.no

Gaurav Negi
Data Science Institute
University of Galway
gaurav.negi@insight-centre.org

Abstract

Our contribution to the SemEval 2025 shared task 10, subtask 1 on entity framing, tackles the challenge of providing the necessary segments from longer documents as context for classification with a masked language model. We show that a simple entity-oriented heuristics for context selection can enable text classification using models with limited context window. Our context selection approach and the XLM-RoBERTa language model is on par with, or outperforms, Supervised Fine-Tuning with larger generative language models.

1 Introduction

Shared task 10, subtask 1 for SemEval 2025 (Piskorski et al., 2025) presents annotated news articles in Bulgarian, English, Hindi, (European) Portuguese, and Russian. For each article, a number of entities are identified and annotated for narrative roles. These entities are in the text framed as playing one of three main narrative roles; protagonists, antagonists or innocent. For each main role, there is a number of fine-grained roles, 22 in total. Each entity may be given multiple fine-grained roles available for the assigned main role. Further details on the task can be found in the technical report (Stefanovitch et al., 2025). By classifying how entities are framed in news articles, we can better understand reporting angles and identify bias variations between different news sources.

Our contribution focuses on the following challenges in modeling the narrative roles of the annotated entities:

a) Each article may contain much irrelevant text with respect to a given entity.

b) A sentence mentioning an entity may also mention other entities and frame each differently.

c) The text segment(s) contributing to the entity framing may span multiple sentences.

As seen in Table 1, the provided training examples are in the hundreds and the thousands for each language. We therefore hypothesize that XLM-RoBERTa-large (XLM-R), a multilingual masked language model, could be a cost-effective starting point. Due to this, we pose the following research questions:

- **RQ1:** Can we find rule-based approaches that mitigate the above mentioned challenges, including irrelevant text and documents that will not fit in the XLM-R context window?
- **RQ2:** Can a fine-tuned XLM-R-based model be outperformed by larger language models where the entire document fits well within the context window?

To answer these questions, our paper presents results from experiments regarding text pre-processing where we fine-tune XLM-R on various text segments and evaluate each pre-processing strategy. These results are compared against zero-shot prompting of a large language model (LLM), and Supervised Fine-Tuning of LLMs with 7-8 billion parameters.

1.1 Context Optimization

Extracting only the relevant text segments for a given task can be named "context optimization". Studies have shown that for long-context LLMs, irrelevant or distractive text as part of an input, reduces model performance (Shi et al., 2023; Wu et al., 2024; Cai et al., 2024; Wang et al., 2024). This task is also being described as "context rewriting" (Wang et al., 2024) or "prompt compression" (Liskavets et al., 2024), but for this paper we prefer the term "context optimization". For MLMs this task is imperative due to the limited context window of, as for XLM-R, 512 subword tokens, which is not enough for many texts longer than microblog messages and short user-submitted reviews.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 440–447

1.2 Supervised Fine-Tuning

Supervised Fine-Tuning (SFT) has proven to to be a viable path for creating text classification models. Depending on the training examples and compute resources available, this approach may lead to better classification than in-context learning where pairs of example text and labels are fed to a LLM before requesting the classification of a new example (Mosbach et al., 2023).

1.3 Dataset

The data for this shared task were released sequentially. The experiments reported here, are trained with the finalized train split and evaluated on the labeled dev split. The number of labeled entities for training and evaluation is found in Table 1.

Language	train	dev
BG	625	30
EN	686	91
HI	2331	280
PT	1245	116
RU	366	86
all	5253	603

Table 1: Annotated entities per language in the train and dev splits for the experiments reported on in this paper.

2 Dataset Pre-Processing

Our contribution to the shared task was trained exclusively on the provided data. To address the above mentioned challenges for narrative role classification and answer RQ1, we experimented with how to best prepare the data for fine-tuning and classification.

2.1 Text Span Extraction

We hypothesize that the text relevant to the entity framing would be located in proximity to the entity mention. As the provided texts are split in sentences and paragraph, and the entities in question are pre-identified within the text, we compare a selection of rule-based context extraction approaches, and measure their performance against a simple LLM-generated baseline. To assess the value of such text span extraction, we performed experiments with the following alternative text extraction heuristics:

a) **Single sentences** For each annotated entity, provide only the sentence where the entity is mentioned.

b) **Single paragraph** For each annotated entity, provide the paragraph in which the entity occurs.

c) **Entire text** For each annotated entity, provide the entire document. The model consumes as much text as possible, ignoring the rest.

d) **Entity-to-entity (ent2ent)** For each annotated entity, provide the sentence where the entity is mentioned, and all subsequent sentences until a new entity occurs.

e) **GPT-extracted** For each annotated entity, provide the replies through the api of ChatGPT with gpt-4o, queried to extract the text span(s) containing information regarding the narrative role of the entity.

2.2 Merging languages

When it comes to classification tasks with a multilingual pretrained model, there is the tradeoff between getting a larger training set, and introducing "noise" from the language variety (Conneau et al., 2020; Rønningstad, 2023). We therefore prepared one dataset per language, and one merged dataset containing all languages.

2.3 Preparing data for SFT

We prepared one prompt per text document for Supervised Fine-Tuning.

Prompt Template The prompt template (see Appendix B) used for making the predictions consists of the following segments: (i) Annotation Instructions, (ii) Taxonomy of the primary and secondary entity roles, (iii) The definitions of primary roles, (iv) Document input along with the entities, and (v) Output format.

It should be noted that the entities in question, occur multiple times in a few documents. To localize the correct instance of these entities an entity tag (<entity> </entity>) is placed around the occurrence using the index values provided in the annotations. This processed document is then included in the prompt.

3 Modeling

We here present the various modeling approaches tested, and their evaluation results. The focus is on answering the research questions by applying the

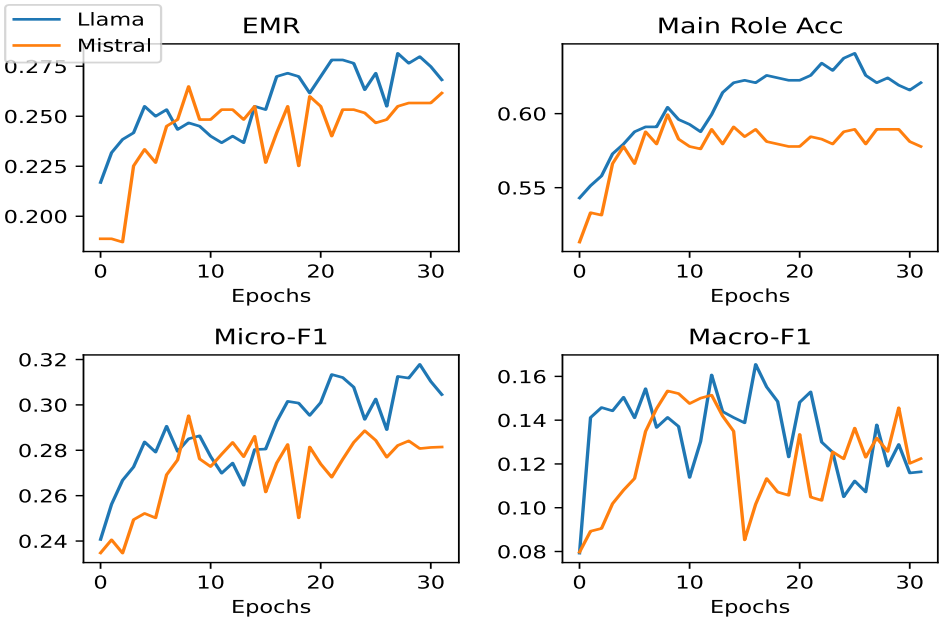

Figure 1: SFT learning trends per epoch as evaluated on dev dataset

various text pre-processing approaches as input for XLM-R fine-tuning. These approaches are compared with classification based on larger language models.

3.1 Modeling with XLM-R

XLM-R-large[1] was used for all XLM-R experiments. No hyperparameters were altered from the standard settings for text classification in the Transformers library. Models were trained for 10 epochs.

Prepend Entity Mention. The text spans provided to the model may be identical when classifying with respect to two different entities, and we therefore prepended the extracted segment with the prefix *"Regarding <entity> :\n"*, where <entity> is placeholder for the entity mention as written in the task annotations. This was done for all XLM-R experiments except for *ent2ent_noprefix*.

We see in Table 2, how the micro F_1 scores were dramatically reduced when there was no prefix presenting the entity in question.

Monolingual vs Multilingual Fine-Tuning. As can be seen in Table 3 and Figure 3 in Appendix A, fine-tuning on all languages improved results noticeably. For the languages with the smallest training set, there were no measurable Micro F_1 results. For subsequent experiments, the training data is understood to consist of all languages in the shared task.

[1]FacebookAI/xlm-roberta-large

Modeling Main Roles First As there are 22 fine-grained roles in total, and an entity may be labeled with multiple fine-grained roles, we attempted to employ the best-so-far method (Entity-to-entity with prefix) in a two-step modeling and inference approach (main2fine). We first trained a classifier for the three main roles, and predicted main roles for the dev set (one per entity). After separating the dev set into each predicted main role, we trained one multilabel classifier per predicted main role. This reduced the number of possible fine-grained roles to 6 for the Protagonist main role, 12 for Antagonist and 4 for Innocent. The results are found in Table 2, the row *ent2ent_main2fine*.

3.2 Prompting an LLM for Classification

The results from the XLM-R-based models were compared against the labels provided by ChatGPT-4o when queried for classifying one entity at a time, including the entire article and the label definitions in the prompt, but not any examples. The results are found under *gpt-inference* in Table 2.

3.3 Modeling with LLMs and LoRA

For these experiments, we used the instruction-tuned versions of Llama-3.1-8B[2] and Mistral-7B[3] models. These models were further fine-tuned with the training dataset that was provided.

[2]meta-llama/Llama-3.1-8B-Instruct
[3]mistralai/Mistral-7B-Instruct-v0.3

Model	Method	BG	EN	HI	PT	RU	All
XLM-R	ent2ent	25.40	31.25	46.49	70.00	**47.73**	**47.75**
	ent2ent_noprefix	15.87	11.46	27.07	58.92	26.29	30.11
	ent2ent_main2fine	25.40	25.00	41.75	**74.69**	40.68	44.51
	sentence	31.75	20.73	**46.88**	70.83	42.46	46.06
	gpt-extracted	25.40	17.71	45.36	64.73	40.00	43.14
	paragraph	25.40	16.75	40.00	67.50	38.64	40.79
	fulltext	28.57	9.42	40.53	62.50	37.29	38.96
ChatGPT-4o	gpt-inference	38.96	**36.95**	36.85	65.64	34.65	41.78
llama	SFT	**43.48**	22.33	20.57	50.00	29.70	31.78
mistral	SFT	36.36	30.77	18.71	49.17	34.83	29.52

Table 2: Evaluation results for the various text extraction and modeling strategies for each test language. Evaluation metric is Micro F_1 for the 22 fine-grained roles. We see that fine-tuning XLM-R on prefixed text segments using the *ent2ent* segment extraction strategy yields the best overall results. All XLM-R experiments contain prefixed segments except the *ent2ent_noprefix* ablation experiment. All experiments classify the 22 fine-grained roles directly, except the *ent2ent_main2fine* experiment.

language	all	in-lang	samples
RU	52.33	0.00	366
BG	26.67	0.00	625
EN	29.67	8.79	686
PT	69.83	44.83	1245
HI	43.21	22.50	2331
all	46.77		5253

Table 3: A comparison of test results (Micro F_1) with XLM-R and the ent2ent context optimization, when training either only on the training data of the test split language (in-lang) with their samples count (samples), or training on the entire train set (all). More results are presented in Figure 3 in Appendix A.

We use Low-Rank Adaptation (LoRA) for the parameter-efficient fine-tuning using the causal language modeling objective. The values prescribed for LoRA parameters in the introductory work were used ($r = 32$ and $\alpha = 64$). The parameters of the models (Llama and Mistral) were loaded with a 4-bit precision configuration. Since the models have multi-lingual capabilities, we combined the training dataset across all languages for fine-tuning.

We fine-tuned LLMs for 32 epochs and selected the checkpoint with the highest Exact Match Ratio (EMR) to make the predictions. We track the metrics on the language-combined development dataset in Figure 1. Per-language final evaluation results are found in Table 2.

4 Analyses

We here present our reflections on the results reported in the paper.

4.1 Finding the Best Text Segments

Table 2 shows that modeling with XLM-R and the ent2ent-approach for segment extraction yields the best overall results. Although this approach is the best alternative for only one of the languages (Russian), we submit these results for all languages. Among our experiments, the ent2ent-approach yields competitive results for all languages except for Bulgarian where the experiments based on larger models are noticeably better. Our contribution ranked from fifth (Hindi and Portuguese) to tenth (English) on the official SemEval results on the test set.

4.2 Performance vs train split size

All our approaches yielded large variations in results between languages. The training data as presented in Table 1 are very different in size per language. Although models were trained on the entire dataset, having data from the same language as the test data (in-language training data) has from experience proven to be important. We therefor compare the results with the size of the in-language train split. Figure 2 shows no clear trend, as Portuguese yielded the best results, while Hindi had almost twice the amount of training data. We see that the XLM-R-based approach is clearly best for the two languages with the most training data. The

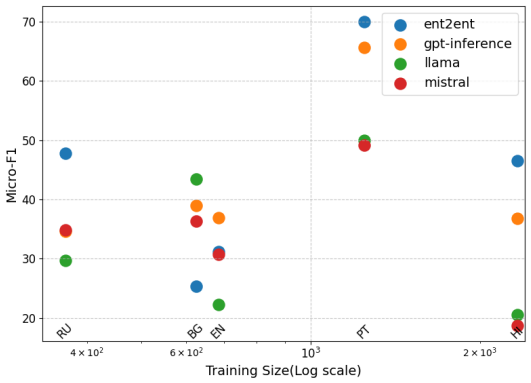

Figure 2: Model performance as a function of in-language training data

need for more than a thousand in-language, in-domain training samples when fine-tuning XLM-R, is in line with previous experience. But again, XLM-R performs best of our approaches for Russian as well, with the fewest training samples. We can assume that languages' presence in the original model pretraining also contributes much to the quality of the resulting inference. A surprise therefore, is all models' poor performance on English data. We can speculate that Portuguese hits a "sweet spot" between language similarity to much of the pretraining data, and size of the task's in-language dataset. But further inspection of the provided dataset's complexity across languages would be required before drawing any conclusion.

4.3 Supervised Fine-Tuning

We were surprised to see how hard it was to train better models than the XLM-R using SFT and Llama or Mistral. These fine-tuning cycles are resource-demanding, and in our prompts, as shown in Appendix B we provide one prompt per text, requiring the model to return all roles for all entities. To simplify the task, one could request classifications only one entity per prompt. Additionally, applying context optimization might prove beneficial here as well. Testing these options with SFT was beyond our resource allocations.

5 Conclusion

We have created a XLM-R-based multilingual model for Entity Framing as a part our contribution to the SemEval 2025 shared task 10 on Multilingual Characterization and Extraction of Narratives from Online News, subtask 1. This model was tested against Supervised Fine-Tuning of Llama and Mistral, and against zero-shot prompting of ChatGPT-4o. We found it imperative to extract entity-oriented text segments in order to effectively utilize XLM-R with long documents containing multiple entities each.

Appendices

A Language-Wise Fine-Tuning

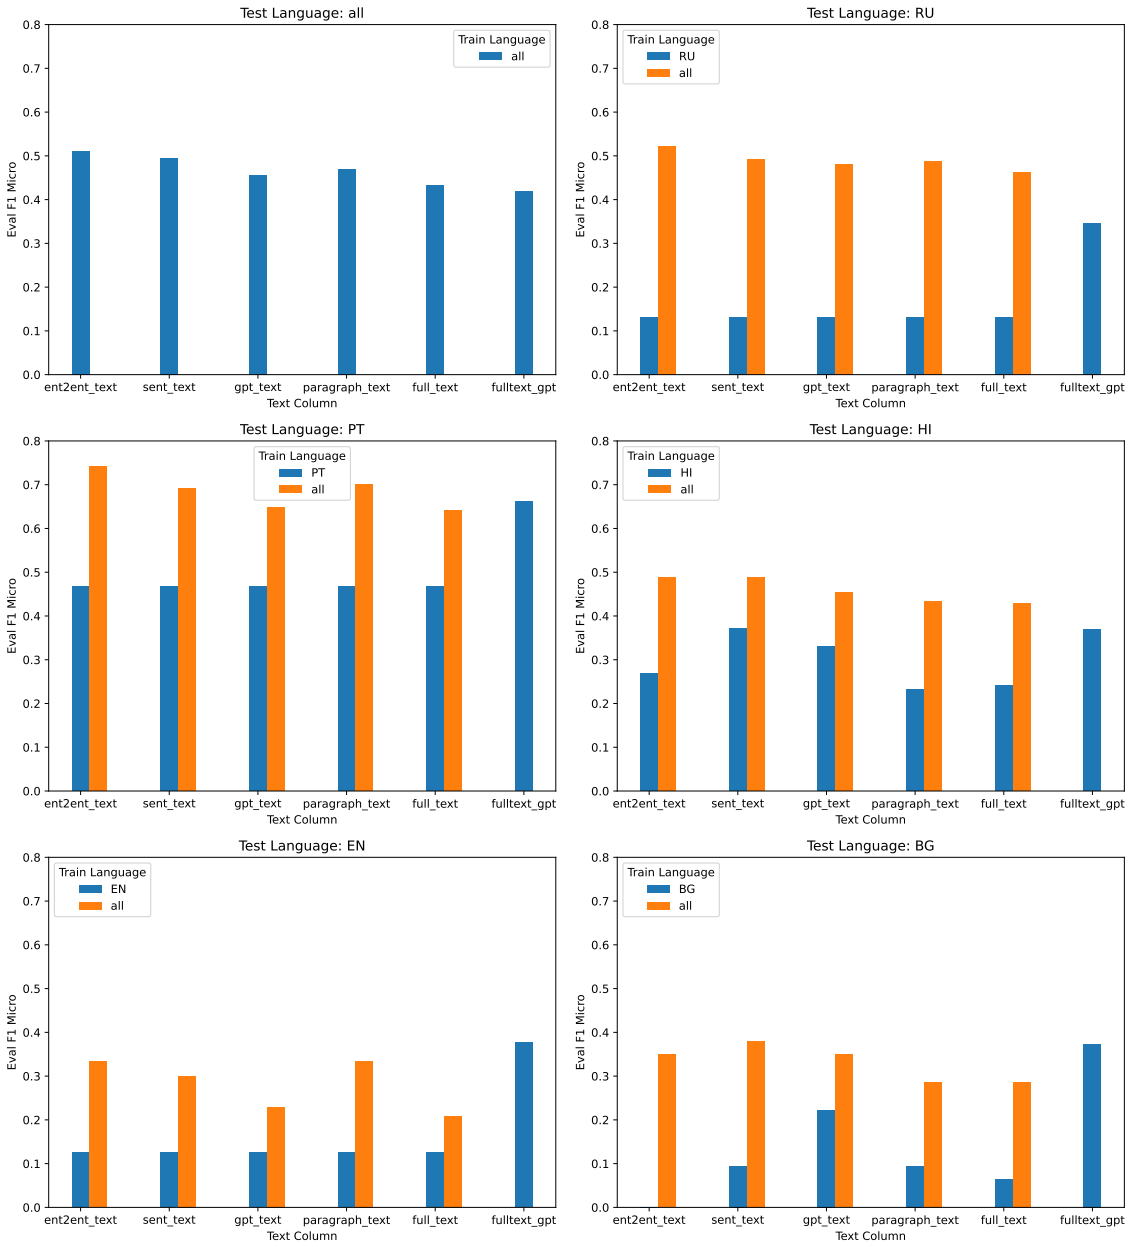

Figure 3: Benefits from training on all languages. For each language, the results improve substantially when fine-tuning the XLM-R on the entire dataset, as opposed to fine-tuning on the test language only.

