Among the five emotions, the model performed best in predicting the intensity of sadness, achieving a Pearson's R of 0.6932. Comparable performance was observed for fear and joy, with correlation coefficients of 0.6434 and 0.6178, respectively. The model exhibited moderate performance in predicting the intensity of surprise, with a Pearson's R of 0.4933.

However, the model faced again notable challenges in predicting the intensity of anger, attaining a Pearson's R of only 0.3813. This highlights a significant performance gap compared to other emotions, emphasizing the need for further refinements to better recognise and predict nuanced variations in anger intensity.

5.2.1 Prediction Correlation Trend

The jittered strip plots in Figure 3 provide further insight into our Track B model's performance. The red dashed diagonal lines represent perfect predictions ($Y_{true} = Y_{pred}$), where predicted values align exactly with the gold-standard intensities. Dots above the dashed line indicate underestimation, while dots below the dashed line indicate overestimation.

Among all emotions, fear and sadness were the most accurately predicted, with most intensity values ranging from 0 to 2 and a considerable number of dots lying on the dashed line. Similarly, joy was well predicted, but the model's predictions were mostly confined to the range of 0 to 1. For surprise, predictions were concentrated between 0 and 1, with the model rarely predicting an intensity of 2. The weakest alignment was observed in anger, where the model's predictions were mostly limited to 0 and 1, failing to capture higher intensity levels.

5.2.2 Prediction Accuracy: Mean Absolute Error (MAE)

Beyond correlation, we further assess Track B model's predictive accuracy using Mean Absolute Error (MAE), which measures the average absolute difference between predicted and true intensity values. While Pearson's R evaluates trend-following ability. MAE provides a more direct measure of prediction accuracy.

As noted in Figure 3, across all five emotions, the lowest MAE was observed for anger (0.246) and joy (0.250), indicating that the model's predictions for these emotions were generally close to the true values. However, as reflected by the low Pearson's R for anger (0.3813), this low MAE primarily results from the model consistently predicting within a limited range (0-1), failing to capture higher intensity variations.

In contrast, the highest MAE was observed for fear (0.487). This aligns with the trend in Figure 3, where several extreme errors, such as cases of predicting 0 when the true intensity was 2 or 3, were observed. The model also exhibited a relatively high MAE for surprise (0.329), largely due to its tendency to underestimate high-intensity instances, as seen in the absence of predictions at intensity levels 2 and 3.

The model's performance on sadness (0.302) represents a balance between strong correlation ($r = 0.6932$) and moderate MAE, indicating that while the model successfully captures the general trend of sadness intensity, it still exhibits noticeable absolute errors in individual predictions. This reflects an important insight: high Pearson's R does not necessarily equate to low MAE, as the model may effectively follow intensity ranking trends while making significant absolute magnitude errors.

5.2.3 Team Ranking of English Track B

Our model did not perform better than the baseline model, which has an average Person's R gap of 0.08. We rank at the place of 37 out of 43 teams.

5.3 Future Enhancement

In both Track A and B, our models struggle to detect anger and high intensity of emotion. It is mainly due to the reason of imbalanced training data. As depicted in Table 1 and 2, comparing to 1,611 fearful instances in Track A provided training data, fear has only 333 instances. For Track B the highest intensity (3) has only 471 examples, while level 0 has 9,505 instances for the model to learn.

To address this issue, we could try boosting the training data, such as data augmentation to artificially generate data that training set does not cover much. Data balancing measures are also crucial to reduce model's bias towards specific classes.

Going further, other training techniques such as transfer learning or ensemble learning, or taking multiple machine learning algorithms on these classification and regression tasks can also be considered for potential experiments.

6 Conclusion

We participated in Tracks A and B of the shared task by fine-tuning BERT-based models for multi-label emotion detection and emotion intensity prediction on English texts. Our model ranked 44th in Track A—around the median—but underperformed compared to the baseline in Track B.

The results highlight the challenges of emotion detection, even in a high-resource language, as emotions are often implicit and not directly conveyed through surface-level text. They also suggest that full fine-tuning may not be optimal given the dataset size and distribution.

We hope our work offers insights for future research and the development of emotion-aware applications using pre-trained language models.

Abstract

While Large Language Models (LLMs) have driven significant progress in Natural Language Generation (NLG), their propensity to hallucinate—generating factually incorrect content—remains a barrier to wider adoption. Most existing hallucination detection methods classify text at the sentence or document level, lacking the precision to identify the exact spans of text containing hallucinations, termed hallucination spans. We propose a methodology that generates supplementary context and processes it alongside the evaluated text through an LLM, extracting the internal weights (features) per token from various layers. These extracted features serve as input for a neural network classifier designed to perform token-level binary classification of hallucinations. Finally, we identify hallucination spans by mapping token-level predictions to character-level predictions. Our hallucination detection model ranked top-ten in 13 of 14 languages and first in French, evaluated on the Mu-SHROOM dataset within the SemEval: Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes (Mu-SHROOM).

1 Introduction

The domain of Natural Language Generation (NLG) is witnessing a remarkable transformation with the emergence of Large Language Models (LLMs) (OpenAI, 2024; Manyika and Hsiao, 2023; Dubey et al., 2024). LLMs have been shown to outperform traditional Natural Language Processing (NLP) approaches across a wide range of applications (Kung et al., 2023; Mousavi et al., 2023). Despite the rapid advancements in LLMs, a concerning trend has emerged where these models generate hallucinations (Bang et al., 2023; Ji et al., 2023a), resulting in content that appears plausible but is factually unsupported. Hallucinations can be categorized into extrinsic errors, where claims conflict with external facts, and intrinsic errors, where claims are not fully grounded in the source material. This issue is particularly critical in sensitive domains such as healthcare, finance, and legal services, where the accuracy of generated content is paramount. Hence, the automatic detection of hallucinated content has become an active area of research, aiming to enhance the reliability and trustworthiness of LLM-generated content (Zhang et al., 2023b; Bai et al., 2024).

Recent studies have explored different methodologies for hallucination detection, including natural language inference (NLI) and factual consistency checking (Zha et al., 2023; Chandler et al., 2024; Tang et al., 2024), as well as textual entailment techniques (Sankararaman et al., 2024; Fan et al., 2024). Additionally, approaches like reference-free (Zero Context) hallucination detection have been investigated (Manakul et al., 2023; Hu et al., 2024a; Li et al., 2024b), alongside evidence retrieval methods utilizing Retrieval-Augmented Generation (RAG) or Web Search (Zimmerman et al., 2024; Tian et al., 2024; Li et al., 2024a).

However, fact-checking models often demonstrate inconsistent performance when evaluating text across different languages. Vu et al. (2024) highlights that even state-of-the-art (SOTA) LLMs, when used for fact-checking, struggle with text in low and medium-resource languages. Moreover, many popular hallucination detection methods classify hallucinations at the sentence or document level, which limits their ability to precisely identify and correct the specific text responsible for these errors.

To address this limitation, Liu et al. (2022) introduced the HaDes dataset (HAllucination DEtection dataSet), enabling fine-grained, reference-free hallucination classification at the token level. Uncertainty-based and consistency-based methods were proposed to detect token level hallucinations (Ji et al., 2023b). For example, Mitchell

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1089–1097

et al. (2023) utilized log-probability curve detection, while Kuhn et al. (2023) estimated semantic likelihoods by clustering generated sequences. Furthermore, Zhang et al. (2023a) explored token type and frequency for detecting hallucinations based on uncertainty. Building on these ideas, Ma and Wang (2024) developed metrics assessing token cohesiveness through successive rounds of random token deletion and measuring semantic differences.

Recent advancements have shown promise in using LLM internal states for detecting token-level hallucinations. For instance, Hu et al. (2024b) focused on identifying hallucinations by analyzing embeddings and gradients to gauge probability distribution differences, while Sun et al. (2025) applied mechanistic interpretability within RAG scenarios. Many of these solutions, however, encounter common challenges. They often rely heavily on large amounts of labeled training data and necessitate multiple inference calls for each sentence, which can be resource-intensive. They also frequently fall short in testing across low and medium-resource languages, or in conducting comprehensive multilingual evaluations.

To boost this area of research further, the SemEval[1] organizers introduced the Mu-SHROOM task. This task focuses on detecting hallucination spans in the outputs of instruction-tuned LLMs in a multilingual context. The contribution of this study are:

- We employed web search to incorporate supplementary contextual information into the model.
- We develop a binary multi-lingual token-level hallucination detection classifier, where the internal weights of LLM are used as a feature vectors. The resulting token-level predictions are then converted into character-level predictions, allowing for the precise identification of hallucinated spans within the text.
- Our model ranks within the top 10 for 13 out of 14 languages on the Mu-SHROOM dataset and secured first place in French.

2 Mu-SHROOM Dataset

The Mu-SHROOM dataset is a multilingual benchmark dataset for detecting hallucination spans in outputs generated by LLM. The dataset encompasses a diverse set of 14 languages: Arabic-Modern Standard (AR), Basque (EU), Catalan (CA), Mandarin Chinese (ZH), Czech (CS), English (EN), Farsi (FA), Finnish (FI), French (FR), German (DE), Hindi (HI), Italian (IT), Spanish (ES), and Swedish (SV).

Language	**Training Samples**	**Test Samples**
Arabic (AR)	50	150
Basque (EU)	0	99
Catalan (CA)	0	100
Chinese (ZH)	50	150
Czech (CS)	0	100
English (EN)	53	154
Farsi (FA)	0	100
Finnish (FI)	50	150
French (FR)	52	150
German (DE)	50	150
Hindi (HI)	50	150
Italian (IT)	50	150
Spanish (ES)	53	152
Swedish (SV)	49	147
Total samples	507	1902

Table 1: Sample distribution across languages in training and test sets of the Mu-SHROOM dataset.

The Mu-SHROOM dataset contains the following columns:

- **id**: a unique datapoint identifier
- **lang**: the language of the question and output text
- **model_input**: the input passed to the models for generation
- **model_id**: denoting the HuggingFace identifier of the corresponding model
- **model_output_text**: the output generated by a LLM when provided the aforementioned input
- **model_logits** : the logits from the model
- **model_tokens** : the tokens created by model
- **soft_labels**: provided as a list of dictionary objects, where each dictionary objects contains the following keys:

[1]https://helsinki-nlp.github.io/shroom/

  - 'start', indicating the start of the hallucination span
  - 'end', indicating the end of the hallucination span
  - 'prob', the empirical probabilty (proportion of annotators) marking the span as a hallucination

- **hard_labels**: provided as a list of pairs, where each pair corresponds to the start (included) and end (excluded) of a hallucination

Table 1 provides a detailed breakdown of sample distribution within the training and testing sets across the various languages represented in the dataset. The dataset comprises 507 samples for training and 1902 samples for testing. For evaluation purpose, the shared task organizers assessed the performance of the submissions on a test set of 1902 samples. The test set labels were not disclosed to participants during the submission phase. Additional details about the task and dataset are available at (Vázquez et al., 2025).

3 Proposed Approach

In this section, we describe our proposed approach for detecting hallucination spans as depicted in Figure 1. The approach encompasses three primary components: **1)** context generation, **2)** extracting token-level internal weights from LLM, and **3)** constructing a binary classifier to produce token-level predictions, which are subsequently transformed into character-level predictions.

3.1 Context Generation

To enhance the model's understanding, we retrieve additional contextual information relevant to the model_output_text. Following Chen et al. (2022); Ousidhoum et al. (2022), we systematically decompose the model_output_text into a structured list of claims using `GPT-4o-mini`, as this decomposition allows for us to increase the recall of needed facts. Subsequently, we input this list of claims into `GPT-4o-mini` to generate queries for each claim for the purpose of fact-checking. The prompts employed for both claim decomposition and query generation are detailed in Appendix Section A. These queries are submitted to the DuckDuckGo search engine to retrieve titles, relevant text snippets, and URLs for each query. Finally, we concatenate all the search results and refer to this aggregated output as the Context.

3.2 Extracting Token-level Features

Once the context has been prepared, we format the input to include a instruction, context, model_input, and model_output_text, structured as follows:

Instruction: "Answer the following question in the language of the question and then compare your answer with the given output."
Context: context
Question: model_input
Output: model_output_text

This above input is processed by the `Llama-3.2-1B/3B-Instruct` models, and the token-level internal weights are extracted from selected layers of the LLM. The specific layers utilized include hook_attn_out, hook_resid_post, and hook_scale (hook_ln1_scale, hook_ln2_scale, ln_final_hook_scale). The motivation for leveraging these internal weights lies in their capacity to capture intricate patterns in language representation, enabling a deeper understanding of the model's decision-making processes.

The hook_attn_out feature reflects the final output of the attention mechanism, which is critical for understanding the relationships and contextual relevance between tokens. The hook_resid_post provides information about the residual connections after the normalization and attention layers in each block, ensuring the retention of critical features throughout the model. Finally, hook_scale represents the scaling factors of the layer normalization in each transformer block. Improper scaling at this stage could cause attention mechanisms to overemphasize or disregard certain tokens, potentially leading to hallucinations. More details on the dimension of each token feature vector are provided in Table 3 in Appendix Section B.

By analyzing these internal weights, we can access the model's learned knowledge and contextual embeddings, which are crucial for accurately detecting hallucination spans. This approach facilitates a more granular analysis of the interactions between tokens, enhancing the predictive performance of our hallucination detection classifier and allowing for more precise assessments of generated content.

3.3 Binary Classifier

The token-level features are subsequently provided as input to a linear classifier consisting of two

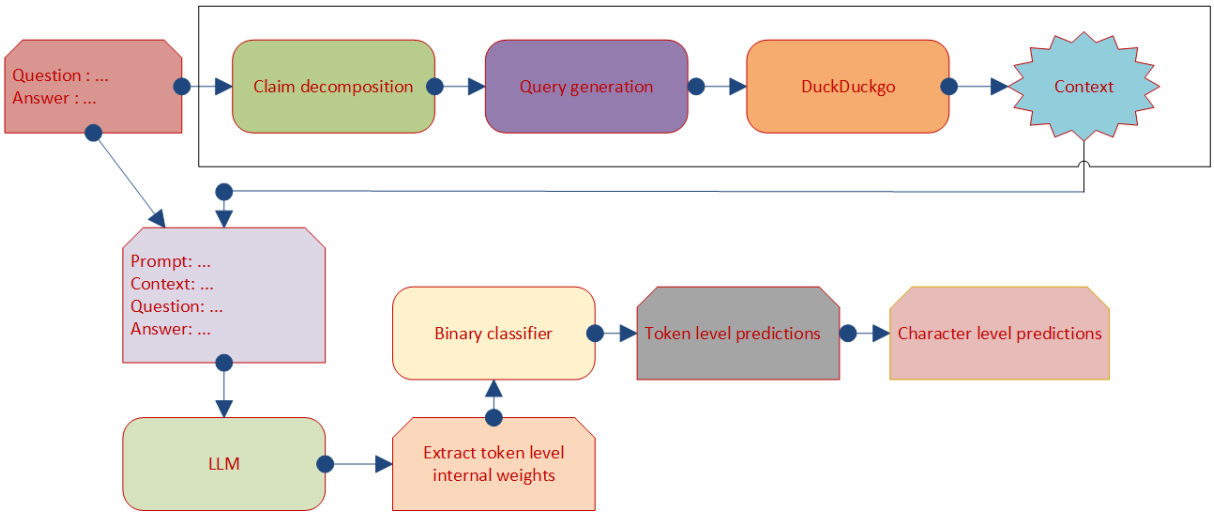

Figure 1: Our End-to-End Pipeline

fully connected layers activated by ReLU, which facilitates the generation of token-level predictions. These token-level outputs are then transformed into character-level features by performing a substring search, aligning each token produced by the language model with its corresponding character-level indices in the model_output_text. From this binary array of character-level predictions, we extract continuous sequences of hallucination spans.

4 Experimemts

This section details the experimental evaluation of our approach. To assess the effectiveness of our method, we employed two established character-level metrics such as Intersection-over-union (IoU) and Spearman correlation (S.Corr). The IoU is calculated as the ratio of the number of characters identified as hallucinations by our model to the total number of unique characters in both the predicted and actual sets. Conversely, Spearman correlation is calculated by comparing the probabilities assigned by the model that indicate a character's classification as part of a hallucination against the empirical probabilities observed from human annotators.

4.1 Results

The performance of our pipeline on the test dataset, evaluated externally, is summarized in Table 2. We report IoU scores, Spearman Correlation, and rank performance based IoU on the Mu-SHROOM Eval Leaderboard.[2] Our pipeline demonstrates competitive performance across all languages except for Chinese, securing first position in French based on IoU metrics.

4.2 Language Model Selection

We experiment with `Llama-3.2-1B-Instruct` and `Llama-3.2-3B-Instruct` models to process input and extract internal attention weights. Table 4 in Appendix Section B shows that the larger model, `Llama-3.2-3B-Instruct`, outperforms `Llama-3.2-1B-Instruct` in 7 out of 14 languages based on IoU scores and 13 out of 14 languages according to S.Corr scores. We limit our study to these lightweight models due to the significant memory overhead required by the TransformerLens[3] library to track and store internal attention weights during inference with longer texts.

4.3 Impact of Including Web Search Results

We conducted experiments to evaluate the impact of enabling versus disabling the search component within our pipeline on hallucination span detection performance. As shown in Table 5 in Appendix Section B, the integration of web search results into the LLM prompt yielded a marginal improvement in performance, with improved performance observed in 12 out of 14 languages as measured by Intersection over Union (IoU) and Spearman correlation. These findings suggest that the inclusion of search results enhances performance detection.

5 Conclusion

In this study, we tackles the critical challenge of hallucination phenomenon observed in LLMs. By

Table 2: Uncertainty-based and consistency-based results for languages and teams in the Mu-SHROOM shared task challenge. Values show IoU scores (with Llama-3.2-1B/3B), Spearman correlation, ranking position (out of total participants for that language), SOTA team with their IoU score in parentheses, and the neural baseline performance.

employing a neural network classifier that utilizes features extracted from various layers of an LLM, we enable precise identification of hallucination spans within generated text. Our model achieved a top ten ranking across 13 languages achieving first place specifically in French.

6 Limitations and Future Work

Our methodology necessitates direct access to the internal states of Large Language Models (LLMs), which restricts its deployment to systems that facilitate such access. Utilizing a limited dataset of approximately 507 labeled training examples, we implemented a rudimentary linear classifier for hallucination prediction. By treating each token independently, we potentially lose important signals for hallucination detection. Although our search-based verification process enhances performance metrics, it introduces increased latency and computational demands.

As part of future work, we plan to investigate advanced sequence modeling architectures capable of leveraging the complete sequential relationships inherent in LLM internal states, thereby integrating both layer-wise and token-wise dependencies. Additional features, such as internal gradients and other attention patterns, may yield more informative signals for detection purposes. With more training data, these architectures could better capture the complex dynamics of hallucination generation. With an expanded dataset, these architectures could potentially capture the intricate dynamics associated with hallucination generation more effectively. Furthermore, assessing the efficacy of our method in identifying intrinsic hallucinations constitutes a significant avenue for continued research.

A Appendix:A

Claim Decomposition Prompt

****Role:****

Your task is to decompose the following output into standalone, decontextualized sentences while retaining all original information. Each sentence should be individually verifiable, free from implied connections or dependencies on other sentences. Avoid introducing information not explicitly stated. If the output cannot be meaningfully decomposed, return it unchanged.

****Guidelines:****
1. Each decomposed sentence must be standalone, without relying on other sentences for context or meaning.
2. Avoid making assumptions or inferring connections not explicitly stated in the output.
- Ensure that all information from the original output is preserved and split into its most granular, decontextualized form.

Query Generation Prompt

****Objective:****
Your task is to generate a query for each fact provided. Each query must be concise, specific, and designed to retrieve or verify the exact information presented in the fact. Use the format provided in the example, separating each query with a new line and a dash.

****Guidelines:****
1. Each query must be standalone, without relying on other facts for context or meaning.
2. Avoid introducing additional information

or rephrasing the fact unnecessarily.
3. Ensure each query is precise enough to verify the specific fact it corresponds to.

ATLANTIS at SemEval-2025 Task 3: Detecting Hallucinated Text Spans in Question Answering

Catherine Kobus, Francois Lancelot,
Marion-Cecile Martin, Nawal Ould Amer
Airbus AI Research

Abstract

This paper presents the contributions of the ATLANTIS team to SemEval-2025 Task 3, focusing on detecting hallucinated text spans in question answering systems. Large Language Models (LLMs) have significantly advanced Natural Language Generation (NLG) but remain susceptible to hallucinations, generating incorrect or misleading content. To address this, we explored methods both with and without external context, utilizing few-shot prompting with a LLM, token-level classification or LLM fine-tuned on synthetic data. Notably, our approaches achieved top rankings in Spanish and competitive placements in English and German. This work highlights the importance of integrating relevant context to mitigate hallucinations and demonstrate the potential of fine-tuned models and prompt engineering.

1 Introduction

LLMs have achieved remarkable proficiency in NLG, enabling significant improvements across various applications, including translation (Alves et al., 2024), classification (Li et al., 2023), synthetic data generation (Dai et al., 2022), Retrieval-Augmented Generation (RAG) systems (Seo et al., 2024). While they have addressed numerous challenges in these domains, they remain prone to hallucination-generating incorrect or misleading content. This issue can undermine system reliability and negatively affect real-world performance, limiting their practical deployment in critical applications.

To tackle this challenge, the SemEval MuSHROOM task focuses on detecting hallucinated spans in generated text, a crucial step toward enhancing the trustworthiness of NLG systems. This multilingual task covers 14 languages and requires identifying specific portions of text where hallucinations occur. The task overview paper (Vázquez et al., 2025) provides a comprehensive analysis of the methodologies and findings, offering valuable insights into hallucination detection in NLG systems. The dataset, the evaluation metrics, and models used in the task are also extensively discussed there.

In this paper, we present a set of approaches for the challenge, which fall into two main categories:
Methods without external context that solely rely on the question and answer as input. We experimented 1) few-shot prompting using LLM and 2) fine-tuning a token-level classifier on our generated synthetic data using MKQA dataset (Longpre et al., 2020).
Methods with external context from Wikipedia, retrieved using our RAG system. This context is then added into our models in three ways: 1) few-shot prompting with LLM, 2) fine-tuning a token-level classifier, and 3) fine-tuning a LLM for hallucinated span detection.

Our models delivered impressive results in several languages. In particular, we ranked first in Spanish, third in English, and fifth in German using few-shot prompting with Gemini Pro, enhanced by contextual information. For French, we achieved the eleventh place with a fine-tuned token classifier model with context.

2 Systems overview

In this section, we outline our different approaches. We begin by introducing the retrieval component of our RAG system. Next, we describe our methods based on few-shot prompting with and without retrieval. Finally, we present the approaches that we fine-tuned for the task using synthetic data.

2.1 Retrieval module

The retrieval module is designed to extract relevant text segments to answer a given question. We used the Wikipedia dataset[1] from November 2023 as

[1] https://hf.co/datasets/wikimedia/wikipedia

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1098–1107

source. The text was chunked into segments of 312 tokens each, with an overlap of 100 tokens, resulting in 21 million indexed chunks. These chunks were indexed using both dense representation with BAAI/bge-large-en-v1.5 embedding model[2] and sparse representation with BM25.

The retrieval process comprises three key steps: retrieval, reranking, and clustering. During the retrieval step, a hybrid search mechanism selects the top 25 chunks. This hybrid search employs both an embedding model and BM25 with distribution-based score fusion (Mazzeschi, 2023). Then, a cross-encoder model[3] reranks these 25 chunks. Based on the computed reranker scores, a k-means clustering algorithm is applied to retain a variable number of the most relevant chunks.

To support multiple languages of the query, we employed a LLM (Mistral-7B-Instruct-v0.2[4]) to translate the query into English. This translation allows the retrieval of relevant Wikipedia context in English from a question in another language.

2.2 Approaches without additional fine-tuning

We evaluated two approaches that do not require additional fine-tuning: an overlap-based baseline method and a LLM with a custom prompt.

2.2.1 Overlap-based method

The overlap-based method is a heuristic approach that predicts a target token as hallucinated if it does not appear in the context; it is inspired from the overlap-based method detailed in (Zhou et al., 2020). Since only the English version of Wikipedia was indexed, this method was tested exclusively for the English language.

2.2.2 LLM and prompt engineering

Prompt Engineering. A more flexible approach leverages LLMs, which have demonstrated strong adaptability across various tasks through prompt engineering. To address our challenge, we designed a custom prompt tailored specifically for this task. The LLM was provided with two examples and instructed to generate responses in a structured format—JSON in our case, as illustrated in the prompt 1 in the appendix. Our objective was to maximize the capabilities of an LLM by first detecting hallucinations, then implement custom functions to extract the hallucinated spans and identify their positions within the sentence.

With retrieval. After testing fixed prompt strategies, we incorporated textual evidence in the prompt. Providing relevant documents has been shown to reduce hallucination. Moreover, in the challenge setup, it allows for a direct comparison between facts and the answer to be evaluated. The relevant chunks are extracted from Wikipedia English and selected for each question as described in 2.1.

To balance between LLM prior knowledge and additional knowledge, rules with different degrees of strictness have been explored, inspired from (Wu et al., 2024). Keeping the flexibility to rely on prior knowledge was important for cases where the retrieval pipeline was unable to find documents with relevant facts or when conflictual information was present in the given chunks. Stricter rules also helped to highlight the minimal hallucinated part in the answer. Finally, we tested with including misspellings, such as "Stoveren" instead of "Staveren" for the first example of the English validation set. However, this type of errors was often not labeled in the challenge dataset, therefore we discarded them.

For the first stage of our experiments, we tested on the English dataset only. To adapt to German, French and Spanish, we simply named the language in the prompt and changed one example with question and answer in this other language. Listing 2 shows the prompt used in the multilingual setting.

Experimental setup. The Gemini 1.5 Pro model (Team et al., 2024) was prompted with a fixed seed and a temperature of 0.0 to foster the replicability of the results. Given the large context size, all the chunks tagged as relevant could be incorporated in the prompt: it represents between 1 and 23 chunks per question, with a median from 4 chunks for French to 6 for Spanish.

2.3 Approaches with additional fine-tuning

The challenge dataset did not provide annotated training data - only small annotated validation dataset. Therefore, we created synthetic data to fine-tune custom models. Using this, we fine-tuned a token-level classifier described in 2.3.2 and a LLM described in 2.3.3.

2.3.1 Data generation process

LLMs have become increasingly popular for synthetic data generation in various NLP applications

[2] https://hf.co/BAAI/bge-large-en-v1.5
[3] https://hf.co/BAAI/bge-reranker-large
[4] https://hf.co/mistralai/Mistral-7B-Instruct-v0.2

(Liu et al., 2024; Seo et al., 2024). To generate our data, we used MKQA dataset (Longpre et al., 2020), and excluding long-answer or unanswerable queries. Given a question and context retrieved using the retrieval module described in 2.1, we prompted a LLM (Gemini 1.5 Pro) to generate a short answer and an answer repeating the question to have a format closer to the challenge dataset. Table 4 shows an example. Once we get the answer, we prompt the LLM to inject a hallucination, with few-shot learning that provides guidance through examples. The resulting generated dataset contains around 48000 samples (12000 samples per language). Appendix 5 shows two generated samples.

2.3.2 Token-level classification

The span hallucination task can be also casted as a more classical token classification task, where each token in the LLM output is assigned a label, either '**I-H**' (if the token is part of an hallucination) or '**O**' (outside an hallucination). This approach takes inspiration from the XLM-R baseline provided by the challenge organizer and from the hallucination detection method for Machine Translation described in (Zhou et al., 2020). The architecture of the approach is illustrated in Figure 1 with an example taken from the English validation set provided in the challenge. A linear layer is added on top of the pretrained XLM-RoBERTa[5] model in order to perform the classification at token level.

We used the synthetic data generated following the procedure detailed in 2.3.1 as training data. Different configurations were tested in the course of the challenge, with or without providing the relevant Wikipedia chunks from 2.1, putting the question either before, after the relevant context or omitting it. For this last configuration, experiments showed that putting the question at the beginning leads to better performances.

Since XLM-RoBERTa has a maximum sequence length of 512 tokens, we only provide the top-1 retrieved chunk of document as input context to the model. By doing so, the total input length to the model (including, at most, the question, a Wikipedia chunk, and the LLM output) never exceeded the model's maximum sequence length.

During the challenge, different fine-tunings in monolingual and multilingual mode were explored; more details can be found in A.1.

[5] https://huggingface.co/FacebookAI/xlm-roberta-large

Experimental setup. The XLM-RoBERTa large model was fine-tuned for 7 epochs on 4 A10G GPUs, with a batch size of 6 and a learning rate of 2×10^{-5}. In the multilingual setting, the training/development data sizes are respectively around 44000/4000 examples, while in the monolingual setting, the training/development data sizes are respectively around 11000/1000 examples.

The checkpoint that gave the best result on the challenge validation set was selected for the test. We also tuned the probability threshold for the '**I-H**' class. By default, the decision threshold is 0.5; however, we noticed that the model was globally under-confident, and, by decreasing the threshold, we could increase the results in terms of IoU.

2.3.3 Fine-tuned LLM

We fine-tuned a LLM for hallucination detection, based on the work of (Mishra et al., 2024) which introduced FAVA (FAct Vericaton with Augmentation), a model for fine-grained hallucinations detections and editing. We adapted this approach to our question-answering task: we modified the training data to include the question along with the context and answer. Additionally, we simplified the training data by focusing on a single type of hallucinated entity (instead of the six presented in the original paper). We also fine-tuned the LLM with the multilingual synthetic data detailed in 2.3.1 compared to the initial FAVA model which was only fine-tuned for English.

Listing 4 shows one sample used for the fine-tuning of the LLM with a French question, the retrieved context in English, and the edited output to correct the hallucination.

Experimental setup. We fine-tuned a Llama-3.2-3B-Instruct model for 2 epochs with LoRA, using a batch size of 36, with $rank = 128$ and $\alpha = 128$, 4-bit quantization, the Adam optimizer and a learning rate of 2×10^{-4} on 1 A10G GPU.

3 Results

3.1 Performance of the retrieval system

Table 1 summarizes the retrieval results obtained on the test set. As only the English articles were indexed, we computed the retrieval performance for the other languages by converting the "English" retrieved Wikipedia URL into the target language URL using the MediaWiki API[6] that links equivalent Wikipedia pages in different languages.

[6] https://www.mediawiki.org/wiki/API:Langlinks

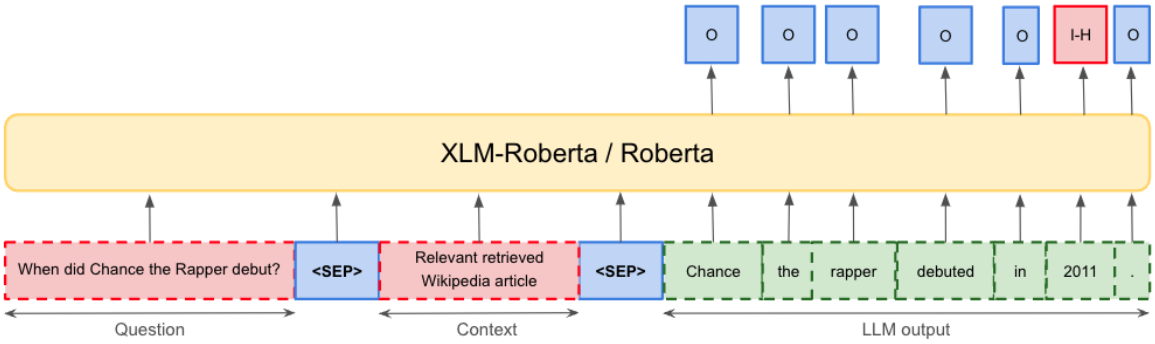

Figure 1: Architecture of the token classification approach illustrated with an example

language	en	de	es	fr
test	0.81	0.63	0.70	0.62

Table 1: Retrieval scores (MAP@5).

The model performs best in English, with scores (MAP@5) around 0.80. The lower retrieval performance in other languages (German, Spanish, and French) can be attributed to the additional translation step and the lack of corresponding English-indexed Wikipedia articles for some relevant articles in those languages.

3.2 Performance of the hallucination detection

Table 2 summarizes the results obtained on the test set for four languages: English, German, Spanish and French.

3.2.1 Performance comparison without retrieval

In this section, we compare the performance of our strategies in a setting without retrieval, thereby evaluating their standalone capabilities for hallucination detection without external knowledge augmentation.

As reported in Table 2, the XLM-RoBERTa large model exhibits moderate performance across languages, achieving its highest test IoU score of 0.50 in French, and its lowest in Spanish, 0.27. In contrast, Gemini 1.5 Pro demonstrates competitive overall performance, outperforming XLM-RoBERTa in German (0.45 vs. 0.38) but underperforming in French (0.43 vs. 0.50).

These findings suggest that, despite the larger scale of general-purpose models like Gemini, smaller models that have been fine-tuned on task-specific data can yield comparable results. Moreover, given that Gemini is pre-trained on general data, our hypothesis is that the fine-tuned XLM-RoBERTa large model would likely exhibit superior performance in domain-specific applications.

3.2.2 Performance comparison with retrieval

Here, we focus on the performance of our strategies in a setting with retrieval, thereby evaluating their capabilities for hallucination detection using external knowledge (RAG). Comparing with the previous section, the scores are better in all languages, without exception.

Gemini 1.5 Pro still outperforms the fine-tuned approaches on 3 over 4 languages in this setting. However, the finetuned Llama-3.2-3B reaches the same average IoU of 0.54 accross all languages, notably given the size difference of these models. Morevover, XLM-RoBERTa, significantly smaller, achieves a score that is relatively close to Llama-3.2-3B in German (0.53 vs 0.57).

These findings suggest that fine-tuning on synthetic data is a promising strategy and leveraging robust retrieval mechanisms with diverse pre-training can yield superior performance in the complex task of hallucinated span extraction.

3.3 Limitations

Our approaches have several limitations.

For the retrieval-based method, we indexed only the English version of Wikipedia. If relevant facts reside in other sources, the information retrieval (IR) system cannot provide the necessary context. Additionally, we relied on a LLM to translate queries into English before retrieval. This approach could have been compared with multilingual embedding models and vocabulary-based retrieval to evaluate its effectiveness.

Our prompt-based methods required extensive manual experimentation to design prompts that

	en	de	es	fr	Avg.
Without retrieval

With retrieval					
Overlap-based	0.36	-	-	-	-
Finetuned XLM-RoBERTa large*	0.51	0.53	0.37	0.55	0.49
Finetuned Llama-3.2-3B*	0.55	0.57	0.39	**0.63**	0.54
Gemini 1.5 Pro	**0.57**	**0.58**	**0.53**	0.50	**0.54**

Table 2: IoU scores on test set. We **bold** the best performance across submitted systems. Approaches with * were finetuned on a synthetic dataset.

aligned with the characteristics of this challenge's dataset. This process was time-consuming and constrained by the limited number of prompts we could test manually. Finding the most effective prompt remains inherently difficult, and a more systematic approach—such as training a model to optimize prompt selection—could have improved our results.

For the token-level classification model, the limited context window constrained our ability to incorporate all relevant information. Only the first chunk of text was appended to the context, which could be problematic when key details were spread across multiple chunks. A potential solution would be to filter and include only the most relevant sentences to enhance classification accuracy.

Finally, both the token-level classifier and the fine-tuned LLM were trained on synthetic data. Ensuring the accuracy and fidelity of this data is a major challenge. If the synthetic data contains errors, hallucinations, or biases, the trained models may fail to generalize effectively to real-world scenarios, leading to unreliable predictions and reduced robustness (van Breugel et al., 2023). Moreover, the quality of synthetic data depends heavily on the data generation process itself. Addressing these issues would require more rigorous validation techniques or alternative data augmentation strategies to improve the reliability of the training data.

4 Conclusion

Different approaches were presented with and without retrieval for the hallucinated span detection task. Overall, the task remains difficult and the performance of the same strategy varies widely depending on the language. This work underlines the importance of adding a relevant context to detect hallucinated spans in the answer. In general, LLM prompting leads to better results and is easily adaptable on other languages but the smaller fine-tuned models show promising results and could thus be preferred, subject to further tuning. Lastly, these approaches would need to be validated on a balanced dataset, containing also a significant part of non-hallucinated answers.

A Appendix

A.1 Monolingual/multilingual token-level classification

This sections contains further details about experiments conducted for the token-level classification strategy, especially with respect to fine-tuning with one or more languages.

Experimental setup. At the beginning of the challenge, we focused on English. We finetuned both RoBERTa[7] and XLM-RoBERTa large models on the English synthetic dataset, with the configurations mentioned in 2.3.2. The maximum sequence length for RoBERTa is also 512 tokens, therefore we added the top 1 chunk retrieved when experimenting with retrieval. Then, we decided to extend to other languages of the challenge for which we could create synthetic data - French, Spanish and German. We fine-tuned XLM-RoBERTa in two ways:

- Multilingual: on the aggregated synthetic data for all languages
- Monolingual: for each of the 3 new languages, on the subpart of the synthetic data with the target language

For each language, the best checkpoint was selected and the probability threshold was adapted. Table 3 shows the IoU scores obtained on the challenge test sets for English, German, Spanish and French. For each configuration, the first score is without adding context, and the second one is with additional context.

Results. First of all, the results of 3.2 are validated: adding a relevant context always leads to better performances regardless of the finetuning setting. Monolingual fine-tuning gives higher performance for German (from 0.53 to 0.55) and English (from 0.51 to 0.54) , whereas better results are reached with multilingual finetuning for French (from 0.46 to 0.50) and Spanish (from 0.35 to 0.37), with retrieval. In this case, it seems to benefit from the training with data from other languages.