B SFT Prompt Template

```
### Annotation Instructions:
You are given a document that includes various entities along with descriptions of events and actions. Your task is to analyze the
text and determine the roles each entity plays according to the taxonomy provided below.

### Taxonomy:
**Protagonist**
- Guardian
- Martyr
- Peacemaker
- Rebel
- Underdog
- Virtuous
**Antagonist**
- Instigator
- Conspirator
- Tyrant
- Foreign Adversary
- Traitor
- Spy
- Saboteur
- Corrupt
- Incompetent
- Terrorist
- Deceiver
- Bigot
**Innocent**
- Forgotten
- Exploited
- Victim
- Scapegoat

### Definitions
- **Protagonist**: A central character or force in a positive role.
- **Antagonist**: A character or force in opposition to the protagonist.
- **Innocent**: Entities that are marginalized or victimized without any active role in the conflict.

### New Input:
<<variable input start>>
**LANG: EN**
**Document:**
According to the Gospel of the Global Warming Hoax, 1850-1910 was the coldest period of the past millennium. Yet glaciers were
retreating rapidly. Now that the planet allegedly has a fever, the retreat has slowed dramatically and even reversed:
Our moonbat rulers canceled the Medieval Warm Period and Little Ice Age for failing to comply with climate ideology. But
preventing glaciers from growing is more difficult than doctoring the historical record to support climate con man <entity>Michael
Mann</entity>'s spurious hockey stick graph.
Nonetheless, prophet of doom <entity>Al Gore</entity> shouts that "we could lose our capacity for self-governance" if we don't
surrender still more freedom to Big Government so that it can fix the supposedly broken weather.
On tips from Lyle and Wiggins.
Anyone can join.
Anyone can contribute.
Anyone can become informed about their world.

**Query entities:**

CCNU at SemEval-2025 Task 3: Leveraging Internal and External Knowledge of Large Language Models for Multilingual Hallucination Annotation

Xu Liu and **Guanyi Chen***
Hubei Provincial Key Laboratory of Artificial Intelligence and Smart Learning,
National Language Resources Monitoring and Research Center for Network Media,
School of Computer Science, Central China Normal University
liuxu@mails.ccnu.edu.cn, g.chen@ccnu.edu.cn

Abstract

We present the system developed by the Central China Normal University (CCNU) team for the Mu-SHROOM shared task, which focuses on identifying hallucinations in question-answering systems across 14 different languages. Our approach leverages multiple Large Language Models (LLMs) with distinct areas of expertise, employing them in parallel to annotate hallucinations, effectively simulating a crowdsourcing annotation process. Furthermore, each LLM-based annotator integrates both internal and external knowledge related to the input during the annotation process. Using the open-source LLM DeepSeek-V3, our system achieves the top ranking (#1) for Hindi data and secures a Top-5 position in seven other languages. In this paper, we also discuss unsuccessful approaches explored during our development process and share key insights gained from participating in this shared task.

1 Introduction

Hallucinations refer to content in outputs that neither follow from the inputs nor are supported by known facts. In 2024, Mickus et al. (2024) organized a shared task on detecting hallucinations in machine translation, definition modelling, and paraphrasing systems. Building on this foundation and expanding to a new domain—question answering—SemEval-2025 Task 3 (Mu-SHROOM; Vázquez et al., 2025) broadens the scope of hallucination detection. This task extends beyond English to cover 14 different languages and moves beyond binary classification (i.e., determining whether an item contains hallucinations) to pinpointing the exact location of hallucinations, as illustrated in Table 1.

Although Large Language Models (LLMs) inevitably produce hallucinations (Xu et al., 2024), they have also proven effective in detecting them:

Question	What did Petra van Staveren win a gold medal for?
Answer	Petra van Stoveren won a silver medal in the 2008 Summer Olympics in Beijing, China.

Table 1: An example test item from Mu-SHROOM. The hallucinations are coloured in red.

four of the six highest-scoring systems in the 2024 challenge leveraged state-of-the-art LLMs (Mickus et al., 2024). However, the new task setting introduced above presents two key challenges for these LLM-based solutions.

First, Mu-SHROOM shifts the focus from hallucinations in generation systems, such as machine translation and paraphrasing, to hallucinations in question-answering (QA) systems. This shift alters the definition of hallucination. As discussed in Thomson and Reiter (2020); Dušek and Kasner (2020); Ji et al. (2023); van Deemter (2024), hallucinations in generation systems refer to outputs that contradict the given inputs. In contrast, within QA, hallucinations pertain to outputs that contradict corresponding "facts". Consequently, detecting hallucinations in a given QA pair requires a model first to determine what constitutes the relevant "facts". Since these facts are not explicitly present in the input, the model must be capable of integrating knowledge from multiple sources.

Second, the fine-grained hallucination annotation scheme in Mu-SHROOM increases the likelihood of annotation disagreements. Different annotators may label the same error in different ways. For example, consider the error "silver" in Table 1: the term is incorrect because Petra van Stroveren won a gold medal in the Olympic Games. However, one annotator might highlight only the word "silver", while another might annotate the entire noun phrase "a silver medal". Such disagreements are natural, and Mu-SHROOM addresses them by

employing multiple annotators and resolving inconsistencies through majority voting. This collaborative approach is difficult to replicate with a single LLM-based hallucination detector.

Following the approach of the 2024 challenge winners, our solution employs LLMs with optimizations to address the two challenges discussed above. To tackle the first issue, our LLM-based hallucination detector retrieves relevant "facts" not only from its internal knowledge but also from external resources, thereby integrating both internal and external knowledge. To address the second issue, our solution mimics the crowdsourced annotation process by leveraging multiple LLMs, assigning them different roles, and having them annotate each QA pair in parallel before reaching a consensus through voting. Notably, our approach requires no fine-tuning or language-specific optimizations. Using an open-source LLM—DeepSeek-V3 (Liu et al., 2024)—as the backbone, our solution achieved #1 ranking on Hindi data and placed in the Top 5 for Arabic, Basque, Catalan, Czech, English, Persian, and Spanish. [1]

2 The Mu-SHROOM Task

The Mu-SHROOM task (Vázquez et al., 2025) asks systems to annotate hallucinations in QA in 14 languages, including Arabic, Basque, Catalan, Chinese, Czech, English, Farsi, Finnish, French, German, Hindi, Italian, Spanish, and Swedish. The annotations contain: (1) **Hard Labels**, i.e., hallucinations in QA pairs as in Table 1; and (2) **Soft Labels**, i.e., probability of each token in the answer being a hallucination term.

Mu-SHROOM evaluates each system using Intersection-over-Union (IoU) for hard labels and Spearman correlation (Cor) for soft labels. See Vázquez et al. (2025) for more details.

3 Methodology

This section starts with explaining how we prompt LLMs to annotate hallucinations in QA systems, followed by how we make them leverage internal and external knowledge during annotation. Figure 1 provides an overview of our hallucination annotation system.

3.1 Prompting LLMs to Mark Hallucinations

As shown in Figure 2, our prompt[2] begins by defining the task and the concept of hallucination to provide the LLM with a clearer understanding of the background. Notably, we refine the definition of hallucination in the context of QA by specifying that hallucinated content is characterized as "factually incorrect", "nonsensical", or "not supported by known facts".

We then incorporate a Chain-of-Thought (CoT), outlining the steps the LLM should follow to improve hallucination annotation. In this CoT, we first instruct the LLM to generate a reference answer based on the given question (see further discussion in Section 3.2). It then compares the provided answer with the generated reference answer to identify hallucinated content. We also ask the LLM to explain why the annotated terms are classified as hallucinations.

Next, we present the LLM with an example, extracted from the first item in the development set. We also specify the expected input and output format. It is worth mentioning that rather than directly

[1] For German and French, we used GPT-4o, ranking #3 and #15, respectively.

[2] For all languages, the prompt is always in English, with the only modification being the replacement of 'lang' with the name of the test language.

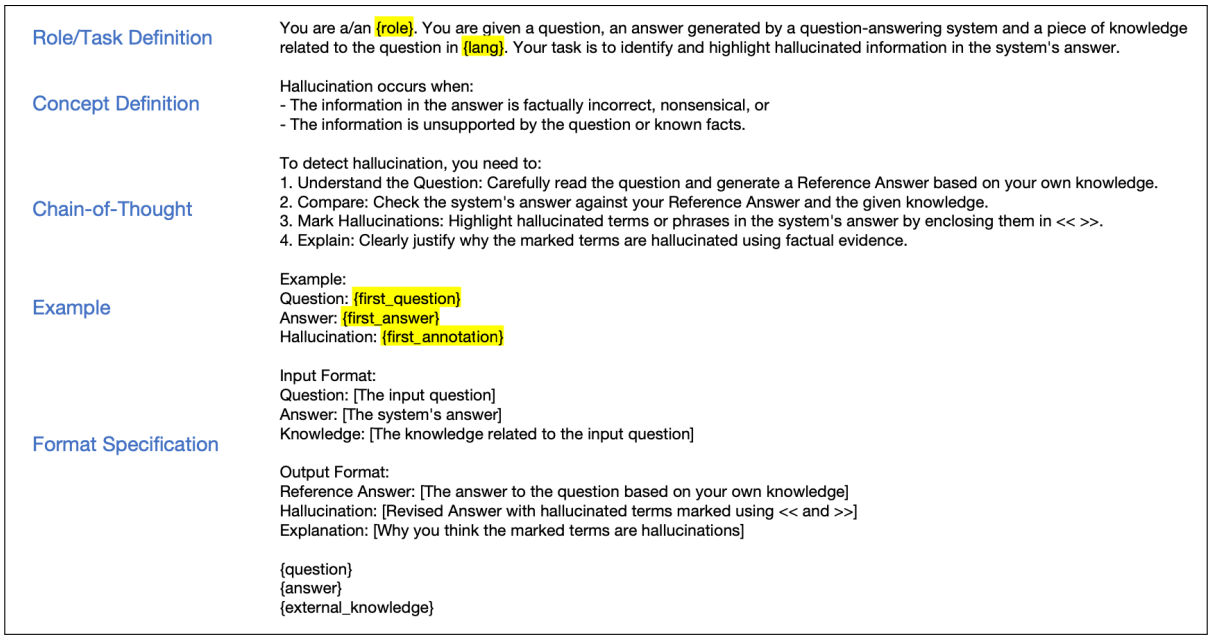

Figure 2: The main prompt in our system. The variables highlighted in yellow will be replaced with their corresponding desired values.

returning soft and hard labels—where hallucinations are represented as integer indices indicating their start and end positions—we instruct the LLM to mark hallucinated terms within the answer. This is achieved by having the LLM generate a revised version of the answer, where hallucinated terms are enclosed within ⟨⟨' and ⟩⟩'. This approach bypasses the LLM's limited ability to accurately count indices. Finally, we provide the LLM with the input QA pair along with external knowledge (see further discussion in Section 3.3).

For each QA pair, we prompt the LLM 12 times and obtain 12 annotations. For each token in a given answer, we calculate the probability of it being hallucinated by computing the proportion of times it was annotated as a hallucination across the 12 annotations.

3.2 Internal Knowledge

We compel the LLM to leverage its internal knowledge when processing a given question by first requiring it to generate an answer based solely on its own knowledge and then annotate hallucinations accordingly. To further diversify the internal knowledge used in this process, we assign the LLM different roles across the 12 runs. This is achieved by employing another LLM to determine a set of distinct roles (i.e., r_i in Figure 1), each capable of evaluating the factual accuracy of the given QA pair and detecting potential hallucinations. Additionally, we instruct this role-assigning LLM to ensure that the suggested roles are as diverse as possible. The corresponding prompt for this role assignment process can be found in Appendix A.

3.3 External Knowledge

We extract external knowledge from Wikipedia based on the given question. Specifically, for each QA pair, we first prompt the LLM to identify key terms from the question (the corresponding prompt can be found in Appendix A). These key terms are then used to construct a query for retrieving relevant knowledge from Wikipedia, with the first returned result serving as the external knowledge. Since the retrieved content may be excessively long, we employ another LLM to summarize and refine it, producing the final external knowledge (the prompt for this summarization process is also provided in Appendix A).

4 Experiments

Figure 3 presents the performance of our system in terms of IoU, which is considered more important than Cor, across data in 10 languages with available development sets. The figure compares the results of our system using GPT-4o-mini as the backbone LLM, both with and without (internal and external) knowledge, as well as a version employing DeepSeek-V3 with knowledge.

As the results indicate, incorporating both inter-

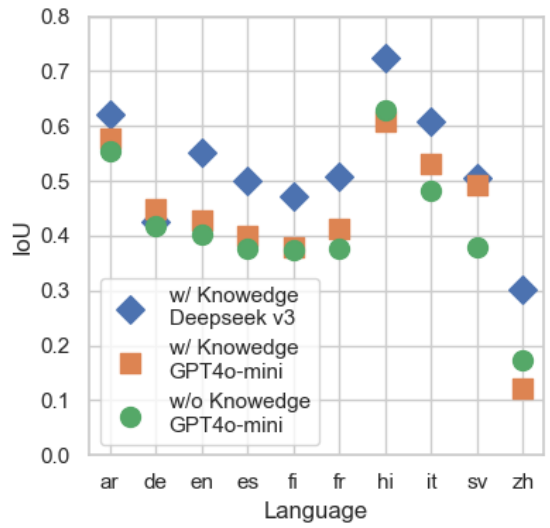

Figure 3: Performance in terms of IoU on 10 languages whose development sets are available.

Lang.	Model	IoU	Cor
EN	DeepSeek-V3	**55.04**	55.88
	GPT-4o-mini	42.74	53.27
	GPT-4o	52.04	**63.27**
FR	DeepSeek-V3	50.70	**51.68**
	GPT-4o-mini	41.37	47.57
	GPT-4o	**57.75**	50.55
ZH	DeepSeek-V3	**30.11**	27.02
	GPT-4o-mini	12.17	**27.87**
	GPT-4o	22.30	26.78

Table 2: Performance of our system for English, French, and Chinese with different backbone LLMs.

nal and external knowledge consistently improves the LLMs' ability to annotate hallucinations across all 10 languages, with the exception of Chinese. This anomaly is mitigated by replacing GPT-4o-mini with DeepSeek-V3, suggesting that the fundamental capability of the backbone LLM plays a crucial role in extracting high-quality knowledge.

Moreover, we observe that: (1) When comparing DeepSeek-3V to GPT-4o-mini, DeepSeek-3V outperforms GPT-4o-mini in all languages except German; and (2) Our system achieves the highest performance on Hindi data and the lowest performance on Chinese data. Its performance remains relatively consistent across other languages, regardless of whether the language is high-resourced or low-resourced.

The Choice of Backbone LLMs. As mentioned earlier, the choice of backbone LLM is crucial for effectively leveraging knowledge. To further investigate this, we conducted a small experiment on English, French, and Chinese data, comparing three backbone LLMs: DeepSeek-V3, GPT-4o-mini, and GPT-4o. Surprisingly, the open-sourced DeepSeek-V3 not only performs best for Chinese (which is expected, given that a Chinese company developed it) but also outperforms the other models for English. The results in Figure 3 further highlight its strong performance for low-resourced languages.

The final decision relies on both the performance and the cost. In our case, an experiment on data in a single language costs $10 using GPT-4o but merely $0.15 using DeepSeek-V3. As a result, we finally used GPT-4o for German and French (see results in Figure 3 and Table 2) and DeepSeek-V3 for all other languages.

Lang.	IoU	Rank	Lang.	IoU	Rank
Arabic	59.95	5/29	Catalan	66.94	2/21
Czech	48.52	5/23	German	59.17	3/28
English	53.94	5/41	Spanish	51.25	4/32
Basque	57.85	3/23	Persian	66.00	4/23
Finnish	51.17	13/27	French	48.23	15/30
Hindi	74.66	1/24	Italian	70.60	7/28
Swedish	50.45	15/27	Chinese	38.34	18/26

Table 3: Performance of our system on the test sets in terms of IoU and rank.

Results on the Test Sets. Table 3 reports the performance of our system on the test sets. It achieved #1 ranking on Hindi data and placed in the Top 5 for the other 8 languages. Consistent with the results on the development sets, the system showed the lowest performance on the Chinese test set (see Section 6 for a potential explanation).

The Effect of Marking Hallucinations in Place. As mentioned in Section 3.1, our system asks LLMs to mark hallucinations directly in the given QA pairs instead of returning the indices of the starting and ending positions of hallucinations. An experiment using Llama-3.1-8B reveals that this improves IoU from 33.68 to 39.97 on English data.

5 Unsuccessful Approaches

In this section, we discuss the unsuccessful approaches encountered during the development of our system.

Ignoring Typos. Through analysing the annotations generated by LLMs, we found that they often classify typos and grammatical errors as hallucinations, and such errors are rarely treated as

hallucinations in the corpus. To address this, we instructed the LLMs to ignore typos and grammatical mistakes. However, in an experiment using Llama-3.1-8B, this adjustment led to a decrease in IoU from 39.97 to 29.12 on English data. This decline suggests that LLMs may struggle to differentiate between typos and hallucinations, as both are perceived as forms of error.

Correcting before Annotating. Our system leverages internal knowledge by prompting the LLM to generate an answer to the input question based on its own knowledge before annotating hallucinations. We experimented with an alternative strategy: instructing the same LLM in two separate runs. In the first run, the LLM was asked to only generate an answer from its own knowledge. This generated response was then used in the second run to assist in annotating hallucinations. While this approach achieved a similar IoU score to our final solution, it was more computationally expensive due to the additional LLM invocation. Therefore, we ultimately abandoned this strategy.

Incorporating External Knowledge without Summarising. Our system incorporates external knowledge by first extracting relevant information from Wikipedia and then summarizing it using an LLM. The summarization step was introduced to mitigate potential issues arising from overly lengthy or irrelevant extracted content with respect to the QA pairs awaiting annotation. Considering the inherent trade-off between information volume and density, where summarization increases information density but reduces overall content, we tested the removal of the LLM-based summarization step. However, an experiment using Qwen2.5-14B revealed that eliminating summarization decreased the IoU score from 42.55 to 38.24 on the English dataset.

6 Discussion

Quality of the Dataset. Our system performs surprisingly poorly on Chinese data (see Figure 3). Interestingly, other participants in this shared task seem to face a similar issue, as the baseline approach—which indiscriminately marks all terms as hallucinations—ranks 7th out of 26 teams (Vázquez et al., 2025). Upon examining the Chinese dataset, we identified problematic cases, with the following serving as an example:

> 安德列·克拉克夫（Andrei Konchalovsky）是一位俄罗斯导演、编剧和制片人，他的作品包括：《俄罗斯方舟》（2011年）、《悲悯世界》(1991)、《莫斯科不相信眼泪》(18% 白人) (Moskva slezam ne verit, 1% blondynki)（10%的白人）等。

This is a problematic data instance because: (1) It exhibits degeneration (Holtzman et al.), making it difficult for annotators to determine which parts should be labelled as hallucinations; and (2) It contains numerous inconsistencies. For example, symbols like '%' and ')' are sometimes marked as hallucinations, while in other cases, they are not.

Comparing the Results on Hard and Soft Labels. We compute the Mean Reciprocal Rank (MRR) of our systems on the final rankings in terms of both IoU and Cor, and obtain 0.26 and 0.34, respectively. This means that our system has better performance in deciding soft labels than hard labels. This is probably attributed to our design of letting multiple LLMs mimic the crowdsourcing annotation process.

Definition of Hallucination. According to Vázquez et al. (2025), the definition of hallucination given to the annotators is:

> **Hallucination**: content that contains or describes facts that are not supported by the provided reference. In other words, hallucinations are cases where the answer text is more specific than it should be, given the information available in the provided context.

For us, this definition poses several issues: (1) The second half of the definition leans more towards describing over-specification rather than hallucination. Its reasoning aligns closely with the Gricean Maxim of Quantity (Grice, 1975) rather than the Maxim of Quality, as discussed in van Deemter (2024). This discrepancy also creates an inconsistency between the two parts of the definition. (2) This Gricean-style definition (i.e., "more specific than it should be") is inherently vague, as the appropriate level of specificity is subjective and uncertain for annotators (see Chen and van Deemter (2023) for discussions). For example, in Table 1, one could argue that specifying "Beijing, China" is redundant, as "2007 Summer Olympics" already serves as an unambiguous referring expression.

7 Conclusion

This paper presents the Central China Normal University (CCNU) team's solution to SemEval-2025 Task 3, the Mu-SHROOM task, which requires submissions to annotate hallucinations in question-answering systems across 14 different languages. Our approach employs multiple LLMs with distinct roles, prompts them in parallel to annotate hallucinations in order to simulate a crowdsourcing annotation process. Each LLM-based annotator integrates both internal and external knowledge related to the input during the annotation process. A small ablation study highlights the importance of incorporating knowledge. Finally, we report several unsuccessful attempts and share key observations gained from participating in this shared task.

In future, we plan to have a closer look at how the choice of different roles would influence the performance of our system and seek an annotation scheme that handles disagreements better (see Section 6) and considers severities of different kinds of hallucinations (van Miltenburg et al., 2020).

A Further Prompts

Table 4: Prompt for assigning roles during internal knowledge extraction.

The task is when given a pair of a question and an answer in {lang}, to try to identify up to 5 distinct expert identities capable of evaluating the factual accuracy of the answer and detecting potential hallucinations. Ensure the suggested identities are diverse and tailored to the specific context of the input. Given question: {question} Given answer: {answer} Please give your output in JSON format with keys 'Identities' and 'Reason'. Under the content of 'Identities', please output the identity, your identity should be correct, clear, and easy to understand. Under the content of 'Reason', explain why you output these identities. Provide a clear and concise response, just give your answer in JSON format as I request, and don't say any other words.

Table 5: Prompt for extracting key terms from the input question.

You are given a question and you need to extract a keyword, which will be used for querying Wikipedia. Input Format: Question: [The input question] Output Format: Keyword: [A keyword directly extracted from the input question, only the essential terms, usually the name and main topic.] Example: Question: What did Petra van Staveren win a gold medal for? Keyword: Petra van Staveren

Table 6: Prompt for summarising and refining the extracted external knowledge.

You are given a question, an answer, and a set of knowledge in JSON retrieved from Wikipedia in lang. We are building a system that detects hallucinations in the given answer. Your task is to refine the given knowledge from Wikipedia to make it helpful to serve as a reference for identifying hallucinations in the answer. To refine the knowledge, you need to: Analyze the Question: Carefully analyze the question and the answer to identify what is being asked and determine the key information needed to identify the factual errors in the answer. Evaluate the Given Knowledge: Review the related knowledge provided and simultaneously assess its relevance to the question, determining whether it is directly useful, partially useful, or not applicable to identify the factual errors in the answer. Generate Knowledge: Based on the judgment, either refine the provided knowledge, integrate it with new insights, or create a standalone response in EN that contains knowledge that helps identify the fact errors in the answer effectively. Input: Question: question Answer: answer Related knowledge: knowledge Please give your output in JSON format with keys 'Knowledge' and 'Reason'. Under the content of 'Knowledge', please output the refined knowledge in a single paragraph. Under the content of 'Reason', explain why you make such refinements. Provide a clear and concise response, just give your answer in JSON format as I request, and don't say any other words.

ClaimCatchers at SemEval-2025 Task 7: Sentence Transformers for Claim Retrieval

Abstract

Retrieving previously fact-checked claims from verified databases has become a crucial area of research in automated fact-checking, given the impracticality of manual verification of massive online content. To address this challenge, SemEval 2025 Task 7 focuses on multilingual previously fact-checked claim retrieval. This paper presents the experiments conducted for this task, evaluating the effectiveness of various sentence transformer models—ranging from 22M to 9B parameters—in conjunction with retrieval strategies such as nearest neighbor search and reranking techniques. Further, we explore the impact of learning context-specific text representation via finetuning these models. Our results demonstrate that smaller and medium-sized models, when optimized with effective finetuning and reranking, can achieve retrieval accuracy comparable to larger models, highlighting their potential for scalable and efficient misinformation detection.

1 Introduction

Given the vast volume of online content, manually fact-checking every claim is impractical and time-consuming. Moreover, many claims are recurrent, which do not need to be verified repeatedly (Shaar et al., 2020a). To address these challenges, retrieving previously fact-checked claims from a database can greatly support an automated fact-checking pipelines (Panchendrarajan and Zubiaga, 2024).

Research on retrieving previously fact-checked claims (claim retrieval) has evolved from traditional methods, such as BM25 (Robertson et al., 2009), to more advanced approaches leveraging sentence transformers (Reimers and Gurevych, 2019) and language models (Shaar et al., 2020a; Choi and Ferrara, 2024; Pisarevskaya and Zubiaga, 2025). However, given the dearth of research tackling the task from a multilingual angle, SemEval 2025 Task 7 (Peng et al., 2025) focuses on multilingual claim retrieval. Given a social media post, the task aims to retrieve a matching claim from a database of fact-checked claims. The task features two challenges: monolingual (posts and claims in the same language) and cross-lingual (posts and claims in different languages) claim retrieval.

We present our experiments for both the monolingual and cross-lingual tasks. We investigate the effectiveness of various sentence transformer models, ranging from 22M to 9B parameters, in combination with retrieval strategies such as nearest neighbors and reranking techniques. Additionally, we finetune these models to assess the impact of learning context-specific representation on claim retrieval tasks. Our findings reveal that smaller and medium-size models can achieve performance comparable to larger models when optimized with effective finetuning and reranking strategies. This suggests that these computationally effective models can still be adapted for accurate retrieval, making them a practical choice for real-world automated fact-checking systems.

2 Background

One of the first studies on claim retrieval was Shaar et al. (2020a), who introduced a pipeline using a fast lexical search to select fact-checked claims, followed by language models for reranking.

The claim retrieval task also featured in the 2020-2022 editions of the CLEF-CheckThat competition (Shaar et al., 2020b, 2021; Nakov et al., 2022). In 2020, the best-performing team, Buster.ai, used data augmentation and additional training datasets (Bouziane et al., 2020). In 2021, the best result in the English task was obtained by team Aschern (Chernyavskiy et al., 2021), which fine-tuned SBERT (Reimers and Gurevych, 2019) and then used LambdaMART to rank the top 20 matches. Finally, in 2022, team RIET ranked first (Shlisel-

[*] These authors contributed equally.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 455–462

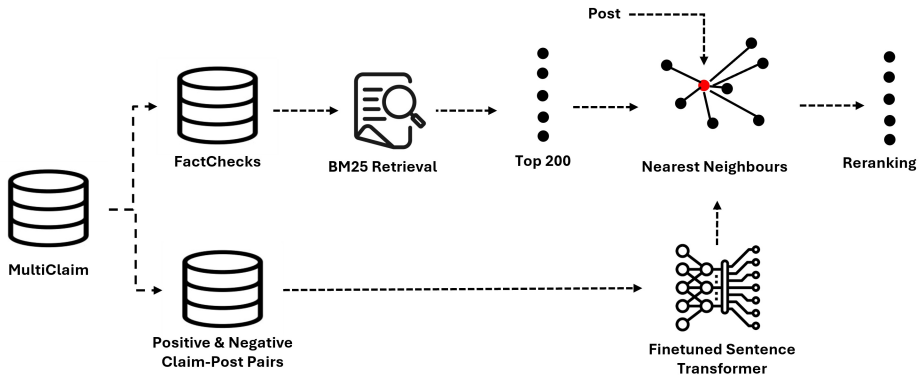

Figure 1: System Overview

berg and Dori-Hacohen, 2022) using Sentence-T5 for candidate selection, instead of BM25. For final reranking, they utilized GPT-Neo, an autoregressive language model (Black et al., 2021). Using LLMs to rerank selected candidates or match claim/post pairs has also been tried (Qin et al., 2023; Choi and Ferrara, 2024).

The task of retrieving previously fact-checked claims has been carried out primarily using datasets in English. Some of the exceptions were the 2021 edition of CheckThat (Shaar et al., 2021) which contained a claim retrieval subtask with Arabic tweet/claim pairs and a dataset presented by Kazemi et al. (2021) with WhatsApp and public group messages in English, Hindi, Bengali, Malayalam and Tamil. The currently most comprehensive dataset with multilingual previously fact-checked claims is MultiClaim (Pikuliak et al., 2023), with 28k posts in 27 languages from social media and 206k fact-checks in 39 languages.

3 System overview

This section discusses our claim retrieval approaches, nearest neighbors search and reranking. We also enhance retrieval by finetuning sentence transformers on training data. Figure 1 illustrates our method.

The task organizers provided social media posts with original text, English translations, and OCR-extracted text (if available), while fact-checks included original and translated text. Given a social media post, we concatenated its translated text and OCR-translated text to form the query for retrieving fact-check translations.

3.1 Nearest Neighbors

The dominant strategy in modern information retrieval aims to combine language model representations with efficient search (Zhao et al., 2024). This approach consists of using language models to generate vector representations for the documents and queries, and then performing the vector search with approximate nearest neighbors (ANN) algorithms. The most widely used ANN algorithm is Hierarchical Navigable Small Words (HNSW) (Malkov and Yashunin, 2018). HNSW works based on a layered graph structure that balances connectedness and shortest path length.

That was the first approach taken for the Semeval task. We generated vector representations for both claims and posts using sentence transformer models of varying sizes, and then HNSW to retrieve the claims for each post.

3.2 Reranking

As seen in the background section, early research on claim retrieval primarily relied on the lexical search to retrieve a small subset of claims, followed by reranking using embeddings generated by a sentence transformer model. This method has the advantage of limiting the use of computationally expensive resources to only a small portion of the data. A potential drawback is that the final result will depend on the selected samples.

We used an optimized version of BM25 (Lù, 2024) to select the top 200 candidates in the reranking approach. Since BM25, a bag-of-words method, is sensitive to noise, we preprocessed text by lowercasing, removing non-alphabetic characters, and stemming. In contrast, for reranking, we generated vector representations from the original text, as language models handle uncleaned text effectively. Finally, the top 200 candidates were ranked based on L2 similarity.

Group	Model	Parameters	Embedding Size	Context Length	Language
Small	sentence-transformers/all-MiniLM-L6-v2	22M	384	512	English

Table 1: Sentence Transformer Models Used

3.3 Fine-tuned models

Finetuning language models on domain-specific data has been widely recognized as effective in the literature (Choi and Ferrara, 2024), as it enables models to learn context-specific sentence representations. To enhance retrieval performance, we finetune sentence transformer models using the Train partition. Sentence transformers (Reimers and Gurevych, 2019) support datasets representing various notions of textual similarity. For finetuning, we adopt the *pair-class* approach, where each training instance consists of a premise, a hypothesis, and a label indicating their similarity.

We used the 25K claim-post pairs from the Train partition as the positive samples. An equal amount of negative samples were generated by randomly selecting claim-post pairs that are not annotated as true pairs in the Train partition. While this method may occasionally introduce false negatives, the likelihood is minimal given the ample number of claims and posts in the dataset. This process resulted in a training set of 51K samples. Sentence transformer models were finetuned using this training set and then leveraged to obtain the sentence representation for the Nearest neighbor and reranking approaches discussed earlier.

4 Experimental setup

4.1 Sentence Transformer Models

We experiment with various sentence transformer models for both monolingual and cross-lingual retrieval tasks. We categorize them into the following three groups based on the number of parameters.

- Small: Fewer than 400 M parameters
- Medium: Between 400M and 1B parameters
- Large: More than 1B parameters

Table 1 lists the models used in the experiments and their characteristics. They range in size from 22M to 9B parameters, with embedding dimensions between 384 and 8960, and context lengths from 512 to 32K. We experiment with monolingual and multilingual models. The largest model in our study, *BAAI/bge-multilingual-gemma2* (Chen et al., 2024), is based on *google/gemma-2-9b* (Team, 2024) and contains 9B parameters. This model was trained on a diverse dataset spanning multiple languages and tasks, including retrieval. All the models used in the experiments are available in Huggingface via the Sentence Transformer library (Reimers and Gurevych, 2019).

5 Results

5.1 Environment Setting

Although the medium and large models support a higher context length, we restrict the maximum text length for obtaining sentence embeddings using sentence transformers to 512. This limitation is primarily due to memory constraints, as higher context lengths often result in out-of-memory errors. However, we were unable to fine-tune large models, as they require additional memory optimization techniques, such as Low-Rank Adaptation (LoRA), to enable efficient fine-tuning with limited GPU memory. Consequently, we fine-tuned only the small and medium-sized models. All experiments were performed using a single GPU (either Volta V100 or Ampere A100) with 8 CPU cores and 11 GB of memory per core for training and testing all models. The other hyperparameters used across retrieval and finetuning processes are discussed in Appendix A.1.

We report Success@10, which measures the fraction of queries where the corresponding fact-check was retrieved within the top 10 results in the train and development data released by the task organizers. For the monolingual task, we compute the language-wise average.

		Monolingual		Cross-lingual

Table 3: Performance of the Finetuned Models on Nearest Neighbors and Reranking Approaches

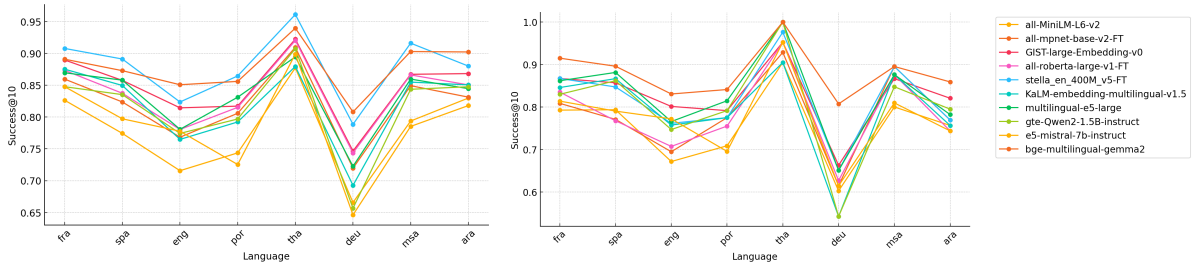
5.2 Performance of Pretrained Models

Table 2 presents the Success@10 scores of various models. Notably, the largest model, *bge-multilingual-gemma2* (Chen et al., 2024), outperforms all other models in both monolingual and cross-lingual tasks. However, most of the medium-sized or large models do not benefit from the reranking approach. This suggests that these models are already powerful enough to retrieve relevant results within the top 200, making the combination with BM25 in a two-step ranking approach ineffective. In contrast, among the smaller models, reranking consistently improves performance—except for *GIST-large-Embedding-v0* (Solatorio, 2024)—with the highest improvement of 5.4% observed with the *all-roberta-large-v1 model* (Liu et al., 2019) model in the cross-lingual task.

Interestingly, *GIST-large-Embedding-v0* (Solatorio, 2024) from the small group and *stella_en_400M_v5* (Zhang et al., 2024) from the medium group outperform most of the medium-sized and large models. This highlights that, despite having fewer parameters, these models are highly effective in representing text as embeddings. We submitted the predictions generated by the pretrained *bge-multilingual-gemma2* (Chen et al., 2024) model using the nearest neighbor approach to the task leaderboard, as this method demonstrated the best performance. Our submission achieved 18th place in the monolingual task and 15th place in the crosslingual task.

5.3 Performance of Finetuned Models

In this section, we discuss the impact of the finetuning process on retrieval approaches. As men-



(a) Train (b) Dev

Figure 2: Language-wise Performance of the Models

tioned earlier, we fine-tuned only the small and medium-sized sentence transformers. Table 3 presents the performance of the fine-tuned models in both nearest neighbor and reranking approaches. Among the models compared, *all-mpnet-base-v2*, *all-roberta-large-v1* and *stella_en_400M_v5* show significant performance gains in *Train* and *Dev* partitions. Notably, *all-roberta-large-v1* (Liu et al., 2019) achieves the highest improvement, with an 11.4% increase in the cross-lingual task. Furthermore, the fine-tuned *stella_en_400M_v5* model attains performance competitive with the largest model, *bge-multilingual-gemma2* (Chen et al., 2024), in both tasks on the *Train* partition. This demonstrates that with further focus on generalizing these models, it is possible to achieve powerful sentence transformer representations comparable to those of larger models. Similar to the behavior of pretrained models, the reranking approach benefits only the smaller models. However, this trend is observed exclusively in the monolingual task, while reranking with fine-tuned models tends to decrease performance in cross-lingual task.

5.4 Language-wise Performance

We analyze the language-wise performance of the pretrained and finetuned models in the nearest neighbor approach. We choose either a pretrained or finetuned model depending on its performance in the Train partition. Figure 2 presents the Success@10 scores across languages, with finetuned models denoted by the postfix *FT*.

All models exhibit strong performance in the *Thai* language, followed by *Malay, French, Spanish* and *Arabic*. Conversely, *German* demonstrates the weakest retrieval performance. Despite being a high-resource language, *English* achieves only moderate performance. These trends, however, are influenced by factors such as imbalanced language samples, translation errors, and data annotation issues (discussed further in Appendix A.2). Among the models evaluated, *bge-multilingual-gemma2* consistently achieves the highest performance across languages in the Dev partition. While the medium-sized model *stella_en_400M_v5* performs best in Train, its performance declines in Dev, suggesting limited generalizability.

6 Conclusion

This paper presents the experiments conducted by the ClaimCatchers team for SemEval task 7, focusing on multilingual fact-checked claim retrieval. We investigate the performance of various sentence transformer models, categorized into three groups—small, medium, and large—based on the number of parameters. These models are evaluated using a range of approaches, including nearest neighbor, reranking, and fine-tuning.

Our experiment results show that the largest pretrained model, *BAAI/bge-multilingual-gemma2* yields the best performance when applied with nearest neighbor approach in both monolingual and cross-lingual tasks. Furthermore, the pretrained medium-sized and large models are powerful enough to retrieve more accurate results than when combined with reranking strategies like BM25. Interestingly, some small and medium-sized pretrained models outperform the larger models, indicating that the number of parameters is not the sole factor in achieving rich sentence representations. Additionally, the finetuned medium-sized model, *NovaSearch/stella_en_400M_v5*, is competitive with the largest model in *Train* partition, indicating that smaller or medium-sized models, with focused fine-tuning, can achieve performance comparable to larger models. These findings highlight the potential of smaller and fine-tuned models to achieve competitive performance, emphasizing the importance of selecting the appropriate ranking and fine-tuning strategies.

A Appendix

A.1 Hyperparameters

Table 4 lists the hyperparameters used across different approaches.

	Hyperparameter	Value
Nearest Neighbour	Distance	l2
	No. bidirectional links per node	48
	No. neighbors considered during graph construction	200
	No. neighbors considered during search	200
BM25	Document length normalization factor	1
Sentence Transformers	Maximum sequence length	512
Finetuning	Batch size	16
	Learning rate	2E-05
	Warmup ratio	0.1
	No. epochs	1

Table 4: Hyperparamets

A.2 Data Labeling Issues

Analysing the data, we observed cases where a fact-check that appears among the top 10 candidates for a post could be considered correct, but it's not mapped as a valid pair. It is natural to expect that there are similar posts and fact-checks in which a small difference is enough to make the pair invalid, but we found cases where potentially valid pairs are not labeled as such, as shown in Table 5. This could explain part of the limited performance of smaller language models: they can identify very close matches, but these matches are not recognized as valid results.

Figure 3 presents the distribution of the cosine distance between valid pairs and posts computed using sentence-transformers/all-MiniLM-L6-v2. With a mean of 0.34, the distribution indicates that smaller cosine distances increase the probability of a retrieved fact-checked being valid. However, among all retrieved results in the top 10 with a cosine distance lower than 0.2, only 40% are mapped as valid pairs. While the remaining 60% likely include incorrect post/fact-check pairs, some of them could potentially be considered correct.

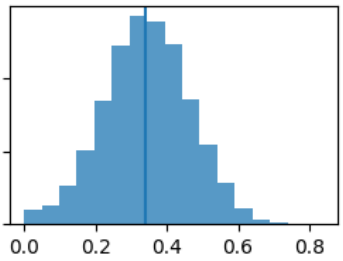

Figure 3: Distribution of cosine distance of valid post/fact-check pairs. With mean value of 0.34

This supports the organizers' decision to use Success@10 as the evaluation metric, as it mitigates the impact of misclassified pairs that should have been mapped and are likely to appear among the top results.

NEKO at SemEval-2025 Task 4: A Gradient Ascent Based Machine Unlearning Strategy

Chi Kuan Lai and Yifei Chen
University of Tuebingen
chi-kuan.lai@student.uni-tuebingen.de
yifei.chen@student.uni-tuebingen.de

Abstract

The power and wide application of large language models (LLMs) has brought the concerns on its risk of leaking private or sensitive information. However, retraining the modules is expensive and impractical, which introduces machine unlearning - removing specific information from language models while preserving general utility. Task 4 at SemEval 2025 consists of a shared task with this exact objective. We present an approach which combines gradient ascent-based forgetting with Kullback-Leibler (KL) divergence-based retention, applied to a 1-billion-parameter causal language model. Despite achieving effective forgetting, the system struggles with maintaining model utility. Our experiments reveal critical trade-off between unlearning effectiveness and performance preservation, highlighting challenges in practical machine unlearning implementations. Our code can be found on GitHub. [1]

1 Introduction

Large Language Models (LLMs) have demonstrated remarkable capabilities in generating human-like text (Touvron et al., 2023), while there are growing concerns about data privacy in the interactions. Their ability to memorize vast amounts of data may lead to significant ethical and security issues (Liu et al., 2025; Xu et al., 2023), including enhancing societal biases and stereotypes, generating sensitive or harmful content, private data leakage, being vulnerable to jailbreaking or other security attacks, or potential misuses for cyberattacks (Hendrycks et al., 2023; Jang et al., 2022; Marchant et al., 2022; Motoki et al., 2024; Singh and Anand, 2017; Wen et al., 2023; Zou et al., 2023). There is an urgent need for solutions that maintain a balance between ensuring the safe use of LLMs and preserving their utility to effectively meet user needs (Chen and Yang, 2023).

Given the substantial time and resources required to train LLMs, retraining them to eliminate harmful influences is often impractical (Brown et al., 2020). As an alternative, machine unlearning has emerged as a method for selectively removing the influence of undesirable data from pre-trained models (Nguyen et al., 2022). Machine unlearning (MU), defined as "forgetting undesirable misbehaviours on large language models (LLMs)" (Yao et al., 2023), aims to eliminate the influence of unwanted data, such as sensitive or illegal information, while maintaining the integrity of essential knowledge generation and not affecting causally unrelated information(Bu et al., 2024).

The SemEval-2025 Task 4 on Machine Unlearning (Ramakrishna et al.) is a shared task focused on machine unlearning for LLMs. Participants are tasked with developing methods to remove specific knowledge from a given trained model without retraining it from scratch. The goal is to ensure the model forgets the designated forget set while maintaining accuracy on the retain set. This challenge consists of three English-language subtasks:

- **Subtask 1**: Long-form synthetic creative documents spanning different genres.
- **Subtask 2**: Short-form synthetic biographies containing personally identifiable information (PII), including fake names, phone numbers, social security numbers (SSNs), emails, and home addresses.
- **Subtask 3**: Real documents sampled from the target model's training dataset.

Our system participated in all three subtasks with the intention to implement and validate a widely adopted unlearning strategy, namely gradient ascent (GA). We employed a dual-objective optimisation strategy that combines gradient ascent and Kullback-Leibler (KL) divergence. GA maximizes

[1] https://github.com/devychen/SemEval2025_Task4_NEKO

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 463–467

the loss on the forget set, driving the model to unlearn specific information, while KL minimisation preserves general knowledge by minimizing divergence from the pre-trained model. This iterative process balances these objectives, ensuring targeted forgetting without severe degradation of overall performance. We implemented our approach on a 1-billion-parameter model due to computational constraints. The evaluation relied on sentence completion and Question and Answer (Q&A) tests to measure both forgetting effectiveness and the retention of general knowledge. The details will be unfolded in the following sections.

2 Methods and experimental setup

Data sets

For each subtask, there are two data sets provided. One forget set, one retain set. Each data set contains disjoint retain and forget splits in parquet files. Examples of full documents and test prompts for the three tasks covered are available at figure 1 in Ramakrishna et al. (2025), and a full copy of data sets can be found on our Github.

After data preprocessing, depending on the subtask, the data input was either structured as question-answer (QA) pairs or free-form text for generation:

Input	Structure
Q&A Pairs	`### Question: ...` `### Answer: ...`
Text Generation	`### Text: ...`

Table 1: Structured input

Model

The base model released by the organisers is a fine-tuned 7-billion-parameter (7B) model called OLMo-7B-0724-Instruct-hf[2], trained to memorise documents from all three subtasks (Ramakrishna et al., 2024). But we use the smaller 1-billion-parameter (1B) model named OLMo-1B-0724-hf[3] (Ramakrishna et al., 2024) which is also fine-tuned to memorise the dataset in the unlearning benchmark similar to the 7B model due to computational constraints.

[2] https://huggingface.co/allenai/OLMo-7B-0724-Instruct-hf

[3] https://huggingface.co/allenai/OLMo-1B-0724-hf

Objectives

Similar to the inspiring work of Yao et al. (2023), our unlearning goal is effectiveness and utility. First, **effectiveness** requires that the updated model forget targeted samples such that its outputs for inputs in the forget set diverge substantially from the original responses. For example, if an input originally produces sensitive content, then after unlearning the model should yield a benign and insensitive response. Second, **utility** ensures that the model's performance on standard tasks remains intact. The expected outputs vary with the task: for question-answering, the model must produce correct answers for the retain set while successfully omitting the forgotten information; for text generation, the system must maintain fluency and coherence, avoiding the inclusion of any content that has been designated for unlearning. This balance is crucial, as the removal of harmful or unwanted content should not come at the cost of overall performance.

Methods

Gradient-based methods are extensively employed for tackling unlearning tasks (Eldan and Russinovich, 2023; Guo et al., 2019; Maini et al., 2024; Neel et al., 2021; Trippa et al., 2024). Following Yao et al. (2023), we opted for Gradient Ascent (GA) in our unlearning framework due to its directness and efficiency. As there are only negative example in our task, gradient ascent would provide a more straightforward method to suppress sensitive outputs without requiring positive reinforcement signals, comparing to reinforcement learning from human feedback (RLHF), which relies on both positive and negative samples to adjust token probabilities indirectly.

To mitigate unintended degradation in general performance, we also incorporated **Kullback–Leibler (KL) divergence**, which enforce a constraint deviations between the updated and original models on non-targeted data. While the gradient ascent loss pushes the model to "unlearn" targeted knowledge, the KL term effectively "pulls" the model back toward its original distribution on unaffected inputs. This ensures the model retains its competence on benign inputs while unlearning harmful content. Without this constraint, aggressive modifications may compromise overall utility. By balancing GA-driven forgetting with KL-based retention, we hope to achieve a controlled unlearning process that maintains fluency and accuracy.

Our framework optimizes two objectives concurrently:

$$\mathcal{L}_{\text{GA}} = -\frac{1}{N}\sum_{i=1}^{N}\text{CrossEntropy}(\hat{y}_i, y_i) \quad (1)$$

$$\mathcal{L}_{\text{KL}} = \frac{1}{N}\sum_{i=1}^{N}\text{KL}\left(\text{softmax}(M_{\text{ref}}(x_i)), \text{softmax}(M(x_i))\right) \quad (2)$$

$$\mathcal{L}_{\text{total}} = \alpha \cdot \underbrace{\mathcal{L}_{\text{GA}}}_{\text{Forgetting}} + \beta \cdot \underbrace{\mathcal{L}_{\text{KL}}}_{\text{Retention}} \quad (3)$$

where $\alpha = 0.2$ (`BAD_WEIGHT`) and $\beta = 1$ (`NORMAL_WEIGHT`). Here, $\mathcal{L}_{\text{GA}}$ promotes forgetting by maximizing prediction error on harmful data, while $\mathcal{L}_{\text{KL}}$ ensures stability by minimizing distributional shifts on benign inputs. This dual-objective design enables effective suppression of harmful content while preserving the model's general utility.

Additionally, we chose GA for its simplicity and clarity as an initial step in our research. Although we plan to explore more refined techniques (e.g., gradient difference methods or Hessian-based unlearning) later, GA provides a solid and interpretable baseline for achieving our unlearning objectives.

Training process

Our training process followed a dual-objective optimisation framework, balancing targeted forgetting with general knowledge retention. The dataset was partitioned into a *forget set* and a *retain set* and restructured. Proper preprocessing ensured correct formatting before training.

A composite loss function was employed, combining gradient ascent (GA) to increase loss on the forget set and Kullback-Leibler (KL) divergence to penalise deviations from general knowledge. The loss weights for retention and forgetting, batch size, and learning rate were systematically tuned to achieve stable training dynamics. Based on empirical evaluation, the optimal configuration was determined as a forget loss weight of 0.2, a batch size of 32, and a learning rate of 5e-5. This setup effectively balanced unlearning and retention while maintaining coherence in the retain set outputs.

Training was conducted with iterative updates using this optimised loss function. An early stopping mechanism with a patience of 4 was implemented to prevent over-fitting, terminating training after 500 steps. The sensitivity analysis of hyperparameters indicated that retention is more fragile than forgetting, underscoring the importance of careful tuning to maintain utility while achieving effective unlearning.

3 Results

Metrics	Scores
MMLU	0.229
MIA	0.824
Task Aggregare	0.0
Final Score	0.351

Table 2: Scores of our system

The evaluation framework provided by the organisers consists of four key metrics: MMLU Score, MIA Score, Task Aggregate Score, and Final Score. Table 2 presents our scores.

The *MMLU Score* measures model accuracy on a comprehensive STEM benchmark across 57 subjects, with a minimum threshold of 0.371 set to ensure sufficient model utility. Our model, however, achieved an MMLU Score of 0.229. Although this is below the specified threshold, it is important to note that the MMLU metric is included primarily for completeness rather than as a strict filter for performance.

The *MIA Score* evaluates the model's resistance to membership inference attacks via a loss-based method. A high MIA score (close to 1) indicates that the model is robust to MIA, meaning it does not leak information about its training data. And our dual-objective unlearning strategy resulted in an MIA Score of 0.824, demonstrating that our approach is highly effective at removing targeted information and reducing the risk of sensitive data leakage. This high score is a clear testament to the success of the unlearning mechanism implemented in our framework.

Additionally, the *Task Aggregate Score* is computed as the harmonic mean of 12 individual task-specific scores, which include metrics such as regurgitation rates measured by ROUGE-L and exact match rates for both the retain and forget sets (with the forget set metrics inverted). For our model, the Task Aggregate Score was recorded as 0.0, reflect-

ing significant challenges in maintaining overall task performance after unlearning. This low score suggests that the model struggled to perform well across multiple tasks. Further analysis of the forget set metrics is required to determine whether the model effectively unlearned the target information.

Finally, the *Final Score*, calculated as the arithmetic mean of the MMLU, MIA, and Task Aggregate Scores, was 0.351. Based on this composite metric, our submission is ranked 15th out of 24 entries. These results collectively underscore a critical trade-off in our dual-objective approach: while our method might have excelled in eliminating targeted content, it also results in a notable degradation of overall task performance.

4 Conclusion

Our experiments faced several practical challenges that influenced both training and model performance. A key constraint was the selection of a 1B parameter model instead of a 7B variant due to computational limitations. While necessary for efficiency, this decision likely contributed to performance degradation, as smaller models struggle to balance knowledge retention and unlearning.

GPU limitations further restricted our approach. Running both teacher and student models concurrently led to high memory consumption, reducing batch sizes and limiting additional loss components like random answer loss. This required careful hyper-parameter tuning with minimal architectural modifications to maintain a feasible balance between unlearning and retention.

Despite these challenges, our systematic adjustments provided valuable insights into optimizing unlearning strategies under resource constraints. Future work should explore more efficient parameter-sharing techniques or distillation-based approaches to mitigate computational burdens while maintaining effectiveness. Addressing these limitations will be essential for advancing unlearning methodologies in large-scale models.

Limitations

Our approach is constrained by computational resources, using a 1B-parameter model instead of a 7B variant, likely impacting performance. Gradient ascent and KL divergence, while effective, may not optimally balance forgetting and retention compared to advanced unlearning techniques. GPU memory limitations restricted batch sizes and architectural modifications, reducing flexibility. Additionally, limited hyper-parameter tuning may have hindered performance optimization. Our evaluation also did not assess potential adversarial vulnerabilities post-unlearning. Future work should explore more scalable methods and robustness analysis to enhance unlearning effectiveness while maintaining model utility.

Acknowledgments

We thank *SemEval 2024 Task 4* organisers for dataset and model curation and the evaluation.

We thank our instructor Mr. *Çağrı Çöltekin* from the course *Challenges in Computational Linguistics* for encouraging and helping us on the completion of the task.

Abstract

This paper describes the approach of the Unibuc - NLP team in tackling the SemEval 2025 Workshop, Task 11: Bridging the Gap in Text-Based Emotion Detection. We mainly focused on experiments using large language models (Gemini, Qwen, DeepSeek) with either few-shot prompting or fine-tuning. With our final system, for the multi-label emotion detection track (track A), we got an F1-macro of 0.7546 (26/96 teams) for the English subset, 0.1727 (35/36 teams) for the Portuguese (Mozambican) subset and 0.325 (**1**/31 teams) for the Emakhuwa subset.

1 Introduction

Task 11 from the International Workshop on Semantic Evaluation (Muhammad et al., 2025b) focuses on identifying emotions that most people would think the speaker might feel given a short piece of text. With all the advances in the AI world, automatic emotion detection plays such an important role: it can lead to more empathetic and context-aware interactions between humans and chatbots / AI assistants, improving user experience and satisfaction; it can help monitoring mental health conditions and provide timely interventions such that more people seek for help before is too late; it can help business to understand the customers sentiments regarding different products or services and can improve their strategies.

The best system developed for Task 11 track A is based on Gemini Flash (et. al., 2024) model using different techniques of few-shot prompting.

We made our models publicly available in a GitHub Repository.

2 Background

The competition is multilingual and it had 3 tracks:

A. Multi-label Emotion Detection (28 supported languages)

B. Emotion Intensity (12 supported languages)

C. Cross-lingual Emotion Detection (28 supported languages)

We participated to track A with our system for 3 languages: Emakhuwa 0.325 F1-macro (position **1**/31 teams), English 0.7546 F1-macro (position 26/96 teams) and Portuguese (Mozambican) 0.1727 F1-macro (position 35/36 teams).

2.1 Dataset

The BRIGHTER dataset (Muhammad et al., 2025a) was collected from 4 different data sources (social media posts, personal narratives, literary texts, and news data) in 28 different languages:

Language	Train	Dev	Test
ENG	2,768	116	2,767
PTMZ	1,546	257	776
VMW	1,551	258	777

Table 1: Train/Dev/Test splits for languages tackled with our system for track A

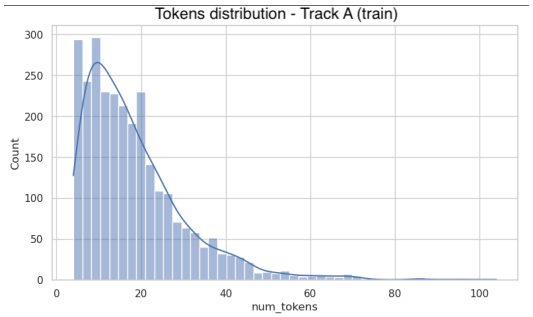

Figure 1: Track A: Distribution of token length for the training dataset in english

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 468–475

2.2 Previous Work

Emotion detection in text has been a subject of study for a considerable time, with early approaches relying on lexicon-based methods. These methods leverage pre-compiled lists of words associated with different emotions. For instance, the presence of words like "happy," "joyful," or "excited" might indicate a positive emotion, while words like "sad," "depressed," or "miserable" could suggest sadness. Later, traditional machine learning classifiers such as Support Vector Machines (SVMs), Naive Bayes, and Maximum Entropy models became popular for emotion detection. These models typically rely on handcrafted features extracted from text, including bag-of-words, TF-IDF, n-grams, and sentiment lexicons.

More recently, Recurrent Neural Networks (RNNs), particularly Long Short-Term Memory networks (LSTMs) and Gated Recurrent Units (GRUs), proved effective in capturing sequential information in text, enabling models to better understand context and dependencies within sentences and documents (Poria et al., 2017). Convolutional Neural Networks (CNNs) were also employed to extract local features and patterns indicative of emotion (Kim, 2014).

Transformer-based models, such as BERT (Devlin et al., 2018), RoBERTa (Liu et al., 2019), and their variants, have achieved state-of-the-art performance in various NLP tasks, including emotion detection. These models, pre-trained on massive amounts of text data, capture rich contextual representations of words and sentences, leading to significant improvements in accuracy and robustness. Fine-tuning these pre-trained models on emotion-annotated datasets became a common practice for achieving high performance in emotion detection tasks. The SemEval challenges have consistently played a significant role in driving research in emotion detection. SemEval 2024 contained Task 10 which tackled emotion discovery and reasoning flip in conversation (EDiReF). The majority of participants used LLMs and achieved best results (Creanga and Dinu, 2024).

3 System overview

In this paper, we focused our research on three approaches: **fine-tuning BERT** based models (3.1), and two techniques for LLMs: **Few-Shot Prompting** (3.2) and **Fine-tuning** (3.3).

3.1 Fine-tuning BERT based models

We experimented with several prominent transformer-based models: DeBERTa v3 Large (He et al., 2021), mBERT (Multilingual BERT) (Devlin et al., 2018), and XLM-RoBERTa-large (Conneau et al., 2019). These models represent advancements in pre-trained language model architectures and have demonstrated strong performance in cross-lingual understanding tasks. We utilized these pre-trained models as feature extractors and appended a simple classification head on top. We extract sentence-level feature representations by specifically using the [CLS] token output from the transformer's final hidden layer. To prevent overfitting, we apply a dropout rate of 0.3 to these features. These extracted features are then fed into a fully connected network, designed for classification. This network comprises two core blocks. Each block progressively reduces the feature dimensionality, starting with 512 neurons and narrowing down to 128. The final layer of the fully connected network has 6 output neurons, corresponding to the 6 emotion categories we are predicting. We apply a higher dropout rate of 0.5 within the fully connected network, again for regularization. The model outputs raw prediction scores without any activation function.

We trained this model over 3 epochs in a two-stage approach, as recommended in (Marchitan et al., 2024). Initially, for the first 2 epochs, we froze the transformer layers, only training the weights of our fully connected classification network. This allows the classification layers to adapt to the pre-trained transformer features without disrupting the transformer's learned representations. In the final 1 epoch, we unfroze the last transformer layer and fine-tuned it along with the fully connected network. This enables the model to slightly adjust the transformer's understanding of the input text to be even more relevant for our specific emotion detection task. We used a batch size of 32 during training and employed the AdamW optimizer, known for its effectiveness in training transformers. For the initial frozen-transformer training phase, we used a learning rate of 3e-4, which was reduced to 2e-4 during fine-tuning to prevent destabilizing the already partially trained model. A linear learning rate scheduler with a 50-step warm-up was used to gradually increase the learning rate at the beginning of training, promoting stable convergence. We used cross-entropy

loss as our objective function.

While our BERT-based models, provided a good baseline, their performance did not reach the levels achieved by LLMs like Gemini Flash (Table 2). However, it's important to note that these BERT models offer a significant advantage in terms of computational resources. They are considerably smaller in model size and demonstrate substantially faster inference speeds compared to LLMs.

Lang	Model	F1 Macro	F1 Micro
ENG	mBERT	0.54	0.56
ENG	DeBERTa	0.70	0.70
ENG	XLM-RoBERTa	0.70	0.71

Table 2: Results of BERT based models for validation set.

3.2 Few-Shot Prompting

We found that Few-Shot prompting beats Zero-Shot by around 7% in performance. Prompts can be inspected in Appendix A. For example Qwen2.5-14B Zero-Shot CoT obtained an F1 Macro of 0.63, while with Few-Shot 0.70. This was observed across all models. Another insight was that increasing the number of examples we gave to the model will result in an increase in performance. We tried giving 6 examples, one that included each emotion and progresively giving it more examples: 100, 300 and 600. Best results were when we gave the most examples (600). A third insight is that we found out that complex prompting techniques like CoT and ToT actually make the models perform worse. We believe this is because the task is a perceived emotion task, where the annotations are not necesarily the ground truth, but what the labelers considered to be true. Following the thinking process of the models, in the examples where they disagreed with the ground truth, we were actually conviced that the models were right in most of the cases.

Our experiments (Table 3) revealed a consistent performance advantage for few-shot prompting over zero-shot prompting, with an approximate improvement of 7% in F1-macro. For example, the Qwen2.5-14B model (Qwen et al., 2025) achieved an F1-macro score of 0.63 using zero-shot prompting, while few-shot prompting boosted performance to 0.70. This trend was observed across all models evaluated. Furthermore, we investigated the impact of increasing the number of examples provided within the few-shot prompts. By progressively increasing the example count (from an initial set of 6 examples, one for each emotion, to 100, 300, and finally 600 examples), we observed a positive correlation between the number of examples and performance. The highest F1-macro scores were consistently obtained when utilizing the largest example set of 600.

Counterintuitively, we found that employing more complex prompting techniques such as Chain-of-Thought (CoT) (Wei et al., 2022) and Tree-of-Thought (ToT) (Long, 2023) did not yield the expected performance gains. In fact, these methods tended to slightly degrade performance in our specific task. We hypothesize that this unexpected outcome stems from the nature of the "perceived emotion" task itself. In this task, annotations do not necessarily represent an objective "ground truth" emotion, but rather reflect human annotators' subjective interpretations of the speaker's likely feelings. Consequently, while CoT and ToT are designed to encourage models to mimic human-like reasoning processes, in this context, forcing the model to explicitly articulate a detailed thought process may not align with the inherently subjective and potentially less consciously reasoned nature of perceived emotion annotation. Indeed, in instances where model predictions diverged from the assigned labels, our qualitative analysis suggested that the models' reasoning, often aligned with alternative, yet plausible, emotional interpretations of the text.

Model	Type	Examples	F1 Macro
Qwen2.5	Zero-Shot	0	0.63
Qwen2.5	Z-S CoT	0	0.63
Gemini	F-S ToT	6	0.63
Gemini	F-S ToT	20	0.64
Gemini	Few-Shot	6	0.69
Qwen2.5	Few-Shot	6	0.70
Gemini	Few-Shot	500	0.76
Gemini	Few-Shot	600	0.77

Table 3: Results of LLM models for validation set. The exemples were given from the training set. We used Qwen2.5-14B and Gemini 2.0 Flash Exp. Z-S means Zero-Shot, F-S means Few-Shot.

3.3 Fine-tuning

We experimented fine-tuning with different large language models (DeepSeek (et. al., 2025), Mis-

tral 7B (Jiang et al., 2023) and Qwen2.5 (Qwen et al., 2025)) as the backbone of our system architecture, on top of which we added a multi-label classification layer in order to classify the emotions present in the given text. We set the maximum number of tokens to 256 and we truncated the longer text by keeping the first part of the text, as suggested in (Marchitan et al., 2024). We then fine-tuned the quanitized model using Low-Rank Adaptation (LoRA) (Hu et al., 2022) with following hyperparameters: $r = 4$ ($r = 2$ for Mistral 7B), $lora\_alpha = 8$ and $lora\_dropout = 0.05$ ($lora\_dropout = 0.1$ for Qwen2.5-1.5B). The fine-tuning was done using the AdamW optimizer (Loshchilov and Hutter, 2019) with a weight decay of 0.01, weight ratio of 1% for Mistral 7B and Qwen2.5-1.5B, but 2% for other 2 models. We set the learning rate to $2e-5$ when fine-tuning DeepSeek and Qwen2.5-1.5B, $5e-5$ for Mistral 7B and $2e-4$ for Qwen2.5-0.5B. Cross entropy loss was used during training to measure the performance. We used different batch sizes (4 for Mistral 7B; 8 for DeepSeek and Qwen2.5-0.5B; 32 for Qwen2.5-1.5B) based on the total number of trainable parameters in order to be able to fit on the available hardware. We set the maximum number of epochs to 15, but the actual number of training epochs varies as we implemented the early stopping strategy and the final model is the one with the smallest loss on the validation set.

LLM Backbone	Epochs	Train Loss	Dev Loss
DeepSeek R1 Distill Llama 8B	5	0.2495	0.3181
Mistral 7B	3	0.2515	0.3455
Qwen2.5-0.5B	3	0.3941	0.3614
Qwen2.5-1.5B	8	0.3714	0.3571

Table 4: Train and validation losses for each model alongside the number of epochs trained.

4 Results

We participated in Track A and tested our proposed system on 3 languages: English, Portuguese (Mozambican) and Emakhuwa. We managed to be over the baseline on 2 out of the 3 languages and secured the first position for one of them, as shown in Table 6. This reflects our model's ability to adapt with few-shot in-context learning especially on languages with limited availability of NLP resources (such as Emakhuwa).

Language Code	F1 Macro	Place
VMW	0.3250	**1** / 31
ENG	0.7546	26 / 96
PTMZ	0.1727	35 / 36

Table 6: Team Unibuc - NLP results on Track A.

4.1 Error Analysis

Examining the confusion matrices (Figure 2, Figure 3, Figure 4, Figure 5, Figure 6), we observe distinct performance profiles across emotions. For fear, while the model achieves its highest True Positive rate (TP) at 88%, indicating strong detection of actual fear, it simultaneously exhibits its lowest True Negative rate (TN) at 70%. This combination suggests a tendency to over-predict fear, potentially misclassifying other emotions as fear. Conversely, for joy, the model shows the weakest performance in detecting the emotion when it is present, achieving the lowest TP of 67% and consequently, the highest False Negative rate (FN) of 32%, indicating a higher likelihood of missing instances of joy. Furthermore, the highest False Positive rate (FP) of 30% is also associated with fear, reinforcing the observation of potential over-prediction for this emotion. It seems like with both approaches we have experimented with LLMs (few-shot prompting and fine-tuning) the models tend to over-predict fear while under-predicting joy (Figure 7).

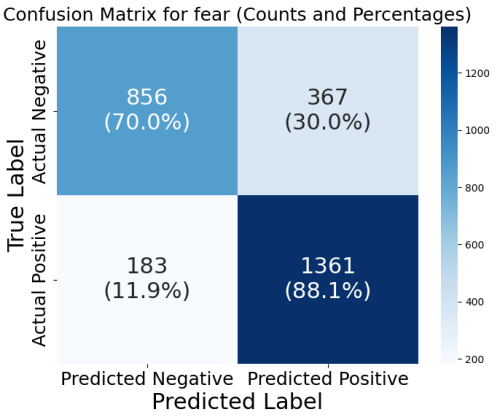

Figure 2: Confusion Matrix for Fear (Counts and Percentages)

LLM Backbone	Validation F1 Micro	Validation F1 Macro	Test F1 Micro	Test F1 Macro
DeepSeek R1 Distill Llama 8B	0.7723	0.7602	0.7744	0.7441
Mistral 7B	0.7696	0.7305	0.7699	0.7268
Qwen2.5-0.5B	0.7496	0.6975	0.7224	0.6840
Qwen2.5-1.5B	0.7340	0.6906	0.7319	0.6826

Table 5: F1 Micro and F1 Macro results on both train and validation datasets.

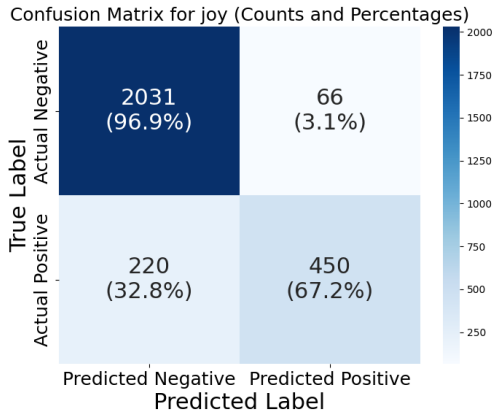

Figure 3: Confusion Matrix for Joy (Counts and Percentages)

5 Conclusions and Future Work

Our investigation explored three primary approaches: fine-tuning BERT-based models and leveraging LLMs through both few-shot prompting and fine-tuning techniques. While fine-tuned BERT models provided a solid performance baseline, they were ultimately surpassed by methods employing LLMs, particularly Gemini Flash with few-shot prompting, which formed the basis of our best-performing system. Interestingly, complex prompting strategies like Chain-of-Thought and Tree-of-Thought did not yield improvements, but degradations, possibly due to the subjective nature of the perceived emotion task.

Building upon the insights gained from this study, several avenues for future research emerge. Firstly, further investigation is warranted to understand the performance disparity observed across languages, particularly the lower F1-macro score for the Portuguese subset. Detailed dataset analysis and error analysis could reveal language-specific nuances or data biases impacting model performance. Secondly, exploring the new "thinking models" like "Gemini 2.0 Thinking" and "Thinking Claude" should be tested, as they show promises in other similar tasks.

A Example of prompts

A.1 Zero shot

Analyze the following sentence and identify all emotions that are present. Select from this list: "Anger", "Fear", "Joy", "Sadness", "Surprise". If multiple emotions are present, list them separated by commas. If no emotions from the list are present, respond with "None".

Sentence: [Sentence]

Emotions:

A.2 Zero shot with CoT

Analyze the following sentence and identify all emotions that are present. Select from this list: "Anger", "Fear", "Joy", "Sadness", "Surprise". If multiple emotions are present, list them separated by commas. If no emotions from the list are present, respond with "None". Let's break down the emotional content step by step.

Sentence: [Sentence]

Reasoning: Consider the specific words used, the context of the sentence, and any implied feelings.

Emotions:

A.3 Few shot with CoT

Analyze the following sentence and identify all emotions that are present.

Examples: 1. Sentence: "But not very happy." Emotions: Joy, Sadness 2. Sentence: "They were dancing to Bolero" Emotions: Joy, Sadness 3. Sentence: Yes, the Oklahoma city bombing." Emotions: Anger,Fear,Sadness,Surprise 4. Sentence: "5 year old me was scarred for life." Emotions: Fear, Sadness 5. Sentence: "How stupid of him." Emotions: Anger 6. Sentence: "I turned around so I could see my back." Emotions: Surprise

Given the following sentence, select from this list: "Anger", "Fear", "Joy", "Sadness", "Surprise". If multiple emotions are present, list them separated by commas. Let's break down the emotional content step by step.

Sentence: [Sentence]

Reasoning: Consider the specific words used, the context of the sentence, and any implied feelings. Output only the emotions that are present. No other words.

Emotions:

A.4 Few Shot with ToT

Analyze the following sentence and identify all emotions that are present. Given the following sentence, select from this list: "Anger", "Fear", "Joy", "Sadness", "Surprise".

Examples: [600 examples]

Given the following sentence, select from this list: "Anger", "Fear", "Joy", "Sadness", "Surprise". If multiple emotions are present, list them separated by commas. Let's break down the emotional content step by step using a Tree of Thoughts approach.

Sentence: [Sentence]

Reasoning:

Thought 1: Initial Impression: What is the first emotion that comes to mind upon reading the sentence? Briefly explain why.

Thought 2: Word-Level Analysis: Are there any specific words or phrases that strongly suggest an emotion? If so, which words and which emotions?

Thought 3: Contextual Considerations: Does the context of the sentence provide any additional clues about the emotional state? Consider the situation being described.

Thought 4: Alternative Interpretations: Are there any other possible interpretations of the sentence that might suggest different emotions? Explore these possibilities.

Thought 5: Synthesis: Based on the previous thoughts, which emotions are most likely present in the sentence? Justify your final selection.

Final Emotions: Output only the emotions that are present, separated by commas. No other words.

Emotions:

B Error analysis

Abstract

This study reports the details of the Entity-Aware Machine Translation model proposed by the YNU-HPCC team to participate in the SemEval 2025, Task 2. The task focuses on Entity-Aware Machine Translation (EA-MT) to enhance the translation of sentences containing challenging named entities. We investigated traditional machine translation (MT) and large language model (LLM)-based approaches, evaluating their performance using metrics such as M-ETA, and COMET. We integrated a BERT-based Named Entity Recognition (NER) module for the traditional MT system. This approach is simple and intuitive, providing fast performance for common NE categories while achieving accuracy at the standard level. In the LLM-based system, we leveraged multiple LLMs and designed tailored prompts supplemented with a few examples, to guide the model in recognizing named entities. The system effectively translated these entities with high precision by incorporating contextual information from the rest of the sentence. A comparative evaluation of both methods aims to provide insights for future research. More details can be found here.[1]

1 Introduction

The definition of named entities was first proposed by Beth M. Sundheim in 1995 (Ide et al., 2003). Named entities typically refer to entities in a text that have a specific identity or name. In machine translation tasks, named entities may be related to language and cultural differences. The meaning of the same named entity can vary significantly in different contexts. The translation result may be unsatisfactory if the model fails to correctly identify potential named entities in a sentence and translate them in the context. In the past, people used methods such as regular matching, traditional machine learning models like SVM (Ju et al., 2011), and context-dependent models like LSTM for translating sentences with named entities. This paper proposes four methods, respectively, based on traditional machine translation models and LLM-based models, aiming to improve the translation accuracy of sentences with named entities and explore the capabilities of LLMs.