The preference to fine-tune specifically on a language or on all varies with respect to the language considered, as well as the performance achieved which is significantly lower for Spanish. Further work could focus on optimizing the fine-tuning to reach a single model that performs well across all these languages. For example, one could use knowledge distillation from the best checkpoints by language into a unique model to obtain multilingual capabilities.

```
You are an expert evaluator for language models, tasked with identifying hallucinations or errors in their responses. A hallucination is defined as:
– Incorrect factual information: Content in the model's response that is unrelated, irrelevant, or factually incorrect with respect to the documents, based on the question.
– Spelling errors: Any word in the model's response that is misspelled or contains typographical mistakes, including incorrect names, places, or other terms.

Your task is to analyze the **Model Output Text** written in {LANGUAGE} and classify hallucinations or errors into two categories:
1. **Factual inaccuracies**
2. **Misspellings**

Ensure the output is in JSON format, following this structure:
'''
{
    "model_input": "<Insert question here>",
    "model_output_text": "<Insert model's response here>",
    "hallucinations": {
        "factual_inaccuracies": [
            "<text_span_1>", "<text_span_2>", ...
        ],
        "misspellings": [
            "<text_span_3>",
            "<text_span_4>",
            ...
        ]
    }
}
'''

### Example 1:
**Model Input**: "Quelle est la capitale de la France ?"
**Model Output Text**: "La capitale de la Grance est Berlin."
**Expected JSON Output**:

Dianchi at SemEval-2025 Task 11: Multilabel Emotion Recognition via Orthogonal Knowledge Distillation

Zhenlan Wang, Jiaxuan Liu and **Xiaobing Zhou***

Abstract

This paper presents our team's approach in SemEval-2025 Task 11: "Task 11: Bridging the Gap in Text-Based Emotion Detection", which aims to predict the speaker's perceived emotions in given target text segments(Muhammad et al., 2025). Our methodology employs a BERT pre-trained model for text processing combined with knowledge distillation and a dynamic data expansion approach. After initializing training parameters, we train student models by calculating classification and distillation losses for parameter updates. New prediction data is generated through periodic evaluation and incorporated into the original dataset to update the data loader for enhanced data augmentation, while synchronously updating both teacher and student model weights. Our system achieved an accuracy of 0.7 in the English multi-label text classification task in Subtask A of SemEval-2025 Task 11. The code is available at https://github.com/w2060772766/a1.

1 Introduction

Multi-label text classification advances beyond the semantic unidimensionality limitation of traditional single-label classification by assigning multiple interrelated labels to a single text, thereby effectively capturing the complexity of coexisting emotions in real-world scenarios (Zheng et al., 2024). As a pivotal technology for revealing human cognitive states, Emotion Recognition (ER) demonstrates significant application value across diverse domains (Alaluf and Illouz, 2019; Muhammad et al., 2025), including consumer behavior analysis (Abdul-Mageed et al., 2018) and community mental health monitoring (Volkova and Bachrach, 2016). However, existing methods often suffer from misdetection of fine-grained emotional features due to insufficient long-range semantic modeling capabilities, while also facing overfitting risks in small-scale annotated data scenarios.

To address these challenges, this study proposes an innovative knowledge distillation framework: (1) By leveraging hidden-layer representations of pre-trained language models as soft target supervision signals, we enhance the capture of deep semantic correlations through a teacher-student parameter transfer mechanism; (2) A pseudo-label extension strategy is integrated with dynamic data augmentation to mitigate distributional shift issues during training. This approach inherits large-scale models' powerful semantic encoding capabilities while enabling robust multi-label emotion inference through a lightweight architecture, thereby providing novel insights for fine-grained emotion detection in complex real-world environments.

2 Background

In the field of Natural Language Processing, BERT—a Transformer-based pre-trained language model (Devlin et al., 2019)—has significantly enhanced textual representation capabilities through its pre-training paradigm of masked language modeling and next-sentence prediction. However, the substantial parameter size of BERT models incurs high computational costs, limiting their industrial deployment. To address this, Knowledge Distillation (KD) has been introduced for model lightweighting. Original KD (Hinton et al., 2015) operates by transferring implicit knowledge—such as output-layer probability distributions and intermediate-layer attention weights—from complex teacher models to compact student models.

In the context of BERT compression, Sanh (Sanh et al., 2019) developed DistilBERT, which

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1108–1112

reduces the model size by 40% while retaining 97% of the original performance through layer reduction and a teacher-student attention alignment loss function. Subsequent work has extended this framework: Jiao et al. (Jiao et al., 2019) proposed TinyBERT, which incorporates attention matrix mapping and hidden state adaptation to enable layer-wise knowledge transfer, achieving an accuracy gap of merely 3% compared to BERT-base on GLUE benchmarks. Notably, knowledge distillation applications in BERT optimization have evolved beyond single-model compression to innovative directions such as multimodal pre-training (Sun et al., 2019) and dynamic architecture pruning, demonstrating its enduring potential to balance model efficiency and performance.

3 System Overview

In this section, we delineate our methodological framework. Our approach leverages the BERT pre-trained model for text sequence processing and contextual representation learning. We synergistically integrate Knowledge Distillation (KD) with advanced textual data augmentation strategies to enhance generalization performance.

3.1 Pre-training

We employ the BERT pre-trained model for text classification. The input text is first tokenized into subword units using BERT's tokenizer and mapped to numerical IDs through its pre-trained vocabulary. The tokenized sequence undergoes hierarchical feature extraction via BERT's multi-layer self-attention mechanisms and feedforward neural networks, generating high-dimensional contextual embeddings(Vaswani et al., 2017). To structure the training data, three containers are initialized: ids for sample identifiers, texts for original text content, and labels for emotion category annotations. During batch iteration, each sample's identifier, text, and label are sequentially appended to their respective containers. For classification, a task-specific fully connected layer is appended to the BERT architecture. During inference, input_ids $tokenIDs$ and attention_mask (sequence padding indicators) are fed into the model to extract final-layer representations. Crucially, the feature vector corresponding to the [CLS] token is leveraged as the aggregated semantic signal to predict emotion categories through the classifier, enabling robust textual emotion analysis within an end-to-end framework.

3.2 Knowledge Distillation (KD)

Knowledge Distillation (KD) is a technique that transfers knowledge from a teacher model to a student model(Ma et al., 2024), aiming to enhance the student's performance or reduce its computational footprint while maintaining high accuracy. In our implementation, both the teacher and student models share an identical BERT architectural structure but are initialized with independent parameters. The teacher model is trained directly on the original task, while the student model is optimized to mimic the teacher's knowledge while retaining lightweight computational demands.

During training, a composite loss function is designed to guide the student model. We integrate a classification loss (task-specific supervision) with a distillation loss (knowledge transfer regularization), mediated by a balancing parameter λ to harmonize their contributions:

$$\mathcal{L}_{\text{total}} = L_{\text{CE}} + \lambda L_{\text{KL}} \tag{1}$$

To ensure the student model can make accurate predictions, we adopt a classification loss function, using cross-entropy loss to measure the discrepancy between predicted probabilities and ground-truth labels. The conventional binary cross-entropy loss formula is expressed as:

$$\mathcal{L}_{\text{CE}_\text{o}} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{c=1}^{C} y_{i,c}\log(p_{i,c}) \tag{2}$$

Normalize the weight vectors so that each w_i satisfies $\|w\| = 1$. Compute the inner product matrix of the normalized weights:

$$\mathcal{S}_{ij} = W_i^* W_j^* \tag{3}$$

Take the upper triangular part (excluding the diagonal) and sum the positive inner product values:

$$\mathcal{L}_{\text{sim}} = \sum_{i<j} \mathcal{S}_{ij} \cdot I(\mathcal{S}_{ij} > 0) \tag{4}$$

Finally, the total loss is obtained as:

$$\mathcal{L}_{\text{CE}} = \mathcal{L}_{\text{CEo}} + \lambda \cdot \mathcal{L}_{\text{sim}} \tag{5}$$

To enable the student model to learn the "soft" knowledge from the teacher model, i.e., the semantic information embedded in its probability

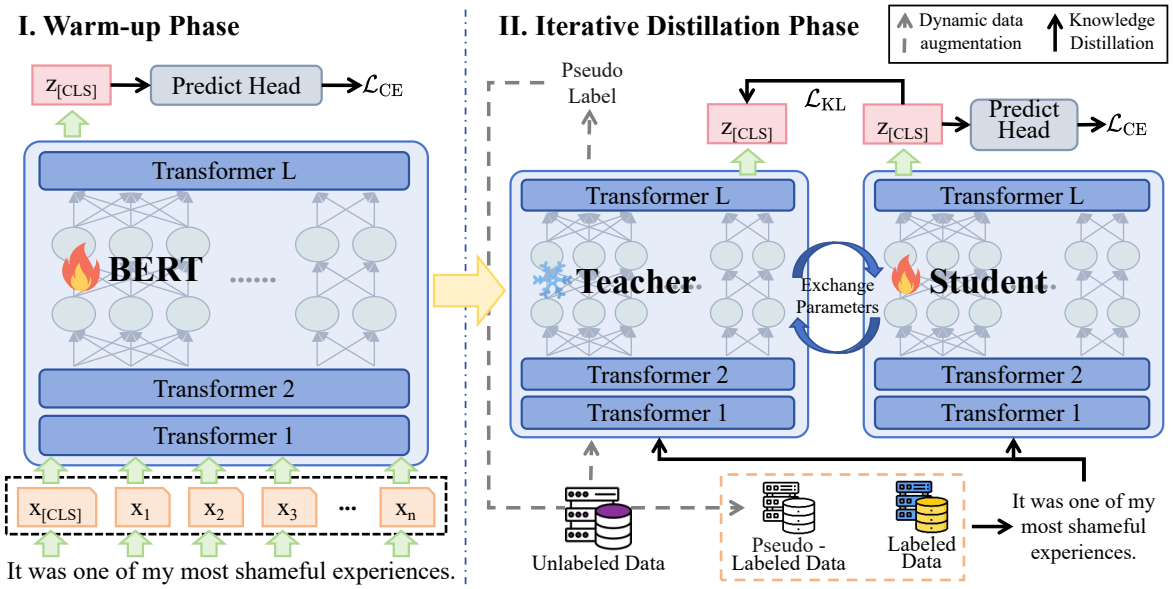

Figure 1: System architecture: left side of the figure is our pre-trained model, and the right side is the distillation model we employed.

distributions, we employ the Kullback-Leibler divergence (KL divergence) to quantify the discrepancy between the probability distributions of the student and teacher models(Li et al., 2023). A temperature parameter T is introduced to smooth out the sharp probability distributions, thereby enabling the student model to better learn the soft knowledge and semantic representations from the teacher model, ultimately enhancing the model's performance and generalization capability:

$$\mathcal{L}_{\mathrm{KL}} = \frac{1}{T^2} KL(p^{\mathrm{t}} \| p^{\mathrm{s}}) \tag{6}$$

The KL divergence is defined as:

$$KL(p^{\mathrm{t}} \| p^{\mathrm{s}}) = \sum_{c=1}^{C} p_c^{\mathrm{t}} \cdot \log \left(\frac{p_c^{\mathrm{t}}}{p_c^{\mathrm{s}}} \right) \tag{7}$$

where p_c^t represents the predicted probability value of the teacher model for the c class, and p_c^s denotes the predicted probability value of the student model for the c class.

The knowledge distillation technique in my work demonstrates three key advantages over conventional methods: Firstly, the soft labels generated by the teacher model (enhanced through temperature scaling) effectively transfer implicit correlations between multi-label emotions, overcoming the semantic rigidity of traditional hard labels (binary 0/1 supervision) to capture compound emotional features. Secondly, the dynamic pseudo-label augmentation mechanism periodically integrates high-confidence prediction samples, expanding training data distribution while preserving multi-label semantic consistency, thereby avoiding the disruption of label co-occurrence relationships caused by traditional static augmentation methods. Finally, the alternating parameter update strategy between teacher and student models establishes an "exploration-consolidation" cycle that preserves historical optimal knowledge while encouraging continuous optimization under new data distributions. Coupled with orthogonal constraints on classifier weights, this approach jointly resolves the feature space collapse issue induced by label co-occurrence in traditional methods, ultimately achieving enhanced precision and generalization in fine-grained emotion detection.

3.3 Model Training

During the training process, we first train the student model (s_model). Each epoch in the main training loop consists of training and evaluation phases. In the training phase, the student model performs a forward pass, calculates the combined loss (including classification loss and distillation loss), and updates model parameters through backpropagation. After specific epochs, s_model switches to evaluation mode to generate predictions on the validation set, which are then

merged into the original training set to enhance data diversity. Each time the training set is expanded, the teacher model (t_model) inherits the weights from s_model, while s_model's weights are overwritten by those of a new_model (a fresh model initialized for continued learning on the updated training data). A step-wise scheduler is adopted for the learning rate, reduced every 10 epochs. Finally, predictions on the validation set are generated using the latest t_model and retained as results. The training process is shown in Figure 1.

4 Experimental Setup

This section details the configuration of Subtask A, including dataset structure and training strategies. The task data originates from the official CSV-formatted dataset released for SemEval 2024, comprising three splits: a training set, a development (dev) set, and a test set, each containing 2,768 annotated samples. Each sample follows a "text + sentiment label" structure: the text field contains the input sentence for classification, while the sentiment labels cover five fine-grained categories (anger, fear, joy, sadness, surprise) under a multi-label annotation scheme.

Through parameter tuning experiments, we identified optimal performance when training the model for 90 total epochs with a 15-epoch learning rate warm-up phase. The batch sizes were set to 32 for the training set and 128 for the validation set. During the warm-up phase (first 15 epochs), the initial learning rate was 3e-5, which decayed by 10% every 10 epochs. Additionally, a learning rate scheduler was implemented to facilitate model convergence and enhance performance.

5 Results and Analysis

5.1 Results

This section presents the results of our model for the English multi-label text classification task in Subtask A of SemEval-2025 Task 11. We compare our outcomes with the official benchmark data, using accuracy as the primary evaluation metric. Three experiments were conducted: (1) A baseline approach utilizing only BERT without knowledge distillation achieved an accuracy of 0.35; (2) When introducing distillation with data augmentation during preprocessing (replicating texts from underrepresented categories), performance significantly deteriorated, as shown in Table 1, where accuracy dropped from 0.7 to 0.68. Further analysis suggests that improper class balancing during augmentation may have disrupted the model's ability to generalize effectively.

5.2 Analysis

Firstly, compared to using the BERT method alone, knowledge distillation mitigates BERT's overfitting to dominant labels by softening the probability distribution of the teacher model(Oliver et al., 2018). However, in the third experiment, while naively replicating minority-class texts increased the dataset size, the mechanical duplication disrupted the complex co-occurrence relationships in multi-label samples (e.g., forcing an increased frequency of a specific label concurrently distorted the semantic distribution of other correlated labels). This introduced a cognitive bias in the model's perception of the true data distribution, thereby compromising the regularization benefits of distillation and impairing generalization capability.

Additionally, preprocessing steps may have inadvertently removed critical features or introduced distribution bias. The preprocessed data might also mismatch the input distribution of pre-trained models (e.g., BERT), compromising their semantic encoding capability. These factors could collectively degrade the final accuracy.

6 Conclusions

This paper details our participation in SemEval 2025 Task 11: Bridging the Gap in Text-Based Emotion Detection, specifically subtask A (English). Our approach employs a BERT-based pre-trained model to encode textual CLS token representations as features, which are then passed through a linear layer to generate logits for multi-label classification via sigmoid thresholding. We innovatively enhanced the cross-entropy (CE) loss by introducing orthogonal regularization on the fully connected layer's weight matrix (using an inverse distance penalty between weight vectors) and incorporated knowledge distillation during later training stages with a KL divergence constraint between the teacher and student model outputs. Throughout the training, validation set predictions were dynamically integrated into the training data every 15 epochs, alongside alternating parameter updates between the teacher and student models for iterative refinement. This

Abstract

This paper introduces our participation in SemEval-2025 task 11, "Bridging the text-based emotion detection gap"(Muhammad et al., 2025a). In order to effectively predict the speaker's informing emotion from text fragments, we propose a transfer learning framework based on the BERT pre-training model through deep semantic feature extraction and cascade structure of dynamic weight linear classifier. In the speaker-informing emotion prediction task, a 0.70 F1 score is achieved, illustrating the effectiveness of cross-domain emotion recognition.

1 Introduction

Our team participated in Track A multi-tag emotion detection in Task 11, "Bridging the text-based emotion Detection Gap". Emotion detection (Sentiment Analysis, SA), as an important research direction in the field of Natural Language Processing (NLP), mainly uses computers to automatically process large-scale comment texts, identify the text information contained in the text, and mine the emotional tendencies expressed in people's texts, so it is also called opinion mining (Kang et al., 2012).

Identifying emotion categories in the text is an important task in NLP and its applications (Zhao et al., 2016). Through the analysis of various forms of information in the dialogue, we can more accurately identify the sources and causes of emotion. This is significant in various fields, including psychology, human-computer interaction, and emotional computing. It is helpful to develop more intelligent and human-centered techniques and systems, improve the efficiency and quality of communication, and promote better understanding and communication between individuals (Wang et al., 2024). For this reason, this study constructs a model that can predict multiple tags simultaneously by building a BERT model, combined with the needs of multi-tag classification(Zheng et al., 2022). The model training process includes key steps such as data loading process optimization, adaptive optimizer setting, and binary cross entropy loss function configuration, and introduces dynamic learning rate scheduling strategy and early stop mechanism (if the Macro-F1 value of 5 consecutive rounds of verification sets is not increased, the training is terminated) to balance the model efficiency and generalization ability.

This article will describe in detail how to use BERT for multi-tag emotion detection(Yin et al., 2020).

2 Background

As the core task of NLP, emotional analysis shows great application value in the fields of public opinion monitoring, mental health assessment (Tausczik and Pennebaker, 2010), and intelligent customer service. Industry analysis shows its market size will exceed 28 billion US dollars in 2025. Early multi-tag emotion detection relies on text template matching or shallow machine learning models such as SVM, but these methods are limited by the semantic representation defects of artificial feature engineering (Bengio et al., 2013), so it is difficult to capture emotional interactions in complex contexts (such as "irony in humor"). Although the introduction of RNN and CNN's deep learning model improves context awareness, its one-way or limited window semantic modeling still cannot solve the coupling problem of long-distance dependent emotional cues (Vaswani et al., 2017). The pretraining language model represented by BERT(Devlin et al., 2019) implements deep bidirectional context coding through full-stack Transformer architecture, which significantly improves the base linearity of multitag tasks.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1113–1117

3 System Overview

In this section, we introduce the method of multitag detection, and we use the BERT pre-training model for text sequence processing and calculation. Our method is to input the original text into Bert and then use the pre-trained token embedding knowledge(Song et al., 2023) and the self-attention structure of Bert to directly transform the text into the corresponding feature vector, in which the first bit [CLS] of the vector is used alone for downstream classification tasks.

We predict emotion from a text fragment first to get two sentences that belong to the context, and we add some special token to the two consecutive sentences: [cls] the last sentence, [sep] the next sentence. [sep]. As shown in the following figure, Token Embedding is the Embedding matrix of the word vector; Segment Embedding is the boundary between the upper and lower sentences; and Position Embedding is the position embedding, which can be added by the alignment of the three Embedding elements.

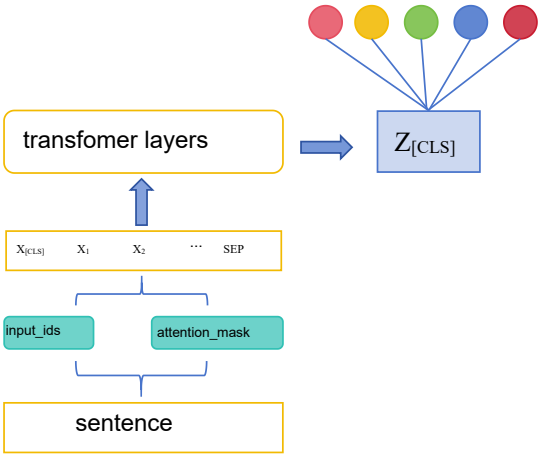

Figure 1: System architecture

3.1 Model

BERT (Bidirectional Encoder Representations from Transformers), proposed by Google, is a pre-training language model based on a self-attention mechanism. This model relies on pre-training massive corpus to master context language features and to fine-tune various downstream tasks. Since the release of the BERT model, remarkable achievements have been made in most NLP tasks, such as text classification, the question-answer system, named entity recognition, and machine translation(Zhu et al., 2023). So, in order to accomplish this task effectively, we mainly use the BERT model as a pre-trained language model; BERT encodes the text through a two-way Transformer structure, which can deeply capture the context information of the text and understand its semantics and potential emotion.

In this study, BERT-base is used to extract the global text representation from the [CLS] token and the contextual features of each token. Additionally, BiGRU sequence features and label semantic information are fused using a gating mechanism.

$$\boldsymbol{H} = \text{BERT}\left([\text{CLS}] \oplus \boldsymbol{X} \oplus [\text{SEP}]\right) \in \mathbb{R}^{d\times(n+2)} \tag{1}$$

$$\boldsymbol{G} = \sigma\left(\boldsymbol{W}_g\left[\boldsymbol{H}_{[\text{CLS}]}; \boldsymbol{C}; \boldsymbol{F}_{\text{seq}}\right]\right) \tag{2}$$

$$\boldsymbol{F}_{\text{fusion}} = \boldsymbol{G} \odot \left(\boldsymbol{W}_h \boldsymbol{H}_{[\text{CLS}]}\right) + (1-\boldsymbol{G}) \odot \left(\boldsymbol{W}_c \boldsymbol{C}\right) \tag{3}$$

Building a three-layer ReLU fully connected network (nodes decline layer by layer), the output layer sigmoid activation to generate multi-label probability(Tsoumakas and Katakis, 2008), optimized by BCE loss function, we use 0.4 threshold for binarization decision; select binary cross-entropy loss function to optimize multi-label classification task. The specific process is shown in Figure 1.

3.2 Loss Function

In this paper, a sequential loss function construction method for multi-tag emotion classification is proposed(Ridnik et al., 2021). First of all, in order to solve the problem of traditional cross entropy loss in sparse multi-tag scenarios (positive signals are easily drowned by high-frequency negative classes), pass linear transformation:

$$\boldsymbol{y}_{pred} \leftarrow (1 - 2\boldsymbol{y}_{true}) * \boldsymbol{y}_{pred} \tag{4}$$

Constructing the symmetric solution space of positive and negative classes, effectively weakens the dominant influence of negative class labels on gradient update(Lin et al., 2017), and on this basis, we introduce a hard mask mechanism to separate the positive and negative classes to calculate the path

to each label k, and pass the position where the real label is 1.

$\hat{\boldsymbol{y}}_{neg,k} = \boldsymbol{y}_{pred,k} - \boldsymbol{y}_{true,k} * 10^6$ Force negative residuals to be depressed, while using the $\hat{\boldsymbol{y}}_{pos,k} = \boldsymbol{y}_{pred,k} - (1 - \boldsymbol{y}_{true,k}) * 10^6$ Constrain positive class errors. At this time, the two kinds of scores form an optimized interval, and then the logarithmic space stabilization technique is adopted. For neg and negrespectively Row logsumexp(Blanchard et al., 2020) operation to avoid numerical overflows while capturing extreme responses across tags(Chen et al., 2020). The compound loss function constructed from this:

$$\boldsymbol{L} = \frac{1}{K} \sum_{k=1}^{K} \log(1 + \boldsymbol{e}^{\hat{y}_{neg,k}} + \boldsymbol{e}^{\hat{-y}_{pos,k}}) \quad (5)$$

Through the chain derivation, the model implicitly learns the decision rule of "keeping an appropriate margin between the positive and the corresponding negative scores". The core idea of this method comes from the extended Softmax contrastive learning mechanism: it not only requires that the scores of positive classes are higher than those of negative samples, but also further restricts that the intra-group differences of all positive classes should be lower than that of cross-class differences. The experimental results show that the cross-entropy of this design is 5.3% higher than that of traditional Sigmoid on F1-Score, and has a significant optimization effect on long-tailed samples whose label sparsity is less than 15%(Cao et al., 2019).

4 Experimental Setup

This study conducted model validation on the multilingual emotion analysis benchmark dataset from SemEval, with the English subset selected as the central evaluation targetcite(Muhammad et al., 2025b). The training set comprises 15,000 manually annotated social media short texts (average length 28 words), while the validation and test sets contain 3,000 and 2,000 samples, respectively, covering fine-grained annotations of five fundamental emotions: anger, fear, joy, sadness, and surprise. To mitigate data bias, a stratified random sampling strategy was employed to ensure a proportional representation of each emotional category across all three datasets (positive case proportions ranging approximately 11-19%). Representative examples of dataset inspection results are presented in Table 1.

Id	Anger	Fear	Joy	Sadness	Surprise
01	1	1	0	1	0
02	0	1	0	1	0
03	1	0	0	0	0
04	1	1	0	1	0
05	0	1	1	0	0
06	1	1	0	1	0

Table 1: Dataset samples

	Dev Score	Test Score
F1	0.70	0.70

Table 2: Scores on development and test sets

The model architecture is based on the BERT-base-uncased pre-trained language model. The original pooling layer was removed, and a 768-dimensional context vector extracted from the [CLS] token position in the final layer serves as the global semantic representation. A fully connected network is used in the output layer to predict five-dimensional emotion probabilities, with weights initialized using the Xavier normal distribution to accelerate convergence. During training, the parameters of the first 8 BERT layers were frozen while fine-tuning the higher-level network layers, combined with a mixed precision training strategy to reduce GPU memory consumption. The optimizer utilizes the Adam algorithm with an initial learning rate of 3e-5 and regularization of L2 (lambda = 0.001)(Loshchilov and Hutter, 2017), accompanied by a step-based learning rate scheduling policy (step size=10, decay factor=0.1). A dynamic early stopping mechanism monitors the validation set macro-F1 score, terminating training after 5 consecutive epochs without performance improvement to prevent overfitting(Prechelt, 2002). The performance of the model on this dataset is in Table 2.

5 Results And Analysis

5.1 Results

This section shows the details of our system's multi-tag emotion detection for track A of SemEval-2025 Task 11. From the experimental results, we can see that the BERT model we use performs stably and well on this data set, especially in terms of accuracy and recall, which shows that the model can better balance the prediction of positive and negative class tags. At the same time, the macro

average F1 value is close to 0.70, indicating that the model can more evenly predict different labels.

5.2 Analysis

In order to further improve the training efficiency and reduce the learning rate in the later stage of training, we use the StepLR learning rate scheduler, which will automatically decay the learning rate to 0.1 times after every 10 epochs (You et al., 2019). It shows significant advantages in sentiment co-occurrence recognition, model training efficiency and migration deployment cost, and empirically verifies its effectiveness in traditional sentiment analysis scenarios. However, its limitations in the sparseness of low-frequency affective category representation, the logical analysis of semantic contradictions, and the robustness of negation and metaphorical structures show that the current model still relies on superficial linguistic features to model complex semantic relationships, and does not fully realize the inference of deep associations of affective symbols. Future research needs to further combine strategies such as dynamic context perception and local-global feature fusion to enhance the ability of models to decouple from emotional conflicts and semantic meanings, and explore lightweight extraction or Mixture of Experts (MoE) to adapt to a wider range of practical application scenarios.

5.3 Limitations

While our approach achieves competitive performance, the model architecture relies on a single linear layer atop BERT's [CLS] embeddings, potentially overlooking inter-label dependencies. Furthermore, the fixed truncation length (128 tokens) may discard critical emotional cues in long-form dialogues. Future work will explore dynamic length adaptation and hierarchical label interaction modules.

6 Conclusion

This article describes our participation in the SemEval-2025 competition. We participate in Track A multi-emotion tag detection, and our method uses the BERT pre-training model for text sequence processing and calculation. In the training process, we combine the optimizer, learning rate schedule, early stop mechanism, and other technical means. Through the reasonable selection of hyperparameters, loss function and optimization strategy, we can effectively train a high-quality text classification model on a given data set, and can quickly evaluate the performance of the model in practical application. With the help of BERT's ability to understand context semantics, we improve the accuracy of emotion analysis and provide a new idea for the follow-up study of daily text emotion analysis. In future research, we can continue to improve the performance of the emotion analysis method from the following aspects: consider the integration of focus technology to improve the attention of the BERT model to some core terms. These in-depth studies will help to grasp the speaker's perceived emotion.

DNB-AI-Project at SemEval-2025 Task 5: An LLM-Ensemble Approach for Automated Subject Indexing

Lisa Kluge
Deutsche Nationalbibliothek
Frankfurt am Main, Germany
l.kluge@dnb.de

Maximilian Kähler