This study proposes a local cache and online retrieval-based method for translating sentences containing named entities, which consists of two modules. The NER module is primarily used to accurately identify named entities in the sentence, preparing for the subsequent translation task. The translation module is mainly responsible for integrating the NE translation results and translating the entire sentence in context. Experimental results show that traditional MT models have speed and deployment cost advantages, while LLM-based models outperform translation accuracy and contextual coherence.

The rest of the paper is organized as follows: First, our team propose four methods to improve the performance of ea-mt based on the two modules mentioned above. Then we test them across all ten languages. Finally, we will analyze the experimental results.

2 Related Work

Named Entity Recognition (NER) is a fundamental task in Natural Language Processing (NLP), with applications in social media (Peng and Dredze, 2015), news (Vychegzhanin and Kotelnikov, 2019), e-commerce (Vychegzhanin and Kotelnikov, 2019), Nested Medical NER (Du et al., 2024) and other fields. NER in the past was performed using methods such as regular expression matching, traditional machine learning models like Support Vector Machines (SVM), Conditional Random Fields

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 476–481

(CRF) (Panchendrarajan and Amaresan, 2018), Maximum Entropy models (MaxEnt) (Saha et al., 2008), Recurrent Neural Networks (RNN) (Lyu et al., 2017), and Long Short-Term Memory networks (LSTM). Although these methods were effective in specific domains, the training process was cumbersome, and the ability to recognize context remained weak. With the introduction of Transformers and the emergence of various pre-trained models (Liu et al., 2023), recent advancements in pre-trained models, such as transformer-based model in name entity recognition (Luo et al., 2022), BERT (Ma et al., 2021), Tacl-BERT, and Nezha (Wei et al., 2019), have significantly improved NER performance. In SemEval 2022 Task 11 (Chen et al., 2022), impressive results were achieved by two teams: one proposed a knowledge-based NER system, while the other enhanced their model's performance by utilizing a gazetteer constructed from Wikidata. In SemEval 2023 Task 2 (Lu et al., 2023), one of the top-performing teams approached NER as a sequence labeling problem. These methods have performed well in their respective tasks and provided valuable insights for our upcoming task.

3 System Description

This section introduces four methods implemented in Task 2 (Conia et al., 2025) and analyzes how each works.

3.1 Method 1: M2M-100 with BERT

The m2m-100 pre-trained translation model performs the overall translation task in this approach (Fan et al., 2021). In contrast, a BERT model pre-trained on the CoNLL-2003 Named Entity Recognition dataset is used for named entity recognition (Sang and De Meulder, 2003). A named entity dictionary is maintained to identify potential named entities in the prediction dataset using the pre-trained model, and their corresponding translations are retrieved from Wikidata.

Considering the model size, named entities in the sentence may not be correctly truncated. Therefore, the position information of each named entity is recorded, and truncation is extended to the nearest space, sentence start, or sentence end. Since potential parentheses, punctuation, numbers, and special symbols may interfere with identifying named entities, a set of regular expression rules is also defined to clean the entities. The recognized named entities' corresponding translation information is searched on Wikidata. Given the complex page information in Wikidata and the tendency for similar entries to point to the same meaning, a similarity algorithm is used for filtering. The top 20 entries are retrieved, and their similarity to the queried entity is calculated. The number of statements and site links are also considered to prevent interference from similar entries. The highest similarity entry translation is obtained by calculating a weighted overall similarity. Before being translated by the m2m-100 pre-trained model, the named entities are replaced using a fixed-length sliding window, and the result is input to the translation model to obtain the final translation.

3.2 Method 2: Qwen2.5-32B with M2M-100

Considering the impact of BERT's model size on named entity recognition (NER) accuracy, the NER module was replaced with the 32b Qwen model. Prompts were carefully designed to guide the model in identifying potential entities within the sentence and returning them as a list (or None if no entities were found). A set of examples, accompanied by step-by-step instructions, was provided to facilitate the model's understanding of the task. The resulting output is then directly provided as input to the m2m-100 model. Through these changes, the average M-ETA score for each language improved by 10 to 15 points.

However, since the translation task was based on the m2m-100 model, the improvement in COMET scores was limited. Furthermore, traditional MT models may alter or re-translate named entities to some extent, leading to potentially uncontrolled results. Fine-tuning a machine translation (MT) model on a given training dataset can help the model memorize translation rules for named entities to some extent. However, this approach has two potential drawbacks: first, the overall translation ability of the model may decrease, as indicated by a slight reduction in COMET scores for each language; second, the model is limited to memorizing the translation rules for named entities in the training dataset and lacks strong generalization ability, making it unable to handle unseen entities or new translation scenarios.

3.3 Method 3: Qwen Ner and Translator

Considering the factors above, the Qwen model replaced the m2m-100 translation model. The Qwen-Max API from the Qwen series expanded

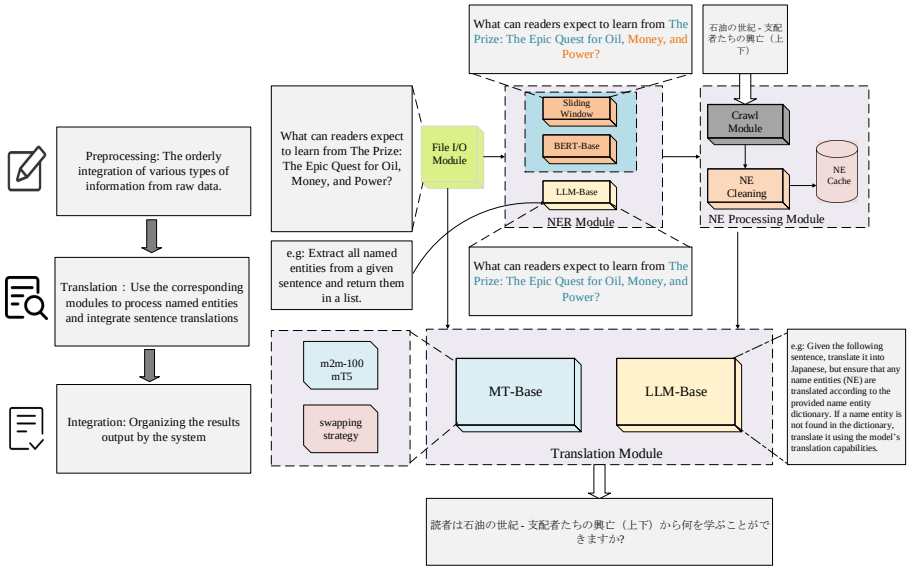

Figure 1: The overview of the system architecture

the model's parameters, enhancing its ability to translate in context and maintain named entities as required. Prompts were designed to guide the model step by step using the stored named entity dictionary to replace the entities in the sentence. A few examples and explanations were provided to assist the model in executing the task more effectively. After the adjustments, the M-ETA score significantly improved, while the comet score remained stable. The approach utilized two LLMs from the same series. It raises the question of whether a single model could be used with different prompts designed for various tasks.

In this method, the following considerations were made: for the languages IT and TR, the model underperformed on the comet metric, possibly due to issues within the translation module. Similarly, the model's performance on the M-ETA metric was suboptimal for TR and ZH-TW, likely stemming from the named entity recognition module. It is being considered whether fine-tuning the corresponding modules on specific languages can improve the model's performance for those languages.

3.4 Method 4: Qwen with Reason and Act

To further explore the capabilities of LLMs, the combination of reasoning and execution abilities in translation tasks involving named entities is investigated. It examines whether the model can effectively handle unexpected situations, such as the absence of corresponding translations in the named entity dictionary, while enhancing human interpretability and translation reliability. The ReAct method (Yao et al., 2023), based on the LangChain framework, is employed to implement the translation task.

In this method, the high generalization ability of the LLM for translation tasks is validated. The model can quickly understand the task requirements and sequentially generate the translation steps by providing only a few examples in the sample. Especially when multiple potential named entities are present in a sentence, the model first identifies them and produces a list of named entities. It then uses a tool function to search for corresponding translations. If no translation is found or the result is deemed unsatisfactory, the model automatically calls a new tool function to search for better matches. The model can theoretically achieve more accurate named entity translation by constructing a feasible tool function and providing effective information sources.

4 Results and Analysis

4.1 Dataset

This section introduces the dataset used in Task 2, which consists of training data, validation data, and predictions provided by GPT-4o and GPT-4o-mini (Conia et al., 2024). Both the training and validation datasets are provided in JSON format. The training data covers six languages: Arabic (ar), German (de), Spanish (es), French (fr), Italian (it), and Japanese (ja). Each data entry includes a unique ID, source language label (uniformly set to English), target language label, source sentence, target sentence, the source of the named entity, and the Wikidata ID. Approximately 5,000 data entries are provided for each language. In addition to the six languages mentioned, the validation data includes four additional languages: Korean (ko), Thai (th), Turkish (tr), and Traditional Chinese (zh-TW). Furthermore, each validation data entry includes all fields from the training data, along with the named entity type (e.g., "Artwork," "Movie"). Each validation entry may contain multiple translation versions. While the scale of validation data for each language is relatively small, it exhibits high diversity in language types and task complexity.

4.2 Evaluation Metrics

This section primarily introduces the evaluation metrics used in Task 2, which assess the translation of named entities (NER) and the overall sentence translation. The final evaluation formula is shown in Equation 2.

Figure 3: Example sentences from dataset

4.2.1 COMET

COMET (Cross-lingual Optimized Metric for Evaluation of Translation) is a metric used to evaluate the quality of machine translation systems. It is based on comparing the output of a machine translation system to the output of a human translation system. COMET uses a pre-trained model to generate a score for each translation, which is then used to evaluate the quality of the translation.

$$Sim = 0.2 * N + 0.3 * M + 0.5 * K \quad (1)$$

4.2.2 M-ETA

M-ETA (Manual Entity Translation Accuracy) is a metric used to evaluate the accuracy of entity translation in machine translation systems. At a high level, given a set of gold entity translations and predicted entity translations, M-ETA computes the proportion of correctly translated entities in the predicted entity translations.

4.2.3 Overall Score

The final evaluation score will be the harmonic mean of the two scores, i.e.:

$$overall = 2 * \frac{M-ETA * COMET}{M-ETA + COMET} \quad (2)$$

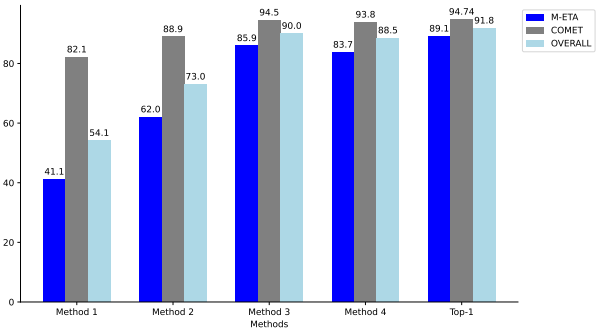

Figure 4: Our four methods compared with the Top-1.

4.3 Implementation Details

This section primarily discusses the details of the implementation of the parameters. When calculating the weighted similarity, experiments showed that the most accurate results and the highest M-ETA score were achieved when the statements, site links,and string ontology similarity weights were set to 0.2, 0.3, and 0.5, respectively. As shown in Formula 1, where N represents the number of statements, M represents the number of site links, and K represents the similarity calculated between two named entity strings using the Levenshtein Distance algorithm. In the regularization and cleaning of named entities, the focus is on potential brackets, excess punctuation, and special characters, without altering their character encoding (since languages like Arabic and Chinese may have multiple writing systems, the original version is retained without modification). In the named entity recognition section, the Qwen model does not involve temperature or top-p parameters adjustments. In the MT translation section, multiple experiments showed that setting the temperature parameter to 0.75 resulted in stable M-ETA values while maximizing the comet score.

5 Results

In the SemEval 2025 Task 2: EA-MT, the system performed translations for all 10 languages. The model ranked fifth without using Wikidata IDs or information, fifth without RAG, and seventh without fine-tuning. The final overall ranking was 11th. As shown in Table 1, the final scores for each language were presented for the four methods. It can be observed that the method combining two LLM models achieved the best result. Although the React method, implemented using the LangChain framework, yielded slightly lower results, it significantly increased human interpretability and the credibility of the outcomes, facilitating subsequent debugging and improvement. The COMET and M-ETA and overall scores for each method are shown in Table 3. The details of each language are shown in the Table 1 and Table 2.

	Average across all languages		
System	**M-ETA**	**Comet**	**Overall**
Method 1	41.133	82.074	54.081
Method 2	61.972	88.893	73.031
Method 3	**85.860**	**94.506**	**89.976**
Method 4	83.719	93.802	88.474

Table 3: Results of four methods on the task.

6 Conclusion

This study implements four methods for accurately translating sentences containing named entities in this shared task. A translation method based on traditional MT models was developed, offering speed, ease of deployment, and a certain level of named entity recognition. Multiple LLMs were combined for models based on LLMs, focusing on named entity recognition and translation. A named entity dictionary was utilized to improve the translation accuracy of entities. Additionally, the LangChain framework was used to test the performance of LLMs in generating reasoning trajectories and task-specific actions in the translation of named entities. Our experiments show that, with an additional named entity dictionary, LLMs can be effectively used for cross-lingual content translation involving unknown or complex named entities. For future work, the tool functions in LangChain to assist LLMs in translation, and it is expected that fine-tuning and RAG techniques will be combined to enhance the performance of LLMs in EA-MT further.

Abstract

Food safety is a critical global concern, and timely detection of food-related hazards is essential for public health and economic stability.The automated detection of food hazards from textual data can enhance food safety monitoring by enabling early identification of potential risks. In the Food Hazard Detection task, we address two key challenges: (ST1) food hazard-category and product-category classification and (ST2) food hazard and product vector detection. For ST1, we employ BertForSequenceClassification, leveraging its powerful contextual understanding for accurate food hazard classification. For ST2, we utilize a Random Forest Classifier, which effectively captures patterns in the extracted features for food hazard and product vector detection. This paper presents the results of the TechSSN3 team at the SemEval-2025 Food Hazard Detection Task, where we achieved a ranking of 21st in Task 1 and 19th in Task 2.

Keywords

t-SNE, TF-IDF, UHF, RFID, BERT, NLTK, Food hazards, Random Forest, NLP

1 Introduction

Food safety is a critical global concern, as contaminated food products can lead to widespread health risks, economic losses, and damage to consumer trust. Identifying food hazards early is essential for preventing outbreaks and ensuring regulatory compliance. Traditionally, food safety monitoring relies on manual inspection, regulatory reporting, and consumer complaints. However, these methods are slow, labor-intensive, and reactive rather than proactive. With the increasing availability of food-related incident reports on the web, there is an urgent need for automated systems that can detect food hazards from unstructured textual data.

The **SemEval-2025 Food Hazard Detection task** (Randl et al., 2025) aims to tackle these challenges by evaluating explainable classification models for food-incident reports. This task consists of two subtasks: (ST1) food hazard and product category classification, and (ST2) food hazard and product vector detection, which aims to identify the exact hazard-product associations. The task focuses on enhancing NLP-based hazard detection models for English-language reports, ensuring their effectiveness for regulatory and industrial applications.

We approach each subtask with methods best suited to their objectives. For ST1, we use **BertForSequenceClassification** to leverage contextual embeddings for accurate classification of food hazard and product categories. For ST2, a **Random Forest Classifier** is applied to engineered features to detect hazard-product associations, providing robustness and interpretability in relational modeling.

2 Related Work

The integration of machine learning (ML) with food hazard detection has been extensively explored, leveraging technologies such as spectroscopy, chromatography, mass spectrometry, and biosensors to identify potential contaminants. ML enhances the accuracy and efficiency of hazard detection by analyzing complex patterns in food composition, enabling real-time identification of chemical, biological, and physical hazards. Recent advancements include RFID (Radio-Frequency Identification)-based contamination sensing (Roberts, 2006), where ultra-high-frequency (UHF) RFID tags detect signal variations caused by contaminants, with ML models like XGBoost (Azmi and Baliga, 2020) achieving high accuracy. Additionally, ML-driven food hazard detection systems utilize cross-media data sources, including government reports, news, and social media, to identify emerging risks. Techniques such as

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 482–486

semantic topic modeling and event detection further improve early warning systems. Despite these advancements, challenges persist in handling data variability, adapting models to detect novel hazards, and ensuring real-world applicability across different regulatory and geographical contexts. Moreover, integrating domain expertise with automated hazard detection remains crucial for refining model predictions and reducing false positives, ensuring the reliability of ML-based food safety monitoring systems.

3 Background

The **SemEval-2025 Food Hazard Detection task** focuses on extracting and classifying food safety incidents from textual data. The task is designed to improve the automated detection of food hazards in real-world reports, supporting early warning systems and regulatory monitoring. It is divided into two subtasks:

- (ST1) Food Hazard and Product Category Classification: Given a food-incident report, the system must classify it into one of several predefined food hazard and product categories
- (ST2) Food Hazard and Product Vector Prediction: The system must identify the exact food hazard and the associated food product from the text, providing structured outputs for fine-grained risk assessment

The SemEval-2025 Food Hazard Detection dataset provided for this task consists of 5,082 labeled samples for training, covering food hazard incidents in English. An additional 565 samples were provided as validation data, followed by 997 test samples for final evaluation. The dataset contains structured and unstructured data relevant to food safety incidents. It includes 'year', 'month', 'day', and 'country' for temporal and geographical context. The 'title' and 'text' describe incidents, serving as inputs for classification.The dataset features 10 unique hazard categories (e.g., biological, Chemical, foreign bodies) and 22 unique product categories (e.g., meat, egg and dairy products, prepared dishes and snacks, cereals and bakery products). Additionally, the hazard and product columns specify the exact contaminant (e.g., escherichia coli, listeria monocytogenes) and affected item (ground beef, hot dogs).

Figure 1 illustrates the frequency distribution of food hazard categories. Figure 2 depicts the

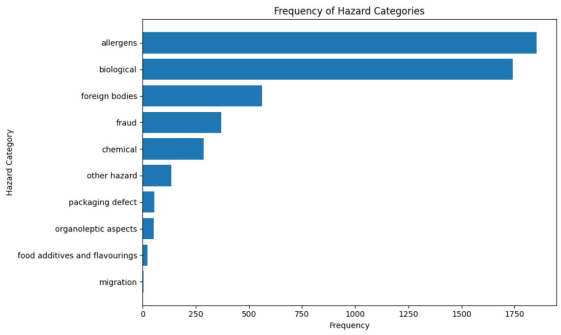

Figure 1: Frequency Distribution of Food Hazard Categories

frequency distribution of Food Product categories. Figure 3 shows a t-SNE (t-Distributed Stochastic

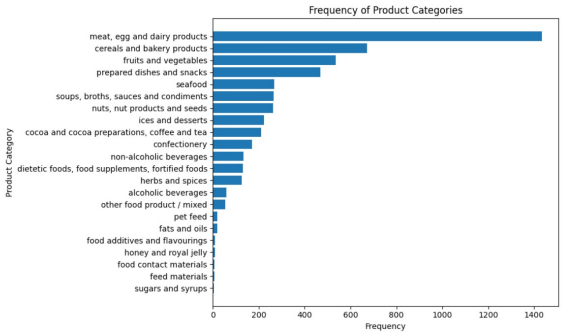

Figure 2: Frequency Distribution of Food Product Categories

Neighbor Embedding) visualization of tokenized inputs, where each point represents a data instance colored by hazard category.

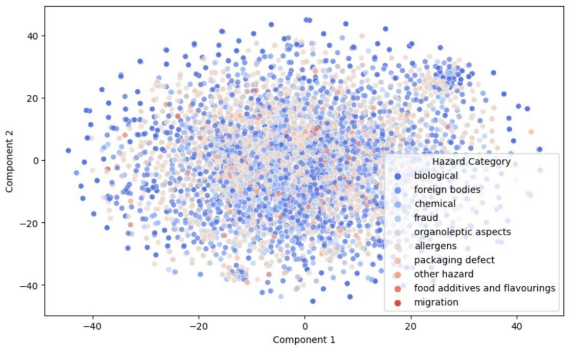

Figure 3: t-SNE Visualization of Tokenized Inputs

Our participation focused on both subtasks (ST1 and ST2) to develop a comprehensive system capable of handling hazard and product category classification and precise vector detection.

4 System Overview

This section outlines the approach taken for the SemEval-2025 Food Hazard Detection task, highlighting the key methodologies, models, and techniques used. It covers the data preprocessing, feature extraction, model selection, and training strategies used to optimize performance across both subtasks.

4.1 Subtask 1: Food hazard and product category detection, predicting the exact hazard-category and product-category.

1. **Data Preprocessing**
   Only the relevant columns were preserved, while the rest, including 'hazard', 'product', and 'title', were not used for the analysis. Categorical labels for 'hazard-category' and 'product-category' were encoded into numerical values using LabelEncoder. The 'text' data was then tokenized using a pre-trained BERT tokenizer (Koroteev, 2021), applying truncation and padding to ensure a consistent input length of 128 tokens.

2. **Feature Extraction**
   BERT Tokenization was performed using the BertTokenizer from the Hugging Face Transformers library, encoding text into input_ids and attention_mask (Clark et al., 2019) for efficient processing. To optimize classification, the dataset was split into two—one for hazard-category and another for product-category—enabling independent training and specialized learning for each task.

3. **Model Selection and Training**
   For classification, the BertForSequenceClassification (Face) model was utilized, leveraging its pre-trained transformer-based architecture. Two separate instances were initialized—one for hazard-category classification and another for product-category classification. Training was conducted with specific hyperparameters, including 10 epochs for hazard classification and 12 for product classification, a batch size of 16 for training and 64 for evaluation, and an epoch-wise evaluation strategy. To prevent overfitting (Ying, 2019), an EarlyStoppingCallback (Prechelt, 2002) was applied, terminating training if no improvement was observed within two epochs. The models were trained separately for each task, with results stored in designated directories for further evaluation.

4.2 Subtask 2: Food hazard and product "vector" detection, predicting the exact hazard and product.

1. **Data Preprocessing**
   The 'text' column was utilized to process textual features. Stopwords were removed, and the text was lowercased to ensure consistency. TF-IDF (Term Frequency-Inverse Document Frequency) (Ramos et al., 2003) was then applied to convert the processed text into numerical vectors, enabling effective feature extraction for classification models.

   For categorical features, labels such as 'product-category', 'hazard- category', 'hazard', and 'product' were transformed into numerical values using Label Encoding. This conversion ensured compatibility with machine learning models while preserving the categorical relationships necessary for accurate classification.

2. **Feature Extraction**
   We employ TF-IDF vectorization to convert raw 'text' into numerical features. This technique assigns importance scores to words based on how frequently they appear in a document while reducing the weight of commonly occurring words across all documents.

   The transformed text representation is then combined with categorical encodings of structured fields such as 'hazard-category', 'product-category'. This integration allows the model to leverage both textual and structured data for improved prediction accuracy.

3. **Model Selection and Training**
   We use Random Forest Classifiers (Salman et al., 2024) for both hazard and product prediction, leveraging their ensemble learning approach to construct multiple decision trees and aggregate outputs for improved accuracy and robustness. This reduces overfitting (Ying, 2019) and enhances generalization, making it suitable for food hazard detection. Two separate classifiers were trained: the Hazard Model, which predicts specific hazard types

(e.g. Salmonella, Listeria, Metal ContaminatioN), and the Product Model, which identifies affected food products (e.g., Dairy, Seafood, Beverages).

Each model utilizes 100 decision trees, balancing performance and computational efficiency, with hyperparameter tuning to address class imbalances and ensure accurate predictions for less frequent hazard and product categories.

5 Experimental Setup

The Experimental Setup section outlines the key tools, libraries, and evaluation strategies used to develop and assess our food hazard detection models. The Results subsection presents the performance outcomes, highlighting the impact of our approach on food hazard classification and product detection.

5.1 External Libraries & Tools

Several external libraries and tools were utilized for data preprocessing, model training, and evaluation. Pandas (v1.3.5) was used for data manipulation and handling missing values. Scikit-learn (v1.0.2) (Pedregosa et al., 2011) provided essential machine learning functionalities, including Random Forest classifiers, TF-IDF vectorization, and evaluation metrics. Additionally, NLTK (Natural Language Toolkit) (v3.6.7) (Bird et al., 2009) was employed for text preprocessing, such as tokenization and stopword removal.

For NLP-based modeling, the Hugging Face Transformers library (v4.17.0) (Face) was used to implement BertForSequenceClassification, enabling efficient fine-tuning of a pre-trained BERT model for predicting the hazard and product vectors.

5.2 Evaluation Metrics

To assess model performance, multiple evaluation metrics were used. The Macro F1-score (Opitz and Burst, 2019) was the primary metric, as it ensures a balanced evaluation across all hazard and product categories, even for underrepresented classes.

6 Results

Table 1 presents the results of individual runs for the Conception phase of Subtask 1, where the final test result achieved a score of 0.6442, demonstrating its effectiveness in classifying food hazards. We conducted multiple submissions to evaluate different modeling approaches for food hazard and product category classification.
Submission 1 utilized a Support Vector Machine (SVM) (Salcedo-Sanz et al., 2014) model. Submission 2 employed BertForSequenceClassification with both ‘text’ and ‘title’ (BERT-TT) as input features. Submission 3 also used BertForSequenceClassification but considered only ’text’ (BERT1-T) as the input feature. Submission 4 experimented with BertForSequenceClassification while increasing the learning rate (BERT2-T), using ’text’ as the sole input feature.

Table 1: Subtask 1 : Food hazard and product category detection

Submission	Macro F1-Score
Submission 1 (SVM)	0.6375
Submission 2 (BERT-TT)	0.7391
Submission 3 (BERT1-T)	0.7069
Submission 4 (BERT2-T)	0.6943

Table 2 presents the results of individual runs for the Conception phase of Subtask 2, where the final test result achieved a score of 0.2712, demonstrating its effectiveness in predicting food hazard and product vectors. Submission 1 utilized a Logistic Regression model (LR) (Maalouf, 2011). Submission 2 employed a Random Forest Classifier with ‘title’ as the input feature (RF-T). Submission 3 also used a Random Forest Classifier but incorporated multiple input features, including ‘title,’ ‘product-category,’ and ‘hazard-category,’ (RF-TPH) to enhance prediction performance.

Table 2: Subtask 2 : Food hazard and product vector prediction

Submission	Macro F1-Score
Submission 1 (LR)	0.0040
Submission 2 (RF-T)	0.0116
Submission 3 (RF-TPH)	0.0991

7 Conclusion

Our system effectively addressed the SemEval-2025 Food Hazard Detection task, achieving competitive results in both food hazard and product category classification and hazard-product vector detection. The model demonstrated strong per-

formance in classifying food hazards, while the challenge of accurately associating hazards with products highlighted areas for improvement.

8 Future Work

Future work will focus on making the model more reliable and adaptable to different datasets for better food hazard detection. Incorporating semi-supervised or self-supervised learning techniques to leverage unlabeled data could improve performance in real-world scenarios with limited annotated samples. Additionally, expanding training data through synthetic data generation or data augmentation may help address class imbalances and enhance model adaptability. Integrating contextual embeddings from domain-specific corpora, such as food safety reports and scientific literature, can provide richer feature representations, enabling the model to capture intricate relationships between hazards and products.

9 Limitations

Our approach utilizes BERT-based models for classification but may face challenges in capturing intricate contextual relationships, particularly when dealing with implicit references or specialized terminology. The computational demands of fine-tuning BERT and training Random Forest on large datasets can be significant, making real-time deployment in low-resource settings difficult. Additionally, while the dataset is well-structured for this task, real-world food safety reports often contain noisy, ambiguous, or incomplete information. The model's ability to generalize to such unstructured or multilingual data remains an area for future exploration.

Abstract

In this paper we expose our approach to solve the *SemEval 2025 Task 8: Question-Answering over Tabular Data* challenge. Our strategy leverages Python code generation with LLMs to interact with the table and get the answer to the questions. The process is composed of multiple steps: understanding the content of the table, generating natural language instructions in the form of steps to follow in order to get the answer, translating these instructions to code, running it and handling potential errors or exceptions. These steps use open source LLMs and fine grained optimized prompts for each task (step). With this approach, we achieved a score of 70.50% for subtask 1.

1 Introduction

Contemporary Natural Language Processing (NLP) is limited by the volume of information (text) that can be processed effectively while maintaining contextual relevance. During response generation this constraint impacts the recall of data needed to produce correct and complete answers (Liu et al., 2024). Tabular data exemplifies this challenge in particular, since it is the day-to-day task most affected by this restriction (Ruan et al., 2024). This paper addresses the SemEval 2025 Task 8: Question-Answering over Tabular Data (Osés Grijalba et al., 2025).

In this paper we present Maximizing Recovery from Tables with Multiple Steps (MRT), a multi-step pipeline that leverages both LLMs and Python code generation to answer questions in the most factual way possible. Instead of an end-to-end strategy our system implements a sequential divide and conquer approach in which at every step either LLMs or heuristics are executed. Those steps cover from describing the tables (frequent values, column descriptions, statistical information), generating the list of instructions (in plain natural language) to carry the task and obtain the result, code execution and answer parsing.

We achieve 70.50% accuracy in the Databench Challenge test set using this approach. The code that generated these results is publicly available[1].

2 Background

Question answering (QA) focuses on retrieving accurate answers from (Wang et al., 2025) data sets. Recent methods for QA on tabular data, such as TAPAS (Herzig et al., 2020), integrate transformers with architectures specifically tuned to extract answers directly from the tables used as context. However, LLMs have also been employed in zero-shot or few-shot strategies, since they are able to respond with a certain quality due to their prior knowledge and thus reduce the need for domain-specific fine-tuning of each domain (Kadam and Vaidya, 2020). Recent LLMs have demonstrated emergent reasoning capability, but still present difficulties with complex queries involving multiple columns, large tables, or ambiguous interpretations of a question.

Another approach is to parse natural language queries and transform them into formal queries such as SQL. Systems such as Seq2SQL (Zhong et al., 2017) or TableGPT2 (Yang et al., 2024b) are designed to generate SQL queries from relational database queries or Python code, respectively. These methods offer advantages such as greater flexibility, as they are theoretically independent of the table size (which might not fit entirely in the context window of an LLM), and greater transparency, by including an intermediate step that allows auditing and reviewing the generated queries.

To evaluate these models, reference datasets have been critical. Wikipedia-based sets, such as WikiSQL (Zhong et al., 2017) and TabFact (Chen et al., 2020), provide structured evaluation environments but do not reflect the heterogeneity of real-world tabular data (Hwang et al., 2019). In

[1] https://github.com/Gradiant/MRT_TableQA/releases/tag/v1.0.0

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 487–493

response, DataBench (Osés Grijalba et al., 2024) has been developed, which brings together 65 real-world datasets with more than 1,300 manually crafted question-answer pairs across multiple domains.

Works such as TableRAG (Chen et al., 2024) propose the use of RAG systems for tabular comprehension tasks, such as QA, employing techniques such as query expansion and a double transformation to query languages. This process translates, on the one hand, the schema to be interacted with and, on the other hand, the operation necessary to identify the cells with the answer. Also noteworthy are proposals such as Chain-of-Table (Wang et al., 2024), which implements Chain-of-Thought as an iterative reasoning mechanism. Instead of executing code in one shot, operations are executed in each iteration to add or discard information from the table until the answer is found.

Despite recent progress, some challenges still remain, such as improving reasoning within multiple rows, handling different domains and languages or integrating several tables and increasing the explainability of the full process.

3 System Overview

The strategy developed in our system consists of loading the table as a Pandas dataframe, and then, with the use of LLMs, generating Python code to interact with the tabular data to finally obtain the answer to each question. For this, we implemented multiple modules that are executed sequentially for each question. Some of these steps are heuristics, whereas others are LLM-based.

Each of the modules can use different LLMs. For this work, we have used multilingual models from the families Qwen2.5 (Yang et al., 2024a), Qwen2.5-coder (Hui et al., 2024), Llama-3 (AI@Meta, 2024) and Phi-4 (Abdin et al., 2024) among others.

The Figure 1 depicts an overview of the workflow of the system. The first step is understanding and analyzing the information of the table (type of data, appearance of null values, etc.). Then, an LLM generates textual instructions with the reasoning steps to follow in order to get the answer. After that, a code generation model converts the instructions to Python code. Then, the Runner executes this code. If an exception occurs during code execution or answer parsing, the system steps back into the Coder in an iterative looping process until it gets a valid answer or a limit is exceeded. Finally, there are formatting steps that implement functions such as getting the answer in the desirable data type or selecting the correct number of decimals in numbers.

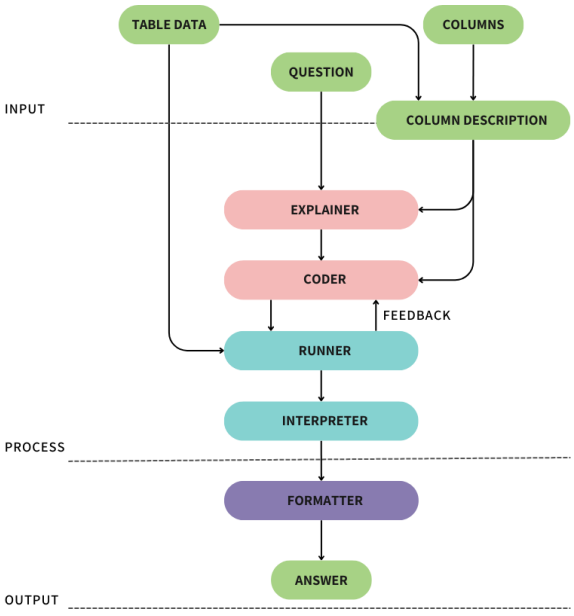

Figure 1: Diagram of the system showing all the steps involved in the generation of the response.

3.1 Column Descriptor

This module aims to analyze and understand the content of the table. First, it analyzes the input table obtaining some statistical data for each column, such as the data type, the number of unique values, if it has missing values, the *max*, *min*, *mean* values and *standard deviation* (when it applies), and the most frequent values.

The second step involves serializing a subset of the table and prompting an LLM to describe the content of each column. While column names are usually descriptive, they can sometimes lack uniqueness, contain abbreviations, or be better explained within the context of the other columns.

The results of this module for each table are cached and hence this step is skipped for the following questions related to the same table.

Examples of the output of this module are shown in Listing 2 in Appendix I.

3.2 Explainer

The Explainer module prompts an LLM to break down the steps required to answer a question using the table information. These instructions must be

written in natural language. The prompt includes relevant details extracted by the Column Descriptor, such as column's name, description, value type, and whether it has missing values. For numeric data types, it includes their range, and for categorical types, it lists their values if there are fewer than a configured number of unique options (fixed to 7), or otherwise just the most frequent values

The range of possible values is relevant for many questions that involve filtering by specific conditions. For example, to filter rows referring to a woman, the 'Gender' column might have various entries indistinctly like *woman*, *W*, *female*, *F*, etc. The same variety is observed in boolean values.

Guidelines are included in the prompt to force the system to use the exact given name of the columns, avoid the use of enumerations or to omit writing any code example.

The Explainer module includes a second step that prompts the LLM to review and refine the generated instructions. This process can help eliminate unnecessary steps or simplify them for greater precision.

Finally, the module parses the response to produce a list of strings, each representing an individual instruction.

Listing 3 in Appendix I contains examples of the explainer output.

3.3 Coder and Runner

The Coder module uses an LLM to generate Python code using the Pandas package that implements the natural language instructions in a method with the following header:

```
def parse_dataframe(df: pd.DataFrame) \
-> str:
    ...
```

The prompt includes guidelines to avoid exceptions, such as using the exact column names, casting specific data types, generating a single Python method, and avoiding the Pandas *groupby* function. The latter directive is based on empirical observations that the models we used tended to overuse this instruction, frequently resulting in numerous errors during code execution.

The LLM response is processed by a parser that employs heuristics to verify and standardize the various syntax generated by the model. As heuristics we employ different already preexisting libraries such as autopep8, autoflake, and lib_23 to fix minimal inconsistencies in the Python code syntax. In particular lib_23 is used to parse python 2 code into python 3, and will check for missing commas/-paretheses (for example). We also employ the AST tree parsing to detect when something doesn't have python code format. When detected (via parsing or exception), the system makes up to four attempts to correct them by returning the response to the LLM for revision.

Finally, the Runner module executes the code generated by the Coder and returns the result. If an exception occurs during execution, the process reverts to the Coder, with a maximum of three retries, to regenerate the code. The exception is added to the prompt to prevent it in subsequent iterations.

3.4 Interpreter

The Interpreter module checks if the format of the answer matches the expected type of data for the question. To achieve this, it first consults an LLM to determine the most suitable type of data to answer the question given the accepted types of the task: *Boolean*, *String*, *Number*, *List of Strings*, and *List of Numbers*.

Then, in a second call to the LLM, asks it to fit the answer to the given format if it is not already correct. With this, we correct many errors like returning numbers of booleans casted to strings (see examples in Table 7 in Appendix I).

3.5 Formatter

The last module in the workflow is the formatter. This module, based on rules is in charge of setting the answer in the most suitable format to match the expected task output. (see examples in Table 8 in Appendix I). For example, checks the data type of the answer, and casts it or make some format transformations.

In most cases, this module does not require any modifications due to the correction performed in previous steps. However, in certain instances, adjustments are necessary to ensure alignment with the gold labels during task evaluation.

4 Experimental Setup

The experimental setup consisted of two approaches for executing the modules plus the combination of configurations of each of the modules. Initially, the modules were run in series, as lighter models that could fit concurrently in memory were used. In this approach, each question for each ta-

ble was processed sequentially through all system modules. However, during testing phase with heavier models, it became necessary to implement a system that allowed to load and unload the models as it was required by each step. This approach executes each of the step in batches. All the questions are processed for each step before passing to the next one. Hence only the model used in each step is loaded in memory. This allows to load bigger models for each of the steps whilst using the same GPU without involving excessive overhead in loading/unloading models.

The hardware used to run the tests was an NVIDIA RTX-a6000 that combines 84 second-generation RT cores, 336 third-generation Tensor cores, and 10,752 CUDA cores with 48 GB of graphics memory for performance.

In 4.2, we define the model configurations used in the test phase. During development, we also used reduced versions of these models with $8B$ parameters.

4.1 Dataset splits

Although no training of any model has been performed, the splits of the dataset are shown below.

Split	Tables	Questions
train	49	988
dev	16	320
test	15	522

Table 1: Distribution of number of tables and questions for each split in the dataset

Train, dev and test splits have been used for the development of the modules.

4.2 Models

Llama 3[2], Phi[3] and Qwen[4] models of different sizes have been used for the different modules of the system.

For Llama 3 only the 8B size model was used[5]. For Phi-4, the 14B version was choosen[6] and, finally, the main family of models used in the tests is Qwen. Two types of Qwen models have been executed: Qwen25 and Qwen25 code.

For Qwen25 two sizes have been selected: 7B[7] and 14B[8]. For Qwen25 code also the same two sizes were used: 7B[9] and 14B[10].

Let us emphasize that the $8B$ models have been used mainly in the first battery of tests and development whilst the $14B$ models were used in the final execution of the system.

4.3 Test and configuration

Table 2 summarizes the different experiments performed, with the model used in each module for each experiment.

Explainer	Coder	Interpreter
$llama3_{8B}$	$qwen25_{14B}$_code	$qwen25_{14B}$
$phi4_{14B}$	$qwen25_{14B}$_code	$qwen25_{14B}$
$qwen25_{14B}$	$qwen25_{14B}\_code$	$qwen25_{14B}$

Table 2: Different configurations for each step that uses LLMs

Table 2 shows that, for the most part, experiments have been performed keeping the *Qwen25 14B-coder* model in the Coder module and selecting different models for the Explainer module. The *Llama*, *Phi-4*, *Qwen2.5 14B*, and *Qwen2.5 7B* models have been tested in the Explainer, whereas *Qwen2.5 7B* was selected to be the main interpreter mainly because during the development time small tests were performed in that module with both Llama and *Phi-4* and the results were not remarkable. Finally, note that the Colum Descriptor module is not in the table to save space. The module used for Column Descriptor was *Qwen2.5 7B* in all experiments and was run separately because the column description process is done per table and not per question.

5 Results

5.1 Performance in Validation split

Table 3 shows the accuracy of the system using different models. The model indicates the one used in the Explainer. For the Column Descriptor and Coder all the models share the *Qwen2.5 7B* and *Qwen2.5 14B-Coder* respectively. The Explainer step is performed by the *Qwen2.5 14B*. The Ensemble is obtained by the majority voting of the three

models. Ties are resolved prioritizing *Qwen2.5* answers over *Phi-4* and *Llama* models.

Models	Run	Interpret	Format
llama3_{8B}	0.563	0.613	0.606
phi4_{14B}	0.756	0.756	0.75
qwen25_{14B}	0.762	0.766	0.759
$\text{Ensemble}_{\text{max}}$	0.778	0.772	0.766

Table 3: Accuracy of the different strategies in the development split using the outputs of the Runner, Interpreter and Formatter step.

As can be seen in the results, the heuristics to format the final predictions sometimes introduce additional errors.

If we filter the prediction by type of response requested (Table 4) we can see that the lists of items (either number or categorical) have a much higher difficulty than the singular responses. As expected boolean responses are easy to handle by the system as only two values are possible. Nevertheless the best individual model, *Qwen2.5 14B*, obtained better results in the categorical answers.

Answer Type	llama3 8B	phi4 14B	qwen25 14B	Ens emble
Boolean	0.75	0.844	0.828	**0.844**
Number	0.627	**0.851**	0.761	0.836
Categ.	0.639	0.754	**0.836**	0.787
List_{Num}	0.538	0.692	0.754	**0.769**
List_{Cat}	0.476	0.603	**0.619**	0.587
All	0.606	0.75	0.759	**0.766**

Table 4: Accuracy of the different strategies per data type of the expected answer in the validation split

After performing the same analysis in the test split (5), we can see that in general all the models experience a poorer performance in all categories but the ranking are almost the same.

Answer Type	llama3 8B	phi4 14B	qwen2.5 14b	Ens emble
Boolean	0.659	0.791	**0.829**	0.814
Number	0.417	**0.628**	0.596	0.596

List_{Num}	0.407	0.560	0.615	**0.626**
List_{Cat}	0.417	0.514	0.542	**0.556**
All	0.480	0.642	0.665	**0.667**

Table 5: Accuracy of the different strategies per data type of the expected answer in the test split

5.2 Manual Error Analysis

We performed a manual error analysis of the results flagged as an error by the official evaluator for the Qwen2.5. The results are summarized in Table 6.

When passing from instructions to code some of them are usually omitted or not treated properly. That was always true when the user requested to resolve ties in alphabetical order. Certain operations such as "group-by" were avoided in the prompt as the Coder was less capable of consistently generating error-free code when using them. Although our solution uses the prompt to discourage the LLM to use certain functions, another interesting option is to provide alternative implementations for them.

One clear flaw of the current design is that the system fails to filter by certain values when they do not appear in the common values of the column (e.g. when asked for *Biden* the system does not know that this value appears as *Joe Biden* in the table unless it is in the frequent values given by the Column Descriptor. This accounts for 15% of the errors. This type of errors could be mitigated by linking values asked in the query with the real ones appearing in the table during a pre-processing step (e.g. after the natural language instructions are given). Formatting issues of the response are almost 10% of the remaining errors. Handling these errors requires careful implementation of additional post-processing heuristics, and it relates greatly to how the metric to measure the performance is actually implemented (e.g. rounding issues, partial match, how lists are expected, if ordering of the elements is taking into account or not, etc.).

The *others* set accounts for all unclassifiable errors, in general due to ambiguous questions or expected answers or incorrect ground truth samples.

Description	% error
Wrong cell value filtering	14.29
Wrong Instructions	37.66
Wrong code (incl. exceptions)	14.29
Formatting (transformations)	6.49
Formatting (answer type)	3.90
Others	23.38

Table 6: Manual analysis of the errors of the Qwen14 model in the validation split

6 Conclusion

This paper has addressed our proposal, MRT, in response to the challenge proposed in Semeval 2025

regarding tabular data question-answering. This technique, which introduced a multi-step pipeline leveraging both LLMs and their ability for code generation, achieved a 70.50% accuracy.

Despite the competitive results, MRT is limited due to several factors, such as formatting the output correctly and some semantic ambiguities that are not interpreted correctly (e.g., double negation in the question). Nevertheless, the largest set of errors is due to an incorrect filter of the column values (either because the value type is incorrectly detected or because the value does not appear in the same way in the question and table). Additionally, MRT encounters difficulties in addressing abstract, more subjective, and less clear questions, which can be attributed to the size of the models employed.

Future work will focus on enhancing several of the modules to eliminate all accuracy losses introduced in the between-pipeline steps and adopting a less code-driven and more linguistic approach to ambiguous questions over tabular data.

Abstract

In response to the increasing demand for efficient ESG verification, we introduce a novel natural language processing (NLP) framework designed to automate the assessment of corporate sustainability claims. This approach combines Retrieval-Augmented Generation (RAG), Chain-of-Thought (CoT) reasoning, and structured prompt engineering to accurately process and categorize a wide range of multilingual ESG disclosures. In the SemEval-2025 PromiseEval competition, our system achieved a score of 0.5611—ranking 4th on the private English leaderboard—and a score of 0.5747—securing 1st place on the private French leaderboard. These results represent substantial improvements over traditional machine learning methods and underscore the framework's potential as a scalable, transparent, and robust solution for ESG evaluation in corporate settings.

1 Introduction

The concept of Environmental, Social, and Governance (ESG) sustainability has emerged as a critical framework for assessing corporate responsibility and long-term viability. As concerns over climate change, social inequality, and governance practices continue to escalate, corporations are increasingly required to demonstrate measurable commitments. However, evaluating these commitments presents significant challenges. Traditional assessment methods heavily rely on manual reviews of corporate reports, third-party evaluations, and media sources—approaches that are labor-intensive, costly, difficult to scale, and often inconsistent across regions and languages.

To tackle these challenges, our team participated in the SemEval-2025 Task 6: PromiseEval—Multinational, Multilingual, Multi-Industry Promise Verification competition(Chen et al., 2025). This competition introduces a novel multilingual dataset encompassing English, French, Chinese, Japanese, and Korean, designed to assess corporate commitments and their fulfillment in the ESG domain. The primary objective is to develop NLP methodologies that automate corporate promise verification by identifying commitments, evaluating supporting evidence, assessing clarity, and inferring appropriate verification timelines.

Advancements in Natural Language Processing (NLP) have demonstrated immense potential in automating the evaluation of large-scale textual data. Early NLP techniques, including sentiment analysis, topic modeling, and named entity recognition, have been widely applied to extract structured insights from ESG disclosures. Nevertheless, these methods remain constrained by rule-based systems, which struggle to adapt to dynamic and diverse ESG datasets. Transformer-based models(Vaswani et al., 2023), such as BERT(Devlin et al., 2019) and GPT(OpenAI et al., 2024), have revolutionized the field through context-aware text analysis, enhancing the scalability and robustness of NLP applications.(Chung and Latifi, 2024) evaluated ESG-specific pre-trained Large Language Models (LLMs), such as FinBERT-ESG and fine-tuned LLaMA models, demonstrating their superior performance over traditional machine learning techniques like SVM and XGBoost in ESG text classification tasks. These models excel at capturing semantic and contextual nuances within ESG-related texts, making them particularly well-suited for analyzing abstract concepts and complex interrelations.

Despite these advancements, challenges remain in applying NLP techniques to ESG evaluation. ESG data originate from diverse formats, sources, and languages, necessitating sophisticated approaches capable of integrating both structured and unstructured information.(Peng et al., 2024) propose an advanced methodology for processing unstructured ESG data, addressing challenges in text extraction, multilingual content, and diverse

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 494–501

document formats to improve the accuracy of ESG assessments. Additionally, many ESG indicators—such as descriptions of social responsibility initiatives or governance strategies—are inherently qualitative, requiring models to not only extract data but also comprehend and reason about complex relationships.(Sokolov et al., 2021) highlight the difficulties in automating ESG scoring using NLP, particularly in handling qualitative ESG factors that require contextual reasoning.

To address these limitations, this study integrates state-of-the-art NLP techniques, including Retrieval-Augmented Generation (RAG)(Gao et al., 2024), Chain-of-Thought (CoT)(Yu et al., 2023),(Wei et al., 2023) reasoning, and Prompt Engineering(Sahoo et al., 2024),(Vatsal and Dubey, 2024), to enhance the automation of ESG commitment verification. The Structured Prompt framework systematically guides the model through a multi-stage reasoning process using explicit definitions, clarification rules, concrete examples, constrained label outputs, and stepwise instructions. This design enables the model to accurately comprehend classification standards and make consistent decisions across diverse contexts. By leveraging these methods, our framework provides a multilingual, efficient, and scalable solution that significantly narrows the gap between corporate commitments and measurable outcomes, while enhancing interpretability and reliability in ESG evaluations.

The ClimateBERT model fine-tuned by (Vinella et al., 2024) demonstrated an accuracy of 86.34% in assessing greenwashing risks within corporate sustainability reports, underscoring the promising capabilities of language models in the domain of greenwashing detection.

By applying cutting-edge NLP methodologies to ESG evaluation and testing them within the ML-Promise challenge framework, we aim to advance more transparent and reliable corporate ESG oversight mechanisms, ultimately fostering sustainable development practices.

2 Dataset

The dataset used in this study is derived from SemEval-2025 Task 6 (Chen et al., 2025), which focuses on verifying corporate commitments disclosed in Environmental, Social, and Governance (ESG) reports. It comprises textual data from multiple companies, annotated with structured labels designed to support the identification and evaluation of corporate pledges and their supporting evidence, thereby facilitating effective ESG statement verification through Natural Language Processing (NLP) models.

Annotations are organized across four principal dimensions: (1) Promise Status, indicating whether a clear commitment has been made ("Yes" or "No"); (2) Verification Timeline, classifying the expected timeframe for fulfillment as "Already," "Less than 2 years," "2 to 5 years," "More than 5 years," or "N/A"; (3) Evidence Status, reflecting the existence of verifiable documentation ("Yes" or "No"); and (4) Evidence Quality, evaluating the clarity and credibility of supporting evidence as "Clear," "Not Clear," "Misleading," or "N/A."

Statistical analysis of the dataset reveals that most corporate statements contain explicit commitments, yet many lack short-term fulfillment targets, potentially undermining their credibility. While documentation often supports pledges, inconsistencies remain due to unverifiable claims and variable evidence quality. Practical challenges such as spelling errors, linguistic variation, and unstructured text also impact multilingual model performance. Nevertheless, the dataset offers a strong structural foundation for ESG commitment verification and highlights directions for future improvements in bias mitigation and model robustness.

3 Methodology

3.1 Structured Prompt Design for ESG Classification

To improve the accuracy, consistency, and interpretability of large language models (LLMs) in ESG-related classification tasks, this study proposes a Structured Prompting approach tailored specifically for corporate sustainability analysis. Traditional methods—such as keyword matching or rule-based classification—often suffer from limitations in handling context, ambiguity, and domain-specific interpretation. To address these issues, we designed a modular structured prompt architecture that guides the model through a multi-step reasoning process, mimicking human annotation logic.

The Structured Prompt comprises five synergistic components:

- **Definition**: Establishes explicit criteria for what constitutes a valid ESG commitment, filtering out vague or aspirational language.

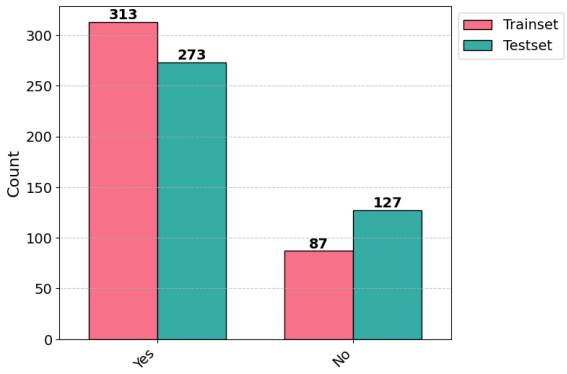

Figure 1: Promise Status Distribution

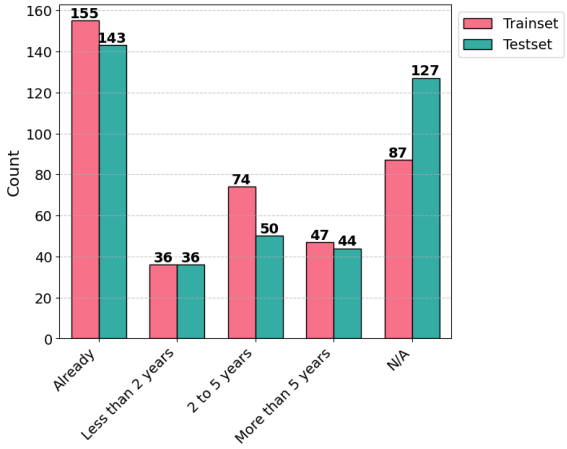

Figure 2: Verification Timeline Distribution

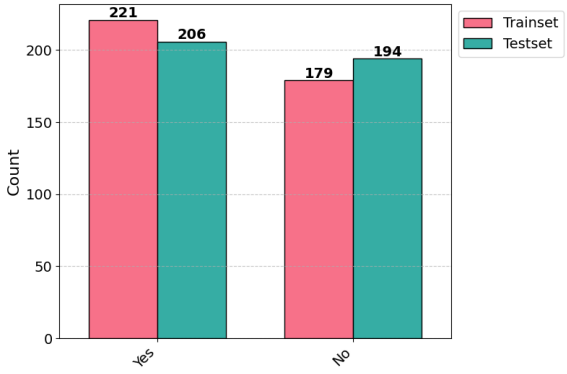

Figure 3: Evidence Status Distribution

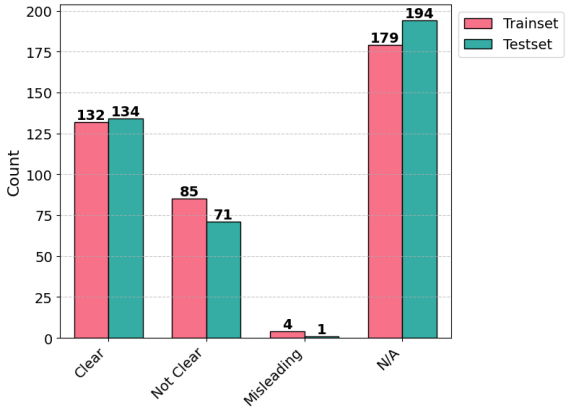

Figure 4: Evidence Quality Distribution

- **Clarification**: Provides further elaboration on borderline cases, helping reduce overclassification by emphasizing semantic precision.

- **Example**: Supplies positive and negative illustrations to operationalize the abstract classification principles and anchor model interpretation.

- **Labels**: Standardizes output to binary classifications (e.g., {"promise_status": "Yes"}), enabling structured evaluation and automation.

- **Instructions**: Enforces conservative reasoning under uncertainty and reinforces task-specific constraints (e.g., ignoring irrelevant corporate statements).

This design was not arbitrary but emerged from iterative testing on noisy, multilingual ESG disclosures. Early prompt variants often led to inconsistent predictions, especially when faced with vague language or complex governance terminology. By integrating structured prompting with logical Chain-of-Thought (CoT), Self-Consistency, and Tree-of-Thought (ToT) mechanisms, the model is prompted to evaluate ESG statements in a context-aware, sequential manner.

Additionally, more advanced prompting strategies such as System 2 Attention and Graph-of-Thoughts (GoT) are optionally applied to encourage deliberate, multi-domain reasoning, particularly in cases involving cross-sectional ESG categories.

This modular yet principled design enables LLMs to simulate human annotation logic at scale, ensuring interpretability, robustness, and alignment with ESG classification standards. The performance gains observed through ablation studies (Section 5.4) further validate the contribution of each prompt component to overall model effectiveness.

3.2 Advantages of the Structured Prompt Approach

To enhance both the accuracy and consistency of ESG-related text classification, we developed a structured prompting framework comprising six interlocking steps. These steps guide large language models (LLMs) to perform multi-dimensional classification based on explicit standards. Among

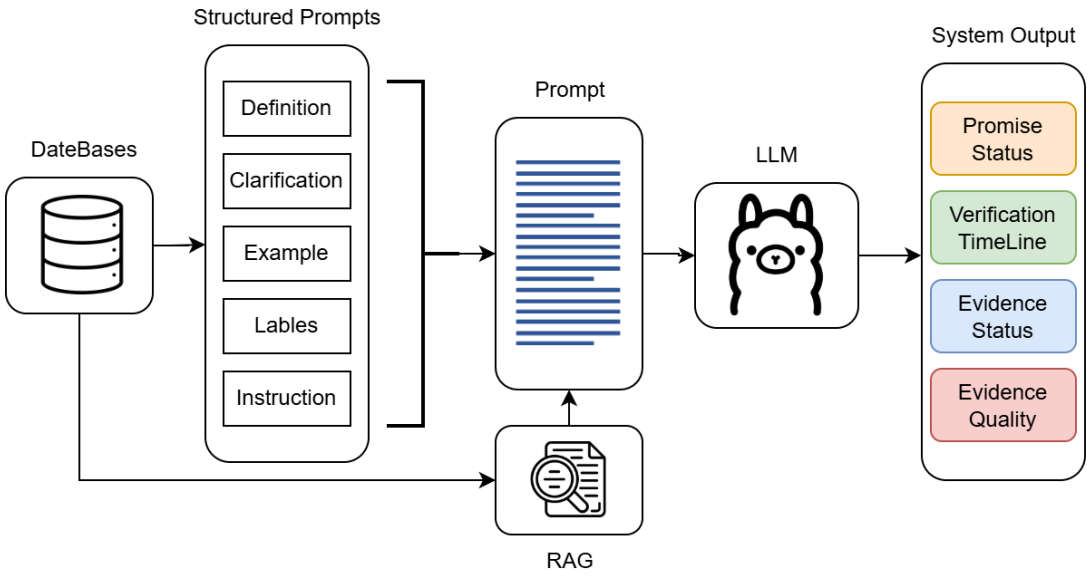

Figure 5: Structured Prompts with Retrieval-Augmented Generation Workflow

them, three core techniques—Definition/Schema-Priming Prompting, Chain-of-Thought (CoT) Prompting, and Few-shot Prompting—serve as the foundation for semantic precision and reasoning reliability(e.g. in Table 1).

To ensure output consistency and machine readability, structured-output prompting was also integrated. The model was instructed to return results in a standardized JSON schema, facilitating downstream processing. Additionally, conditional prompting was used to enforce logical constraints between fields (e.g., if Commitment = No, then Timeline and Evidence Quality must be marked as "N/A").

Collectively, this structured prompting framework provides a reproducible and interpretable mechanism for guiding LLMs in ESG classification tasks. It not only articulates what the model should judge, but also dictates how it should reason and in what format the results should be conveyed—thereby offering a concrete blueprint for future high-consistency, scalable semantic classification applications.

4 Experimental setup

To rigorously evaluate the effectiveness of our proposed ESG verification framework, we conducted experiments focusing on computational efficiency, model accuracy, and multilingual generalization. This section outlines the technical framework, hardware configuration, retrieval methodology, preprocessing techniques, and evaluation strategy.

4.1 Core Framework and Hardware Configuration

Our system is built on Ollama, a lightweight yet powerful framework optimized for large-scale NLP applications. It runs on a high-performance setup featuring an Intel i7-12900K processor, an RTX 3090 Ti GPU, and 32GB of RAM, enabling efficient ESG text processing and fast document retrieval with reasonable computational costs.

4.2 RAG

We employ FAISS (Douze et al., 2025) for scalable nearest-neighbor search, enabling rapid retrieval of relevant ESG documents. For embedding generation, we use Multilingual-E5 (Wang et al., 2024), a transformer-based model designed for cross-lingual tasks. The integration of FAISS and RAG ensures efficient retrieval of semantically relevant ESG statements, enhancing verification accuracy.

4.3 Base Model and Preprocessing

The Base Model serves as the foundation for ESG commitment verification. During preprocessing, defaultdict is utilized to optimize data structure handling, improving the speed and accuracy of classification.

4.4 Experimental Evaluation

Experiments were conducted to assess different RAG configurations and prompt structures, aiming to identify the most effective setup for ESG-related

tasks. The focus was on analyzing how retrieval strategies and prompt engineering impact key performance metrics.

4.5 Evaluation Metrics

We adopt standard classification metrics—Accuracy, Recall, Precision, and F1-score—to evaluate model performance, with Macro F1-score reported unless otherwise specified. For different ESG subtasks (Promise Status, Verification Timeline, Evidence Status, Evidence Quality), we select metrics tailored to task-specific requirements to ensure comprehensive performance analysis.

5 Results

5.1 Model and RAG Quantity Analysis

In this study, we evaluated different model configurations for the ESG commitment classification task by varying the number of Retrieval-Augmented Generation (RAG) instances. The RAG quantity refers to the number of top-relevant documents retrieved during inference—for example, RAG-3 retrieves the three most similar results to support the model's reasoning. An appropriate number of retrieved documents can significantly enhance prediction accuracy.

We systematically compared the F1-scores across various model and RAG configurations, as shown in Table 2. The results indicate that model performance varies considerably depending on the RAG setting, underscoring the importance of tuning retrieval parameters(e.g. in Table 2).

Additionally, a comparative analysis was performed between models with and without RAG to assess the necessity and effectiveness of RAG in improving performance (e.g. in Table 3).

5.2 Detailed Evaluation of the Optimal Model

Once the best-performing model and the optimal RAG quantity were identified, further analysis was conducted to evaluate specific task components, including promise status, verification timeline, evidence status, and evidence quality. The performance of each of these aspects was recorded and analyzed in detail (e.g. in Table 4).

5.3 Comparative Experiments Using CoT vs. Not Using CoT

To investigate the impact of Chain-of-Thought (CoT) on reasoning tasks, we conducted comparative experiments for "with CoT" and "without CoT" across four subtasks: Promise Status, Verification Time, Evidence Status, and Evidence Quality. In all experiments, we used Retrieval-Augmented Generation (RAG) with a retrieval count of 6, and the unified base model was Llama 3.1 (70B) (Grattafiori et al., 2024) ,(Touvron et al., 2023). (e.g. Table 5) summarizes the Accuracy performance for both configurations across the four subtasks:

The results show that, for Promise Status and Evidence Status, the model using CoT achieves noticeably higher Accuracy than the one without CoT. Meanwhile, for Verification Time and Evidence Quality, which require deeper reasoning, the CoT-based model also significantly outperforms the non-CoT setting, demonstrating CoT's advantages in multi-step reasoning scenarios. Since all experiments in this study fixed RAG at 6 and utilized Llama 3.1 (70B) as the base model, future adjustments to the retrieval count or strategy may further affect performance on different subtasks and could serve as a reference for subsequent prompt engineering and model optimization.

5.4 Ablation Study on Prompt Engineering

To assess the impact of our prompt engineering strategies, we conducted an ablation study by systematically removing different structural components of the prompt. The performance variations observed across different configurations provided insights into the contribution of each prompt component to the overall system effectiveness in (e.g. in Table 6).

Overall, the results demonstrate the effectiveness of our approach in optimizing the ESG promise task, highlighting the importance of both RAG and structured prompt engineering in achieving high performance.

6 Conclusion

This study presents an advanced NLP-driven framework for ESG commitment verification, addressing the limitations of traditional assessment methods. By leveraging Retrieval-Augmented Generation, Chain-of-Thought reasoning, and structured prompt engineering, our approach enhances the automation, accuracy, and interpretability of ESG evaluations. The experimental results from our participation in the SemEval-2025 PromiseEval task validate the effectiveness of our model, demonstrating its superior performance in classifying corporate commitments, verifying evidence, and assess-

ing the credibility of ESG-related claims. Future research could explore further improvements in multilingual adaptability and the integration of external knowledge sources to enhance contextual understanding. Ultimately, our methodology contributes to the development of scalable, reliable, and transparent ESG verification systems, supporting global efforts in corporate sustainability assessment.

Step	Prompt Engineering Method	Description	Example / Use Case
1	Instruction-based Prompting	Use a clear sentence or paragraph to explicitly tell the model what to do, establishing a clear objective.	Start with a prompt like: *"Objective: Systematically assess . . . "*
2	Definition / Schema-Priming Prompting	Define key terms or schema to ensure consistent and accurate understanding.	*"A promise must. . . "*; define all key labels.
3	Chain-of-Thought (CoT) Prompting	Guide the model through logical steps such as "Step 1. . . Step n" to encourage multi-step reasoning.	*"1. Promise Status → 2. Verification Timeline → 3. . . "* style step guidance.
4	Few-shot / Demonstration Prompting	Provide 1 to k real examples to help the model learn the output pattern and reduce bias.	Each item includes Example: *"Yes: . . . ", "No: . . . "*.
5	Structured-Output Prompting / JSON-schema Prompting	Specify the output format, such as JSON or table, to enhance structure and consistency.	Final section defines the output format, e.g., JSON schema.
6 (Optional)	Conditional / Guardrail Prompting	Set conditional rules (e.g., if–then statements) to handle exceptions and enforce constraints.	Rules like: *"If Promise = No, then Timeline = N/A"*.

Angeliki Linardatou at SemEval-2025 Task 11: Multi-label Emotion Detection

Angeliki Linardatou **Paraskevi Platanou**
Athens University of Economics and Business (AUEB)
Athens, Greece
Email: angela2003linardatou@gmail.com, platanou@aueb.gr

Abstract

Multi-label emotion detection is challenging due to contextual complexity and irony. Most sentiment models classify text into single categories, missing overlapping emotions.

This study, competing in SemEval 2025 Task 11 - Track A, detects anger, surprise, joy, fear, and sadness, in English texts. We propose a hybrid approach combining fine-tuned BERT transformers, TF-IDF for lexical analysis, and a Voting Classifier (Logistic Regression, Random Forest, SVM, KNN, XGBoost, LightGBM, CatBoost), with grid search optimizing thresholds.

Our model achieves a macro F1-score of 0.6864. Challenges include irony, ambiguity, and label imbalance. Future work will explore larger transformers, data augmentation, and cross-lingual adaptation.

This research underscores the benefits of hybrid models, showing that combining deep learning with traditional NLP improves multi-label emotion detection.

1 Introduction

Sentiment Analysis (SA) and Emotion Detection are key NLP tasks for analyzing emotional tone in text, essential for understanding human behavior. While SA classifies text as positive, negative, or neutral, Emotion Detection identifies specific emotions (joy, anger, sadness) but faces challenges like sarcasm, ambiguity, and overlapping emotions.

Transformer models such as BERT and XLNet have greatly improved sentiment classification, with hybrid approaches emerging. Jlifi et al. (2024) (Jlifi et al., 2024) combined BERT with Random Forest (Ens-RF-BERT), while Danyal et al. (2024) (Danyal et al., 2024) proposed BERT-XLNet for long-text classification. However, multi-label emotion detection remains underexplored.

SemEval 2025 Task 11 addresses this by providing a benchmark for detecting anger, surprise, joy, fear, and sadness. In our study, we develop a fine-tuned BERT model, enhanced with TF-IDF for lexical analysis, and a Voting Classifier. We also explore RoBERTa-large for better predictions.

Our model achieves an F1-score of 0.68, demonstrating the effectiveness of combining transformers with traditional ML techniques. Future improvements include data augmentation, cross-lingual adaptation, and larger transformer models to enhance performance.

2 Related Work and Background

Sentiment Analysis (SA) and Emotion Detection are key NLP tasks, but traditional methods rely on single-label classification, failing to capture multiple coexisting emotions.

SemEval 2025 Task 11 - Track A addresses this by requiring models to detect multiple emotions per text. Multi-label classification is essential, as texts can express mixed emotions (e.g., joy and surprise, sadness and fear). Existing single-label methods struggle with this complexity, necessitating models that learn emotional dependencies.

This task involves five core emotions: joy, sadness, anger, surprise, and fear. Effective multi-label classification requires techniques like binary relevance, classifier chains, and deep learning to improve detection accuracy.

3 Previous Studies

Several studies have explored multi-label sentiment analysis using ML and deep learning approaches:

Jin and Lai (2020) (Jin and Lai, 2020) proposed a hybrid model combining BERT's contextual embeddings with a modified TF-IDF weighting technique. Their approach enhanced key term importance while leveraging deep contextual

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 502–507

representations, leading to a 4.2% F1-score improvement over traditional TF-IDF and standalone BERT models.

Ni and Ni (2024) (Ni and Ni, 2024) introduced a sentiment correlation modeling approach to capture interdependencies between emotions. Their correlation-aware mechanism refined sentiment prediction, improving F1-score by 3.8% compared to conventional multi-label models.

These studies highlight the benefits of hybrid and correlation-aware approaches in multi-label sentiment classification.

4 Comparison with the Proposed Model

Unlike prior studies relying solely on transformers or traditional ML, our approach combines both for improved accuracy. We fine-tune BERT for contextual understanding while integrating TF-IDF for lexical features. A Voting Classifier (Logistic Regression, Random Forest, SVM, KNN, XGBoost) optimizes classification via ensemble learning. Grid search refines probability thresholds, balancing precision and recall. To handle overlapping emotions and class imbalance, we fine-tune decision boundaries. Training efficiency is improved through reduced learning rates, minimal epochs, and cross-validation, ensuring robust predictions.

5 Innovative Aspects of Our Approach

Our proposed method differentiates itself from previous studies in several key ways:

Our approach stands out by integrating deep learning with traditional NLP techniques for multi-label emotion detection. By combining BERT for contextual understanding with TF-IDF for lexical emphasis, we ensure that important words are not downweighted, enhancing interpretability and classification accuracy. Additionally, we incorporate ensemble learning through a voting classifier, which combines multiple models to improve stability and reduce variance. To further refine classification performance, we apply grid search for optimal probability threshold selection, maximizing the F1-score. This hybrid methodology effectively balances semantic understanding and lexical precision, leading to a more robust and accurate emotion detection system.

6 Dataset and Examples

The dataset used in our experiments consists of **English** textual data annotated with multiple emotional labels. The data is provided by the SemEval 2025 Task 11 competition (Track A), which focuses specifically on English-language emotion detection. Below, we present representative examples from the dataset along with their detected emotions:

Text	Emotions Detected
"I can't believe I did it!"	**Joy, Surprise**
"What happened was truly terrifying."	**Fear**
"I feel so alone right now..."	**Sadness**
"How dare you say that to me?!"	**Anger**

Table 1: *Representative examples from the dataset with their detected emotions.*

These examples demonstrate the necessity of multi-label classification, as a single sentence can express multiple emotions simultaneously (refer to Fig. 2). Capturing such nuances is crucial for improving the accuracy of emotion detection models. Our approach introduces an effective fusion of modern NLP techniques and traditional text analysis, demonstrating the potential of hybrid methodologies for improving multi-label emotion detection.

The following figure illustrates the frequency distribution of detected emotions in the dataset, highlighting which emotions appear more frequently in the text samples.

7 System Overview

Our system for multi-label emotion detection combines state-of-the-art transformer models with traditional feature engineering and ensemble learning to maximize classification performance. Below, we describe the key components and methodological choices that define our approach.

8 Key Algorithms and Modeling Decisions

Our hybrid approach integrates deep learning, feature engineering, and ensemble learning for multi-

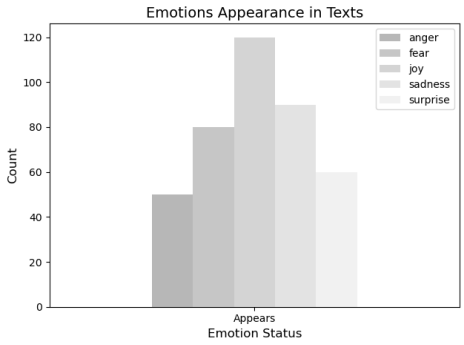

Figure 1: *The X-axis represents the detected emotions, while the Y-axis shows the number of texts in which each emotion appears. The chart illustrates how frequently each emotion is detected, highlighting the most commonly recognized emotion.*

label emotion detection. We fine-tune BERT and RoBERTa for contextual embeddings, complemented by TF-IDF for lexical features. A soft voting ensemble (Logistic Regression, Random Forest, SVM, KNN, XGBoost, LightGBM, CatBoost) enhances classification, leveraging each model's strengths. Grid search-based threshold optimization refines decision boundaries, maximizing the F1-score. To prevent overfitting, we use a reduced learning rate and minimal training epochs for BERT fine-tuning.

9 Data Preprocessing and Feature Extraction

The dataset consists of English text snippets labeled with five emotions: anger, fear, joy, sadness, and surprise. Some data samples are multi-labeled, while others contain only one label.

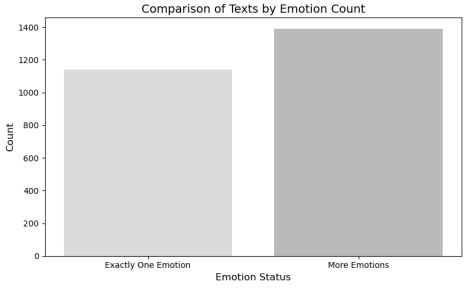

Figure 2: *The figure shows the number of texts that contain only one emotion versus those that contain multiple emotions.*

The dataset is split into 80% training and 20% testing. Text is preprocessed using the **BERT tokenizer** for subword embeddings with padding and truncation. **TF-IDF** (vocabulary size: 8000) extracts numerical features, which are concatenated with BERT embeddings to form an enriched feature space. **Lemmatization, stemming, and stopword removal** are not applied.

10 Model Training

The transformer model is fine-tuned for **two epochs** using the AdamW optimizer and Binary Cross-Entropy Loss.This choice was made to *minimize overfitting* and ensure *efficient training*. To support this decision, we conducted additional experiments by training BERT for 1, 2, 3, and 4 epochs and monitoring the macro F1-score. The model achieved its highest performance at epoch 2, with F1-scores plateauing or slightly decreasing afterward, indicating potential overfitting.This empirical finding aligns with **Jin and Lai (2021)** (**Jin and Lai, 2020**), who observed that *2–3 epochs were optimal* when fine-tuning BERT on emotion-labeled datasets of similar size. After training, sentence embeddings are extracted from the final hidden layer of the BERT model. These are then concatenated with TF-IDF features to form a hybrid representation, which is used to train an ensemble classifier. Binary Cross-Entropy Loss was selected as it is well-suited for multi-label classification, treating each label as an independent binary task. It effectively handles overlapping labels and produces well-calibrated probability estimates. Finally, we perform grid-based hyperparameter tuning to adjust the number of estimators, learning rates, and maximum depths of the ensemble classifiers (e.g., Random Forest, XGBoost, LightGBM, CatBoost), ensuring the best possible configuration for robust performance.

11 Threshold Optimization

Since our task involves multi-label classification, we needed to decide how to convert the model's probabilistic outputs into binary predictions for each emotion. To do this, we optimized the probability thresholds using a grid search approach. We tested a range of threshold values from 0.30 to 0.70, increasing by 0.05 each time. This process was carried out separately for each emotion, allowing the model to adjust its sensitivity depending on the characteristics of each label — which is especially helpful in cases of class imbalance. For example, emotions like *surprise* or *fear*, which appear less frequently in the data, may benefit from a lower threshold. Our goal was to find the com-