Deutsche Nationalbibliothek
Leipzig, Germany
m.kaehler@dnb.de

Abstract

This paper presents our system developed for the SemEval-2025 Task 5: LLMs4Subjects: LLM-based Automated Subject Tagging for a National Technical Library's Open-Access Catalog. Our system relies on prompting a selection of LLMs with varying examples of intellectually annotated records and asking the LLMs to similarly suggest keywords for new records. This few-shot prompting technique is combined with a series of post-processing steps that map the generated keywords to the target vocabulary, aggregate the resulting subject terms to an ensemble vote and, finally, rank them as to their relevance to the record. Our system is fourth in the quantitative ranking in the all-subjects track, but achieves the best result in the qualitative ranking conducted by subject indexing experts.

1 Introduction

The LLMs4Subject task (D'Souza et al., 2025) aims at utilising large language models (LLMs) for the task of automated subject indexing on a dataset of open-access publications. Automated subject indexing is a task that helps enabling access to user-relevant publications by identifying and recording their most important themes and topics in the tagged subject terms. The ever-growing number especially of digital publications requires reliable automated systems for this task, which has become infeasible to achieve manually. In our previous work on automated subject indexing on a similar dataset (Kluge and Kähler, 2024), we found that the performance of LLMs, while succesfully applied to a range of other tasks (Zhao et al., 2023; Yang et al., 2024; Patil and Gudivada, 2024), was not yet on par with classical supervised machine learning methods. Therefore, it is important to do further research on the capabilities of LLMs in this context.

Rather than fine-tuning models ourselves, the main strategy of our system is to leverage the existing capabilities of off-the-shelf foundational or instruction-tuned open-weight LLMs. In contrast to our previous work, the key contribution of this system is that it does not rely on only one LLM, but a combination of different language models along with varying prompts to generate the subject terms. We found this ensemble approach to dramatically improve the performance of our system. To handle the challenge of the controlled vocabulary unknown to the LLMs, we first generate free keywords with generative LLMs and then map these onto the vocabulary with a smaller embedding model.

The official quantitative results put us in fourth place, the qualitative results even in first place. We think that our approach provides valuable insights into the chances and bounds of the few-shot prompting approach, showing that competitive results are possible without fine-tuning and large training corpora, simply by combining several LLMs into an ensemble.

Our code is publicly available.[1]

2 Background

Outlining the field of automated subject indexing, Golub (2021) presented important fundamentals, approaches and best practices for the task. Referring to it as index term assignment, Erbs et al. (2013) compared and combined two strategies to perform this task: multi-label classification (MLC) and keyword extraction. Detecting separate strengths, their results aligned with Toepfer and Seifert (2020), who also found the combination of approaches to be beneficial.

Regarding frameworks for automated subject indexing, the Annif system (Suominen, 2019) is an important contribution. Annif has established

[1] https://github.com/deutsche-nationalbibliothek/semeval25_llmensemble

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1118–1128

methods built in, like Omikuji[2], which is based on partitioned-label-tree-method Bonsai (Khandagale et al., 2020), or MLLM[3], a lexical approach building on Medelyan (2009)'s Maui.

In earlier work (Kluge and Kähler, 2024), we presented experiments with a closed-source LLM on automated subject indexing, but the two baseline methods implemented in Annif mentioned above were found to be as good as or even outperform our LLM-based method.

LLMs have also been utilised for MLC (Peskine et al., 2023; D'Oosterlinck et al., 2024; Zhu and Zamani, 2024) and keyword extraction (Maragheh et al., 2023; Lee et al., 2023).

Recently, building ensembles or fusioning (the results of) LLMs has been addressed as a promising research direction. There are different works sharing the idea of exploiting the individual strengths and diminishing the weaknesses in different LLMs (Jiang et al., 2023b; Lu et al., 2023; Wang et al., 2023; Fang et al., 2024; Wan et al., 2024). Exploring the goal of building ensembles, Tekin et al. (2024) aimed at maximising diversity and efficiency, whereas Chen et al. (2023) targeted the reduction of inference cost. Not only LLMs have been combined, but also prompts (Pitis et al., 2023; Hou et al., 2023). Combining both prompts and models on the task of phishing detection, Trad and Chehab (2024) contrasted prompt-based ensembles (with one prompt and several LLMs), model-based ensembles and an ensemble consisting of a mixture of prompts and models.

3 System Overview

Our system is an enhancement from our previous LLM-based subject indexing approach, described in Kluge and Kähler (2024). In total, it consists of 5 stages, *complete*, *map*, *summarise*, *rank* and *combine*, as depicted in the overview in Figure 1. At its core, the system approaches the subject indexing task as a keyword generation problem which is solved by a few-shot prompting LLM procedure. As these generated keywords are a priori not restricted to the target vocabulary, a mapping stage with a smaller word embedding model is needed as a supplementary step. In comparison to our previous approach, we have extended the system by combining multiple LLMs and prompts to an ensemble and by introducing an LLM-powered ranking step as in D'Oosterlinck et al. (2024).

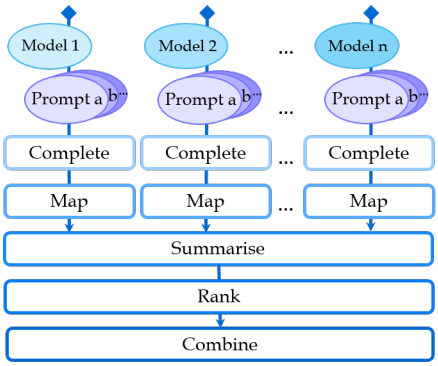

Figure 1: Illustration of our LLM-ensemble approach.

3.1 Complete

The first step in our subject indexing system, *complete*, is the generation of keywords following the few-shot paradigm, similar to the procedure in Lee et al. (2023). The *complete*-step is repeated over a range of diverse off-the-shelf open-weight LLMs and prompts with varying few-shot examples. Our plan and intention of employing a broad variety of models and prompts are twofold. In comparison to a single-model single-prompt setting, we aim to:

- Improve recall with an overall greater set of generated subject terms in the ensemble.
- Improve precision by utilising the overlap of various model×prompt combinations.

Each prompt consists of an instruction and a set of 8-12 examples illustrating how to perform the subject indexing task with example texts and their gold-standard subject terms.

Details for LLM selection and the composition of the few-shot prompts will be discussed in Sections 4.3 and 4.4.

3.2 Map

Keywords generated in the first stage are *mapped* to controlled subject terms in the target vocabulary using a word embedding model as in Zhu and Zamani (2024).

For our *map*-stage, we used Chen et al. (2024)'s BGE-M3-embeddings. Both generated keywords and target vocabulary are embedded with the same model.[4] To perform nearest neighbour search, we uploaded the embeddings to a Weaviate[5] vector

[2] https://github.com/tomtung/omikuji

[3] https://github.com/NatLibFi/Annif/wiki/Backend:-MLLM

[4] We embedded the keywords and vocabulary entries without integrating them into a context sentence (which we did in our previous approach).

[5] https://weaviate.io/

storage enabling efficient HNSW-Search (Malkov and Yashunin, 2016) in $\mathcal{O}(\log L)$ complexity, where L is the vocabulary size. One feature of the vector storage is that it may be used in a hybrid search mode (Cardenas, 2025), combining vector search and traditional BM25 search (Robertson and Zaragoza, 2009). Thus, each suggested keyword is mapped to the most similar subject term and the similarity score is stored for later use in the *summarise*-step. Matches with a low similarity score can be discarded at this stage with a tunable threshold, eliminating keywords not represented in the vocabulary.

3.3 Summarise

Each prompt and model outputs its own set of predicted subject terms per document after *complete* and *map*. In the subsequent *summarise*-step, the subject terms are aggregated over all model×prompt combinations by summing the similarities obtained in the *map*-stage (3.2). This score is normalised to a value between 0 and 1 by dividing it by the overall number of model×prompt combinations. Hence, we obtain an ensemble score s_{ens} for each suggested subject term. This ensemble score acts as a confidence measure of the individual suggestions and will be included in the final ranking score in the later *combine*-stage (3.5).

3.4 Rank

In the *rank*-stage, that D'Oosterlinck et al. (2024) also incorporated in their approach on MLC, another LLM is employed to rank the subject terms by their relevance. For each predicted subject term, we ask the model to assess its relevance to the test record at hand on a scale from 0 (not relevant) to 10 (extremely relevant). Normalised to a value between 0 and 1, we obtain a relevance score s_{rel} for each suggested subject term. Including this additional *rank*-step has two reasons: Firstly, the relevance score may improve the ensemble score that is, by now, purely based on frequency and mapping similarity. Asking an LLM to rate the suggestions also takes into account the context of the text and can thus determine the *relevance* of the suggestions. Secondly, this step can be an additional control step for the *map*-stage.

3.5 Combine

In the *combine*-stage, a final ranking score for each suggested subject term is obtained as a weighted average from the ensemble and relevance scores.

$$s_{\text{fin}} = \alpha \times s_{\text{ens}} + (1 - \alpha) \times s_{\text{rel}} \qquad (1)$$

In our experiments, we learned setting $\alpha = 0.3$ in equation 1 resulted in the best ranking (refer to Appendix A.4 for more details). In other words, the ordering of the subject terms was best when relying more on the *ranking* than on the *summarisation*.

4 Experimental Setup

4.1 Data Handling

We used two randomly sampled disjoint subsets ($n = 1000$) taken from the union of the development sets given in the all-subjects and the tib-core collection for optimisation and results analysis. On the first subset, *dev-opt*, we tuned parameters like the model×prompt selection (see Section 4.5) and *combine*-parameter α. The second one, *dev-test*, comprises the data on which we conducted our own evaluation. In both subsets, we included both English and German texts, as well as all five text types (Article, Book, Conference, Report, Thesis), while keeping the proportions of the overall development set through stratified sampling.

For both input texts and prompts, we used the concatenation of title and abstract as text representation.

4.2 Vocabulary Adaptation

When inspecting early results of our system, we found that the provided vocabulary, GND-Subjects-all, was insufficient to represent the free keywords resulting from the *complete*-stage. One particular issue was the absence of named entities, that do appear in the full GND but not in this collection. Plausible keyword candidates, such as country names, are missing and therefore falsely mapped to unrelated subject terms. Choosing a threshold for minimum similarity between keyword and subject terms was not enough to prevent this kind of error. Thus, we extended the vocabulary to also include named entities. As the full GND would comprise over 1.3 million concepts, we chose to only include named entities that are actually used in the catalogue of the DNB. In total, our extended vocabulary includes 309,417 distinct concepts (including 200,035 subject terms from the all subjects collection as well as 109,382 named entities from the DNB-catalogue). We found that our system produces fewer false positives if we map the named entities cleanly to the extended GND vocabulary

HF user	Model Name

Table 1: LLMs used for the completion on the test set.

and exclude subject terms not belonging to the targeted GND-Subjects-all collection afterwards. Note that this is also why we only work with the broader GND-Subjects-all vocabulary and not with the tib-core subset.

4.3 Language Models

We experimented with a range of different models for the *complete*-step. We used Llama 3 in 3B-Instruct and 70B-Instruct variants (Grattafiori et al., 2024), a few versions of Mistral 7B (Jiang et al., 2023a), Mixtral of Experts (Jiang et al., 2024) and Teuken-7B-Instruct (Ali et al., 2024). The overview of models in our final selection is presented in Table 1. We used Llama-3.1-8B-Instruct (Grattafiori et al., 2024) as the ranking model.

For the *complete*-stage, the number of keywords generated by the LLMs was controlled by setting the minimum number of tokens to 24 and the maximum tokens to 100. Find the rest of the hyperparameters affecting the LLMs on our Github[6].

4.4 Prompts

We sampled different sets of prompt examples from the train splits of the all-subjects and tib-core datasets. To account for the multilinguality of the data, we assembled prompts with only German, only English and mixed-language texts. However, the gold-standard subject terms that we show to the LLMs are always in German. Additionally, we also created prompts with a restricted number of subject terms and lemma overlap. Lemma overlap is a measure for similarity between the example text and its subject terms, which we also used in Kluge and Kähler (2024).

Note that we leave the handling of multilinguality completely to the LLMs. Analysing the keywords resulting from the *complete*-stage on dev-test, it wasn't the case that the models tended to generate English terms, but instead they followed the few-shot demonstrations and output German keywords.

You can view an overview of the prompt example sampling in Appendix A.1. You can also see the instructions for the *complete*- and *rank*-stages there. The list of examples for each prompt is available on our system's Github[7]. The templates we used to build the final prompt are also on our system's Github[8].

4.5 Ensemble Optimisation

On the dev-opt subset we ran experiments with 9 models $\times$ 15 prompts, resulting in 135 sets of subject term suggestions. However, one cannot expect ever increasing the number of models and prompts to unlimitedly lead to better performance. Naturally, there is a tipping-point where ensemble performance deteriorates when adding more models or prompts. Also, there is a trade-off between the number of models and prompts and the computing effort at inference time involved in the *complete*-step. Therefore, we conducted an additional optimisation step to find the best subset of models and prompts.

Our optimisation strategy was twofold: In a first Monte-Carlo-like approach, we repeatedly sampled model$\times$prompt combinations and tested their joint performance as an ensemble, yielding a subset of 50 out of 135 combinations that achieve the best precision-recall (PR) balance in terms of area under the precision-recall curve (PR-AUC) on the dev-opt set. In a second step, we used a chain strategy, where we iteratively removed model$\times$prompt combinations that did not contribute to the overall performance, narrowing down the selection to 20 combinations. See Appendix A.2 for further results comparing our ensemble strategy with other strategies as in Trad and Chehab (2024). Also, see the impact of α on the results on the dev-test set in Appendix A.4.

4.6 Implementation Details

We used vLLM (Kwon et al., 2023) to serve the LLMs in the *complete*- and *rank*-stages. Embeddings for the keywords and the vocabulary were generated using HuggingFace's Text Embeddings

Inference[9]. As previously stated, we used Weaviate[10] as vector storage. To create our pipeline and to manage our experiments, we used DVC (Kuprieiev et al., 2025).

5 Results

5.1 Quantitative Findings

Table 2 shows the quantitative results on the all-subjects data of our system and the highest-ranking other teams sorted by averaged recall (R_{avg}). In this metric, we are in fourth position. Note that our approach, in contrast to supervised MLC algorithms, does not estimate a probability for each subject term in the entire vocab, but rather positively suggests a set of subject terms for each document. Modifying the hyperparameters affecting the number of output tokens can slightly increase the number of different keywords, but our approach doesn't produce result lists of arbitrary length. For recall@k values with high k, the average length of our submitted label lists of 18 makes these scores less adequate to properly estimate our system's performance. Therefore, we also included the scores precision@5 (P_5), recall@5 (R_5) and F1@5 ($F1_5$) in the table, as we find these metrics to be more insightful to our system's performance. Figure 4 in the Appendix demonstrates how our system drops off early in recall, while showing competitive results for lower values of k.

Looking at the more detailed results for our system (depicted in Appendix 7), we learned that, language-wise, one can observe better performance on the German than on the English documents (F1@5=0.332/F1@5=0.307). This could be attributed to the facts that we use a German instruction and that the vocabulary is presented in German. Potentially, using an English instruction and translating the vocabulary to English - both for the few-shot examples and the mapping stage - would help decrease this gap. Record-type-wise, Articles are by far the worst category for our system with F1@5=0.157. One reason for this could be the absence of articles in most of our prompts. All other text types achieve an F1@5 of at least 0.318. Interestingly, Articles are the best record type for the other leading teams, F1@5-wise.

5.2 Qualitative Findings

Table 3 shows the overall results for the top five teams in the qualitative ranking. Here, we see our system in the top position. In particular, the evaluation scenario (case 2) that eliminates those keywords that are technically correct but irrelevant puts a margin of 2.8% between our system and the second best team w.r.t. F1@5. It is unsurprising that the qualitative results are better than the quantitative ones, as our approach does not involve fine-tuning to the gold-standard. Subject terms may be helpful and specific in describing the text content, but at the same time not follow the formal rules applied by TIB's subject specialists when annotating the gold-standard.

Table 8 in the Appendix shows the F1@5 scores for different subject categories. Our system was rated particularly high in architecture, computer science and economics. Worst performance was in history, traffic engineering and mathematics.

5.3 Error Analysis

To get an understanding of the struggles our system faces, we put a small subset of the dev-test set under manual inspection and compared our system's suggested subject terms to the gold-standard. We also analysed the content of title and abstract for these documents. The questions we had in mind while making this analysis were:

- Are there groups of gold-standard subject terms we completely miss?
- Are there gold-standard subject terms that are difficult to infer from the given text content?

Upon this manual inspection, we noticed that our system benefits from two factors: specificity of a term and its presence in the concatenated content

[9] https://huggingface.co/docs/text-embeddings-inference/index

[10] https://weaviate.io/

of title and abstract. Specific subject terms that are either directly present in the text or are paraphrased in it seem to have the best chance of being correctly predicted. Generic subject terms are often not found or falsely assigned (e.g. gold-standard: law, found: international law, European law; gold-standard: agricultural policy, found: agriculture). Still, in the list of the most frequent subjects assigned to the dev-test set, there are a lot of general terms, such as history, politics and culture. Especially when analysing results for the Article text type, which our system performs worst on, we noticed many gold-standard subject terms we suspect to be difficult to directly infer from the given text alone. For example, see the text and its assigned keywords in Appendix A.8. In this record, a lot of words related to the keywords are mentioned in the text (e.g. economic development/growth, agriculture). The exact concepts are not in the text and are also not predicted by our LLM-ensemble. Our system relying only on the prompt examples and the concatenation of title and abstract struggles with these types of more complex/abstract relationships between text and subject terms. This is where supervised learning approaches might have an advantage, as they can learn these relationships from the training data.

Refer to Appendix A.8 for more details regarding this error analysis.

6 Conclusion

To sum up, we have demonstrated that our ensemble appoach is a promising way to combine the strengths of different models and prompts, achieving competitive results in the LLMs4Subjects task. As we have covered a wide range of prompts and LLMs, we expect our system to provide a good estimate of the results possible by prompting LLMs even without fine-tuning. While our system comes with no extra training costs, a significant drawback is the high cost involved in prompting multiple LLMs at inference time. Appendix A.9 demonstrates the costs of processing the documents with each of the LLMs used in our ensemble. Particularly larger models use up an enourmous amount of GPU-ressources that may be infeasible in productive settings. In future work, we would like to further investigate techniques for automated prompt optimisation, such as DSPy (Khattab et al., 2023), or methods belonging to the family of Parameter-Efficient-Fine-tuning (PEFT). Also we would like to investigate more sophisticated methods for the ensemble combination.

A.2 Ablation Study Ensemble Strategy

An interesting insight into our system is to evaluate the additional value of our ensembling approach. As in Trad and Chehab (2024), we complemented the top-20-set of models×prompt combinations with other strategies:

- `top-20-ensemble`: with varying models and prompts that generate candidates in the complete stage.
- `one-model-all-prompts`: All prompts are used with a single model.
- `one-prompt-all-models`: All models are used with a single prompt.
- `one-prompt-one-model`: A best performing single model-prompt combination is used.

All strategies include the rank step and the final combination step as in our overall system description. Figure 2 shows the PR-curves for the different strategies on the dev-test set. Table 5 shows the values of recall, precision and F1-score that could be obtained with an (F1-)optimal calibration of the system, also marked with a cross in Figure 2. Note, unlike the PR-curves in Figure 4, the curves in Figure 2 are not built only on the rank of the suggested subject terms, but also their confidence scores s_{fin}, as in Equation 1. Therefore, the curves achieve higher precision values in comparision to the curves that are built on rank only.

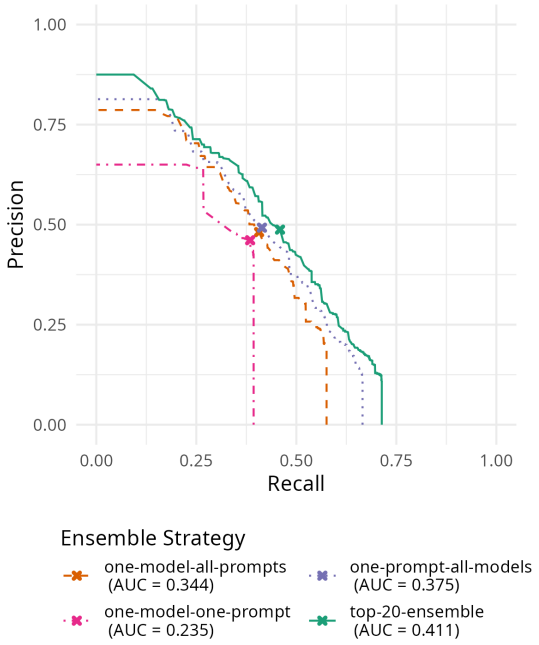

Figure 2: Precision-Recall curves for different model and prompt combinations, evaluated as doc-averages over our dev-test set.

Ensemble Strategy	Precision	Recall	F1
`top-20-ensemble`	0.488	0.459	0.420
`one-model-all-prompts`	0.481	0.407	0.393
`one-prompt-all-models`	0.492	0.414	0.407
`one-prompt-one-model`	0.461	0.385	0.380

Table 5: Precision, recall, F1-score for F1-optimal calibration of the system w.r.t. thresholding on confidence scores and limiting on rank, computed on dev-test set.

Comparing the precision-recall curves in Figure 2 , we can see that the `top-20-ensemble` is well above the other strategies in the high precision as well as the high recall domain. However, in

the part of the curve where the F1-score is optimal, the ensembling strategies are quite close so that the added value of the ensemble is not as pronounced compared to the other strategies. This may indicate that the selection of models and prompts is good (yielding high precision and high recall in the extreme), but the weighting mechanism of the model-prompt combinations might be improved. Furthermore, we may conclude that varying the LLMs adds more value to the ensemble in contrast to varying the prompts.

A.3 Ablation Study: Single Model Performances

Another interesting insight into our system is how each different LLM combined with various prompts performs on its own. To illustrate the spread of precision and recall for the different model×prompt combinations, see Figure 3. These results are computed on the bare candidate sets suggested by the llm and mapped to the vocabulary. In this figure, no ranking stage has been applied.

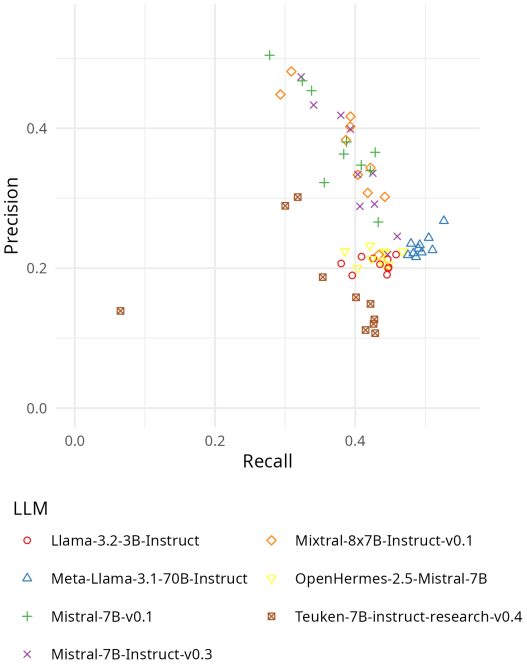

Figure 3: Precision-Recall Balance of single prompt-model combinations on the dev-test sample.

We can see that the most resource-intense model Llama-3.1-70B achieves highest recall with all prompts. However, precision is not as high as with the results stemming from the Mistral family. The Teuken model performs generally worst. Note, however, that even though a model-prompt combination may have low performance individually, it may still add value to an ensemble, as it may provide a different suggestion set than other models. Indeed, for overall ensemble performance we still found the Teuken model useful, probably due to its unique tokenizer.

A.4 Influence of α on PR-AUC

α	1M-1P	1M-AP	1P-AM	top20
0	**0.239**	0.285	0.297	0.301
0.1	0.235	0.344	0.373	0.402
0.2	0.235	**0.345**	**0.377**	**0.411**
0.3	0.235	0.344	0.375	**0.411**
0.4	0.234	0.340	0.369	0.408
0.5	0.232	0.335	0.366	0.405
0.6	0.232	0.333	0.363	0.402
0.7	0.231	0.330	0.359	0.397
0.8	0.230	0.327	0.355	0.394
0.9	0.229	0.324	0.350	0.391
1.0	0.170	0.312	0.328	0.384

Table 6: PR-AUC scores on the dev-test set for different values of α, which determines if the final ranking relies more on the relevance score (α<0.5) or the ensemble score (α>0.5). The ensembles are abbreviated: one-model-one-prompt (1M-1P), one-prompt-all-models (1M-AP), one-prompt-all-models (1P-AM) and top-20-ensemble (top20).

A.5 Comparing Precision-Recall Balance among Top Five Teams

Figure 4 shows the PR curves for the top five teams on the all-subjects task, plotting the values of precision@k and recall@k along the increasing values of k as reported in the shared task's leaderboard.

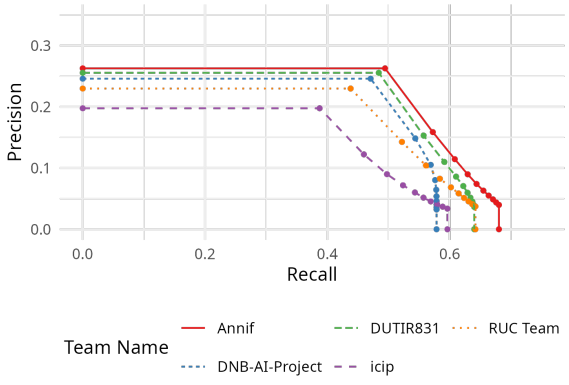

Figure 4: Precision-Recall curves for the top five teams on the all-subjects task.

A.6 Results by Language and Record Type

Record Type	P_5	R_5	$F1_5$
Article	0.1108	0.2685	0.1569

Traffic Engineering	0.343

Table 8: F1@5 scores in the qualitative ranking for different subject categories.

A.8 Ablation Study: Error Analysis

In addition to the quantitative results, we had a look at $n = 50$ random items from the dev-test split. The results are in Table 9.

Gold	Found	Not found		Difficult
		Close	Distant	
140	86 (61.4%)	20 (14.3%)	34 (24.3%)	44 (31.4%)
26	10 (38.5%)	6 (23.1%)	10 (38.5%)	17 (64.4%)

Table 9: Overview of how many of the gold subject terms in the ablation set are *found*, *not found* but have one or more *close* suggestions, *not found* with only *distant* suggestions found and *difficult*. Bottom row is `Article`-only.

Sample text[12] to illustrate difficulties of our system with the text type *Article*:

> Chapter 29 Agriculture and economic development "This chapter takes an analytical look at the potential role of agriculture in contributing to economic growth, and develops a framework for understanding and quantifying this contribution. The framework points to the key areas where positive linkages, not necessarily well-mediated by markets, might exist, and it highlights the empirical difficulties in establishing their quantitative magnitude and direction of impact. Evidence on the impact of investments in rural education and of nutrition on economic growth is reviewed. The policy discussion focuses especially on the role of agricultural growth in poverty alleviation and the nature of the market environment that will stimulate that growth.

NYCU-NLP at SemEval-2025 Task 11: Assembling Small Language Models for Multilabel Emotion Detection and Intensity Prediction

Zhe-Yu Xu, Yu-Hsin Wu and Lung-Hao Lee*
Institute of Artificial Intelligence Innovation
National Yang Ming Chiao Tung University
*lhlee@nycu.edu.tw

Abstract

This study describes the design of the NYCU-NLP system for the SemEval-2025 Task 11 that focuses on multi-lingual text-based emotion analysis. We instruction-tuned three small language models: Gemma-2 (27B), Mistral-small-3 (22B), and Phi-4 (14B) and then assembled them as our main system architecture. Our NYCU-NLP system participated the English Track A for multilabel emotion detection and English Track B for emotion intensity prediction. Experimental results show our best-performing submission produced a macro-averaging F1 score of 0.8225, ranking second of 74 participating teams for Track A, and ranked second among 36 teams for Track B with a Pearson correlation coefficient of 0.8373 in the task official rankings.

1 Introduction

Emotion recognition is a well-known NLP task that focuses on identifying affective states from texts. People express their perceived feelings using commonly used language in highly variable ways even within the same culture or social groups (Wiebe et al. 2005, Mohammad and Kiritcheko 2018, Mohammad et al. 2018). How to detect multiple perceived emotions and predict their emotion intensities is still a challenging research problem.

SemEval-2025 Task 11 (Muhammad et al., 2025b) aims to determine what emotion most people would think the speaker may be feeling given a short text written by the speaker. This shared task consists of three tracks, including 1) Track A (multilabel emotion detection): Given a target text, predict the perceived emotions of the speaker by selecting whether each of the following emotions apply: joy, sadness, fear, anger, surprise or disgust. 2) Track B (emotion intensity): Given a target text and target perceived emotions, predict the intensity for each of the classes. The set of ordinal intensity includes: 0 (no emotion), 1 (low degree of emotion), 2 (moderate degree of emotion), and 3 (moderate degree of emotion). 3) Track C (cross-lingual emotion): given a text written in one of 32 involved languages, predict the perceived emotion labels of a new text in a different target language. The dataset in this track has the same format as in Track A. Participating teams can choose to join in one or more languages and tracks based on their preference.

This paper describes the **NYCU-NLP** (**N**ational **Y**ang Ming **C**hiao Tung **U**niversity, **N**atural **L**anguage **P**rocessing Lab) system for the SemEval-2025 Task 11. Given the promising results obtained by Large Language Models (LLM) for various NLP tasks, we aggregate several Small Language Models (SLM), which are essentially smaller versions of LLM counterparts for this text-based emotion analysis task. We participated in English Tracks A and B only. Our system explored the use of instruction-tuned SLMs, including Gemma-2 (27B) (Riviere et al., 2024), Mistral-small-3 (22B) and Phi-4 (14B) (Abdin et al., 2024) and then assembled the SLMs to detect multilabel emotions and predict their intensities for given text-based emotion analysis. Experimental results showed our best submission achieved a macro-averaging F1-score of 0.8225, ranking second of 74 participating teams for Track A, and produced a Pearson correlation coefficient of 0.8373, also ranking second of 36 teams for Track B.

The rest of this paper is organized as follows. Section 2 reviews recently related studies on emotion detection and intensity prediction. Section

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1129–1135

3 describes the NYCU-NLP system for this shared task. Section 4 presents results and performance comparisons. Conclusions are drawn in Section 5.

2 Related Work

Empirical evaluations showed that transformer-based language models usually outperformed conventional neural networks for emotion intensity prediction (Lee et al., 2022). Sentiment-enhanced RoBERTa transformers were used to predict emotion and empathy intensities (Lin et al., 2023). A transformer-based fusion model was proposed to integrate semantic representations at different degrees of linguistic granularity for emotional intensity predication (Deng et al., 2023). Recently, transformer-based large language models (LLM) have been used for emotion detection. EmoLLM (Liu et al., 2024) is a series of instruction-following LLMs for affective analysis based on fine-tuning various LLMs with instruction data. The LLM-GEm (Hasan et al., 2024) system was designed to use GPT 3.5 for empathy intensity prediction. EmoTrigger (Singh et al., 2024) was proposed to evaluate the ability of CPT-4, Llama-2-Chat-13B and Alpaca-13B to identify emotion triggers and consider their importances for emotion detection. An assembly of the Starling-7B and Llama-3-8B was fine-tuned to prediction cross-lingual emotion intensity (Lin et al., 2024).

Small language models (SLM) are smaller in scale and scope than their original large model counterparts, and typically include fewer than 70 billion parameters, as opposed to LLMs with up to trillions of parameters. SLM are thus usually compact and efficient with less memory and computational power. Given limited computation resources, we are motivated to explore systems based on SLMs for emotion detection and intensity prediction.

3 The NYCU-NLP System

Figure 1 shows our NYCU-NLP system architecture for the SemEval-2025 Task 11. We instruction-tuned several SLMs and then assembled them by averaging the predicted results for multi-label emotion detection (Track A) and emotion intensity prediction (Track B).

3.1 Small Language Models

The following SLMs were used to detect emotions and predict the corresponding emotion intensity.

(1) Gemma-2 (27B)

Gemma-2 (Riviere et al., 2024) with 27B parameters is a new addition to Google's Gemma family, and provides higher-performing and more efficient inference. It applies interleaving local-global attentions and group-query attention to offer a competitive alternative to models more than twice its size.

System Prompt:
You are an emotion classification assistant. Your task is to predict the intensity of emotions expressed in the input sentences for the following categories: 'Anger', 'Fear', 'Joy', 'Sadness', and 'Surprise'.
- The intensity levels are:
  - 0: No emotion,
  - 1: Low intensity,
  - 2: Moderate intensity,
  - 3: High intensity.
- Provide the intensity for each emotion as a number between 0 and 3.
- Always output the result in the format: 'Anger: X, Fear: X, Joy: X, Sadness: X, Surprise: X' where X is the predicted intensity for each emotion.
- Ensure your prediction reflects the perceived intensity of the input sentence for all emotions, even if some intensities are 0.

User Prompt:
Input sentence: {sentence}
Output format: Provide the intensity for each emotion in the following format: 'Anger: X, Fear: X, Joy: X, Sadness: X, Surprise: X', where X is a number between 0 and 3

Assistant Prompt:
{intensity}

Figure 2: Prompts used for instruction tuning.

(2) Mistral-small-3 (22B)

Mistral-small-3 set a new benchmark in the small LLMs below 70B, successfully converting a mixture-of-experts architecture into a single dense 22B parameter model.

(3) Phi-4 (14B)

Phi-4 (Abdin et al., 2024) is the latest SLM in Microsoft's Phi family, offering high quality results at a small size with 14B parameters. It outperforms larger models due to the use of high-quality datasets and post-training innovations.

3.2 Instruction Fine-tuning

We used instruction tuning (Wei et al., 2022) and LoRA (Hu et al., 2021) techniques with prompts shown in Fig. 2 to optimize the above-mentioned three pre-trained SLMs model for this task. The system was configured as an emotion classification assistant. We asked the SLM to classify a given sentence into four defined emotion intensities, including 0 for no emotion, 1 for low intensity, 2 for medium intensity and 3 for high intensity. We also guided the SLM to provide the intensity score for each emotion using the given output format.

3.3 Assembly Mechanism

During the inference phase, each SLM conducts an independent prediction for each testing instance. We then used an averaging-based assembly mechanism to determine the system output by averaging the predicted intensity scores for each emotion.

For the multilabel emotion detection subtask (Track A), if a testing instance obtained an average intensity value exceeding 0, we predicted perception of the emotion, otherwise no emotion.

For the emotion intensity prediction subtask (Track B), if a testing instance obtained an average intensity that is a non-integer value, we rounded the value to predict as its intensity score for each emotion.

4 Experiments and Results

4.1 Data

The datasets were mainly provided by task organizers (Muhammad et al., 2025a). Tracks A and B shared the same datasets, respectively including 2768, 117 and 2768 instances in the training, development and test sets. We only used the training set for instruction-tuning the SLMs without data augmentation. The average instance length is 15.5 tokens with about 1.5 emotion labels per instance. The English datasets used do not include the disgust emotion. The mostly common emotion was found to be fear (total 1,611 cases accounting for 58.20%), followed by sadness (878 cases/31.72%), surprise (839 cases/30.31%), joy (674 cases/24.35%), and anger (333 cases/12.03%).

4.2 Settings

All pre-trained models were downloaded from HuggingFace[1]. We continuously fine-tuned these models using only the training set provided by task organizers. All experiments were conducted on a server with four Nvidia V100 GPUs (Total 128GB memory). The hyperparameter values of our used LLMs were finally optimized as follows: epochs 10; batch size 4; optimizer paged AdamW (32 bit); learning rate 1e-4; LoRA r 16; LoRA alpha 32 and LoRA drop 0.01.

4.3 Metrics

For Track A on multilabel emotion detection, the macro-averaging F1 was used to measure the model performance based on predicted emotion labels and the ground truth.

Table 4: Testing results on the evaluation set of Track B.

For Track B on emotion intensity prediction, the Pearson correlation between the predicted intensity for each emotion and gold standard was used to evaluate performance.

4.4 Results

Tables 1 and 2 respectively show the evaluation results for Tracks A and B on the development sets. Among three independent SLMs, Mistral-small-3 (22B) outperformed the others on both tracks. Assembly models usually outperformed independent ones. However, assembly SLMs showed slightly reduced performance on both tracks. The small size of the development (only 117 instances) may have introduced bias. Each participating team was allowed to submit at most three submissions for evaluation and the last submission will be regarded as the official submission. We submitted the independent Mistral-small-3 (22B) and the assemble model as our final submission for official ranking.

Tables 3 and 4 respectively show the submission results for Tracks A and B on the evaluation set. The assemble SLMs usually outperformed Mistral-

small-3 (22B) in terms of both overall performance and individual emotion for both tracks. Our assemble SLM-based model respectively achieved a macro-averaging F1 of 0.8225 for Track A on multilabel emotion detection and a Pearson correlation coefficient of 0.8373 for Track B on emotion intensity prediction.

4.5 Rankings

Our final assemble submission ranked second for English Track A among a total of 74 participating teams and second for English Track B among all 36 official submissions.

4.6 Discussion

Due to limited time and computational resources, we did not use prompt engineering techniques to configure other prompts for optimization. Therefore, prompts used for instruction fine-tuning may need to be improved for performance enhancement.

We only used the training set for instruction-tuning the SLMs, and data augmentation techniques may further improve model tuning.

Since the SLMs were pre-trained using multi-lingual data, the distribution of emotion classes in small fine-tuned data may not affect model performance for individual emotion categories in our experiments.

We selected the SLMs based on the recent performance of the general benchmarks, which may not be appropriate for multilabel emotion detection and intensity prediction tasks.

The SLMs are multi-lingual so that they may be expanded to languages other than English with language-specific fine-tuned data for text-based emotion analysis task.

5 Conclusions

This study describes the NYCU-NLP system for the SemEval-2024 text-based emotion analysis task, including system design and performance evaluation. We instruction-fine-tuned the SLMs to effectively detect emotion categories and predict their emotion intensities. Experimental results indicate that our best submission is an assembly of the Gemma-2 (27B), Mistral-small-3 (22B) and Phi-4 (14B) models, achieving a macro-averaging F1 score of 0.8225 for the multilabel emotion detection track (ranking second out of seventy-four submissions) and a Pearson correlation coefficient of 0.8373 for the emotion intensity prediction track (ranking second of thirty-six).

This pilot study is our first exploration based on applying SLMs to text-based emotion analysis tasks. Future work will exploit other advanced SLMs to further improve performance.

Limitations

This work does not propose a new model to address this task for multilabel emotion detection and intensity prediction. Experiments were conducted with basic settings without other advanced explorations due to computational resource limitations.

Acknowledgments

This study was partially supported by the National Science and Technology Council, Taiwan, under the grant NSTC 111-2628-E-A49-029-MY3. This work was also financially supported by the Co-creation Platform of the Industry Academia Innovation School, NYCU.

Abstract

This paper describes our system used in the SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection. To address the highly subjective nature of emotion detection tasks, we propose a model ensemble strategy designed to capture the varying subjective perceptions of different users towards textual content. The base models of this ensemble strategy consist of several large language models, which are then combined using methods such as neural networks, decision trees, linear regression, and weighted voting. In Track A, out of 28 languages, our system achieved first place in 19 languages. In Track B, out of 11 languages, our system ranked first in 10 languages. Furthermore, our system attained the highest average performance across all languages in both Track A and Track B.

1 Introduction

The objective of Task 11(Muhammad et al., 2025b) is to determine, within different linguistic contexts, what emotion most people would perceive the speaker to be feeling based on a sentence or short text snippet uttered by the speaker(Muhammad et al., 2025a)(Belay et al., 2025). Track A of Task 11 includes 28 languages, while Track B consists of 11 languages. The task requires detecting the presence of the following emotions and assessing their intensity: joy, sadness, fear, anger, surprise, and disgust.

Given the highly subjective nature of emotion detection in textual content, different annotators may provide varying answers regarding whether a certain emotion is present in the text (or the degree to which it is present). Similarly, for large language models (either untrained or only lightly fine-tuned), different models may output differing judgments for the same textual content. Therefore, bridging the gap between these two sources of subjectivity—annotator variability and model inconsistency—becomes the central focus and optimization goal of our system.

Considering the powerful capabilities of large language models and the potential for catastrophic forgetting resulting from improper training, we select both the original and lightly fine-tuned versions of several models as base models. We then employ ensemble strategies such as neural networks, decision trees, linear regression, and weighted voting to combine the outputs of multiple base models, ultimately providing the final prediction. The rationale behind using a ensemble strategy is that the independent predictions made by multiple base models resemble the behavior of multiple annotators independently labeling data, each with their own judgment tendencies. We hypothesize that, when there is sufficient divergence between the prediction results of different base models, appropriate ensemble strategies can better capture the annotators' labeling outcomes.

2 System Overview

2.1 Prompt Optimization

We present an iterative data-driven prompt optimization framework. The pipeline evaluates and evolves a prompt set through up to $T_{\max}$ iterations, dynamically expanding candidates via `ContextAugment` – labled data examples into prompts to improve their alignment with training data; and `StructVar` – prompt the LLM to Generate syntactically diverse prompt variations (e.g., rephrasing, synonym substitution) to explore broader prompt spaces and avoid overfitting to specific formulations. Then pruning low-performing options (threshold τ). The process terminates early if no improvement exceeds threshold η or reaches $T_{\max}$ iterations. The final output selects the top-k prompts with highest F1 scores, balancing perfor-

mance and generalization.

Algorithm 1 details the full optimization process, including early termination checks and pruning strategies to maintain efficiency.

Algorithm 1 Iterative Prompt Optimization with Early Termination and Multiple Outputs

Input: Initial prompt set $\mathcal{P}_0 \subseteq \mathcal{P}_{\text{baseline}}$,
Training dataset D, validation set D_{val},
Eval Metric: $M = \text{F1 score}$,
Hparams: $\Theta = \{\eta, \tau, T_{\max}, k\}$
Output: k $\mathcal{P}_{\text{final}} = \{p_1^*, p_2^*, ..., p_k^*\}$; Best score s^*

$s^* = -\infty$
for $t = 1$ ***to*** T_{max} **do**
  for $p \in \mathcal{P}_t$ **do**
    Generate responses $\{R_{p,d}\}_{d \in D_{\text{val}}}$ using p
    $S_p = \frac{1}{|D_{\text{val}}|} \sum_{d \in D_{\text{val}}} \text{F1}(R_{p,d})$
  end
  if $S_{p^*} > s^*$ **then**
    $s^* = S_{p^*}$
  end
  if $t \geq T_{max}$ **then**
    Break loop
  end
  $\mathcal{P}_{t+1} = \emptyset$ **for** $p \in \mathcal{P}_t$ **do**
    $p' = \text{ContextAugment}(p, D)$
    $p'' = \text{StructVar}(p)$
    $\mathcal{P}_{t+1} \leftarrow \mathcal{P}_{t+1} \cup \{p', p''\}$
  end
  $\mathcal{P}_{t+1} = \text{Prune}(\mathcal{P}_{t+1}, \tau)$
end
$\mathcal{P}_{\text{final}} = \arg\max_{\mathcal{P}_t} \{S_p \mid p \in \mathcal{P}_t\}$
return $\mathcal{P}_{final}$ *and* s^*

In addition to the prompts mentioned earlier, during inference, we also randomly select 2-3 training samples from the training dataset to serve as few-shot examples.

2.2 Training LLM as Embedding Model

This approach trains smaller LLMs to generate robust embeddings that capture both the semantic and emotional nuances of text, enabling accurate emotion classification. The core principle, inspired by (Liu et al., 2024; Li and Zhou, 2024), lies in extracting representations that reflect the underlying emotional state of a sentence.

Adapter We employed AdaLoRA (Zhang et al., 2023) for parameter-efficient fine-tuning of our pre-trained language model. This method leads to significant computational savings while maintaining or improving performance, particularly when resources are limited.

Emotion Representation We formalize the task as follows: Given an input sentence x, we aim to derive an embedding vector $\mathbf{v}_x \in R^d$ that preserves both its semantic content and emotional salience. Using a prompt template "Detect the emotion of this sentence: {x}", the sentence is processed through a language model Φ with L transformer layers.

To distill sentence-level emotional semantics, we apply a meaning pooling operator Ψ that aggregates token-level representations across the entire sequence. The final-layer hidden states $\mathbf{H}^L$ are used to compute the sentence embedding:

$$\mathbf{v}_x = \Psi(\mathbf{H}^L) = \frac{1}{N} \sum_{i=1}^{N} \mathbf{h}_i^L$$

In the final layer of the model, we added a fully connected layer to transform the embedding vector outputs into outputs suitable for the classification task.

2.3 Ensemble Strategy

We will implement a two-round ensemble strategy, adopting a stacking-like approach for both rounds of fusion. In this section, we will describe the ensemble strategy for the first round.

The first-round ensemble strategy involves using several ensemble schemes to generate individual prediction results, which will then serve as inputs for the subsequent second-round ensemble. In the first round, our system employs four ensemble schemes: neural network, XGBoost, LightGBM, and linear regression, with the five prediction outputs from the large language models mentioned earlier serving as inputs.

The neural network strategy employs a three-layer neural network, with each layer consisting of a fully connected layer of dimension 16, followed by a ReLU activation function. The final output layer uses mean squared error (MSE) as the loss function.

The XGBoost strategy: In Track A, a binary classification approach is used, with negative log-likelihood (NLL) as the evaluation metric. In Track B, a regression approach is adopted, with root mean squared error (RMSE) as the evaluation metric.

The LightGBM strategy: In Track A, a binary classification approach is adopted, with accuracy

as the evaluation metric. In Track B, a regression approach is employed, using root mean squared error (RMSE) as the evaluation metric. The boosting method used for all models is Gradient Boosting Decision Trees (GBDT).

The linear regression strategy: A second-order polynomial regression fitting approach is used.

2.4 Data Analysis and Voting Strategy

In this section, we describe the ensemble strategy for the second round. The ensemble strategy in this round employs a weighted voting approach, where the voting weights of each model are determined through statistical data. The implementation of this voting ensemble strategy differs between Track A and Track B.

This round's weighted voting strategy consists of three steps. The first step is to select the models eligible for voting, the second step is to calculate the voting weights for each model, and the third step is to derive the final prediction results based on the voting outcomes.

Step 1: After training the models on the training dataset, we evaluate them using the development dataset to obtain an evaluation score (F1 score for Track A and Pearson correlation coefficient(PCCr) for Track B). For each language in both tracks, the model with the highest score is selected as the baseline. Models whose scores are lower than the baseline model by 0.2 points are excluded from the subsequent voting and ensemble steps.

Step 2: The voting weight of a model, denoted as $weight$, is derived by multiplying several sub-weights. The first sub-weight, $weight_1$, is the evaluation score of the model on the development dataset, representing the accuracy of the model's predictions.

$$weight_1 = \begin{cases} \text{f1 score} & \text{if Track A} \\ \text{PCCr} & \text{if Track B} \end{cases} \quad (1)$$

The second weight, $weight_2$, is the Jensen-Shannon Divergence (JS divergence), which characterizes the similarity between the distributions of the training dataset and the development dataset. The intermediate variable for calculating the JS divergence is the KL divergence (Kullback-Leibler Divergence). This weight is used to assess and correct the confidence of $weight_1$. Let P and Q represent the distributions of the training dataset and the development dataset, respectively, and let M denote their average distribution.

$$M = \frac{1}{2}(P + Q) \quad (2)$$

$$KL(P\|M) = \sum_x P(x) log \frac{P(x)}{M(x)} \quad (3)$$

$$weight_2 = \frac{1}{2}KL(P\|M) + \frac{1}{2}KL(Q\|M) \quad (4)$$

The third sub-weight, $weight_3$, is used only in Track A. It is calculated based on the ratio between the number of labels in the development dataset and the number of corresponding labels predicted by the model. This weight corrects for potential subjective bias in the model's label predictions.

$$weight_3 = \begin{cases} \sqrt{\frac{count(\text{gold label = 0})}{count(\text{predict label = 0})}} & \text{if label=0} \\ \sqrt{\frac{count(\text{gold label = 1})}{count(\text{predict label = 1})}} & \text{if label=1} \end{cases} \quad (5)$$

Final weight:

$$weight_{TrackA} = weight_1 * weight_2 * weight_3 \quad (6)$$

$$weight_{TrackB} = weight_1 * weight_2 \quad (7)$$

Step 3: In Track A, labels 0 and 1 are first mapped to -1 and 1, respectively. Then, the label predictions from all models are weighted and summed. Finally, a threshold of 0 is applied, where predictions greater than or equal to 0 are classified as 1, and those less than 0 are classified as 0. In Track B, the label predictions from all models are weighted and summed to obtain a score. Based on this score, all cases are sorted in descending order. Next, we combine the labeled data from both the training and development datasets and calculate the percentage of cases labeled with scores from 3 to 0 in the total dataset. Finally, using this percentage, we assign the sorted scores proportionally to the labels from 3 to 0.

3 Experimental Setup

Models Training-free: ChatGPT-4o [1]; Deepseek-V3[2]. Training LLMs as Embedding Models:

[1] https://chatgpt.com/
[2] https://chat.deepseek.com/

Gemma-9b-it[3]; qwen-2.5-32b-instruct[4] Mistral-Small-24B[5]

Hyperparameters

- Training-free: $T_{\max} = 10$, pruning threshold $\tau = 0.5$, top-k prompts $k = 5$.
- Fine-tuning: Learning rate = 1×10^{-5}, attention dimension = 128, batch size = 32. Models trained for 10 epochs with early stopping, evaluated using 5-fold cross-validation.

Ensembling The learning rate for the three-layer neural network model used for the ensemble is set to 3e-2, with the AdamW optimizer and a weight decay of 1e-3. The model is trained for 15 epochs.

For the XGBoost model, the maximum depth is set to 6, and the learning rate is set to 0.1.

For the LightGBM model, the maximum depth is set to 8, the learning rate is set to 0.3, and the number of leaves is set to 31.

4 Results

Due to limited time and GPU resources, we initially conducted experiments and exploration only on the ENG and PTBR languages (Table 1)(Table 2).

In devlopment dataset, compared to the performance metrics of single-path large language models (either untrained or lightly fine-tuned), the fusion strategy consistently provides an additional improvement of 0.01 to 0.02 on top of the optimal single-path model's metrics.

After the release of the test dataset, we plan to apply the same strategy to the 28 languages in Track A and the 11 languages in Track B.

In the final test dataset, we achieved first place in 19 out of 28 languages in Track A(Table 3), and first place in 10 out of 11 languages in Track B (Table 4).

5 Conclusion

Similar to the emotion detection task discussed in this paper, strongly subjective tasks are prevalent in industry. At both ends of such tasks, on one side, users or annotators have their own subjective judgment criteria, and on the other, language models, due to the nature of their training data, also

develop their own judgment standards. This results in biases and gaps between the two. With the emergence and development of large language models (LLMs), and owing to their powerful capabilities, industry applications are increasingly inclined to use untrained models or those only lightly fine-tuned. Therefore, there is a need to explore suitable methods to replace the traditional approach of fitting task labels by training language models extensively. Considering the differences in subjective biases across different large language models, and the generally high accuracy of these models, we were inspired by the concept of Fourier transformations and attempted a ensemble strategy to bridge the gap between these two. From the evaluation results, we observe that the ensemble strategy provides an additional improvement of 0.01 to 0.02 on top of the optimal single-path model's metrics.

In Task 11, the ensemble strategy we employed is based on traditional NLP algorithmic solutions. If similar tasks arise in the future, we aim to explore whether there are applicable solutions within the LLM domain, such as the MoE strategy. Additionally, in the Dev Dataset, we found that transferring the more fine-grained annotation results from Track B to Track A could further improve the performance metrics of Track A. However, due to time constraints, we were unable to test this approach on the Test Dataset, presenting an opportunity for future exploration.

6 Related Work

We select Gemma-9b-it(Gemma Team et al.), Qwen-2.5-32b-Instruct(Qwen et al., 2025), Mistral-Small-24B(noa), DeepSeek-v3(DeepSeek-AI et al., 2024), and ChatGPT-4o as the base models.

Recent advances in emotion detection have primarily focused on two key approaches: leveraging pre-trained large language models (LLMs) (Zhuang et al., 2023; Li et al., 2025) and fine-tuning smaller models for specific tasks (Ren and Sutherland, 2024; Zhang et al., 2023).

Recent studies leverage large, closed-source models like GPT-3 and ChatGPT for zero-shot or few-shot emotion detection, utilizing dynamic prompt generation and optimization to enhance performance without fine-tuning (Amin et al., 2023; Li et al., 2025; Fu et al., 2025).

Techniques like mixture-of-experts (MoE) models and attention-weighted pooling have improved efficiency and accuracy in emotion detection by emphasizing relevant input features (Liu et al., 2024; Zhang et al., 2023).

Traditional ensemble strategies such as XGBoost(Chen and Guestrin, 2016), LightGBM(Ke et al., 2017), and stacking(Ting and Witten, 1997) were applied in our system.

Abstract

Large Language Models (LLMs) have significantly advanced Natural Language Processing, however, ensuring the factual reliability of these models remains a challenge, as they are prone to hallucination - generating text that appears coherent but contains innacurate or unsupported information. SemEval-2025 Mu-SHROOM focused on character-level hallucination detection in 14 languages. In this task, participants were required to pinpoint hallucinated spans in text generated by multiple instruction-tuned LLMs. Our team created a system that leveraged a Retrieval-Augmented Generation (RAG) approach and prompting a FLAN-T5 model to identify hallucination spans. Despite contradicting prior literature, our approach yielded disappointing results, underperforming all the "mark-all" baselines and failing to achieve competitive scores. Notably, removing RAG improved performance. The findings highlight that while RAG holds potential for hallucination detection, its effectiveness is heavily influenced by the retrieval component's context-awareness. Enhancing the RAG's ability to capture more comprehensive contextual information could improve performance across languages, making it a more reliable tool for identifying hallucination spans.

1 Introduction

The rapid advancement of Large Language Models (LLMs) has significantly transformed Natural Language Processing (NLP), pushing breakthroughs in text generation, reasoning, and contextual understanding (Wang et al., 2024a). As these models continue to evolve, researchers have explored their potential across various domains, yet some challenges persist in ensuring the reliability and factual accuracy of their outputs (Ji et al., 2023).

A significant challenge in assessing LLM output is the phenomenon of hallucination, where models produce text that appears coherent but contains factually incorrect or unsupported information (Farquhar et al., 2024). This issue can stem from limitations in training data (McKenna et al., 2023), overgeneralization (Zhang et al., 2024), and the tendency of models to prioritize linguistic fluency over factual accuracy (Wang et al., 2024b). Existing evaluation metrics often focus on grammaticality and coherence, which is not able to properly account for, and penalize factual inconsistencies, making hallucinations more common (Honovich et al., 2022). Addressing this challenge is important for applications such as automated knowledge retrieval (Shi et al., 2025), decision support systems (Handler et al., 2024), and scientific content generation (Rossi et al., 2024), where misinformation can lead to potential consequences (Rawte et al., 2023; Asgari et al., 2024).

In a collaborative effort to develop the field of mitigating LLM hallucinations, the SemEval-2025 Mu-SHROOM shared task focuses on detecting hallucinated spans in text generated by instruction-tuned LLMs across multiple languages (Vázquez et al., 2025). Unlike its previous iteration, this task focuses on character-level hallucination detection in 14 different languages. Participants were given LLM-generated text, produced by multiple LLMs, and had to identify hallucinated characters while assigning confidence scores to their predictions. Evaluation was based on intersection-over-union (IoU) accuracy and the correlation between assigned probabilities and empirical annotations.

To approach this task, our team used a RAG approach for passage retrieval and the prompting of a FLAN-T5 model (Chung et al., 2022) as a method to detect spans of hallucinations. This method relied on using relevant and factually correct passages to be given to the T5 model, then leveraging its abilities to specifically identify what parts of a given piece of text could be a hallucination with a probability estimate. While our experiments showed middling results, it provides promis-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1143–1151

ing insight into using RAG as a tool for detecting hallucination spans. Our evaluations across 14 languages indicate that while the RAG component sometimes aids in pinpointing hallucinated spans, it often falls short. Our findings offer practical insights into further refining retrieval-augmented methods in hallucination detection.

2 Background