bination of thresholds that would maximize the macro F1-score across all five emotions. To make the results more reliable, we used 5-fold cross-validation on the training set. The best thresholds were then applied to the test predictions. This per-label tuning led to a better balance between precision and recall, especially for texts expressing subtle or overlapping emotions. By avoiding a "one-size-fits-all" threshold (like the default 0.5), we were able to make the model more adaptable to the specific behavior of each emotion category.

12 Model Evaluation

Our final model achieves:

Metric	Value
Macro Precision	0.6814
Macro Recall	0.7094
Macro F1-Score	0.6864
Accuracy	0.3827
SemEval Baseline	0.7083

Table 2: *Performance Metrics showing the results of model evaluation for macro precision, recall, F1-score, and accuracy, with a comparison to the baseline.*

The results confirm that combining deep learning with traditional machine learning improves multi-label emotion classification. LightGBM and CatBoost further boost performance alongside XGBoost.

The model's low accuracy (0.3827) reflects the difficulty of multi-label classification, where texts express multiple emotions. The macro F1-score (0.6864) suggests an imbalance between precision (0.6814) and recall (0.7094), likely due to class imbalance, overlapping emotions, or suboptimal threshold selection. Additionally, language subjectivity and ambiguity pose challenges, as the same phrase can convey different emotions depending on context.

13 Experimental Setup

Our experimental setup consists of carefully designed steps to ensure reliable model training and evaluation. Below, we describe the dataset splitting strategy, preprocessing steps, hyperparameter tuning, and external tools utilized.

13.1 Data Splitting Strategy

The dataset was divided into three subsets: the Training Set (80%), which was used to train the models, and the Testing Set (20%), which was used for final evaluation. No separate validation set was used, as hyperparameter tuning was conducted using internal cross-validation techniques.

13.2 Preprocessing Steps

To optimize model performance, several preprocessing steps were applied. **BERT tokenizer** converted text into subword tokens, while **TF-IDF transformation** (vocabulary size: 8000) extracted lexical features. These were combined with **BERT embeddings** to form a hybrid feature set.

Data normalization was applied via standard scaling. Text cleaning included **lowercasing, removing digits, punctuation, and stopwords** (NLTK). These steps ensured consistency across the dataset, where text served as input (X) and emotion labels as output (Y).

13.3 Hyperparameter Tuning

For model training and evaluation, we employed a combination of individual classification models and an ensemble classifier.

13.3.1 Individual Classification Models

The study utilizes multiple classifiers: **Logistic Regression (LR)** with 1500 iterations (`max_iter=1500`) and class balancing (`class_weight='balanced'`); **Random Forest (RF)** with 200 trees (`n_estimators=200`) and depth 15 (`max_depth=15`); **Support Vector Machine (SVM)** with a linear kernel (`kernel='linear'`) and probability estimation (`probability=True`); **K-Nearest Neighbors (KNN)** using 5 neighbors (`n_neighbors=5`); and **XGBoost (XGB)** with 200 estimators (`n_estimators=200`), disabled label encoding (`use_label_encoder=False`), and `mlogloss` as the evaluation metric.

13.3.2 Ensemble Classifier

To enhance performance, an ensemble learning strategy was applied using the following models:

Random Forest with 200 trees and a maximum depth of 15, **XGBoost** with a learning rate of 0.1 and 200 estimators, **LightGBM** with 150 estimators and a maximum depth of 10 and **CatBoost** with a learning rate of 0.05 and 100 estimators.

Additionally, a grid search was applied to optimize probability thresholds for multi-label classification.

13.4 External Tools and Libraries

The following external tools and libraries were utilized for model training and evaluation: **Transformers Library** was used for BERT tokenization and training, while **Scikit-learn** handled TF-IDF extraction, model training, and evaluation. **XGBoost, LightGBM, and CatBoost** contributed to ensemble learning, with **PyTorch** used for BERT fine-tuning and embedding extraction. **Joblib** ensured efficient model storage. These components structured our experimental setup for multi-label emotion detection.

14 Results

In this section, we analyze the performance of our model based on official evaluation metrics, competition ranking, and additional qualitative observations.

14.1 Overall Performance

As shown in Table 2 in Section 12, these results indicate that our approach performs well in detecting multiple emotions simultaneously, with a balanced trade-off between precision and recall, as demonstrated by the F1 score of 0.6864.

Model	Macro F1-Score
TF-IDF only (Logistic Regression)	0.5141
BERT only	0.5594
Hybrid (BERT + TF-IDF + Ensemble)	0.6814
RoBERTa-large (planned future work)	0.7437

Table 3: Comparison of Macro F1-scores across different configurations: traditional methods, deep learning, hybrid models, and future improvements.

Table 3 summarizes the macro F1-scores achieved by various configurations. The TF-IDF model combined with Logistic Regression achieves limited performance due to its lack of contextual understanding. The BERT-only setup improves performance but still lacks lexical precision. Our proposed hybrid model significantly outperforms both baselines by combining the strengths of deep embeddings and lexical features.

Preliminary experiments with RoBERTa-large show further improvements, indicating promising directions for future work in enhancing semantic representations.

14.2 Error Analysis

To investigate misclassifications, we analyzed false positives and false negatives. Sentences containing sarcasm or irony were often misclassified. Additionally, short text samples with ambiguous wording had lower prediction confidence. Some labels also overlapped significantly, making a clear distinction difficult. To address these issues, future research could focus on improving semantic representations through larger models such as RoBERTa-large and integrating emotion lexicons.

14.3 Observations About the Data

Our analysis revealed class imbalance, with emotions like *surprise* being underrepresented. Some samples contained conflicting emotions, making labeling challenging. More data and augmentation could improve generalization.

Our approach—combining transformers, ensemble learning, and feature engineering—proved effective. Future work should focus on class balancing and integrating external emotion lexicons for better accuracy.

15 Conclusion

We proposed a hybrid approach for multi-label emotion detection, combining transformer models (BERT, RoBERTa) with TF-IDF and ensemble learning. This method leveraged deep embeddings and classical ML models, achieving an F1-score of 0.6864.

Challenges like ambiguous text, sarcasm, and label imbalance persist. Future work includes larger transformers (e.g., RoBERTa-large) with potential F1-score improvements to 0.74, alongside emotion lexicons, sentiment-aware embeddings, and advanced augmentation.

Our results highlight the benefits of integrating deep learning with traditional NLP, with further refinements promising enhanced performance.

16 Limitations

Our work presents several limitations. First, the dataset used in our experiments is limited to English texts. This may restrict the generalizability of the model to multilingual texts.

Second, although the hybrid approach combining BERT embeddings and TF-IDF features improves performance, it remains sensitive to subtle linguistic phenomena, such as sarcasm, irony, and

cultural differences in emotional expression. Misclassifications frequently occur in cases involving multiple or ambiguous emotions.

Third, due to limited computational resources, we restricted the fine-tuning of large transformer architectures (such as RoBERTa-large) and did not apply extensive data augmentation techniques, which could have further improved performance.

Finally, class imbalance in the dataset affects the detection of rare emotions, such as "surprise." Future work could focus on improving class imbalance handling, applying multilingual transfer learning, and exploring sentiment-aware pretrained embeddings.

17 Ethical Considerations

The proposed model presents ethical concerns regarding misuse, bias, and applicability.

17.1 Misuse and Bias

It could be exploited for manipulating individuals or spreading misinformation. Additionally, biases in training data may impact performance across demographics and languages, leading to uneven recognition of emotions.

17.2 Use Cases and Risks

The model should be used responsibly in sentiment analysis and mental health applications with consent, avoiding privacy violations. It is unsuitable for high-risk fields like law or medicine, where misclassification could have severe consequences. Safeguards are necessary to prevent misuse.

Abstract

This paper investigates multilingual emotion classification across three tasks: binary classification, intensity estimation, and cross-lingual emotion detection. To address challenges posed by linguistic diversity and limited annotated data, we explore a range of deep learning approaches, including transformer-based embeddings and traditional classifiers. Following extensive experimentation, language-specific embedding models were selected as the final approach due to their superior capability to capture linguistic and cultural nuances. Evaluations on both high- and low-resource languages demonstrate that this method yields strong performance, achieving competitive macro-average F1 scores across tasks. Notably, in the cross-lingual detection task, our approach secured first-place rankings in Oromo, Tigrinya, and Kinyarwanda, driven by the integration of advanced preprocessing techniques and tailored language modeling. Despite these advances, challenges persist due to data scarcity in underrepresented languages and the inherent complexity of emotional expression. This study underscores the importance of developing robust, language-aware emotion recognition systems and highlights future directions, including the expansion of multilingual datasets and continued refinement of modeling techniques.

1 Introduction

The analysis and processing of emotions from textual data have become crucial in understanding human communication across different languages and cultures. This study focuses on the detection and classification of emotions across diverse linguistic contexts, spanning regions from South America to East Asia. Our objective is to categorize emotions into key dimensions, namely sadness, anger, fear, disgust, joy, and surprise, while considering cross-lingual variations and linguistic complexities.

To address these challenges, we structure our study into three distinct tracks: (1) Track A involves binary emotion classification, determining whether a given text expresses a particular emotion; (2) Track B measures the intensity of emotions on a scale from 0 to 3, enabling a more granular understanding of emotional expressions; and (3) Track C explores cross-lingual emotion detection, facilitating insights into emotional patterns across different languages.

Understanding emotions based on textual data plays a pivotal role in various applications, including social media analysis, behavioral research, and the study of emotions' influence on social interactions. Our work contributes to the development of robust emotion recognition systems, enabling better comprehension of multilingual emotional expressions and their implications in computational linguistics.

Despite the significant advancements in emotion classification, several challenges persist. Some languages exhibit highly complex grammatical structures, making it difficult to train effective models. Additionally, the classification of emotions in low-resource languages is hindered by data scarcity and syntactic intricacies. Furthermore, certain machine learning models demonstrate suboptimal performance when applied to multilingual emotion classification, necessitating the development of novel techniques to enhance model adaptability and generalization.

To address these limitations, we present a comprehensive analysis of state-of-the-art methodologies and evaluate their effectiveness across multiple languages. Our findings highlight the critical role of innovative preprocessing techniques, domain adaptation strategies, and transfer learning in improving multilingual emotion classification.

All code implementations, including the models and experimental setups employed in this study, are publicly available on GitHub:[1]. This repository pro-

2 Related Work

Multi-label emotion detection has emerged as a significant task in NLP[2], particularly for low-resource languages. The task is structured in two main output formats: (1) a binary format, which indicates whether an emotion is present in the text, and (2) an intensity scale ranging from 0 to 3, which represents the strength of the emotion in the text.

Given that this task follows a text classification paradigm, various models have been explored to identify the most effective architectures. A considerable amount of research has focused on evaluating different structures to determine the optimal approach. In (Wang et al., 2016), a combination of LSTM[3] networks and CNNs[4] was explored, where various model configurations were compared based on their F1-score performances. These insights were leveraged to identify suitable model structures for developing a custom model tailored to the specific requirements of this task.

For low-resource languages, text preprocessing plays a crucial role in improving model performance. The work presented in (Muhammad et al., 2023) highlighted the effectiveness of multiple preprocessing algorithms specifically designed for African languages. The study demonstrated that well-structured preprocessing pipelines lead to better text representations, ultimately improving classification accuracy.

Moreover, datasets specifically curated for emotion detection in underrepresented languages have been explored. The datasets presented in (Muhammad et al., 2025a) and (Belay et al., 2025) serve as essential resources for training models and evaluating performance in real-world settings. These datasets enable the training of robust models capable of handling linguistic diversity.

To enhance model performance, modifications to existing architectures have been proposed. Based on the insights from (Wang et al., 2016), additional layers were incorporated into custom models to improve the representation of low-resource languages. This ensures that the models can capture intricate linguistic patterns that might otherwise be overlooked.

3 System Overview

In this section, we present a comprehensive overview of our system for multi-label text classification, which integrates various deep learning architectures and machine learning classifiers. The system follows a pipeline that includes text preprocessing, feature extraction using neural network models, and classification through different machine learning algorithms.

3.1 Preprocessing

The preprocessing pipeline involves several steps to clean and standardize the text data. These include converting text to lowercase, removing unnecessary whitespace, filtering out special characters, URLs, and emojis by replacing with their textual description, normalizing tokens, performing language-specific tokenization, and removing stopwords. These steps ensure the data is consistent and suitable for NLP tasks.

3.2 Feature Extraction

To extract features, we employed a diverse range of models, including LSTM networks, MLMs[5], and LLMs[6]. The LLMs were fine-tuned using LoRA[7] (Hu et al., 2021), a parameter-efficient tuning method that facilitates task-specific adaptation while maintaining computational efficiency.

The extracted feature vectors were derived using two distinct approaches. The first approach utilized the output from the embedding layer of the models, which captures contextual word representations in a lower-dimensional vector space. The second approach involved extracting the final hidden state of the neural network, which encapsulates high-level semantic information of the text.

3.3 Classification Approach

Following feature extraction, we applied multiple classification algorithms to perform the multi-label classification task. One of the classifiers used was the MLP[8], a feedforward artificial neural network capable of modeling complex relationships between the extracted features and the target labels. Additionally, the system employed XGBoost, a gradient boosting framework renowned for its effectiveness in structured data classification (Chen

[7]Low-Rank Adaptation
[8]Multi-Layer Perceptron

and Guestrin, 2016). Furthermore, SVMs were utilized as a classification method due to their ability to operate effectively in high-dimensional feature spaces by identifying optimal hyperplanes for classification (Cortes and Vapnik, 1995).

For languages with sufficient pretrained models available using MTEB[9](Muennighoff et al., 2022), we identified the best-performing embedding model and paired it mainly with SVM as the classifier. This approach leverages the strengths of the pretrained embedding models in capturing language-specific nuances, while the SVM classifier ensures robust performance for multi-label classification. On the other hand, for languages with limited pretrained resources, we utilized the multilingual embedding model "Multilingual E5 large instruct" (Wang et al., 2024) in combination with XGBoost as the classifier. The model, designed to generalize across diverse languages, enabled the system to maintain high performance even in resource-constrained settings.

4 Experimental Setup

This section outlines the experimental setup, including data splits, preprocessing, hyperparameter tuning, computational resources, and the tools and libraries used, aiming for reproducibility and transparency. All experiments and evaluation protocols in this work are conducted following the guidelines specified in SemEval-2025 Task 11 (Muhammad et al., 2025b), which establishes the framework for text-based emotion detection.

4.1 Data Splits and Usage

The dataset(Muhammad et al., 2025a) was divided into three subsets: training, development (validation), and testing. Specifically, 80% of the training dataset was allocated for training, while the remaining 20% was reserved for validation to facilitate model selection. Once the best-performing model was identified during the validation phase, the entire training and development datasets were combined to retrain the final model. This final model was then evaluated on the test dataset, which was held out during the entire training process to ensure an unbiased assessment of the model's generalization performance. This approach adheres to standard practices in machine learning research to prevent data leakage and ensure robust evaluation (Goodfellow et al., 2016).

[9]Massive Text Embedding Benchmark

4.2 Preprocessing

Preprocessing of the dataset was performed using the `clean-text` library. The preprocessing pipeline involved multiple steps to clean and standardize the text data. Initially, all text was converted to lowercase, and unnecessary whitespace was removed to eliminate redundancy. Special characters, URLs, and emojis were filtered out using regular expressions. Emojis were replaced by their corresponding textual descriptions (e.g., ☺→ "smiling face"). Punctuation was also removed, and tokenization was performed using language-specific tokenizers to ensure optimal segmentation, and stopwords were removed to further reduce noise. These steps ensured the data was clean and consistent across all subsets. Preprocessing was applied consistently to the training, validation, and test datasets to avoid introducing biases or inconsistencies. Such preprocessing steps have been shown to improve the performance of NLP models by reducing noise and simplifying the input representations (Zhang and Wang, 2020).

4.3 Hyperparameter Tuning

Hyperparameter tuning used Optuna (Akiba et al., 2019) to optimize SVM and XGBoost hyperparameters. Bayesian optimization balanced exploration and exploitation, with configurations assessed on the validation set. The best configuration was selected based on the performance metric.

4.4 Model Training and Optimization

The model fine-tuning with LoRA, and the training of the MLP and XGBoost models, utilized Binary Cross-Entropy (BCE) as the loss function for Tracks A and C, and Cross-Entropy for Track B, owing to its appropriateness for classification tasks. Meanwhile, the training of the SVM model employed hinge loss.Using LoRA, we fine-tuned the Q, K, and V matrices for feature extractor transformer models, as shown in Table 3. Given the unbalanced dataset, a weighted loss approach was employed to ensure that the model adequately learned from all classes. Optimization for fine-tuning deep learning models was performed using the `AdamW` optimizer, which improves upon the standard Adam optimizer by decoupling weight decay and learning rate updates (Loshchilov and Hutter, 2019). To further enhance training stability and convergence, a cosine annealing learning rate scheduler with restarts(Loshchilov and Hutter, 2017) was em-

ployed. This scheduling approach helped adaptively reduce the learning rate over time, facilitating better exploration of the loss landscape and improving generalization. The model was trained for a fixed number of epochs, and early stopping was used to terminate training if the validation performance plateaued, thus avoiding overfitting.

4.5 Tools and Libraries

The implementation of the experiments utilized several state-of-the-art tools and libraries. The deep learning models were implemented and trained using `PyTorch` (Paszke et al., 2019). For data manipulation and evaluation metrics, `Scikit-Learn` was employed (Pedregosa et al., 2011). Gradient boosting models were benchmarked using `XGBoost` (Chen and Guestrin, 2016). Pre-trained transformer models were fine-tuned using `Hugging Face Transformers` (Wolf et al., 2020). Additionally, the `Sentence Transformers` library was used to load embedding models (Reimers and Gurevych, 2019)(Reimers and Gurevych, 2020a). These tools and libraries are well-regarded in the machine learning community and were chosen for their reliability and performance.

4.6 Computational Resources

Experiments used a Kaggle Tesla P100 GPU for efficient model training, evaluation, and hyperparameter tuning, ensuring reproducibility with com-

parable hardware.

5 Results

Extensive experiments were conducted on multiple models to determine the most effective approach for multi-label emotion detection across various languages. The selected model was trained on datasets corresponding to each language, and its performance was analyzed using the test dataset. The evaluation results are presented in Table 1. More detailed results and additional analysis can be found in the Appendix A.

Notably, our approach achieved first rank in the Oromo, Tigrinya, and Kinyarwanda languages in Track-C of the competition. This strong performance highlights the effectiveness of the use of language-specific model embeddings tailored to the linguistic characteristics of each language.

A comparison of our findings with reference studies (Muhammad et al., 2025a) highlights the effectiveness of our approach. By leveraging domain-specific model embeddings, our models were able to bridge the gap in emotion classification for low-resource languages.

Table 2 highlights key limitations in the model's contextual understanding. For instance, the model misidentified fear with sadness in "I'm just numb," due to an oversimplified link between numbness and fear, showing lexical misinterpretation without context. Another example shows the model's failure to recognize temporal contrast in "at the time," missing the current sadness implied by past indifference, indicating a need for deeper semantic processing. In the third example, the model detected sadness and fear in a father's terminal illness revelation but missed anger and surprise embedded contextually, particularly the implicit anger towards "she" who knew about the cancer and the surprise of receiving life-altering news before a significant event, revealing deficiencies in extracting emotional implications from complex narratives.

Figure 1 presents the pooled confusion matrices for Tracks A, B, and C, highlighting the classification performance and misclassifications across different intensity levels and languages.

6 Conclusion

This study presented a comprehensive examination of multilingual multi-label emotion detection, addressing binary classification, intensity estimation, and cross-lingual detection tasks. Our findings indicate that language-specific embedding models, when paired with classifiers such as SVM and XGBoost, offer a robust approach to capturing the nuanced linguistic and cultural features inherent in diverse textual data. The experimental results, measured in competitive macro-average F1 scores, underscore the potential of these tailored models to bridge performance gaps, particularly in low-resource languages where data scarcity and complex grammatical structures present significant challenges.

The significance of this research lies in its demonstration that integrating innovative preprocessing techniques with state-of-the-art embedding models can lead to substantial improvements in emotion recognition performance. This has broad implications for applications in social media analysis, behavioral research, and other domains where understanding nuanced emotional expressions is crucial.

Nonetheless, current limitations in multilingual emotion analysis include the lack of annotated data for underrepresented languages and challenges in capturing nuanced emotional expressions, both of which hinder model performance. Future research should prioritize expanding multilingual datasets, improving preprocessing techniques, and developing new architectures to boost model generalization and adaptability. Fine-tuning models for low-resource languages could also enhance emotion detection accuracy, advancing the field and creating more effective, language-aware emotion recognition systems.

A Model Selection

The training dataset of Track A was utilized for model selection, where it was split into an 80/20 ratio to create a training set and a validation set. Several models were evaluated on this split to identify the optimal model based on performance metrics such as recall, precision, and F1-score. The model that achieved the best balance across these metrics was selected as the final model and applied consistently across all three tracks—A, B, and C. A detailed comparative analysis of the performance of different models for each language is presented in Table 3, where each row corresponds to a specific language and includes results for multiple models, with columns reporting recall, precision, and F1-score for each.

Table 3 provides a comprehensive comparison of the models' performance for each language, aiding in the selection of the final model applied to Tracks A, B, and C.

Table 3: Performance comparison of models for different languages

Language	Model	Metrics

Abstract

This paper describes our system used in SemEval-2025 Task 4: Unlearning sensitive content from Large Language Models. In this work, we propose a method for controlling the fine-tuning of a model's linear layers, referred to as CTL-Finetune (Control-Tuned Linear Fine-tuning). The goal of our method is to allow the model to forget specific information while preserving the knowledge it needs to retain. The method consists of four main components: 1) shuffling data labels, 2) shuffling label gradient calculation, 3) determination of control layers, and 4) fine-tuning using a combination of gradient ascent and gradient descent. Experimental results demonstrate that our approach effectively enables the model to forget targeted knowledge while minimizing the impact on retained information, thus maintaining the model's overall performance.

1 Introduction

Large Language Models (LLMs) have achieved significant advancements in understanding and solving natural language tasks. However, during the training process, LLMs tend to memorize vast amounts of data (Liang et al., 2022; Ouyang et al., 2022), which may lead to the reproduction of creative content or private information. This, in turn, poses legal risks to model developers and suppliers. These issues are typically identified post model training during testing or red teaming. Moreover, stakeholders may request the removal of their data from the model to protect copyright or exercise their right to be forgotten. However, retraining the model after each data deletion request is prohibitively costly and unsustainable. In light of these challenges, Anil Ramakrishna et al. introduced Task 4, named "Unlearning Sensitive Content from Large Language Models," in SemEval 2025 (Ramakrishna et al., 2025a,b). This task aims to develop a comprehensive evaluation framework to effectively eliminate sensitive data from LLMs, thereby providing a novel solution for the application of unlearning techniques in the domain of LLMs.

The three subtasks are designed with different types of textual data to evaluate the model's "forgetting" capability when handling sensitive information. These include: long-form synthetic creative documents (covering multiple genres), short synthetic biographies containing Personally Identifiable Information (PII) such as fictional names, SSNs, and home addresses, as well as real documents sampled from the target model's training dataset. These tasks aim to comprehensively test the model's ability to identify and eliminate sensitive content across various scenarios.

For this task, we employ the fine-tuned OLMo-7B-0724-Instruct-hf model. Building upon this foundation, we propose a method called CTL-Finetune (Controllable Layer Finetuning), which achieves selective (Dai et al., 2021; Tian et al., 2024b; Liu et al., 2024) information forgetting and retention by fine-tuning the model's linear layers. Figure 1 shows the overview of our framework. This approach involves transforming data labels, calculating relevant gradients, identifying control layers, and combining gradient ascent with gradient descent during fine-tuning. This enables the model to erase specific information while preserving essential knowledge.our system ranked 9th in this competition.

2 Background

2.1 Dataset Description

The challenge consists of three distinct subtasks, each focused on different types of documents. Subtask 1 involves long-form synthetic creative documents spanning various genres. Subtask 2 focuses on short-form synthetic biographies containing per-

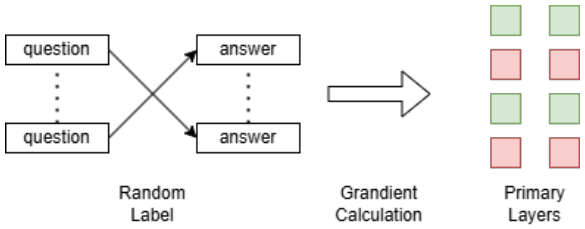

Figure 1: The overview of our framework, we should only unlearn knowledge within the Unlearn Scope while retaining the knowledge within the Retention Scope.

sonally identifiable information (PII), including fake names, phone numbers, Social Security numbers (SSNs), email addresses, and home addresses. Subtask 3 includes real documents sampled from the target model's training dataset.

For each subtask, there are two sets of documents: a Retain set (documents the model should retain in memory) and a Forget set (documents the model should forget). The training set contains 1,110 documents in the Forget set and 1,134 documents in the Retain set, while the validation set consists of 253 Forget documents and 277 Retain documents.

2.2 Related Work

The task of precise knowledge forgetting in neural networks (Yao et al., 2023; Thaker et al., 2024) has gained significant attention, particularly in response to growing concerns around privacy and model security. Several methods have been proposed to allow models to unlearn specific information while retaining essential knowledge. This section reviews key approaches, including gradient ascent-based forgetting, random label fine-tuning, and the use of adversarial examples.

A widely explored approach is gradient ascent, which aims to adjust the model's parameters to weaken its memory of certain knowledge while preserving other information (Jang et al., 2022). This technique explicitly increases the loss associated with specific examples, making the model "forget" particular data points. It is particularly useful for unlearning sensitive or private information without affecting the model's overall performance.

Another method involves random label fine-tuning. In this approach, training data labels are randomly shuffled (Golatkar et al., 2019), creating a disturbance in the model's memory. This disruption helps identify sensitive layers, which can then be fine-tuned to forget specific knowledge while minimizing overfitting. Several studies have shown that randomizing labels effectively aids in forgetting while retaining crucial knowledge.

Adversarial examples have also been explored as a means (Cha et al., 2023) of inducing forgetting. Typically used to test model robustness, adversarial attacks can be leveraged for precision forgetting by generating data points that deliberately disrupt the model's memory. These examples force the model to adjust its parameters, forgetting unwanted information while keeping essential knowledge. However, the challenge lies in balancing the trade-off between forgetting and maintaining performance.

In summary, these methods demonstrate the potential of fine-tuning strategies for precise knowledge forgetting in neural networks. Despite the progress made, challenges remain in effectively controlling the forgetting process, especially in ensuring that models can forget sensitive information without sacrificing their ability to retain useful knowledge. Continued development of targeted techniques, such as gradient ascent, random label manipulation, and adversarial examples, will be critical for advancing this field, particularly in domains requiring high levels of data privacy and security.

3 Methodology

In this work, we propose a fine-tuning approach for the OLMo model, enabling it to selectively forget sensitive knowledge while minimizing the impact on the knowledge that needs to be retained. Our method focuses on fine-tuning specific layers of the model, and it is composed of four main steps. By utilizing this method, we achieve a more nuanced control over the model's memory, allowing it to forget sensitive information without compromising the retention of important knowledge and the model's overall performance. The fine-tuning process ensures that the model adapts to new memory constraints while maintaining its core capabilities.

3.1 Random Shuffling of Dataset Labels

Given that the model has fully memorized the knowledge contained within the documents, we introduce perturbations to the model's memory by constructing new data-label pairs. To achieve this, we randomize the labels in the dataset, which creates a new training set that serves as the foundation for identifying layers of the model that exhibit a significant response to changes in memory. This process of randomization helps to disrupt the model's

established memory, allowing us to evaluate which layers are most influenced by such perturbations.

3.2 Gradient Calculation

Using the shuffled labels, we fine-tune the model on two subsets: the "forget" set and the "retain" set. During fine-tuning, we compute the gradient increments during backpropagation but do not apply these gradients to the model's parameters. This ensures that we capture the gradient information without altering the model's weights. The gradients calculated from the two datasets allow us to analyze which parts of the model are most sensitive to the forgetting and retention processes.

3.3 Identifying Primary Memory Layers

To determine which layers of the model are crucial for memory retention or forgetting, we establish upper and lower bounds for the gradient increments. Layers that fall outside these bounds are excluded from the subsequent gradient update steps. Additionally, we calculate the cosine similarity between the gradient increments from the "forget" and "retain" datasets. If the cosine similarity between these gradients is high for a particular layer(Tian et al., 2024a), it suggests that the layer is simultaneously influencing both the knowledge that should be retained and the knowledge that should be forgotten. Such layers are excluded from further fine-tuning. Only layers with low cosine similarity are retained for updating, ensuring that the model focuses on the layers most relevant for the selective memory process.

3.4 Selective Gradient Update

Once we have identified the layers that are most affected by the forgetting and retention processes, we apply gradient ascent to the layers responsible for forgetting sensitive knowledge. Conversely, for the layers that help retain critical knowledge, we apply gradient descent to preserve this information. This selective application of gradient ascent and descent enables the model to effectively forget sensitive content while safeguarding the knowledge that needs to be maintained.

4 Experimental setup

4.1 Pre-processing

The model and dataset were provided by the task organizers through a Python script that downloads the necessary data and processes it into the appropriate JSON format. For the subsequent model fine-tuning process, we converted the dataset into the standard PyTorch format to facilitate training.

4.2 Dataset Splitting

During the gradient increment computation, all data with shuffled labels were used for fine-tuning based on the Forget and Retain sets. After identifying the model layers to focus on, we randomly selected 50% of the data from the Forget set to perform gradient ascent operations. This approach aimed to minimize the impact on other aspects of the model's performance. For the Retain set, 80% of the data was selected for gradient descent operations, ensuring the model retains the necessary knowledge.

4.3 Evaluation Metrics

The evaluation metrics provided by the task organizers are as follows:

- **Task-specific regurgitation rates**, which were measured using *ROUGE-L* scores on the sentence completion prompts, and the *exact match rate* for question answers, applied to both the Retain and Forget sets. The Forget set metrics were inverted (i.e., $1 -$ metric value) to reflect the model's ability to forget information.
- A **Membership Inference Attack (MIA)** score was computed using a loss-based attack on a sample of member and non-member datasets. The MIA score is given by:

$$1 - |\text{MIA\_loss\_auc\_score} - 0.5| \times 2$$

- Model performance was also evaluated on the **MMLU (Massive Multi-task Language Understanding) benchmark**, which measures test accuracy across 57 STEM subjects.

For the awards leaderboard, only submissions with an MMLU accuracy above 0.371 (which corresponds to 75% of the pre-unlearning checkpoint) are considered. This threshold ensures that the model's utility is not compromised due to unlearning.

Finally, the three scores mentioned above are aggregated to generate a single numeric score for comparing model submissions. The aggregation is done using the **arithmetic mean**.

Algorithm	Final Score	Task Aggregate	MIA Score	MMLU Avg.
Gradient Ascent	0.394	0	0.912	0.269
Gradient Difference	0.243	0	0.382	0.348
KL Minimization	0.395	0	0.916	0.269
Negative Preference Optimization	0.188	0.021	0.080	0.463
CTL-Finetune for 1B	0.172	0.260	0.026	0.229
CTL-Finetune for 7B	0.266	0.205	0.128	0.467

Table 1: Performance Comparison of Various Algorithms

5 Results and Analysis

The final results of our experiments are presented in two models: 7B and 1B, as shown in Table 1. The 7B model achieved a final score of 0.266, which qualifies for the leaderboard in this evaluation. Notably, our model performed well in terms of both the MIA score and the task-aggregate score. When comparing our results with those of other teams, we observed that some teams had MIA and task-aggregate scores of 0, indicating that while our method successfully forgets sensitive information, it also effectively retains the core performance of the model. This highlights the advantage of our approach.

The 1B model, on the other hand, achieved a final score of 0.172. Compared to the 7B model, this result shows a noticeable decline, which could be attributed to the lower structural complexity of the 1B model relative to the 7B model, leading to a reduction in the effectiveness of our method. Overall, while our method demonstrates promising results, there is room for improvement in the forgetting performance, and further optimization is needed to enhance its effectiveness.