As per the definition provided by the Mu-SHROOM organizers, hallucinations are understood as content that contains or describes facts that are not supported by the provided reference (Vázquez et al., 2025). Broadly, hallucinations in LLMs can be classified into intrinsic and extrinsic hallucinations. Intrinsic hallucinations arise when some generated text is inconsistent with the input or reference material, introducing inaccuracies even when the model remains within its contextual boundaries. On the other hand, extrinsic hallucinations occur when a model produces information that extends beyond the provided context, fabricating unsupported claims (Ji et al., 2023; Wang et al., 2024c). In the context of the Mu-SHROOM task, detection of hallucination spans must be able to specifically identify intrinsic hallucinations, as extrinsic hallucinations do not fall under the definition of the task.

Although several methods have been explored for handling hallucinations in LLM output (Sanyal et al., 2024; Zhang et al., 2025), one notable method is RAG, which integrates external knowledge sources into LLM generation to improve factual consistency (Ayala and Bechard, 2024). This is typically implemented through a neural retriever, which retrieves relevant passages from a structured dataset (Lewis et al., 2020). Unlike traditional sparse retrieval methods like BM25, which rely on keyword matching, neural retrievers use dense embeddings to capture semantic relationships, which should improve retrieval accuracy (Lewis et al., 2021). By incorporating external knowledge retrieval, RAG has been shown to improve factual accuracy in NLP tasks as it reduces hallucinations by grounding responses in verifiable sources (Ayala and Bechard, 2024; Reichman and Heck, 2024; Karpukhin et al., 2020).

A key component that enhances RAG's retrieval process is Dense Passage Retrieval (DPR), which is a technique that uses dense vector representations to index and retrieve relevant passages for a given input. DPR uses a dual-encoder framework, where one encoder processes the input query while another encoder retrieves semantically similar documents. This allows DPR to efficiently retrieve top-k passages, which are then given to the RAG model for more context-aware generation (Karpukhin et al., 2020). Although more traditional methods could be effectively employed for RAG applications (Huly et al., 2024), by retrieving high-quality relevant passages, DPR has been shown to improve the factual reliability of RAG-based models (Lee and Kim, 2024).

The model focused on in this study, FLAN-T5, is a fine-tuned variant of the T5 model trained on diverse instruction-following tasks, and it is well-suited for applications that require contextual consistency and fact verification (Chung et al., 2022; Guan et al., 2024). Its ability to generalize across unseen tasks makes it particularly effective for detecting semantic inconsistencies in generated texts, which is a great benefit in hallucination detection. Since FLAN-T5 works in a text-to-text format, it could also be prompted to extract hallucinated spans directly, making it a promising tool for fine-grained hallucination detection. In last years SHROOM task, a study fine-tuned a FLAN-T5 for definition modeling, where it achieved an accuracy of 72.4% in detecting inconsistencies between input and generated definitons, demonstrating its potential for hallucination detection (Griogoriadou et al., 2024).

3 System Overview

The implementation of our system is publicly available on GitHub [1]. Figure 1 shows the pipeline of our system.

3.1 Data description

The data is provided in JSONL format, where each line corresponds to a single data entry structured in JSON. Each entry contains the prompt given to the language model and the generated output. Additionally, the model id is included for each entry. In the validation data, two additional types of annotations are included, which are soft and hard labels indicating hallucinations. The soft labels provide token spans (start and end indices) with an associated probability, which is calculated based on annotator agreement. Hard labels are a binary subset of these spans, derived by including only

[1] https://github.com/ivobruinier1/mu-SHROOM.git

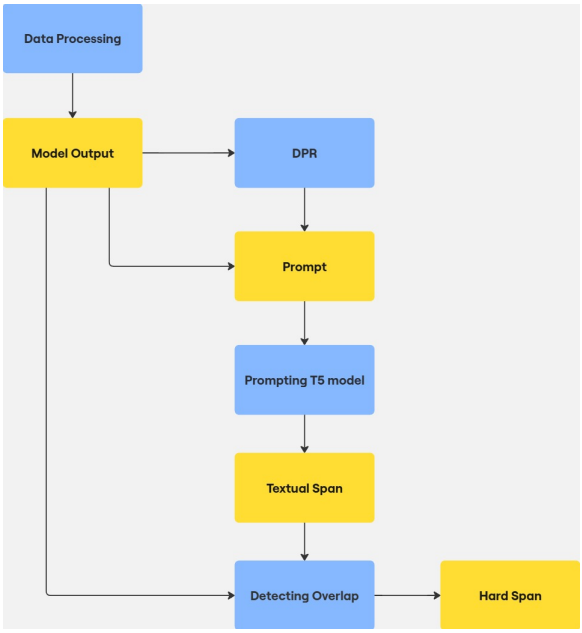

Figure 1: Pipeline for Extracting Hard Spans from Model Outputs

those soft labels with prob values above a threshold of 0.5. In both the training and test data, model output logits as well as model output tokens are provided.

For clarity, an example line from each subsection of the dataset is provided in Appendix A, where the structure and annotations can be examined in detail.

3.2 Dense Passage Retrieval

In our effort to optimize our prompt-based approach to detect hallucination spans, we leverage Dense Passage Retrieval (DPR) to provide context to the model. We aim to utilize this process in a manner that balances accuracy and performance to ensure usability in real world scenarios. To achieve this, we adopt a three-step approach for retrieving relevant passages.

After inspection of the training and validation data, we note that to answer most questions correctly, we would need to access domain-specific knowledge to some extent. For example, answering the question "*Do all arthropods have antennae?*" requires us to know the specific characteristics of arthropods. Based on this assumption, we implement Named Entity Recognition (NER) to extract named entities from each input query. For each of these entities, we search for the most likely Wikipedia pages using the Python Wikipedia module [2], which we then split into shorter passages. In our pipeline, we leverage multilingual transformer-based NER models to ensure optimal accuracy. Four distinct models are used, namely *roberta-ner-multilingual* [3] (Schelb et al., 2022), *robeczech-NER* [4] (trained using the *robeczech-base* model by Straka et al. (2021)), berteus-base-cased [5] (Agerri et al., 2020) and finbert-ner [6].

The second step in our pipeline involves the generation of more concise passages that can be used to provide context to the T5 model. After retrieving the most likely Wikipedia pages for each relevant entity, we split each page into sections of at most 5 sentences. Each section shares two sentences that overlap with the previous section in an attempt to retain context as much as possible.

As a final step in our DPR pipeline, we perform a semantic search where we compare each query in the test data to each passage relevant to the query. To achieve this, we implement a dual-encoder framework; we embed all passages for each query into a 384-dimensional dense vector space using *Sentence-BERT* [7] (Reimers and Gurevych, 2019). We then encode each input query using the same procedure. Finally, we retrieve the top-k=5 passages that are most relevant to the query to pass as context in the RAG prompt.

The language support for each individual NER model is shown in appendix C. As displayed here, none of these models offer support for Swedish and Farsi. As a workaround, we instead rely on Cohere Embed v3 [8] to perform a semantic search for both of these languages; however, due to computational cost and time constraints, we limit the number of included passages to the first 1,000,000 results.

3.3 T5 Span Detection

In our pipeline, the T5 model (google/flan-t5-base) is utilized to detect hallucination spans within the generated text. The process begins by reading data from JSONL files, which include model outputs and corresponding passages retrieved by a DPR system. The data is combined into pairs for further processing. Prompts are then generated using this

[2] https://pypi.org/project/wikipedia/
[3] https://huggingface.co/julian-schelb/roberta-ner-multilingual

[8] https://cohere.com/blog/introducing-embed-v3

data, which include context and hypotheses, and are formatted to query the T5 model. The model generates outputs based on these prompts, identifying potential hallucinations. To find the longest contiguous overlapping span between the T5 output and the text that could contain hallucinations, a sequence matching system is used. This involves preprocessing both texts by converting them to lowercase, removing punctuation, and normalizing whitespace to ensure consistent comparison. Python's SequenceMatcher (Python, 2025) is then applied to detect the longest common substring between the two inputs. The algorithm determines the start index and length of the best matching substring within the first text. If a valid overlap is found, the function returns the start and end indices of the match. If no overlap is detected, the function returns None. This method enables efficient detection of exact matches while ignoring variations in punctuation and capitalization, although it does not account for semantic similarity or minor textual differences, which could affect the precision of the span detection.

3.4 Evaluation

For evaluation the SemEval organizers released a scoring system [9] that could be implemented for reference and development of the system. The evaluation of intersection-over-union (IoU) of characters marked as hallucinations has been incorporated as way of providing feedback on how well the system scores. Our analysis does not include an evaluation of the correlation between the probability assigned by our system to a character being part of a hallucination and the empirical probabilities observed by the annotators. This decision was made due to limitations in the scope of the study. Future research may explore this aspect to better understand the alignment between automated predictions and human judgment.

$$\text{IoU} = \frac{\text{area of overlap}}{\text{area of union}} \quad (1)$$

4 Experiments & Results

4.1 Experimental setup

Experiments with the validation set were conducted using various prompting templates to evaluate their effectiveness. Multiple prompt variations were tested to determine which yielded the best performance. The most effective prompt template, as can be seen in the appendix 2, was then selected for the test set, where it was run both with and without DPR to assess the impact of retrieval augmentation on the results.

4.2 Results and Discussion

Language	**IoU** FLAN-T5	**IoU** FLAN-T5 + DPR	**IoU** Baseline*
Arabic	0.00	0.05	0.36
Catalan	0.18	0.15	0.24
Czech	0.11	0.05	0.26
German	0.16	0.12	0.35
English	0.19	0.15	0.35
Spanish	0.13	0.13	0.19
Basque	0.13	0.13	0.37
Farsi	0.00	0.00	0.20
Finnish	0.09	0.07	0.49
French	0.08	0.08	0.45
Hindi	0.00	0.00	0.27
Italian	**0.23**	**0.28**	0.28
Swedish	0.12	0.09	0.54
Chinese	0.00	0.04	0.48

Table 1: IoU scores for all languages on the test data with the baseline (mark all)* scores for comparison

Previous studies (Ayala and Bechard, 2024; Reichman and Heck, 2024; Karpukhin et al., 2020) prove that RAG demonstrates potential in improving generative model performance. However, when the information retrieved by the DPR component is overly general or insufficiently relevant to the query, it can mislead the generative model, impairing its ability to accurately identify hallucinations. The study of Wu et al. (2022) highlights this by noting that passages often consist of multiple sentences, each potentially addressing different topics. Modeling such a passage as a single dense vector can be suboptimal. Error analysis of our results confirm the study of Wu et al. (2022), as DPR often retrieved information directly related to specific noun phrases but failed to capture information pertaining to the overall context of the entire sentence. This limitation has lead to incomplete or less relevant retrieval results which correlates to the lower IoU scores for most tested languages as can been seen in Table 1. Here, we observe that FLAN-T5 alone struggles across many languages, with scores of 0.00 or slightly higher for Arabic, Farsi, Hindi, and Chinese. Adding DPR seems to offers minor improvements in some cases, such as Arabic and Chinese, providing increases of 0.05 and 0.04, respectively. However, for several languages,

like Czech and Catalan, combining FLAN-T5 with DPR leads to a decrease in IoU compared to using FLAN-T5 alone. For Farsi, the IoU remains the same at 0.00. For all languages, our FLAN-T5 setup fails to improve on the baseline scores. For the FLAN-T5 with DPR setup, Italian stands out as an exception, as it achieves an IoU identical to the baseline (0.28). This shows that only when testing the Italian dataset for hallucinations the DPR component was beneficial. Notably, scores for Italian are consistently high across all participating systems, indicating that the task may be inherently easier in Italian rather than reflecting an intrinsic advantage of this specific system for the language.

Additionally, the system's performance falls below the "mark all" baseline across all evaluated languages. Error analysis further supports the conclusion that a more generous span detection strategy could have led to improved results. However, when changing the prompt template in Figure 2 to be more generous, the system failed to achieve competing results.

4.3 Error Analysis

When analyzing the English textual output of the FLAN-T5 model, its performance varied. The model sometimes accurately detected hallucinations and maintained strong alignment with the content. However, it struggled with identifying hallucinations in long and complex outputs. FLAN-T5 was unable to produce multiple spans and often failed to label any hallucination at all. Additionally, information loss occurred during the conversion of FLAN-T5's output into hard labels, particularly due to the overlap detection segment of the system. Even when the model successfully identified hallucinations, some details were lost in the hard labeling process. As a result, the system's overall scores remained low. Notably, the model performed best when detecting hallucinations involving names of people or places. An example can be found in the appendix as Table 2.

4.4 Limitations

Languages that use non-alphabetical characters, such as Arabic, Farsi, and Chinese, do not perform well with this system. However, the FLAN-T5 + DPR system still attempted to detect some spans, suggesting that it is not entirely incapable of processing these languages, though its effectiveness is limited. The basis for this observation could be the model's tokenization and embedding process, which may not be well-suited for non-alphabetical scripts. Notably, overlap detection was minimal, indicating that the model struggled to correctly identify shared spans. Improving overlap detection could have led to better overall scores by enhancing the system's ability to capture relevant spans more accurately. For example, The overlap detection did not account for semantic similarity or minor textual differences which could have significantly affected the precision of the span detection. Furthermore, FLAN-T5 nor the overlap detection were able to capture multiple hallucination spans, outputting only a single span of hard labels for each detected hallucination. This limitation led to inaccurate detection, particularly when hallucinations were distributed across different parts of the text. Next to that, this study focused solely on the use of the FLAN-T5 model and did not explore other models that might have been more effective for hallucination span detection. Examining alternatives, such as GPT-style models or other instruction-tuned architectures, could have provided a more comprehensive evaluation of the system's approach.

5 Conclusion

This study explored hallucination span detection as part of the SemEval-2025 Mu-SHROOM task using RAG with the FLAN-T5 model. This approach integrated DPR with generative capabilities to identify hallucination spans. However, the system underperformed across all languages compared to the "mark-all" baselines. Notably, the removal of the RAG component led to improved performance, highlighting fundamental challenges with the retrieval mechanism's contextual relevance. The findings underscore the importance of robust retrieval mechanisms that can capture comprehensive contextual information. Future work could explore using different generative models, running detailed tests on the parts of the RAG system, and studying how language differences affect performance. Improving overlap detection could also help the system better identify hallucination spans. By working on these areas, RAG could become a more reliable method for detecting hallucinations.

GUIR at SemEval-2025 Task 4: Adaptive Weight Tuning with Gradual Negative Matching for LLM Unlearning

Hrishikesh Kulkarni, Nazli Goharian, Ophir Frieder

Information Retrieval Lab
Georgetown University, Washington DC, USA
first@ir.cs.georgetown.edu

Abstract

Machine Unlearning for Large Language Models, referred to as LLM Unlearning is getting more and more attention as a result of regurgitation of sensitive and harmful content. In this paper, we present our method architecture, results, and analysis of our submission to Task4: Unlearning sensitive content from Large Language Models. This task includes three subtasks of LLM Unlearning on 1) Long Synthetic documents, 2) Short Synthetic documents, and 3) Real Training documents. Getting rid of the impact of undesirable and unauthorized responses is the core objective of unlearning. Furthermore, it is expected that unlearning should not have an adverse impact on the usability of the model. In this paper, we provide an approach for LLM unlearning that tries to make the model forget while maintaining usability of the model. We perform adaptive weight tuning with Gradient Ascent, KL minimization and Gradual Negative Matching loss functions. Our submission balances retain and forget abilities of the model while outperforming provided benchmarks.

1 Introduction

The explosion of information with learning mechanisms trying to capture data from every corner raises serious privacy concerns. Comprehensive data privacy laws require commitment to protect sensitive and personal information. The legal mandate in the form of the European Union's General Data Protection Regulation, the California Consumer Privacy Act, raises serious concerns with respect to the results produced by machine learning mechanisms and data sets used for learning. Basically, large language models (LLMs) use large datasets to learn and memorize those data and regurgitate information when asked about it (Carlini et al., 2021). However, that might include very sensitive information, such as personally identifiable information (PII) or harmful information. Regurgitation of such copyrighted or harmful information poses some serious legal and ethical issues that make the use of LLM in practical real-life applications questionable. A variety of methods have been proposed to address LLM limitations (Kulkarni et al., 2023, 2024) but have not addressed regurgitation of sensitive data. One of the rudimentary solutions to handle this issue is retraining the model when any of such outcomes are detected. This could result in retraining the model again and again. This is simply very expensive and impractical when it comes to real life scenarios (Thudi et al., 2022). These practical limitations of re-training further resulted in increasing interest in unlearning LLMs. In short, taking Generative AI to a safe and legal level, demands LLM unlearning.

SemEval-2025 Task 4 of 'Unlearning sensitive content from Large Language Models' deals with LLM unlearning on three types of documents. Subtask 1 is on long form synthetic creative documents covering different genres. Subtask 2 is on short form synthetic biographies that contain personally identifiable information (PII). PII includes names, contact details, SSN, and addresses. Subtask 3 is on real documents sampled from the target model's training dataset. This task releases forget and retain sets along with finetuned LLMs inorder to unlearn.

In our submission, to address the unlearning problem, we introduce adaptive weight tuning with two-stage deviation-based loss functions for unlearning. The approach proposed in this submission performs adaptive weight modifications to losses from specifically chosen set of unlearning loss functions to determine final loss value. We first performs a detailed study of loss functions in the literature to determine the most suited and effective ones for the task of LLM unlearning. We then define a formulation to adjust the weights effectively and tune them with each iteration contributing to the final loss in each iteration. Our submission

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1152–1158

considers Gradient Ascent on forget set, KL divergence on retain set, and most importantly Gradual Negative Matching (GNM) (Kulkarni et al., 2025), which is performed on gradual negative results that are systematically generated to make the model forget the forget set. The use of weighted sum of Gradient Ascent loss, KL divergence loss, and GNM loss in each iteration and adaptive weighting separate our submission from other approaches in the literature and provided benchmarks. This achieves the unique objective where the weights of the loss function on the retain set go on increasing and that of the loss function on the forget set go on decreasing with each iteration. This approach makes sure to free the method from the catastrophic collapse and maintains usability of the model while achieving the unlearning objective. We compare the results with the benchmarks provided by the task organizers and show that our submission outperforms them.

Our contributions are as follows.

- We present a detailed study of loss functions used for LLM unlearning.
- We present adaptive weights formulation for Gradient Ascent, KL divergence, and GNM for LLM unlearning.
- We report results of our submission which outperform the provided benchmarks.
- We also provide analysis of results and pointers for further improvements.

2 Related Work

The efforts to make LLM more applicable resulted in increased research efforts in the area of LLM unlearning. This is mainly to address concerns related to trustworthiness (Lu et al., 2022), fairness, copyright, and privacy (Yu et al., 2023; Eldan and Russinovich, 2023), and sensitive knowledge. Previous unlearning approaches used mainly alignment techniques to achieve the unlearning objective (Liu et al., 2024). Such techniques aim to deliver expected results for specific inputs. Gradient Ascent is basically the retrogression of Gradient Descent learning (Jang et al., 2023). But it results in poor retention. This led to efforts to improve retainability. With this objective, the Gradient Ascent approach is combined with methods that could provide higher retention. Rather than simply applying Gradient Ascent, use of Gradient Ascent on the forget set is combined with Gradient Descent on retain set (Liu et al., 2022). The Gradient Ascent-based unlearning comes with the challenge of catastrophic collapse resulting in serious harm to model usability (Liu et al., 2024). This seriously limits the usability of this approach. To counter this issue, other approaches are proposed to use on retain set. One of such approaches is the use of the KL divergence term on retain set (Yao et al., 2023). The objective was to make the model forget what is expected to forget and retain what is already learned useful information. This led to efforts where multiple combinations of Gradient Ascent, Gradient Descent, and KL divergence were used (Chen and Yang, 2023). Further, in order to obtain the best retain-forget tradeoffs Gradual Negative Matching (GNM) was proposed (Kulkarni et al., 2025). GNM is a two-stage approach where the first stage involves generation of gradual negative outputs for forget set inputs. While the second stage matches these input, generated output pairs through Gradient Descent.

Additionally, in LLM unlearning it is necessary to have a relevant benchmark and proper mechanisms for evaluations. Furthermore, the benchmark needs to be specific to the application and context. This led to different benchmarks. Some of such popular benchmarks include harmful content (Ji et al., 2023), copyrighted books (Eldan and Russinovich, 2023), biographies (Maini et al., 2024), PII, and creative documents (SemEval'25-Task4). A FR-rouge based evaluation is proposed to measure the effectiveness of unlearning models (Kulkarni et al., 2025).

In general, having sensible handling of sensitive information where the legal and ethical violations by LLM regurgitation of sensitive information could be avoided poses a need for better LLM unlearning methods. With this need in focus, in this submission, we propose a method which comprises of Gradient Ascent, KL divergence and Gradual Negative Matching loss functions along with adaptive weight tuning.

3 Data and Setting

The SemEval 2025 task 4 of 'Unlearning sensitive content from Large Language Models' (SemEval'25-Task4; Ramakrishna et al., 2025a,b) has released forget and retain sets for both question-answering and sentence completion across the three subtasks of synthetic long, synthetic short

and real training documents. They have also released the train and validation parts of this data. Additionally, they also provided fine-tuned open source LLM OLMo-7B-0724-Instruct-hf (Groeneveld et al., 2024), trained to memorize documents from three document types. The first one contains long synthetic creative documents. They include different genres. While the second one has short synthetic biographies where fake personal information is present. This includes PII with fake names, phone number, social security numbers, email and home addresses. The third type is a sample of real documents used for training the original LLM.

Evaluation is performed across three metrics namely: Task-specific regurgitation rates measured using rouge-L and exact matching scores, membership inference attack (MIA) score and model performance on MMLU benchmark. Further, a threshold of 75% of pre-unlearning checkpoint is placed on MMLU score to maintain a minimum model utility. Finally, using arithmetic mean, a final aggregate score is calculated from the above three metrics. For calculating task-specific regurgitation rate, rouge-L scores are evaluated for sentence completion and exact matching scores are evaluated for question answering on both forget and retain sets across the three subtasks. The final task-aggregate is determined by considering harmonic mean of the six retain set scores and six inverted (1-score) forget set scores. For calculating MIA scores a sample of member and non-member data is released. Final MIA score is defined as $1-|\text{mia loss auc score}-0.5|*2$. The MMLU score is calculated on the MMLU benchmark consisting multiple choice questions on 57 STEM subjects. The objective is to develop an unlearning method that effectively unlearns information in the Forget set without affecting model usability i.e. with minimal model degradation.

4 Loss Function Components

Gradient Descent is the most common choice for fine-tuning LLMs. Gradient Descent as shown in Equation 1 is based on cross-entropy loss summed over all tokens in the output sequence. Here, we note that the cross entropy is calculated only for tokens in output y and not for input x.

$$L_{GD}(S,\theta) = \sum_{(x,y)\in S}\sum_{i=1}^{|y|} CE(f_\theta(x, y_{<i}), y_i) \quad (1)$$

4.1 Gradienst Ascent

Gradient Ascent tries to reverse the effects of Gradient Descent on the LLM by negating the calculated loss before back-propagation as shown in Equation 2.

$$L_{GA} = -L_{GD} \quad (2)$$

The Gradient Ascent loss is calculated on the forget set input output pairs as it is to be unlearned. This is evident in Equation 3 where θ is the LLM being unlearned. FS is the forget set and RS is the retain set.

$$Loss = L_{GA}(FS,\theta) \quad (3)$$

4.2 Gradient Difference

Gradient Difference (see Equation 4) considers both Gradient Ascent on forget set and Gradient Descent on retain set in order to unlearn forget set content while maintaining model usability on the retain set.

$$Loss = L_{GA}(FS,\theta) + L_{GD}(RS,\theta) \quad (4)$$

4.3 KL Divergence

KL Divergence between two LLMs θ' and θ is calculated using the output probability distributions of the two models for given inputs as shown in Equation 5. This KL divergence is minimized inorder to make θ outputs more like those of θ' for the same input.

$$L_{KL}(S,\theta',\theta) = \sum_{(x,y)\in S}\sum_{i=1}^{|y|} KL(f_{\theta'}(x, y_{<i})||f_\theta(x, y_{<i})) \quad (5)$$

4.4 Other Combinations

Prior research efforts have underlined the effectiveness of unlearning by combining the above loss functions. Chen and Yang proposed combining Gradient Ascent on forget set, Gradient Descent on retain set and KL minimization on both forget and retain sets. The final loss is a weighted sum of above terms as shown in Equation 6. Here, ω_j denotes the weight values for respective loss functions.

$$\begin{aligned} Loss = \omega_1 \cdot L_{GA}(FS,\theta) - \omega_2 \cdot L_{KL}(FS,\theta',\theta) \\ + \omega_3 \cdot L_{GD}(RS,\theta) + \omega_4 \cdot L_{KL}(RS,\theta',\theta) \end{aligned} \quad (6)$$

Another approach was proposed by Yao et al. which introduced Random Matching. Along with

Algorithm	Aggregate	Task Aggregate	MIA Score	MMLU Average
~~Gradient Ascent~~	~~0.394~~	~~0.000~~	~~0.912~~	~~0.269~~
Gradient Difference	0.243	0.000	0.382	0.348
~~KL Minimization~~	~~0.395~~	~~0.000~~	~~0.916~~	~~0.269~~
Negative Pref. Optimization	0.188	0.021	0.080	0.463
Our submission (val)	0.267	0.429	0.000	0.373
Our submission (test)	**0.308**	**0.433**	0.000	**0.492**

Table 1: Results of the provided benchmarks and our submission across the metrics of Task Aggregate, MIA score and MMLU Average score. We note that our submission leads to the best overall Aggregate score when compared to the baselines. The ~~striked~~ methods lead to MMLU Average scores below the threshold (75% of the pre-unlearning benchmark) and are hence disqualified.

Gradient Ascent on forget set and KL minimization on retain set they also perform Gradient Descent on forget input and randomly matched output pairs. This is shown in Equation 7 where Y^{rdn} is a set of random outputs from retain set. For slower progress towards catastrophic collapse minimizing Negative Preference Optimization loss was also proposed (Zhang et al., 2024).

$$Loss = \omega_1 \cdot L_{GA}(FS, \theta) + \omega_2 \cdot L_{KL}(RS, \theta', \theta) + \omega_3 \cdot \sum_{(x,)\in F} \frac{1}{|Y^{rdn}|} \sum_{y \in Y^{rdn}} \sum_{i=1}^{|y|} CE(f_\theta(x, y_{<i}), y_i) \tag{7}$$

4.5 Gradual Negative Matching

Gradual Negative Matching is a two stage approach which first involves generating gradual negative outputs and then match these outputs to respective forget set inputs. This matching is performed along with Gradient Ascent on forget set and KL minimization on retain set as shown in Equation 8. Here, $Y^{gn}[x]$ denote the gradual negative outputs generated with respect to the input x. The $Loss_{GNM}(x, Y^{gn})$ term in Equation 8 is defined in Equation 9. For example, a question requesting a person's email address would be matched with similar but gradually different email addresses.

$$Loss = \omega_1 \cdot L_{GA}(FS, \theta) + \omega_2 \cdot L_{KL}(RS, \theta', \theta) + \omega_3 \cdot \sum_{(x,)\in F} \frac{1}{|Y^{gn}[x]|} Loss_{GNM}(x, Y^{gn}) \tag{8}$$

$$Loss_{GNM}(x, Y^{gn}) = \sum_{y \in Y^{gn}[x]} \sum_{i=1}^{|y|} CE(f_\theta(x, y_{<i}), y_i) \tag{9}$$

5 Adaptive Weight Tuning

We consider a weighted sum of Gradient Ascent loss, KL divergence loss and GNM loss for each iteration as shown in Equation 8. We perform adaptive weight tuning by making each weight value a function of the number of iterations depending upon the type of loss. We want the weight of loss functions on the retain set to go on increasing while the weight of loss functions on the forget set to go on decreasing with increasing number of iterations. This ensures an increased focus on model usability in the latter iterations after unlearning is performed to some extent. We determine ω_1 and ω_3 using Equation 10 where we go on decreasing the weight with increasing number of iterations i. On the other hand, we determine ω_2 using Equation 11 where we go on increasing the weight with increasing number of iterations i. Here k is the tuning constant and α and β are initial weight values.

$$\omega_1 = \alpha - \frac{i}{k} \tag{10}$$

$$\omega_2 = \beta + \frac{i}{k} \tag{11}$$

6 Experiments

We perform unlearning and save model at every 100 iterations to understand the forget and retain set regurgitation with respect to unlearning iterations. We use the provided validation set to determine the optimal number of iterations in the final submission. We also determine input output lengths of the forget and retain sets in the unlearning data to analyze the results further with respect to input length. We plot the regurgitation rougeL scores for each subtask for both question answering and sentence completion to analyze subtask based regurgitation. Gradient Ascent and KL Minimization are compo-

Left: Question Answering, Right: Sentence Completion

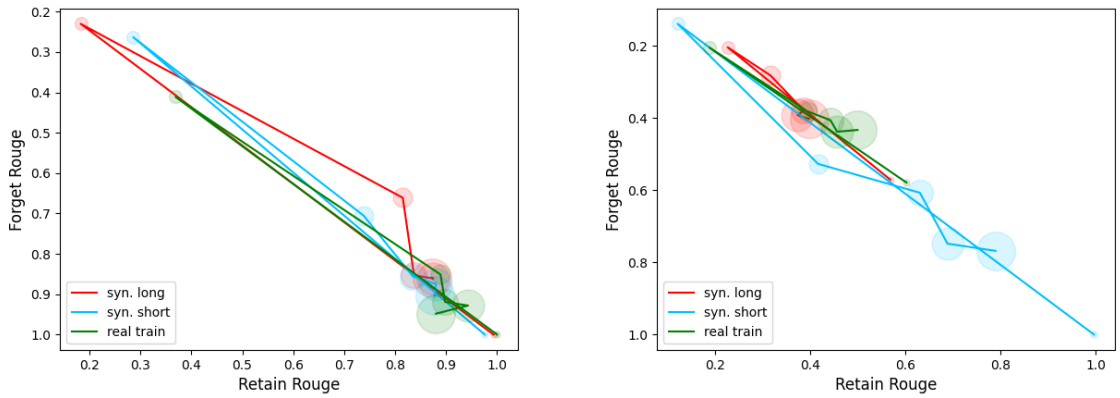

Figure 1: Forget and Retain RougeL performance of our submission on the validation set with increasing number of training batches. Points are plotted after every 100 batches up to 600. Increasing size of points denotes a higher number of batches. In the above plots we can observe a trade-off between Forget and Retain performance. Further, we also note that our submission performs well in all three subtasks namely: synthetic long, synthetic short and real training documents shown by different colors. Most importantly, our submission does not lead to catastrophic collapse of the model during unlearning.

nents of our submission and their respective results represent the ablation study.

7 Results and Analysis

As evident in Table 1, our submission on the test set leads to a Task Aggregate score of 0.433 and MMLU Average score of 0.492 making the overall Aggregate score of 0.308. While on the validation set it leads to a Task Aggregate score of 0.429 and MMLU Average score of 0.373 making the overall Aggregate score 0.267. On the other hand, the provided benchmark of Gradient Difference leads to MIA score of 0.382 and MMLU Average score of 0.348 resulting in an overall Aggregate score of 0.243. Also, Negative Preference Optimization leads to Task Aggregate score of 0.021, MIA score of 0.080 and MMLU Average score of 0.463 resulting in an overall Aggregate score of 0.188. Hence, we can infer that our submission clearly outperforms Gradient Difference and Negative Preference Optimization benchmarks.

On the other hand, Gradient Ascent leads to MIA score of 0.912 and MMLU Average score 0.269, resulting in an overall Aggregate of 0.394. And, KL Minimization leads to MIA score of 0.916 and MMLU Average score of 0.269 resulting in an overall Aggregate of 0.188. Here, we note that both Gradient Ascent and KL Minimization lead to an MMLU Average of 0.269 which is below 75% of pre-unlearning model MMLU threshold (0.371). Hence, these models are discarded because of the highly degraded utility of the unlearned model.

We note a trade-off between Task Aggregate and MIA scores, and decide to prioritize Task Aggregate giving importance to addressing regurgitation and maximizing final Aggregate score. Further analysis as evident in Figure 1 show that our submission does not lead to catastrophic collapse i.e. complete degradation of model. It is also evident that our submission results in significant unlearning of the model but at the same time a trade-off with retain effectiveness is observed. We also note that our proposed approach leads to better performance than the benchmarks specifically on the input output pairs of shorter length i.e. question answering and short synthetic documents.

8 Conclusion

LLM unlearning has gained importance due to GDPR and CCPA laws in Europe and United States respectively. Further, regurgitation of sensitive and harmful content is a violation of ethics and moral values. In the paper, we present a detailed architecture of our submission to the SemEval 2025 Task4: 'Unlearning sensitive content from Large Language Models.' We show that our submission outperforms the provided benchmarks. Further, we also show that our submission performs unlearning while maintaining above threshold model usability while avoiding catastrophic collapse.

Abstract

Fact-check retrieval plays a crucial role in combating misinformation by ensuring that claims are accurately matched with relevant fact-checks. In this work, we present a hybrid retrieval pipeline that integrates lexical and semantic retrieval models, leveraging their complementary strengths. We evaluate different retrieval and reranking strategies, demonstrating that hybrid ensembling consistently outperforms individual models, while reranking provides only marginal improvements.

1 Introduction

Social media has transformed the way information is shared by enabling instant, unfiltered access to news and various perspectives. Unlike traditional media, it allows anyone to publish content without verification, making it more difficult to distinguish between true and misleading claims (Hale et al., 2024). The traditional approach of manual fact-checking has proved its reliability in providing high-quality results, however, it lacks the scalability to address the volume and speed of online information spread. The amount of data is rapidly growing as the same misinformation is often spread across different platforms while slightly altered in format, detail, length, or even language. It is often the case that the users are unaware of the veracity of the claims, especially in non-English contexts where fact-checking resources may be limited or less accessible (Balalau et al., 2024; Kazemi et al., 2021b). This highlights the need to develop and automate fact-checking systems to help maintain the accuracy and reliability of information shared online (Panchendrarajan and Zubiaga, 2024).

SemEval-2025 Shared Task 7 (Peng et al., 2025) tackles the challenge of multilingual and crosslingual Previously Fact-Checked Claim Retrieval (PFCR) (Pikuliak et al., 2023), a critical task in combating misinformation across languages. The task is divided into two subtasks: monolingual and crosslingual retrieval. In the monolingual subtask, the search space is restricted to fact-checked claims in the same language as the query claim. In contrast, the crosslingual subtask allows retrieval across multiple languages, enabling corresponding fact-checks in any language to be retrieved for a given query. The monolingual subtask includes data for Arabic, English, French, German, Malay, Portuguese, Spanish, and Thai, with Polish and Turkish added to the test set.

This paper explores the effectiveness of hybrid retrieval architectures for monolingual and crosslingual PFCR. We focus on zero-shot retrieval (Shen et al., 2024; Thakur et al., 2021), avoiding fine-tuning to ensure general applicability across diverse topics, languages, and platforms. By leveraging pre-trained models, our approach maintains competitive performance with minimal resource demands, demonstrating their effectiveness in multilingual settings without task-specific adaptations.

In both subtasks, we achieved our best results with a retriever ensembler, ranking 8th out of 28 teams in the monolingual and 12th out of 29 teams in the crosslingual task with over 177 participants and 1400 submissions.

The remainder of this work is structured as follows: we introduce the task and give a fact-checking pipeline overview in Sec. 2. Sec. 3 describes the modules of our system, while Sec. 4 presents key experiments and evaluation results that guided our design choices. Lastly, Sec. 5 summarizes our findings and outlines directions for future work.

2 Background

A survey on monolingual, multilingual, and cross-lingual research (Panchendrarajan and Zubiaga, 2024) outlines the key components of an automated fact-checking pipeline: claim detection, claim prioritization, retrieval of evidence, veracity prediction, and explanation generation (Nakov et al.,

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1159–1167

2021; Balalau et al., 2024). In addition to these core steps, there is an additional component responsible for retrieving previously fact-checked claims. This component identifies claims that have already been verified, linking them to existing fact-checks. Aligning similar claims across languages can improve fact-checking efficiency and combat misinformation more effectively. This task is commonly referred to as verified claim retrieval (Barrón-Cedeño et al., 2020) or claim matching (Kazemi et al., 2021a), though it is also known as PFCR (Pikuliak et al., 2023) or fact-checked claim detection (Shaar et al., 2020). In this work, we focus on this retrieval component.

One could argue that the limitation of this task is the assumption of the existence of a fact-checked article for a given claim. However, it is important to remember that PFCR is an additional component that aims to create a shortcut in the fact-checking pipeline in case the same, perhaps reformulated, claim reappears online after it has been verified, reducing redundancy and improving response time in tackling misinformation.

MultiClaim dataset (Peng et al., 2025) includes 205,751 fact-checks in 39 languages and 28,092 social media posts in 27 languages. The dataset contains 31,305 verified post-fact-check pairs, with 4,212 being crosslingual. More details on the used dataset are given in Appendix A.

3 System Overview

This section presents the system architecture shown in Figure 1, outlining the key components of the pipeline: (1) Data preprocessing module, (2) Retrieval-ensemble module, (3) Reranking-ensemble module, (4) Evaluation module. Given a collection of fact-checks, our system retrieves the top k relevant fact-checks for any given claim.

3.1 Data Preprocesing Module

The data preprocessing module prepares claims and fact-checks for downstream retrieval and reranking. For lexical models, preprocessing focuses on cleaning and normalizing the text, while for semantic models, the text is enriched with additional contextual descriptions.

3.2 Retrieval-Ensemble Module

The retrieval-ensemble module returns the top k relevant fact-checks for a given claim as an ensemble of lexical and semantic retrievers. Each retriever independently ranks fact-checks based on their similarity to the claim, selecting the most relevant ones from the pool of verified claims. We compare a range of pre-trained retrieval models and select those with the best average performance across languages. We avoid language-specific adaptations and adopt a zero-shot retrieval setup (Shen et al., 2024; Thakur et al., 2021), avoiding model fine-tuning. This approach ensures robustness and applicability across diverse topics, languages, and platforms while minimizing resource demands.

The ensembler balances the strengths of sparse lexical and dense semantic retrievers, ensuring that the lexical model provides high-precision results for explicit term matches while semantic models capture implicit relationships and conceptual similarities.

3.3 Reranking-Ensemble Module

The reranking-ensemble module refines the top candidates obtained from the previous module using a set of cross-encoder rerankers. Each reranker returns its top candidates, which are then aggregated by a final ensembler into the final top 10 results.

Cross-encoders jointly encode claim–fact-check pairs, enabling fine-grained relevance scoring by capturing context-sensitive semantic interactions between the claim and the fact-check. While computationally more intensive, their use is justified at this stage due to a smaller pool of candidates, allowing for higher ranking precision without compromising efficiency.

3.4 Evaluation Module

We use the Success@k (S@k) metric for evaluation, which measures the proportion of claims for which at least one relevant fact-check appears within the top-k retrieved results.

4 Experiments and Results

4.1 Preprocessing Module

Preprocessing for Lexical Models. We evaluated BM25 retrieval using S@10 scores on both original-language and English-translated text without preprocessing. The translated version outperformed the original (0.5569 vs. 0.5171), likely due to greater linguistic consistency with fact-check sources. To further improve performance, we developed a preprocessing pipeline including URL and HTML entity removal, stop-word and punctuation

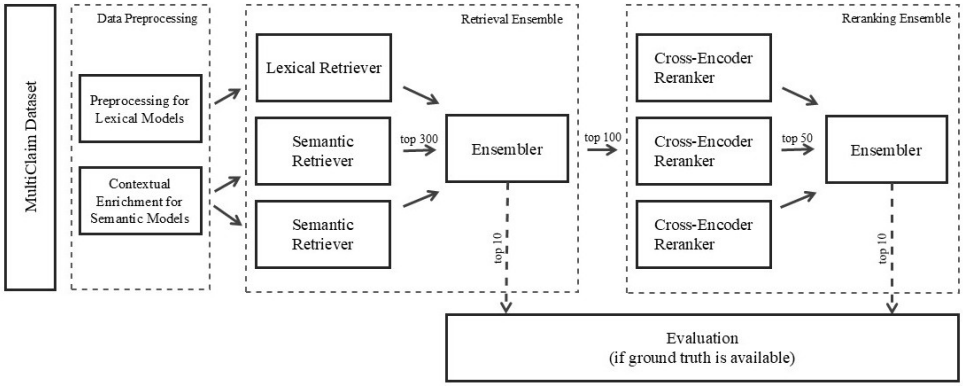

Figure 1: System architecture overview

filtering, Unicode and case normalization, character repetition reduction, whitespace standardization, emoji and date normalization, and lemmatization (Appendix C). Applying our full preprocessing pipeline led to a substantial improvement: S@10 increased to 0.7851 on original text and 0.7967 on translations.

Contextual Enrichment for Semantic Models. We optimized the input formatting, finding that explicitly defining components of fact-checks and posts significantly improved retrieval accuracy, enhancing the model's ability to understand contextual relationships between elements.

The best-performing format was:

> The following claim was posted: *OCR+text*, posted on *date*. The content is labeled as: *verdict*.
>
> This is a fact-checked claim: *claim*, with the title *title* posted on *date*.

Additionally, we evaluated simpler formats, such as concatenating components without descriptions and prefixing them with their names only, but both approaches led to lower retrieval accuracy, likely due to the lack of contextual guidance. We compare the retrieval performance of semantic models with the different input formats using S@100 in Table 1.

Model/Setting	No Descriptions	Prefixing	Contextual Guidance
E5	0.9440	0.9555	0.9586
BGE	0.9471	0.9531	0.9537

Table 1: Average S@100 scores for E5 and BGE models using different input formats and English-translated text

4.2 Retrieval-Ensemble Module

In the retrieval-ensemble module, the top 300 candidate fact-checks are retrieved using each retriever model and then aggregated into the top 100 candidates using an ensembler.

4.2.1 Retrievers

For evaluation of retrievers, we report S@100 scores ($k = 100$) rather than S@10, as the retrieval stage is responsible for producing a larger candidate set of fact-checks, which is later refined. Thus, performance on a broader set is more indicative of retrieval effectiveness at this stage.

Lexical models. BM25 is a widely used baseline in modern information retrieval (IR) research (Barrón-Cedeño et al., 2020; Nakov et al., 2022; Shaar et al., 2020; Aarab et al., 2024), making it a natural choice for our lexical retrieval component.

Model	Avg S@100	Model size (params)
Multilingual-E5-Large-Instruct	0.9330	560M
BGE-Multilingual-Gemma2	0.9293	9.24B
NV-Embed-v2	0.9201	7.85B
GTR-T5-Large	0.9019	1.24B
BGE-M3	0.8731	568M
MiniLM-L6-v2	0.7947	22.7M
stella_en_1.5B_v5	0.5288	1.54B
XLM-RoBERTa-Large	0.1467	561M

Table 2: Retriever model comparison on S@100 using original languages on the monolingual data

Semantic models. To identify the most effective retrievers in the zero-shot setting, we evaluated several pre-trained models using S@k scores on the training set. The results, shown in Table 2, informed our selection.

Among the evaluated models, `multilingual-E5-Large-Instruct`[1] (E5)

[1] https://huggingface.co/intfloat/multilingual-e5-large-instruct

was the top performer, achieving the highest average S@100 score of 0.9330. Despite its modest size (560M parameters), E5 outperformed the performance of much larger models, making it an efficient and effective choice. `BGE-Multilingual-Gemma2`[2] (BGE) followed closely with an average S@100 score of 0.9293. However, it comes at a significantly higher computational cost, with 9.24B parameters — over 16 times the size of E5. We included BGE as a complementary bi-encoder due to its strong performance. However, its latency was notably higher: E5 averaged 0.08 seconds per claim, while BGE required 0.39 seconds.

These findings highlight that larger models do not guarantee better retrieval. Instead, architecture design, training objectives, and multilingual optimization play a more critical role. For real-world deployments, especially in latency-sensitive or resource-constrained settings, mid-sized models like E5 provide an effective balance between retrieval performance and computational efficiency.

4.2.2 Ensembler

Aggregation Function. To combine outputs from multiple retrievers, we evaluated several aggregation strategies: majority voting, exponential decay weighting, and reciprocal rank fusion (RRF). Across both monolingual and crosslingual settings, RRF delivered the best retrieval performance.

In the monolingual setting, RRF achieved an S@100 score of 0.9720, outperforming exponential decay weighting (0.9674) and majority voting (0.9649). Similarly, in the crosslingual setting, RRF led with an S@100 of 0.8967, compared to 0.8897 for exponential decay weighting and 0.8813 for majority voting. Based on these results, we adopted RRF as the aggregation strategy in our final ensemble.

RRF (Cormack et al., 2009) assigns a score to each document d based on the reciprocal value of its rank between different retrievers:

$$R_{\text{score}}(d) = \sum_{r \in R} \frac{1}{k + \text{rank}_r(d)} \quad (1)$$

where R is the set of retrievers, $\text{rank}_r(d)$ is the rank of the document d assigned by the retriever r, and k is a constant added to prevent division by zero.

[2] https://huggingface.co/BAAI/bge-multilingual-gemma2

Retrieval Set Size. We evaluated the ensembler's S@k performance across retrieval set sizes (k = 50, 100, 200, 300, 400) in both monolingual and crosslingual settings to determine its optimal value. Performance improved as k increased, plateauing around k=300. In the monolingual setting, S@k increased from 0.9693 at k=50 to 0.9720 at k=300, with no further improvement beyond that. Similarly, in the crosslingual setting, scores increased from 0.8914 to 0.8970. We selected k=300 as an effective balance between retrieval quality and computational efficiency. The ensembler's robustness at higher k values can be attributed to the RRF aggregation method, which ensures that highly ranked fact-checks remain prioritized while lower-ranked ones have minimal impact.

Ensemble Weighting. We explored ensemble weighting strategies to optimize retrieval performance. Our findings show that assigning a lower weight of 0.5 to the lexical BM25 and a weight of 1.0 to the semantic E5 and BGE improves retrieval effectiveness. This reflects the stronger contribution of semantic retrieval in capturing the relationships between queries and fact-checks, whereas BM25, though effective for keyword matching, benefits more as a complementary component rather than a dominant factor. Experiment details are given in Appendix D.

4.2.3 Retrieval-Ensemble Module Performance

Table 3 compares the performance of retrievers and ensemble configurations. The results show that dense retrievers (E5, BGE) consistently outperform the lexical BM25 in all languages, demonstrating the effectiveness of semantic models. However, the ensemble methods that combine BM25 with dense retrievers show further performance gains, achieving the highest average S@100 scores of 0.9703.

Additionally, we assess the module's effectiveness as a standalone component instead of as an intermediate step in the pipeline using S@10. Table 5 presents a performance comparison between our retrieval-ensemble module and the best-performing baseline model (GTR-T5-Large) from the Multiclaim dataset paper (Pikuliak et al., 2023). Our retrieval-ensemble consistently outperforms the baseline across all languages, improving the average S@10 from 0.82 to 0.9237.

Table 3: Retrieval performance (S@k) using original-language text across models and ensembles on the training set

4.3 Reranking-Ensemble Module

Each reranker in the reranking ensemble module processes the top 100 fact-checks (obtained from the retrieval-ensemble module) and returns its top 50 candidates, which are then aggregated by a final ensembler into the top 10 results.

4.3.1 Rerankers

To select the rerankers for our pipeline, we prioritized models that demonstrated strong zero-shot performance while remaining computationally feasible. We used the MTEB[3] (Massive Text Embedding Benchmark) as a starting reference point and evaluated its leading reranker models.

QWEN (`gte-Qwen2-7B-instruct`[4]), NV (`NV-Embed-v2`[5]), and GRITLM (`GritLM-7B`[6]) were chosen for their strong reranking performance and compatibility with our resource constraints. Their average per-claim latencies were 0.40s (QWEN), 1.23s (GRITLM), and 1.28s (NV). In contrast, the retrievers, E5 (0.08s) and BGE (0.39s), are significantly faster, highlighting the importance of narrowing down the candidate set size during first-stage retrieval to keep reranking computationally feasible, especially in latency-critical or large-scale applications.

Evaluation Setups. We evaluated rerankers in three setups to analyze the impact of language representation and instruction translation: (1) using the original-language text with English task instructions, (2) using English-translated text and instructions, and (3) using the original language text with the task instructions translated into that language. While instruction translation in setup (3) improved performance in some cases, such as with Malay (MSA), where linguistic alignment aided retrieval, other languages, like Thai (THA), experienced performance drops. This suggests that instruction translation is not always beneficial and depends on both the complexity of the language and translation quality. The model performances under the three setups are compared in Table 4.

4.3.2 Reranking-Ensemble Module Performance

Table 4 presents the S@50 and S@10 scores of rerankers and ensembles across languages. GRITLM achieves the highest average S@50 score (0.9541), followed by NV (0.9512) and QWEN (0.9494). The original-language text paired with English task instructions (setup 1) consistently achieved the highest average scores across all three models and was therefore selected for use in the ensemble configurations. Performance on English-translated version (setup 2) shows mixed results across languages. Arabic (ARA) and Thai (THA) benefit the most, suggesting that translation into English can normalize morphologically rich languages, improving retrieval for models trained on English-heavy corpora. However, for others, as French (FRA) and Portuguese (POR), translation yields inconsistent results.

Our full ensemble strategy (QWEN + GRITLM + NV) achieves the highest average S@10 score (0.9202), outperforming pairwise ensembles and the baseline (0.9202 vs. 0.82).

4.4 Effectiveness of Reranking

Despite the expected advantages of reranking, the results in Table 5 indicate that the reranking-ensemble pipeline delivers only marginal improvements in Arabic, English, and French, failing to consistently outperform the retrieval-ensemble approach. Our results demonstrate that hybrid retrieval strategies — combining lexical and dense models — are both more effective and computa-

Table 5: Comparison of retrieval-ensemble and reranking-ensemble approaches with the baseline using S@10

tionally efficient than stacking increasingly complex neural architectures. The limited improvements from reranking suggest that retrieval bottlenecks cannot always be resolved through additional processing, reinforcing the importance of well-designed ensembling over the reliance on increasingly complex models. This highlights that retrieval performance can be optimized efficiently without excessive computational overhead.

4.5 Test Set Performance

For the monolingual submission, we selected the best-performing setup per language, choosing between retrieval-ensemble and reranking-ensemble configurations. We used the retrieval-ensemble for Arabic, Malay, German, Thai and Turkish, and the full reranking-ensemble pipeline for English, French, Spanish, Portuguese and Polish. For crosslingual retrieval, we used the retrieval-ensemble setup. On the test set, our approach outperformed the organizer's baseline in both monolingual (S@10: 0.93 vs. 0.84) and crosslingual retrieval (S@10: 0.75 vs. 0.59). The top leaderboard model achieved 0.96 and 0.86, respectively.

4.6 Error Case Analysis

We analyzed retrieval errors in two scenarios: when individual retrievers failed but the ensembler succeeded, and when the ensembler was unsuccessful as well. In the first case, retrievers often identified relevant fact-checks but ranked them too low, favoring semantically related yet incorrect ones. The ensembler overcame this by integrating lexical and semantic cues, demonstrating the strengths of hybrid retrieval. In contrast, failure of ensembler typically involved vague or context-lacking claims, where implicit references made correct retrieval difficult. Overall, retrieval errors arise from limitations in ranking semantically relevant content and handling ambiguity. While ensembling improves robustness, performance remains sensitive to the clarity and specificity of claim formulation.

5 Conclusion

In this work, we show that reranking provides only marginal improvements over hybrid ensembling, while ensembling offers a balance between accuracy and efficiency. By combining strategic ensemble design and zero-shot retrieval, the retrieval-ensemble provides a scalable and effective solution for multilingual fact-checking. Its simplicity leaves room for further enhancements, such as k-shot retrieval or fine-tuning with fact-check data. Future work could explore improving retrieval robustness for ambiguous claims, alternative architectures, and adapting retrieval strategies based on language or claim complexity.

A MultiClaim Dataset

MultiClaim dataset (Peng et al., 2025) was created to overcome the lack of data for crosslingual and non-English PFCR. This task was previously done mostly in English while many other languages or even language families were not considered. The new dataset contains 205,751 fact-checks in 39 languages and 28,092 social media posts in 27 languages. With the help of professional fact-checkers, 31,305 pairs of posts and corresponding fact-checks were gathered, out of which 4,212 pairs are crosslingual, meaning that the language of the post and the fact-check is different. The organizers provided datasets for the training, development and testing stages. Three datasets are provided for each stage; fact checks, social media posts, and mappings between them. Each post is paired with at least one fact-check. The use of any external data apart from the Shared Task Dataset to prepare the submission was not allowed, but using pre-trained language models and data augmentation of the Shared Task Dataset was.

B Implementation Details

We used the Massive Text Embedding Benchmark (MTEB)[7] as a starting reference point for the choice of retriever and reranker models. We implemented a BM25 model with BM25Okapi[8]. For cross-encoder implementation, we used Sentence-Transformer[9] library, and for bi-encoders AutoModel from transformers library[10].

Due to the large sizes of the models, we used mixed precision to improve efficiency, reduce memory footprint, and accelerate computation.

Inference was conducted on NVIDIA GeForce GTX 1080 Ti or NVIDIA TITAN RTX GPUs.

C Multilingual Preprocessing for Lexical Models

The pipeline standardizes case and whitespace, removes URLs, HTML entities, punctuation, digits, and normalizes Unicode to ASCII for consistency. While we experimented with transcribing emojis into text, removing them consistently improved retrieval. Repeated characters are collapsed, stopwords are eliminated using language-specific resources, and dates are converted to a standardized (month day, year e.g. February 12, 2025) format. The most impactful step was ensuring the correct matching of inflected words through lemmatization. We used WordNetLemmatizer[11] for English and Simplemma[12] for other languages. We also evaluated stemming, but it reduced retrieval performance likely due to overly aggressive reductions that produced non-standard word forms which no longer matched fact-checked claims, weakening lexical alignment. While digit removal had a minimal effect, date normalization improved retrieval. We evaluated grammar and spell correction; however, reduced performance due to overcorrection altering key terms.

D Ensemble Weighting

BM25	E5	BGE	S@100
1.0	1.0	1.0	0.8947
0.5	1.0	1.0	0.8967
0.25	1.0	1.0	0.8940
0.5	2.0	1.0	0.8856
0.5	1.0	2.0	0.8947

Table 6: Comparison of ensemble weighting schemes on S@100 performance in the crosslingual setting

The results in Table 7 show that reducing BM25's weight while maintaining higher weights for semantic models in the monolingual setting leads to improved retrieval effectiveness. Specifically, assigning a weight of 0.5 to BM25 and 1.0 to both E5 and BGE achieves the highest average S@100 score of 0.9720, slightly outperforming the equal-weighted (1.0, 1.0, 1.0) ensemble, which scored 0.9718. Further reducing BM25's weight to 0.25 (0.25 BM25 + 1.0 E5 + 1.0 BGE) resulted in a slight performance drop with S@100 of 0.9711, indicating that BM25 still provides useful lexical matching and should not be completely minimized. Interestingly, increasing the weight of E5 to 2.0 (0.5 BM25 + 2.0 E5 + 1.0 BGE) or BGE to 2.0 (0.5 BM25 + 1.0 E5 + 2.0 BGE) led to slightly lower performance (0.9701 and 0.9694, respectively), suggesting that the ensemble benefits from the strengths of each semantic model, rather than favouring one over the other.

Table 6 compares ensemble weighting schemes on S@100 performance in the crosslingual setting. Consistent with monolingual results, reducing

BM25's weight while maintaining higher weights for semantic models improved performance.

E BM25 Hyperparameters

To approximate the optimal hyperparameters b and k_1 for the BM25 model, we conduct a grid search. The optimal value for b is 0.85 and for k_1 it is 1.5 which means a higher normalization of the field length and slower term frequency saturation in comparison to the default settings.

BM25	E5	BGE	ARA	DEU	ENG	FRA	MSA	POR	SPA	THA	AVG
1.0	1.0	1.0	0.9726	0.9742	0.9497	0.9731	0.9805	0.9632	0.9651	0.9962	0.9718
0.5	1.0	1.0	0.9708	0.9742	0.9509	0.9722	0.9825	0.9632	0.9662	0.9962	**0.9720**
0.25	1.0	1.0	0.9691	0.9742	0.9513	0.9722	0.9805	0.9608	0.9641	0.9962	0.9711
0.5	2.0	1.0	0.9657	0.9649	0.9521	0.9722	0.9825	0.9616	0.9655	0.9962	0.9701
0.5	1.0	2.0	0.9657	0.9719	0.9477	0.9749	0.9766	0.9592	0.9631	0.9962	0.9694

Table 7: Ensembler performance comparison on S@100 based on different ensemble weighting schemes in the monolingual setting

Tarbiat Modares at SemEval-2025 Task 11: Tackling Multi-Label Emotion Detection with Transfer Learning

Abstract