6 Conclusion

In this paper, we introduced a novel approach for enabling selective forgetting in large pre-trained models while preserving their core knowledge. Our method, which focuses on fine-tuning specific layers of the model, integrates data shuffling, gradient calculations, and selective updates through gradient ascent and descent. Experimental results demonstrate that our approach can effectively forget sensitive information while maintaining the model's essential performance. The 7B model achieved a final score of 0.266, qualifying for the leaderboard, and showed promising results in terms of MIA and task-aggregate scores, reflecting its ability to balance forgetting and retention. However, the 1B model, with its simpler architecture, exhibited a performance drop, indicating that model complexity plays a significant role in the effectiveness of the forgetting mechanism. Overall, while our method provides a solid foundation for model unlearning, further refinements and optimizations are needed to improve its performance, particularly in terms of the forgetting process.

Zuifeng at SemEval-2025 Task 9: Multitask Learning with Fine-Tuned RoBERTa for Food Hazard Detection

Dapeng Sun, Sensen Li, Yike Wang, Shaowu Zhang†
Dalian University of Technology
{sdp19990218,lisensen1106,yike}@mail.dlut.edu.cn , zhangsw@dlut.edu.cn

Abstract

This paper describes our system used in the SemEval-2025 Task 9 The Food Hazard Detection Challenge. Through data processing that removes elements and shared multi-task architecture improve the performance of detection. Without complex architectural modifications the proposed method achieves competitive performance with 0.7835 Marco F1-score on subtask 1 and 0.4712 Marco F1-score on sub-task 2. Comparative experiments reveal that joint prediction outperforms separate task training by 1.3% F1-score, showing the effectiveness of multi-task learning of this challenge.In subtask 1 and sub-task 2,our detection capabilities are ranked 9/26 and 10/27.

1 Introduction

Food safety hazards pose persistent threats to public health and economic security, driving societal demand for real-time detection of emerging risks. While early incident reports proliferate on social media platforms, automated systems are urgently needed to accurately parse vast unstructured data. The development of efficient automated detection algorithms thus emerges as a critical research focus, directly addressing the pressing imperative for risk mitigation.

The SemEval-2025 Task 9(Randl et al., 2025) is a food hazard detection task which extract food issues from web sources like social media, and we participate in sub-task 1 and sub-task 2.Sub-task 1 focus on text classification for food hazard prediction,predicting the type of hazard and product.Subtask 2 focus on food hazard and product "vector" detection, predicting the exact hazard and product.

Though machine learning approaches have demonstrated promise in food safety monitoring, two challenges persist in real-world deployment scenarios. First, social media texts exhibit inherent linguistic complexity through abbreviated syntax, domain-specific jargon (e.g., "Salmonella spp."), and implicit hazard references that resist traditional keyword matching. Second, the long-tail distribution of both hazards and products creates class imbalance - our analysis reveals that the top 3 hazard categories account for nearly 70% of occurrences in training set.

Our work addresses these challenges by systematically integrating transformer architectures with multi-task learning paradigms. Unlike baseline methods that process hazard and product detection sequentially, we perform joint optimization of these closely related tasks using shared semantic representations. This approach enables mutual reinforcement between hazard context understanding and product-specific recognition. The choice of RoBERTa(Liu et al., 2019) as the base architecture stems from its proven capability in robust token-level representation learning, which is particularly crucial for detecting implicit hazard mentions in short texts. In our training process, we treat the prediction tasks for hazard and product labels equally.

2 Related Work

2.1 Multi-task Learning

In recent years, the multi-task learning (MTL) approach in the field of natural language processing (NLP) has seen significant development and application(Yu et al., 2024). By effectively utilizing task-specific information and shared information to simultaneously solve multiple related tasks, MTL offers a more efficient training process and inference efficiency compared to single-task learning, and it enhances the model's generalization ability.Recent advancements in MTL have revolutionized natural language processing by enabling concurrent optimization of complementary tasks(Chung et al., 2022; Lewis et al., 2019; Raffel et al., 2023). A notable advancement is the work by Wang who

†Corresponding author.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 527–531

introduced InstructionNER(Wang et al., 2022), a unified neural architecture that establishes shared latent representations for cross-task generalization in named entity recognition (NER). Their framework demonstrates how structured task instructions and auxiliary objective integration can enhance performance metrics by 12-15% across multiple benchmarks.The efficacy of MTL becomes particularly evident in low-resource information extraction scenarios. Chen addressed this through their 2INER(Zhang et al., 2023) framework, implementing hierarchical prompt tuning for few-shot MTL. By jointly optimizing span recognition and entity typing sub-tasks with task-specific prompt layers, their approach achieves 8.2% F1-score improvement over single-task baselines under 100-shot learning conditions, significantly enhancing cross-domain adaptability.

2.2 Extreme Multilabel Classification

Although our task is relatively moderate in scale compared to tasks involving millions of possible labels — with only a little over a thousand product labels in the sub-task with the most labels (sub-task 2) — characteristics such as long-tailed distribution and sparsity are also evident in our data, similar to what is observed in Extreme Multi-Label Classification (XMC) scenarios. The objective of extreme multi-label classification is to learn feature architectures and classifiers that can automatically tag a data point with the most relevant subset of labels from an extremely large label set.(Bhatia et al., 2016) DeepXML(Dahiya et al., 2021) framework addresses these challenges by decomposing the deep extreme multi-label task into four simpler sub-tasks each of which can be trained accurately and efficiently. MatchXML(Ye et al., 2024) is an efficient framework designed for the problem of XMC. It generates dense label embeddings by combining the Skip-gram model and utilizes BERT as the text encoder, effectively handling large-scale label spaces.

3 Data and Methodology

3.1 Data Description

The dataset from Task 9 of SemEval-2025 contains 6,644 short texts with an average length of 88 characters. These texts primarily consist of English food recall titles sourced from official food agency websites, such as the FDA. Each text has been meticulously labeled across four categories: hazard,product,hazard category and product category. Hazards include 128 distinct hazard categories.Hazard Category can be understood as a higher-level classification of different types of hazards, totaling 10 categories. Products comprises 1,142 specific product categories.Product Category with a total of 22 categories. The core objective of the task is to identify the relevant hazard category from the given texts. For instances in subtask1 and sub-task2 only both hazard and product completely right will score 1.0,while hazard completely wrong will directly score 0.0.This evaluation method shows the importance of the hazard prediction.

3.2 Preprocessing

In this section, we will detail the preprocessing steps applied to our data, which is then used throughout all training processes. Initially, a space normalization operation is performed: this step aims to eliminate unnecessary consecutive whitespace characters in the text, retaining only single whitespace characters to ensure textual tidiness and consistency. Following that, there is a filtration of numerical information: this process focuses on removing irrelevant numeric details such as times, location numbers, and sequential product and document numbers. Furthermore, for isolated symbols existing outside of numbers in product and document numbers, these have also been cleaned up to minimize noise data impact on subsequent analysis, ensuring the quality and accuracy of the dataset.

3.3 Methodology

Our multi-task architecture leverages the RoBERTa transformer to jointly model hazard classification and product categorization. Given an input sequence X, the RoBERTa encoder generates contextualized representations through successive transformer layers:

$$H = RoBERTa(X) \in \mathbb{R}^{L*d} \quad (1)$$

where L denotes sequence length and d is the hidden dimension size. We extract the [CLS] token's embedding $h_{[CLS]} \in \mathbb{R}$ from the final layer's output H as the aggregated text representation.

Two parallel classification heads process this shared representation for their respective tasks. For hazard prediction:

$$y_h = W_h h_{[CLS]} + b_h \quad (2)$$

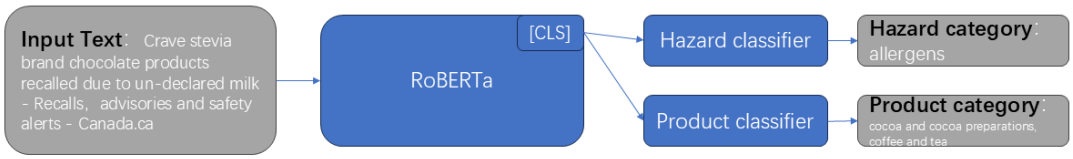

Figure 1: This image shows our frame of our method. CLS in RoBERTa represent the CLS token of the last hidden state in the model.

and for product prediction:

$$y_p = W_p h_{[CLS]} + b_p \tag{3}$$

where $W_h \in \mathbb{R}^{N_h \times d}$, $W_p \in \mathbb{R}^{N_p \times d}$are task-specific weight matrices, with denoting the number of hazard classes and product categories respectively. For sub-task1 hazard category label is 10,product category label is 22. For sub-task 2 hazard label is 128,product label is 1142.

Despite the evaluation metrics focusing more on correctly predicting hazards during the assessment phase, we simplify the problem by treating the predictions of both hazard and product equally. Specifically,the unified loss combines both objectives through balanced averaging:

$$L = \frac{1}{2}(L_h + L_p) \tag{4}$$

where $\mathcal{L}_h$ and $\mathcal{L}_p$ represent standard cross-entropy losses of hazard and product,and L represent the unified loss. This approach means that during the training process, we do not directly account for the complexity of calculating the accuracy of the product part only when the hazard prediction is correct. Instead, by treating the losses of both tasks equally, we aim to simplify the training process. We expect that this simplified strategy will provide sufficient guidance in practice, enabling the model to learn effective feature representations, thereby indirectly improving performance under specific evaluation criteria.

4 Experiments

In the experiments, we selected RoBERTa as the base model, and we also conducted some preliminary experiments using BERT(Devlin et al., 2019). We employed the official script to calculate the macro F1 score for evaluating our experimental results, and we will strive to present the results of our direct submissions to the official platform, even if these results may be incomplete. Detailed hyperparameter settings are provided in Table 1. All experiments were conducted on an NVIDIA GeForce GTX 3090 GPU.

Parameter	Sub-task1	Sub-task2
Epochs	10	10
Batch size	2	2
Learning rate	1e-5	1e-5
Warmup steps	500	500
Loss function	CrossEntropy	CrossEntropy

Table 1: Training configuration for sub-task1 and sub-task2. The table lists the key parameters used during the training phase for both tasks.

4.1 Results and Analysis

Model	Sub-task1	Sub-task2
Baseline(Valid)	0.6381	/
Ours(Valid)	0.8004	/
Ours(Test)	0.7835	0.4712

Table 2: Main experimental results focusing on Macro F1 scores for sub-task1 and sub-task2. All results were uploaded to the official website for computation. The validation set contains 565 unlabeled instances, while the test set contains 997 instances. This table displays the performance of the baseline and our model on both validation and test sets.

Table 2 shows the capability of our system in detecting food hazards. Compared to methods that separately predict hazards and product labels, our system demonstrates superior performance. This achievement indicates that adopting a multi-task learning strategy not only helps the model more accurately determine categories but also further enhances the effectiveness of food hazard detection by strengthening the learning of semantic features. Specifically, multi-task learning allows the model to share and utilize information across different yet related tasks, thereby improving overall performance.

Based on the results in Table 3, it is clear to see the significant improvement brought by the

Model	Prediction Mode	Result
BERT	Separate	0.6381
	Joint	0.6557
RoBERTa	Separate	0.7317
	Joint	0.7446

Table 3: Comparison of Macro F1 scores for predicting hazard and product labels separately versus jointly using BERT and RoBERTa as model backbones on sub-task1. The joint prediction shows the improvement when both labels are predicted simultaneously.

multi-task learning strategy in predicting food hazards and product labels. Specifically, performance improvements were observed in joint prediction mode whether using BERT or RoBERTa as the model backbone. For BERT, the Macro F1 score in separate prediction mode was 0.6381, which increased to 0.6557 in joint prediction mode. Similarly, RoBERTa saw an increase from 0.7317 in separate prediction to 0.7446 in joint prediction. These results strongly indicate that simultaneously predicting two related tasks, namely food hazards and product labels, can effectively enhance the overall performance of the model.

5 Conclusion

In this paper, we present our solution for SemEval-2025 Task 9:The Food Hazard Detection Challenge. The task objective focuses on simultaneously predicting hazard types and corresponding food products from social media texts. To address this challenge, we implemented a systematic pipeline beginning with data preprocessing steps that removed semantically irrelevant elements like timestamps and document IDs. Subsequently, we developed a multi-task learning framework based on the RoBERTa architecture, which enables joint prediction for both hazard and product classification through parameter sharing. Our final system achieved competitive performance with macro-F1 scores of 0.7835 on sub-task 1 and 0.4712 on sub-task 2 in the official evaluation.

Limitations

In this section, we discuss several limitations of our study and indicate potential directions for future improvements.

Firstly, while the utilization of the [CLS] token is effective for many classification tasks, it may fall short in capturing task-relevant local information. Particularly in scenarios involving long texts or when specific sections of the text are crucial for decision-making, relying on a token that aggregates information from across the entire input sequence might overlook key local details. Secondly, in multi-task learning settings, simply averaging losses across different tasks could overlook the intricate relationships and dependencies among these tasks, such as conditional dependencies or differences in their relative importance. Certain tasks may be more critical under specific conditions, or their outcomes might depend on each other in subtle ways that averaged loss functions fail to capture. Lastly, although our data processing strategy proved effective within the scope of our experiments, it largely depends on empirical observations rather than a solid theoretical foundation. In summary, while we have achieved certain results in our current research, there remain several limitations as outlined above. We aim to address these issues in future work, striving to propose more comprehensive and universally applicable approaches.

IEGPS-CSIC at SemEval-2025 Task 11: BERT-based approach for Multi-label Emotion Detection in English and Russian texts

Albina Sarymsakova[1], **Patricia Martín-Rodilla**[1]
[1]Instituto de Estudios Gallegos Padre Sarmiento (IEGPS-CSIC), Santiago de Compostela, Spain
{albina.s, p.m.rodilla}@iegps.csic.es

Abstract

This paper presents an original approach for SemEval 2025 Task 11. Our study investigates various strategies to improve Text-Based Multi-label Emotion Detection task. Through experimental endeavors, we explore the benefits of contextualized vector representations by comparing multiple BERT models, including those specifically trained for emotion recognition. Additionally, we examine the impact of hyperparameters adjustments on model performance. For Subtask A, our approach achieved F1 scores of 0.71 on the English dataset and 0.84 on the Russian dataset. Our findings underscore that (1) monolingual BERT models demonstrate superior performance for English, whereas multilingual BERT models perform better for Russian; (2) pretrained emotion detection models prove less effective for this specific task compared to models with reduced vocabulary and embeddings focused on specific languages; (3) exclusive use of BERT-based models, without incorporating additional methods or optimization techniques, demonstrates promising results for multilabel emotion detection.

1 Introduction

The emotion mining framework (Liu, 2020) represents a recently established specialized task that allows for evaluation and identification of emotional tone conveyed in textual data. Traditionally, sentiment analysis classified textual content as positive, negative, or neutral (Rosenthal et al., 2017). However, emotion mining techniques enable the assignment of a broader range of emotions to texts (Troiano et al., 2023; Greschner and Klinger, 2024), such as those defined by the Ekman (Ekman and Friesen, 1978; Ekman, 1992), which identifies six basic emotions (sadness, joy, disgust, surprise, anger, and fear) and the absence of emotion. With rise of Large Language Models (LLM), this emotion classification has been also widely applied in domains like marketing (Wemmer et al., 2024), health (Yang et al., 2023), and media (Zhang et al., 2023), helping researchers and organizations understand emotional aspects, make informed decisions, and improve services.

To date, emotion analysis has shown promising results, especially in English, due to abundant resources (Maks and Vossen, 2011; Valitutti et al., 2004). SemEval 2025 Task 11 (Muhammad et al., 2025b) seeks to bridge the gap in text-based emotion identification across 32 languages, focusing on emotion perception—how most people interpret a speaker's emotions from text (Mohammad, 2022). This is challenging as perceived emotions may differ from actual emotions due to cultural and individual factors (Woensel and Nevil, 2019; Wakefield, 2021). It is also important to highlight that Subtask A accounts for the complexity of expressed emotions in text by allowing multi-label emotion classification. This approach not only enhances the accuracy of emotion extraction but also acknowledges that some emotions can emerge from the interaction of two or more emotions, as described by Muhammad et al. (2025a).

Based on these outcomes, our study seeks to advance the field of text-based emotion detection by providing the following contributions:

1. Comprehensive evaluation and fine-tuning of fifteen pretrained monolingual and multilingual BERT-based models for emotion classification on English and Russian datasets, including those specifically trained for this task.

2. Analysis of the performance of BERT-based models without additional techniques or methods for emotion detection, aimed at evaluating their ability to handle this task independently.

3. Release of the best-performing multi-label emotion detection models for English and Russian.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 532–538

This paper is structured as follows: Section 2 reviews state-of-the-art models for text-based emotion identification. Section 3 discusses dataset insights and our approach to architecture selection. Section 4 presents the experimental results. Section 5 provides a qualitative analysis and error categorization of the best-performing models. Finally, Section 6 concludes the paper.

2 Background

Several antecedent works have addressed the problem of emotion annotation and identification in text-based sources. A foundational contribution within the SemEval framework is by Mohammad et al. (2018), who introduced multi-label emotion annotation across 174,356 tweets in English, Arabic, and Spanish, covering twelve emotion categories (e.g., "anger" included related emotions like annoyance and rage). For English tweets, the best results were achieved using an ensemble of pretrained models, feature extraction, and traditional classifiers (e.g., SVM, logistic regression), reaching a Pearson's r of 79.9. Building on this, Chatterjee et al. (2019) improved performance through ensemble methods combined with transfer learning. Since then, particularly in SemEval 2020, 2023, and 2024, BERT models (Devlin, 2018) and transfer learning have become the dominant approaches for emotion detection, consistently achieving high F1 scores (see Table 1).

Description	F1 macro
Chatterjee et al. (2019)	0.7731
Sharma et al. (2020)	0.33
Vallecillo Rodrguez et al. (2023)	0.8245
Wang et al. (2024)	0.3223

Table 1: F1 scores of SemEval BERT-based state-of-the-art models for text-only emotion identification

According to these results, BERT-based approaches are not only regarded as the most effective and preferred method for emotion detection in text within the SemEval NLP community, but their effectiveness has also been confirmed in recent studies by Imran (2024) and Aslan (2024). However, it is important to note that most of the reported results primarily involve English datasets for training and evaluation of the systems (Bujnowski et al., 2024; Šmíd et al., 2024).

Table 2 presents selected BERT-based models specifically trained for emotion detection in English and Russian, chosen based on their reported performance. These models were trained on large-scale emotion datasets using only BERT-based architectures, without additional optimization techniques, as reported by the authors in Table 1. Most were trained and evaluated on the GoEmotions dataset (Demszky et al., 2020), except Model 4, which uses the CEDR corpus for Russian (Sboev et al., 2021). The selection ensures consistency in emotion categorization, as all models overlap in their identification of the same emotional categories.

4	Seara (2021b)	Rus	0.74

Table 2: F1 scores of BERT fine-tuned models for text-based emotion classification

It is important to note that selecting and matching fine-tuned BERT models for emotion analysis in English and Russian is highly challenging due to the limited availability of resources. Consequently, we had to rely on two Russian-targeted models since, as mentioned earlier, the field of text-based emotion identification in Russian remains underexplored.

Building on these insights and in line with the contributions outlined in Section 1, we aim to propose a system for emotion identification in both English and Russian texts. The choice of these languages is motivated by two following reasons: (1) to introduce the Russian language into the SemEval competition board, as there is a notable lack of studies addressing this language; (2) to explore how a system with a similar architecture performs on two linguistically unrelated languages.

3 Datasets and Model

The dataset by Muhammad et al. (2025a) contains English and Russian short text snippets. We provide a statistical overview for each dataset in Table 3. It is worth noting that while the Russian dataset follows Ekman's traditional six-emotion classification (Ekman and Friesen, 1978; Ekman, 1992), the English dataset includes only five emotions due to an insufficient representation of the Disgust class (Muhammad et al., 2025a). The En-

English

	Fear	1611	58.20		63	54.31		1544	55.80
	Joy	674	24.35		31	26.72		670	24.21
	Sadness	878	31.72		35	30.17		881	31.84
	Surprise	839	30.31		31	26.72		799	28.88
	Total	2768	100		116	100		2767	100
Russian									
Train	Anger	543	20.27	**Dev**	47	23.62	**Test**	226	22.60
	Disgust	273	10.19		26	13.07		122	12.20
	Fear	328	12.24		21	10.55		108	10.80
	Joy	555	20.72		34	17.09		192	19.20
	Sadness	421	15.71		39	19.60		141	14.10
	Surprise	355	13.25		26	13.07		122	12.20
	Total	2679	100		199	100		1000	100

Table 3: Dataset sizes and emotion distribution for English and Russian in Subtask A

glish dataset exhibits a notable imbalance, with Fear dominating the training set at 58.2%, and other emotions, like Anger (12.03%), being more underrepresented. This trend continues in the development and test sets, where Fear makes up 54.31% and 55.80%. In contrast, the Russian dataset is more balanced, with Joy (20.72%, 17.09%, 19.20%) and Anger (20.27%, 23.62%, 22.60%) being the most common across the subsets. Other emotions like Disgust (10.19%, 13.07%, 12.20%) and Fear (12.24%, 10.55%, 10.80%) also have a reasonable presence.

Overall, while there is some variation in class sizes, the Russian dataset provides a more equitable distribution of emotions, which may benefit the model while predicting across different categories. In contrast, the English dataset is slightly more imbalanced, with Fear overrepresented, which may bias model toward this class.

3.1 Architecture selection

To address the multi-label classification of emotions in English and Russian textual data, we rely on sequence classification module from BERT pretrained models exclusively to predict probabilities across multiple emotion categories. The architecture of our proposed method is illustrated in Figure 1.

The BERT models we used have already demonstrated strong performance in emotion classification tasks (Creanga and Dinu, 2024). To adapt them for our specific task of multi-label emotion

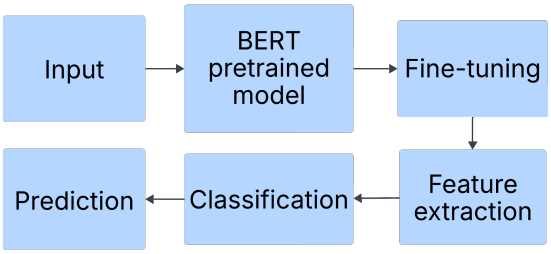

Figure 1: Model architecture

detection, we fine-tuned the models. We used a standard fine-tuning method with pretrained transformer models, based on the *transformers* library[1] from HuggingFace (Wolf et al., 2020). For each model, we experimented with different batch sizes (8, 16, 32) and learning rates ($1e^{-5}$, $2e^{-5}$, $3e^{-5}$, $4e^{-5}$, $5e^{-5}$), selecting the best checkpoint based on its F1 score on the development set after fifty epochs. The final hyperparameters set included a learning rate of $2e^{-5}$, a batch size of 16, and forty epochs.

We used pretrained multilingual and monolingual BERT-based models as the first step in our pipeline to preprocess input. This process involves reading text data from datasets, tokenizing it with a pretrained tokenizer, truncating and padding sequences, converting text into tensors, and finally creating batches for training and evaluation. The tokenized input is then passed through the pretrained transformer models. The models employs a self-

Table 4: The results on multilabel emotion detections task with BERT-based models and evaluated on English and Russian development set

attention mechanism across multiple layers to generate contextualized embeddings for each token. These embeddings capture semantic relationships between tokens in the context of the entire input sequence, allowing the model to understand the emotion conveyed in it.

For multi-label classification (5 for Russian or 6 for English emotion labels), the model produces logits that represent the prediction for each emotion class. The logits are passed through a sigmoid activation function to obtain probabilities (p) for each emotion, using the following formula:

$$p(x) = \frac{1}{1 + e^{-x}}$$

where x is the logit for a given emotion. Since each emotion is independent, a sigmoid function is applied to each logit to obtain a probability between 0 and 1 for each emotion. The predictions are then used for evaluation or testing.

4 Experiment results

Using the architecture detailed above, we experimented with 15 different models for both English and Russian datasets. As shown in Table 4, the best-performing model for English was roBERTa-base, while for Russian, it was xlm-roBERTa-large trained with a reduced vocabulary and embeddings specifically tailored to Russian and English. Emotion-specific models like GoEmotions consistently underperform vanilla BERT-base, offering less precision on emotion classification task.

These development dataset evaluation results were subsequently tested on the final test dataset described in Section 3. The final F1 Macro scores achieved were *0.71* for English and *0.8418* for Russian, demonstrating the effectiveness of our chosen models and approach across both languages.

5 Discussion

The scores illustrated in Figure 2 represent the accuracy of our model in correctly predicted emotions. In English, Fear has the highest accuracy (82%), followed by Joy and Sadness, while Surprise and Anger perform slightly lower. The Russian dataset shows higher overall accuracy, with Joy at 91% and Fear 88%, while Disgust is the less accurate (77%).

These results could be attributed to both the model's performance and the dataset used for fine-tuning. Nonetheless, as discussed in Section 3, Fear is the most overrepresented emotion in the English dataset, which aligns with our model strong performance predicting it, as shows the Figure 2.

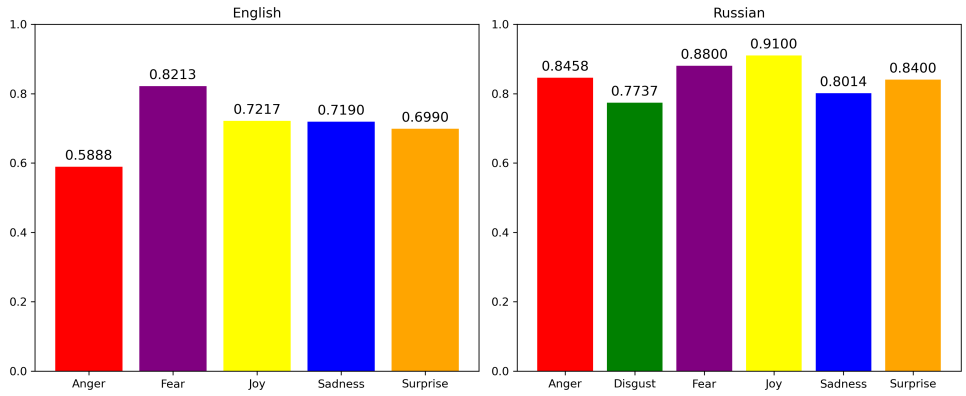

Figure 2: Accuracy of correctly labeled emotions for English and Russian datasets

On the contrary, Anger, being underrepresented in the English dataset, exhibits the lowest accuracy. This indicates that the model is moderately sensitive to class imbalance—performance on minority emotions drops, especially in the English dataset where Fear dominates. The Russian dataset is more balanced, allowing the model to maintain stable performance across different classes. As future research, we aim to improve this dataset by incorporating a more diverse range of text snippets, which, we hope, will benefit the model.

Finally, we analyzed the accuracy of our model in performing multilabel emotion classification based on textual data. As shown in Table 5, the model demonstrated higher accuracy in correctly predicted Russian text snippets compared to English. This suggests that multilabel emotion prediction is more reliable for the Russian dataset. These findings will be also considered in future research to improve multilabel accuracy further.

Language	Total	Correct	%
English	2767	1190	56.99
Russian	1000	771	77.10

Table 5: Multilabeling accuracy data of our model

6 Conclusions

To the best of our knowledge, this study presents several novel contributions to the field of emotion detection in English and Russian, which have not been explored in previous works:

First, the evaluation and fine-tuning of various BERT-based models for emotion detection reveal that monolingual BERT models achieve superior performance for English, while multilingual BERT models perform better for Russian. Notably, a BERT model with a reduced vocabulary and embeddings specifically tailored to Russian and English demonstrated the highest accuracy for the Russian dataset. Compared to the baseline by Muhammad et al. (2025b), which used only fine-tuned multilingual RoBERTa on each language's training data, our approach—fine-tuning the classifier layer with both multilingual and monolingual BERT models—achieved better results. We ranked 44th in Track A for English and 25th for Russian.

Second, the architecture of our model follows state-of-the-art principles used in emotion detection tools. While prior studies suggest that incorporating additional methods and techniques alongside BERT-based models enhances emotion detection performance, our experiments reveal that BERT models alone achieve sufficient accuracy.

In summary, we have contributed to the area of emotion detection in English and Russian by reutilizing the available BERT-based models, refining them for this specific task, which has provided positive results (71% for English and 84% for Russian) showing the high accuracy in multilingual emotion labeling and outperforming results, reported in previous works.

As for limitations, we have not yet extensively explored LLMs due to resource constraints, though we recognize their potential for improving contextual understanding in multilabel emotion classification. While this work focused on transformer-based models, we acknowledge that exploring alternative classifier architectures (e.g., Conv1D + MLP) and traditional methods (e.g., SVM, XGB) could enhance accuracy. We also aim to apply regularization and data augmentation techniques to reduce overfitting and improve generalization in future work.

Acknowledgments

The authors are extremely grateful to Olga Zamaraeva, PhD in Computational Linguistics, for her technical and theoretical support. This study is funded by CSIC Momentum project, financed by European Union's Recovery and Resilience Facility-Next Generation, in the framework of the General Invitation of the Spanish Government's public business entity Red.es to participate in talent attraction and retention programmes within Investment 4 of Component 19 of the Recovery, Transformation and Resilience Plan.

Abstract

In this paper, we describe our approach for the SemEval 2025 Task 2 on Entity-Aware Machine Translation (EA-MT). Our system aims to improve the accuracy of translating named entities by combining two key approaches: Retrieval Augmented Generation (RAG) and iterative self-refinement techniques using Large Language Models (LLMs). A distinctive feature of our system is its self-evaluation mechanism, where the LLM assesses its own translations based on two key criteria: the accuracy of entity translations and overall translation quality. We demonstrate how these methods work together and effectively improve entity handling while maintaining high-quality translations.

1 Introduction

Entity-Aware Machine Translation (EA-MT) focuses on accurately translating sentences containing named entities, such as movies, books, food, locations, and people. This task is particularly important because entity names often carry cultural nuances that need to be preserved in the translation process (Conia et al., 2024). The challenge lies in the fact that named entities typically cannot be translated through simple word-for-word or literal translations. For instance, the movie "Night at the Museum" is translated as "박물관이 살아있다" (meaning "The Museum is Alive") in Korean, rather than the literal translation "박물관에서의 밤." This example illustrates why literal translations of entity names can be inappropriate. This issue becomes particularly critical in domains such as journalism, legal, or medical contexts, where incorrect entity translations can significantly compromise factual accuracy and trustworthiness.

The SemEval 2025 Task 2 (Conia et al., 2025) addresses this challenge by requiring participants to develop systems that correctly identify named entities and transform them into their appropriate target-language forms. In this paper, we present our system, which combines Retrieval-Augmented Generation (RAG) and self-refine (Madaan et al., 2024) approaches. Our system first retrieves entity information (labels and descriptions) from Wikidata (Vrandečić and Krötzsch, 2014) IDs provided by the task organizers. This information is then incorporated into prompts for a Large Language Model (LLM). However, we discovered that merely providing entity information to the LLM does not guarantee accurate entity-aware translations. To address this limitation, we implemented the self-refine framework where the same LLM model evaluates the initial translation based on two criteria: entity label accuracy and overall translation quality. In summary, our approach integrates both RAG and self-refine frameworks to achieve optimal translation results. We also present case studies demonstrating concrete improvements achieved through our feedback mechanism.

2 Related Work

2.1 Entities in Knowledge Graph

Knowledge graph component retrieval from source texts has been extensively studied through various approaches, including dense retrieval (Conia et al., 2024; Karpukhin et al., 2020; Wu et al., 2020; Li et al., 2020) and constrained decoding (De Cao et al., 2021; Rossiello et al., 2021; Lee and Shin, 2025). These retrieved information has been successfully applied to various tasks, such as question answering and machine translation. In the context of machine translation, several studies have focused on entity name transliteration, converting entity names from one script to another (Sadamitsu et al., 2016; Ugawa et al., 2018; Zeng et al., 2023). However, these studies did not address the transcreation of entity names. Another line of research has explored improving MT models by augmenting training datasets to enhance entity coverage (Hu

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 539–545

et al., 2022; Liu et al., 2021). While our approach directly utilizes gold Wikidata IDs and retrieves related information, it can be potentially combined with the aforementioned retrieval methods.

2.2 Retrieval Augmented Generation

Retrieval Augmented Generation (RAG) has been widely adopted to enhance machine translation accuracy. Zhang et al. (2018) demonstrated its effectiveness in improving MT quality, particularly for low-frequency words. Bulte and Tezcan (2019) employed fuzzy matching techniques for dataset augmentation. More recently, Conia et al. (2024) leveraged RAG with Large Language Models to achieve cross-cultural machine translation.

2.3 Post Editing and Refinement

Post-editing has become a crucial part of machine translation workflows to enhance initial translation quality. Large Language Models (LLMs) have emerged as particularly effective tools for providing translation feedback. Raunak et al. (2023) employed GPT-4 to generate feedback and post-edit Microsoft Translator outputs, while Kocmi and Federmann (2023) utilized GPT-4 to provide MQM-style feedback for machine translation results. The concept of self-refinement, introduced by Madaan et al. (2024), allows Large Language Models to generate outputs, feedback and iterate by itself, leading to improved performance across various tasks. In our work, we adapt this self-refinement framework for entity-aware machine translation, as we found that RAG alone is insufficient for accurate translation.

3 Dataset

The dataset for this task was provided by the organizers in multiple stages: sample, training, validation, and test sets as shown in Table 1. The sample data served as an initial reference to demonstrate the format and task requirements. Each dataset, except for the test set, contains English source texts paired with translations in ten target languages: Italian, Spanish, French, German, Arabic, Japanese, Chinese, Korean, Thai, and Turkish. A typical data entry consists of an English sentence, at least one corresponding translation in a target language, and an associated Wikidata ID for reference. For instance, the English question "What year was The Great Gatsby published?" is paired with its Korean translation "위대한 개츠비는 몇 년도에 출판되었나요?" and linked to the Wikidata ID Q214371. The test set, which contained approximately 5,000 sentences for each language direction (totaling 49,606 sentences), was released without ground-truth target references. The official evaluation was conducted using withheld references that were later made available by the organizers.

Language	Train	Valid	Test
Italian	3,739	730	5,097
Spanish	5,160	739	5,337
French	5,531	724	5,464
German	4,087	731	5,875
Arabic	7,220	722	4,546
Japanese	7,225	723	5,107
Chinese	-	722	5,181
Korean	-	745	5,081
Thai	-	710	3,446
Turkish	-	732	4,472
Total	32,962	7,278	49,606

4 System Description

This section provides a detailed description of our system for entity-aware machine translation. Our approach combines Retrieval-Augmented Generation (RAG) with self-refinement to ensure accurate entity labeling and high-quality translation.

4.1 Retrieval-Augmented Generation

Our system utilizes the gold entity (Wikidata ID) provided in the test dataset. We begin by extracting the entity labels, which are essential for accurate translation of entity names. Additionally, we incorporate entity descriptions, as they play a vital role in entity identification and context understanding (De Cao et al., 2021; Wu et al., 2020). These descriptions help the model distinguish between different entity types and generate contextually appropriate translations. As illustrated in Example 1, we embed the entity information within the prompt, instructing the model to consider this information when generating the translation. The entity information is retrieved using the Wikidata REST API[1].

Formally, given a source text x, prompt p_{gen}, entity information e, and model M, the initial translation y_0 is generated as:

$$y_0 = M(p_{gen}||e||x) \quad (1)$$

[1]https://www.wikidata.org/w/rest.php/wikibase/v1

```
Translate the following text from English to Korean, ensuring that
↪  entity names are accurately translated.

Here are some examples of this translation:

Text to translate:
What type of place is the Strahov Monastery?

Reference entity information:
Korean Label: 스트라호프 수도원
English Label: Strahov Monastery
Description: church complex in Prague

Translation:
스트라호프 수도원은 어떤 곳인가요?

###

(other few shot examples)

###

Text to translate:
When was White Army, Black Baron first performed?

Reference entity information:
Korean Label: 붉은 군대는 가장 강력하다
English Label: White Army, Black Baron
Description: song composed by Samuel Pokrass performed by Alexandrov
↪  Ensemble

Translation:
```

Listing 1: Prompt template for initial translation

```
Score the following translated text from English to Korean on two
↪  qualities: i) Entity Correctness and ii) Overall Translation.

Here are some examples of this scoring rubric:

Text to translate:
What type of place is the Strahov Monastery?

Reference entity information:
Korean Label: 스트라호프 수도원
English Label: Strahov Monastery
Description: church complex in Prague

Translation:
스트라호브 수도원은 어떤 곳인가요?

Score:
* Entity: 'Strahov Monastery' should be translated as 스트라호프
↪  수도원.' 1/5
* Translation: The sentence structure is correct, but the entity label
↪  is incorrect. 4/5
Total score: 5/10

###

(other few shot examples)

###

Text to translate:
When was White Army, Black Baron first performed?

Reference entity information:
Korean Label: 붉은 군대는 가장 강력하다
English Label: White Army, Black Baron
Description: song composed by Samuel Pokrass performed by Alexandrov
↪  Ensemble

Translation:
붉은 군대는 가장 강력하다가 처음 공연된 것은 언제인가요?

Scores:
```

Listing 2: Prompt template for feedback

4.2 Self-Refine

After generating the initial translation, we implement an iterative refinement process to enhance the output quality. Given a feedback prompt p_{fb} and a generated translation y_t, the process begins with the model generating self-feedback:

$$fb_t = M(p_{fb}||e||x||y_t) \quad (2)$$

As shown in Example 2, the model evaluates with two key criteria: the accuracy of entity label translation and the grammatical correctness of the translation. Both criteria are weighted equally, 5 points each—total 10, to align with the task's evaluation metric, which uses the mean of M-ETA and COMET. To ensure structured feedback, we created few-shot examples across languages, which will be described in Section 5.2.

Given a refine prompt p_{rf} and a feedback history, the refinement process alternates between feedback and improvement steps.

$$y_{t+1} = M(p_{rf}||e||x||y_0||fb_0||...||y_t||fb_t) \quad (3)$$

The process terminates when either the feedback achieves a perfect score of 10 or reaches the maximum number of iterations. Because each feedback–refinement cycle requires two additional LLM calls (one to generate feedback and one to revise the translation), the computational cost grows linearly with the number of iterations and should therefore be carefully considered. We set the maximum number of trials to 2 due to budget constraints.

As shown in Equation 3, the model incorporates the history of previous translations and their feedback, enabling it to learn from past mistakes and improve both accuracy and overall translation quality. For detailed prompt, refer to Appendix A.

5 Experimental Setup

5.1 Model and Inference

Our system employs the GPT-4o model as the primary translation and feedback generator. We used the model without any fine-tuning, relying solely on prompt engineering to achieve the desired results.

5.2 Few-shot Example Generation

For the feedback and iteration prompts, we carefully crafted few-shot examples to guide the model's behavior. The process of creating these examples varied by language. Being native Korean speakers, we manually created examples by deliber-

Method	AR	DE	ES	FR	IT	JA	KO	TH	TR	ZH
GPT-4o	56.54	57.86	62.32	55.49	58.52	56.15	49.28	33.44	56.98	48.89
+RAG	92.75	88.94	92.18	91.44	93.54	92.02	91.94	91.72	88.27	84.68
+Refine	93.03	89.43	92.37	91.71	94.01	93.17	92.98	92.87	89.93	85.06

Table 2: Results across languages with the harmonic mean of M-ETA and Comet scores. Language codes: Arabic (AR), German(DE), Spanish (ES), French (FR), Italian (IT), Japanese (JA), Korean (KO), Thai (TH), Turkish (TR), and Chinese(ZH). For the per-metric results, refer to Appendix B.

(Entity Feedback)
Source: "When was White Army, Black Baron first performed?"
Init: "백군, 흑남작이 처음 공연된 것은 언제인가요?"
Feedback: "...the reference Korean label for this entity is '붉은 군대는 가장 강력하다,' which is a more established and accurate translation of the song's title in Korean"
Refined: "붉은 군대는 가장 강력하다가 처음 연주된 것은 언제인가요?"

(Translation Feedback)
Source: "Can you recommend any similar webcomics to Please Take My Brother Away!?"
Init: "비슷한 웹툰으로 오빠를 고칠 약은 없어!를 추천해 주실 수 있나요?"
Feedback: "The original asks for recommendations of *similar* webcomics, but the translation asks if '오빠를 고칠 약은 없어!' itself can be recommended ..."
Refined: "오빠를 고칠 약은 없어!와 비슷한 웹툰을 추천해 주실 수 있나요?"

Table 3: Case study of feedback and refinement

ately introducing errors into reference translations. This allowed us to demonstrate various types of translation errors and appropriate feedback. We then leveraged GPT-4o to generate examples for the remaining nine language pairs, using our Korean examples as templates. This ensured consistency in the feedback and iteration patterns across all language directions.

5.3 Evaluation Metrics

The shared task evaluation combines two metrics using their harmonic mean. COMET (Rei et al., 2020) is a metric based on pretrained language models that evaluates the overall quality of machine translation outputs. Additionally, M-ETA (Manual Entity Translation Accuracy) (Conia et al., 2024) serves as a specialized metric designed to assess translation accuracy specifically at the entity level. This combination of metrics ensures that both general translation quality and entity-specific accuracy are considered in the final evaluation.

6 Results and Analysis

6.1 Overall Performance

Table 2 presents a comprehensive analysis of our system's performance across different configurations and language pairs on the test dataset. In the baseline GPT-4o model, we use a basic translation prompt suggested by Xu et al. (2024). Despite the source texts being simple and concise questions, the baseline GPT-4o model demonstrates relatively poor performance across different language pairs. This is primarily due to its inaccuracy in translating entity labels, which results in a lower M-ETA score.

The application of Retrieval-Augmented Generation (RAG) leads to substantial performance improvements across all language pairs. This significant enhancement is attributed to our utilization of oracle Wikidata IDs from the dataset, from which we extract precise entity labels and descriptions. Our results demonstrate Large Language Model's capability to successfully incorporate the provided entity information into accurate translations.

The addition of the self-refinement process further enhances the translation quality, albeit with more modest improvements. We observe consistent performance gains across all language directions, with improvements ranging from 0.19 to 1.66 %p. These results validate the effectiveness of both RAG approach and self-refinement mechanism in the context of entity-aware machine translation.

6.2 Case Study

Our feedback prompt incorporated two primary evaluation criteria: entity name accuracy and translation quality. To validate the model's ability to effectively evaluate these criteria, we present two

Lang	ρ	r
DE	0.17	0.21
ES	0.08	0.12
FR	0.07	0.11
IT	0.03	0.07

Table 4: Correlation between Levenshtein edit distance ratio and M-ETA scores, measured using Spearman's rank correlation coefficient (ρ) and Point-Biserial correlation coefficient (r).

representative cases where improvements were observed in either entity naming or translation quality, as shown in Table 3.

In the first case (Entity Feedback), we observe how the model handles entity name translation. The initial translation attempted a literal, word-for-word approach, translating "White Army" and "Black Baron" directly into their Korean equivalents "백군" and "흑남작". The feedback procedure identified this literal translation as inadequate, noting that the established Korean title for this entity is "붉은 군대는 가장 강력하다". This case demonstrates that merely providing entity information in the prompt is insufficient for accurate translation; the model requires explicit feedback to generate the correct entity labels.

The second case (Translation Feedback) illustrates the model's ability to correct contextual misunderstandings. The initial translation misinterpreted the source text's intent, transforming a request for "finding similar webcomics" into a request for "recommending the webcomic itself". Through the feedback process, the model recognized this semantic error and generated a refined translation that accurately conveyed the original meaning, asking for recommendations of webcomics similar to the referenced webcomic. This example highlights the effectiveness of our feedback mechanism in improving not just lexical accuracy but also semantic coherence.

6.3 Label Similarity and Accuracy

We additionally investigated whether the similarity between an entity's English label and its foreign label influences translation accuracy (M-ETA score). Our hypothesis was that greater differences between entity labels might negatively impact the LLM's translation performance. To measure label similarity, we used the Levenshtein edit distance ratio. We analyzed the relationship using two correlation metrics: Spearman's rank correlation coefficient and the Point-Biserial correlation coefficient. These metrics were chosen for their suitability in analyzing relationships between a continuous variable (edit distance ratio) and a binary outcome (correct/incorrect translation).

We limited our analysis to languages using the Latin script (German, Spanish, French, and Italian) as other languages would consistently yield edit distance ratios approaching 1. As shown in Table 4, the correlation coefficients are consistently low across all languages. These results suggest that the similarity between entity labels in English and foreign languages has little impact on translation accuracy, indicating that other factors likely play more significant roles in determining translation success.

7 Conclusion