The SemEval-2025 Task 11 addresses multi-label emotion detection, classifying perceived emotions in text. Our system targets Amharic, a morphologically complex, low-resource language. We fine-tune LaBSE with class-weighted loss for multi-label prediction. Our architecture consists of: (i) text tokenization via LaBSE, (ii) a fully connected layer with sigmoid activation for classification, and (iii) optimization using BCEWithLogitsLoss and AdamW. Ablation studies on class balancing and data augmentation showed that simple upsampling did not improve performance, highlighting the need for more sophisticated techniques. Our system ranked 14th out of 43 teams, achieving 0.4938 accuracy, 0.6931 micro-F1, and 0.6450 macro-F1, surpassing the task baseline (0.6383 macro-F1). Error analysis revealed that anger and disgust were well detected, while fear and surprise were frequently misclassified due to overlapping linguistic cues. Our findings underscore the challenges of multi-label emotion detection in low-resource languages.

1 Introduction

Emotion detection is a key task in NLP with applications ranging from social media monitoring to mental health and human-computer interaction. Unlike sentiment analysis, it identifies nuanced emotions such as anger, joy, sadness, fear, disgust, and surprise. SemEval-2025 Task 11 (Muhammad et al., 2025a,b) focuses on perceived emotions shaped by cultural and contextual cues.

We tackle this challenge in Amharic, a low-resource and morphologically complex language, by exploring the effectiveness of transfer learning in this setting.

We fine-tune LaBSE (Feng et al., 2020), a multilingual sentence embedding model, using a dropout-enhanced dense layer and BCEWithLogitsLoss. Our method avoids hand-crafted features, instead relying on pre-trained embeddings.

Our decision to focus on Amharic was motivated by both strategic and linguistic considerations. As native speakers of Persian—a low-resource and morphologically rich language—we were naturally drawn to Amharic, which shares similar linguistic challenges and characteristics. Although Persian was not included in the competition's dataset, Amharic was available, and we saw this as an opportunity to engage with a language that, like Persian, is often underrepresented in NLP research. Furthermore, we anticipated that the low-resource nature of Amharic might lead many teams to overlook it, which strengthened our motivation to select it and address the gap.

Despite solid performance on high-confidence emotions, our model struggled with overlapping expressions and class imbalance. It ultimately ranked 14th out of 43 teams.

Code is available at: https://github.com/Amin-Saeidi/SemEval2025-Task11.

2 Background

Emotion detection has been widely explored in NLP, with recent advancements driven by deep learning and transformer-based models. Unlike early lexicon-based approaches (Mohammad and Turney, 2013), modern methods leverage contextual embeddings from models like BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), and XLM-R (Conneau et al., 2020). The SemEval-2025 Task 11 (Muhammad et al., 2025b) aims to advance perceived emotion detection by providing multilingual datasets and a structured evaluation framework. The task consists of three tracks. Track A, Multi-label Emotion Detection, involves assigning zero, one, or two emotion labels to a given text snippet. Track B, Emotion Intensity Estimation, focuses on predicting the intensity of a given emotion.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1168–1173

Track C, Cross-lingual Emotion Detection, aims to transfer knowledge between languages, facilitating emotion recognition across linguistic boundaries.

Our work focuses on Track A, where each text snippet is labeled with multiple emotions as binary values (1 for presence, 0 for absence). This multi-label classification setup poses unique challenges due to emotion co-occurrence and ambiguous expressions. The dataset includes multiple languages, but we specifically study Amharic, leveraging the dataset from Belay et al. (2025), which provides a benchmark for emotion detection in low-resource languages.

Several studies have contributed to advancing multi-label emotion detection. Zhang et al. (2020) introduced a multi-modal framework capturing label dependencies, while Firdaus et al. (2020) proposed a dataset for emotion recognition in dialogues. A comprehensive review by Nandwani and Verma (2021) emphasized the role of cultural context in emotion perception.

Recent research has explored multi-label classification techniques to improve accuracy. Ni and Ni (2024) demonstrated models that effectively capture emotion correlations, while Wang et al. (2023) showed that modeling label dependencies enhances emotion recognition. For low-resource languages, Belay et al. (2025) introduced EthioEmo, highlighting the challenges of applying pre-trained models to Amharic.

For Amharic-specific emotion classification, Bayu et al. (2024) focused on deep learning for analyzing social media comments, while Birara (2024) evaluated LSTM, BiLSTM, CNN, and GRU models for multi-label classification. These studies demonstrate the potential of deep learning but also expose the need for better adaptation of transformer-based models for Amharic.

Our research builds on these foundational works, focusing on low-resource Amharic and applying transfer learning through LaBSE embeddings.

For model training, we utilize publicly available datasets and pre-trained models. Our experiments are based on the dataset *Evaluating the Capabilities of Large Language Models for Multi-label Emotion Understanding* (Belay et al., 2025). For feature extraction and classification, we employ LaBSE, a language-agnostic sentence embedding model, available via Hugging Face's `sentence-transformers/LaBSE` repository.

3 System overview

Our system is based on the Language-agnostic BERT Sentence Embedding (LaBSE) model, a multilingual transformer-based model designed for cross-lingual sentence representations (Feng et al., 2020). Given the nature of the SemEval-2025 Task 11 as a multi-label classification problem, we introduced specific modifications to adapt LaBSE for effective emotion detection. This section outlines our model architecture, preprocessing pipeline, and key challenges, along with the solutions implemented to address them.

3.1 Model Architecture

Our model architecture follows a structured pipeline, as shown in Figure 1. We fine-tuned LaBSE for multi-label classification by adding a fully connected layer atop the transformer encoder. To mitigate overfitting, we incorporated a dropout layer ($p = 0.4$) and applied early stopping based on validation loss. While we experimented with data augmentation and upsampling for class balancing (Section 5), their impact on final performance was minimal. However, dropout and early stopping effectively stabilized training and prevented excessive memorization of majority-class patterns.

The fully connected layer contains 768×6 neurons, where 768 is LaBSE's hidden size and 6 corresponds to the number of emotion categories. A sigmoid activation function outputs probability scores for each label. The architecture generates a contextualized embedding h from an input sentence x using LaBSE, passing it through additional layers to compute the final probability distribution:

$$h = LaBSE(x) \tag{1}$$

$$y = \sigma(Wh + b) \tag{2}$$

where $W \in R^{6\times768}$ is the fully connected layer's weight matrix, $b \in R^6$ is the bias term, and σ represents the sigmoid activation function. This setup enables independent probability estimation for each emotion label, making it well-suited for multi-label classification.

3.2 Loss Function and Optimization

We employed Binary Cross-Entropy with Logits Loss (BCEWithLogitsLoss) for this multi-label classification problem. This loss function computes the error between the predicted probabilities and the true labels. The loss is computed as follows:

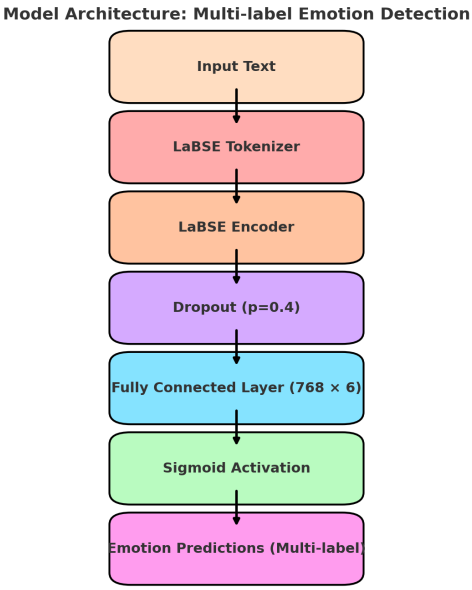

Figure 1: Schematic of our multi-label emotion detection model. The LaBSE encoder generates sentence embeddings, followed by dropout, a fully connected layer, and sigmoid activation for classification.

$$\mathcal{L} = -\sum_{i=1}^{6} [\hat{y}_i \log \sigma(y_i) + (1 - \hat{y}_i) \log(1 - \sigma(y_i))] \quad (3)$$

For optimization, we used the AdamW optimizer (Loshchilov and Hutter, 2019), which decouples weight decay from the optimization process. Unlike the standard Adam optimizer, which applies weight decay directly within the update rule, AdamW applies weight decay independently, preventing unintended updates to the learning rate. This decoupling results in better generalization and faster convergence, especially for transformer-based models, making AdamW a more suitable choice compared to the original Adam optimizer for this task.

3.3 Evaluation Metrics

We used several evaluation metrics to assess the performance of our model, which are well-suited for multi-label classification tasks and provide a comprehensive understanding of model performance. These metrics include Micro F1-score, which aggregates contributions of all classes and calculates the F1-score globally; Macro F1-score, which computes the F1-score for each class independently and averages them; Accuracy, which evaluates the percentage of correctly predicted labels; and the Confusion Matrix, which provides insight into class-wise predictions and misclassifications. Together, these metrics help us understand the overall performance of the system and identify areas where the model may be struggling.

3.4 Addressing Class Imbalance

Class imbalance was a significant challenge, with certain emotion labels underrepresented in the training data. To address this, we employed multiple strategies. First, we used class-weighted BCEWithLogitsLoss, assigning higher weights to underrepresented classes to enhance classification performance.

Additionally, we expanded the dataset using an Amharic sentiment dataset[1] containing approximately 9.4k Amharic tweets. Since it was originally annotated for sentiment analysis rather than multi-label emotion classification, we re-annotated the tweets using large language models (LLMs), specifically DeepSeek (DeepSeek-AI et al., 2025) and ChatGPT.

Due to the lack of publicly available multi-label emotion datasets in Amharic, we employed LLMs as practical tools for semi-automatic annotation. Their multilingual and culturally aware capabilities made them suitable for generating preliminary labels, which were manually reviewed by a trained Amharic educator. These models were not used as evaluators, but solely as bootstrapping tools to expand the training set under limited annotation resources.

Finally, we applied oversampling to improve minority-class representation and balance the emotion categories. The label distributions before and after augmentation and upsampling are presented in Tables 1, 2, and 3.

Table 1: Distribution of Emotion Labels in Main Data - TrainSet

Emotion	Not Exist (0)	Exist (1)
Anger	2360	1188
Disgust	2280	1268
Joy	3000	548
Fear	3439	109
Sadness	2777	771
Surprise	3397	151

[1] https://github.com/liyaSileshi/amharic-sentiment-analysis/tree/main

Table 2: Distribution of Emotion Labels After Data Augmentation - TrainSet

Emotion	Not Exist (0)	Exist (1)
Anger	3062	1574
Disgust	3237	1399
Joy	3997	639
Fear	3729	907
Sadness	3522	1114
Surprise	4298	338

Table 3: Distribution of Emotion Labels After Upsampling - TrainSet

Emotion	Not Exist (0)	Exist (1)
Anger	6891	3474
Disgust	6651	3714
Joy	8721	1644
Fear	10038	327
Sadness	8052	2313
Surprise	9912	453

3.5 Experiments with Alternative Architectures

We compared LaBSE with multilingual alternatives, including XLM-RoBERTa (Conneau et al., 2019) and a SentenceTransformer fine-tuned for Amharic retrieval (Belay et al., 2025). LaBSE outperformed both in F1-score, likely due to its robust cross-lingual representations, and was thus chosen as our final model.

4 Experimental Setup

4.1 Dataset and Splits

For this task, we used the dataset provided by SemEval-2025 Task 11, specifically focusing on the Amharic subset from *SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection* (Muhammad et al., 2025a). The dataset was divided into three splits: the training set contained 3,549 samples, the test set included 1,774 samples, and the validation set consisted of 592 samples. Table 4 presents the distribution of emotion labels across the dataset splits.

During hyperparameter tuning, we trained on the training set and used the validation set for evaluation and parameter selection. For the final model, we excluded the validation set and trained solely on the original training data, evaluating performance on the test set.

Table 4: Distribution of emotion labels across dataset splits

Emotion	Train	Dev	Test
Anger	1188	207	582
Sadness	771	127	355
Joy	549	93	276
Fear	109	22	54
Surprise	151	27	82
Disgust	1268	209	628

4.2 Preprocessing

Preprocessing was minimal, as the LaBSE tokenizer inherently handles multilingual text. We tokenized the input text using the LaBSE tokenizer without additional processing such as lowercasing, punctuation removal, or stopword filtering. The tokenized sequences were padded or truncated to a maximum length of 180 tokens to maintain computational efficiency while preserving meaningful context.

4.3 Model Training and Hyperparameter Tuning

We tuned hyperparameters iteratively based on validation F1-score and accuracy. The final model used a batch size of 64, a sequence length of 180, a learning rate of 1×10^{-5}, and AdamW optimizer with 1×10^{-6} weight decay. Training ran for 11 epochs using BCEWithLogitsLoss and was performed on CUDA.

Hyperparameter tuning was conducted through manual iterative adjustments based on validation performance. While this approach yielded competitive results, future work could explore more systematic tuning methods, such as grid search or Bayesian optimization, to refine parameter selection further.

4.4 External Tools and Libraries

The implementation relied on several external libraries for model training, preprocessing, and evaluation. The `transformers` library from Hugging Face (v4.36.1) was used for model loading and fine-tuning. PyTorch (v2.1.0) was utilized for deep learning computations, while Scikit-learn (v1.3.0) was employed for evaluation metrics such as F1-score, accuracy, and confusion matrices. Additionally, Pandas (v2.1.1) and NumPy (v1.25.0) were used for data handling and numerical computations.

Table 5: Performance metrics of various models on the dev set

Model	Using main data	Add data	Upsampling	Accuracy	F1-score (micro)	F1-score (macro)
LaBSE	Yes	No	No	0.512	0.701	0.652
LaBSE	Yes	Yes	No	0.472	0.673	0.632
LaBSE	Yes	No	Yes	0.478	0.646	0.611
xlm-r-retrieval-am	Yes	No	No	0.433	0.632	0.559
xlm-r-retrieval-am	Yes	Yes	No	0.433	0.632	0.559
xlm-r-retrieval-am	Yes	No	Yes	0.425	0.627	0.586
xlm-roberta-base	Yes	No	No	0.449	0.637	0.586

5 Results

5.1 Error Analysis and Observations

Table 6 summarizes the confusion matrix findings. The model performed well in classifying anger and disgust, achieving high true positives and low false negatives. However, it struggled with fear and surprise, which had low true positives and high false positives, indicating difficulty in distinguishing these emotions. Joy and sadness showed moderate performance, with room for improvement in reducing misclassifications.

Table 6: Error patterns across emotion categories

Observation	Finding
Strong perf.	Anger, Disgust (High TP, Low FN)
Weak perf.	Fear, Surprise (Low TP, High FP)
Moderate perf.	Joy, Sadness (Decent TP, some errors)

Class imbalance remained a challenge, as some emotions appeared far less frequently than others, limiting generalization. While automatic evaluation provided insights, a qualitative evaluation was conducted to assess the quality of LLM-generated labels.

A trained Amharic educator reviewed 100 augmented samples, comparing annotations from ChatGPT and DeepSeek based on contextual relevance, linguistic coherence, and cultural fit. DeepSeek was preferred in 72% of cases for its better handling of idiomatic expressions and emotional nuance, supporting its use for dataset expansion.

5.2 Quantitative Findings

Our best-performing model was evaluated using the official SemEval-2025 Task 11 metrics. As shown in Table 7. One possible factor affecting our performance is the complexity of multi-label emotion detection in Amharic, a morphologically rich and low-resource language.

We performed an ablation study to assess the impact of class balancing and data augmentation, as summarized in Table 5. The results indicate that upsampling the minority classes did not improve performance. In fact, models trained without class balancing achieved slightly better accuracy and F1 scores. This suggests that simple oversampling may have introduced redundant or noisy examples, which did not enhance generalization.

Table 7: Final model performance on the test set

Metric	Score
Accuracy	0.4938
F1-score (Micro)	0.6931
F1-score (Macro)	0.6450

6 Conclusion

This work explored multi-label emotion detection in Amharic using a transfer learning approach. We fine-tuned LaBSE with class-weighted loss and evaluated its performance on the SemEval-2025 Task 11 dataset. Our model achieved competitive results, ranking 14th out of 43 teams, with an accuracy of 0.4938, a micro-F1 score of 0.6931, and a macro-F1 score of 0.6450.

Through ablation studies, we found that simple upsampling for class balancing did not improve performance, suggesting the need for more effective data augmentation techniques. Error analysis revealed strong classification performance for anger and disgust but difficulties distinguishing fear and surprise, highlighting the challenge of context-dependent emotional expressions.

Future work can explore paraphrasing-based augmentation, adversarial training, and more adaptive loss functions to better handle class imbalance. Additionally, incorporating context-aware embeddings and expanding the dataset with high-quality labeled examples could further enhance multi-label emotion detection in Amharic.

OPI-DRO-HEL at SemEval-2025 Task 9: Integrating Transformer-Based Classification with LLM-Assisted Few-Shot Learning for Food Hazard Detection

Martyna Śpiewak, Daniel Karaś

National Information Processing Institute
{mspiewak,dkaras@opi.org.pl}

Abstract

In this paper, we propose a hybrid approach for food hazard detection that combines a fine-tuned RoBERTa classifier with few-shot learning using an LLM model (GPT-3.5-turbo). We address challenges related to unstructured text and class imbalance by applying class weighting and keyword extraction (KeyBERT, YAKE, and Sentence-BERT). When RoBERTa's confidence falls below a given threshold, a structured prompt which comprising the title, extracted keywords, and a few representative examples is used to re-evaluate the prediction with ChatGPT.

1 Introduction

The SemEval-2025 Food Hazard Detection task (Randl et al., 2025) focuses on automatically identifying mentions of food hazards, such as allergens or chemical contaminants, in textual data. This challenge is critical for public health, as rapid and accurate detection can help prevent outbreaks and protect consumers.

Our system employs a two-stage classification pipeline. First, we use a RoBERTa-based classifier (Liu et al., 2019), fine-tuned on the training data, to predict whether a document includes a food hazard. If the model's confidence is below a given threshold, we move on to a secondary check with an LLM model. In this step, we provide ChatGPT with the document's title, a list of keywords, and a few examples of how to identify hazards — a few-shot learning setup (Snell et al., 2017; Wang et al., 2020; Brown et al., 2020; Schick and Schütze, 2021). This additional step helps detect subtle or rare hazard mentions that RoBERTa might overlook.

Despite these efforts, our system ranked 17th out of 27 teams. Further analysis showed that our approach struggled with complex language describing hazards. In addition, the automatic extraction of keywords and the variability in ChatGPT's responses sometimes led to different outcomes. These results suggest that improved keyword selection, more precise threshold tuning, and better domain guidance for ChatGPT could lead to higher performance. Our complete codebase, including preprocessing and training scripts, is publicly available at: https://gitlab.com/mspiewak/food-hazard-detection.

2 Background

The SemEval-2025 Food Hazard Detection task provides a structured dataset for identifying food hazard information in text documents. Each record in the dataset contains metadata (e.g., year, month, day, country), a title, and a full-length text field that describes a food recall event. The labels include both product and hazard each of which belongs to a higher-level category: product-category (22 possible categories) and hazard-category (10 possible categories).

2.1 Related work

Natural Language Processing (NLP) has played a major role in automating food hazard detection using text classification and information extraction methods. Recent studies have used large language models and deep learning techniques to improve food safety monitoring.

One key study, CICLe (Randl et al., 2024), presented a dataset of food recall announcements and compared NLP models like RoBERTa and XLM-R with traditional machine learning techniques. They found that logistic regression using tf-idf features outperformed transformer models in low-resource settings, highlighting the need for efficient, flexible methods. Motivated by these findings, our approach uses conformal prediction techniques to improve classification while reducing computational costs.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1174–1180

Other related studies, such as (Özen et al., 2024), have applied LLMs to extract chemical hazards from scientific literature with high accuracy. Similarly, (Nogales et al., 2022) demonstrated the effectiveness of deep learning with categorical embeddings for predicting food safety risks from European Union data.

3 System overview

The SemEval-Task combines two sub-tasks: (ST1) text classification for food hazard prediction, predicting the type of hazard and product, and (ST2) food hazard and product "vector" detection, predicting the exact hazard and product.

This task prioritizes accurate hazard detection and employs a two-step evaluation metric based on the macro F1 score, emphasizing hazard classification in both sub-tasks. In this study, we focused exclusively on ST1, developing a classification system tailored to the prediction of food hazards and associated product categories.

3.1 Data Analysis

The dataset is divided into three subsets: training, validation, and test sets. The training set consists of 5,082 records and is used for model development, learning and fine-tuning hyperparameters. The validation set, comprising 565 records, and the test set, containing 997 records, serves as an independent evaluation dataset to assess the generalization performance of the model.

Hazard Category (10 classes)	Train (%)	Notes
allergens	36.48%	comparable across splits
biological hazards	34.26%	comparable across splits
foreign bodies	11.04%	comparable across splits
fraud	7.30%	comparable across splits
chemical hazards	5.65%	minor variations observed
microbiological hazards	2.00%	comparable across splits
physical contaminants	1.00%	comparable across splits
other hazards	1.00%	comparable across splits
food additives & flavorings	0.47%	underrepresented in all splits
migration	0.06%	underrepresented in all splits

Table 1: Distribution of hazard categories (10 classes) in the training set, sorted by percentage (descending).

A strong imbalance is observed in the distribution of both the hazard category and product category variables. Tables 1 and 2, highligh the difficulty of detecting underrepresented categories. The hazard category is dominated by allergens and biological hazards, which together account for over 70% of all cases. Other categories, such as foreign bodies, fraud, and chemical hazards, appear less frequently, while some categories like migration and food additives and flavorings are particularly underrepresented.

Similarly, the product category variable shows a high concentration in a few categories. Meat, egg, and dairy products represent the most frequently reported category, followed by cereals and bakery products and fruits and vegetables. Other categories, such as sugars and syrups, feed materials, food contact materials, and honey and royal jelly, are significantly less common.

Product Category (22 classes)	Train (%)	Notes
meat, egg & dairy products	28.22%	minor variations observed
cereals & bakery products	13.20%	comparable across splits
fruits & vegetables	10.53%	comparable across splits
prepared dishes & snacks	9.23%	comparable across splits
seafood	5.27%	minor variations observed
soups, broths, sauces & condiments	5.19%	minor variations observed
nuts, nut products & seeds	5.16%	comparable across splits
ices & desserts	4.37%	comparable across splits
cocoa & cocoa preparations, coffee & tea	4.13%	minor variations observed
confectionery	3.35%	minor variations observed
non-alcoholic beverages	2.64%	minor variations observed
dietetic foods, food supplements, fortified foods	2.58%	comparable across splits
herbs & spices	2.46%	minor variations observed
alcoholic beverages	1.16%	comparable across splits
other food product / mixed	1.08%	comparable across splits
pet feed	0.39%	minor variations observed
fats & oils	0.37%	underrepresented in all splits
food additives & flavourings	0.16%	underrepresented in all splits
honey & royal jelly	0.16%	underrepresented in all splits
food contact materials	0.14%	underrepresented in all splits
feed materials	0.12%	underrepresented in all splits
sugars & syrups	0.10%	underrepresented in all splits

Table 2: Distribution of product categories (22 classes) in the training set, sorted by percentage (descending).

The distribution of categories is generally consistent across dataset splits; however, minor discrepancies, such as differences in the proportions of cocoa, coffee, and confectionery, could introduce subtle biases. The underrepresentation of rare categories may limit the model's ability to generalize to less common incidents.

The analysis will concentrate on the title and text fields, which are unstructured and irregular. Because these fields lack a consistent format, it is not possible to automatically extract discrete features from them. Representative examples of frequently occurring textual patterns are provided in Table 3. Instead, we examine the complete content using text analysis techniques. This approach provides a comprehensive understanding of the underlying content and the linguistic patterns present in the data.

Table 3: Sample text entries from the training dataset.

3.1.1 Text Preprocessing Strategy

We applied a focused preprocessing to standardize the text fields prior to model training. Key steps included:

- **HTML Removal** Stripping out HTML tags to eliminate irrelevant markup.
- **Whitespace and Special Character Normalization** eplacing non-breaking spaces with regular spaces and consolidating multiple spaces and line breaks.
- **Case Conversion** Converting text to lowercase to ensure consistency.
- **Numeric and URL Removal** Eliminating numbers and hyperlinks that rarely convey hazard information
- **Stopword Elimination (Optional)** Removing common English stopwords based on experimental settings.

This cleaning pipeline reduces data variability and ensures that the model focuses on meaningful terms related to food hazards and products.

3.2 Two-Step Classification Pipeline

Our approach combined a fine-tuned RoBERTa model with an LLM model in a sequential classification setup. First, we trained the RoBERTa classifier on the cleaned text field of each record. After obtaining a probability estimate for the predicted class, we compared it to a threshold. If RoBERTa's confidence exceeded this threshold, we accepted its prediction as final.

However, whenever the probability was below the threshold, we triggered a secondary check. In this step, we extracted keywords from the text and the recall notice's title are used to construct a prompt. We then used few-shot learning promps with ChatGPT, providing a small set of labeled examples to guide the model in predicting the hazard category. This two-stage process harnesses RoBERTa's high precision for clear-cut cases while leveraging ChatGPT's contextual understanding for ambiguous instances.

4 Experimental setup

To ensure that our findings can be reproduced, we detail our experimental design below. The dataset is divided into 5,082 training records for model development and hyperparameter tuning, 565 validation records for model selection, and 997 test records for independent evaluation. Our text preprocessing pipeline involves removing HTML tags, normalizing whitespace, converting all text to lowercase, and eliminating numeric elements and URLs, with an optional step for stopword removal as needed.

4.1 RoBERTa-Based Classification with Imbalance Handling

The training dataset is highly imbalanced, with some hazard categories appearing much more frequently than others. This imbalance can cause the model to favor majority classes and perform poorly on rare hazards. To fix this, we added class weighting to the cross-entropy loss function, giving more emphasis to underrepresented categories.

Model Architecture and Training Setup We fine-tuned a RoBERTa model for both hazard and product category classification, treating each as a multi-class classification task. Importantly, the same architecture is employed for both variables. For hazard classification, the model's output layer was configured with 10 neurons corresponding to the 10 hazard categories, and similarly, the product category classification used an output layer sized to the number of product categories. To handle imbalance in the hazard data, we computed class weights using the formula:

$$w_c = \frac{N}{k \times N_c}$$

where N is the total number of samples, N_c is the number of samples in class c, and k is the total

number of unique classes. This "balanced" weighting scheme is inspired by the approach described in (King and Zeng, 2001), which proposes adjusting the loss function to counteract the bias introduced by imbalanced datasets.

Our structured training approach included:

- **Tokenization and Encoding** We used RoBERTa's subword tokenization (Sennrich et al., 2016) to break words into smaller units, which helped preserve technical terms related to food hazards and handle rare or domain-specific words effectively.
- **Optimization Strategy** The model was trained using AdamW with weight decay (Loshchilov and Hutter, 2019) to prevent overfitting. A linear learning rate scheduler was applied to gradually reduce the learning rate, stabilizing updates and improving convergence.
- **Hyperparameter Tuning** We optimized learning rate, batch size, dropout rate, weight decay, and warmup steps using Optuna (Akiba et al., 2019), selecting the best configuration based on macro F1-score.

Due to the severe imbalance in the data, accuracy can be misleading since it is often dominated by the majority classes. Instead, we used the macro F1-score to fairly evaluate performance on both common and rare categories. This metric helped the model better identify rare hazards and improved recall in critical cases.

4.2 Keyword Extraction Process

To reduce the input length for few-shot learning and focus the prompts, we applied three keyword extraction methods – KeyBERT, YAKE, and Sentence-BERT – after cleaning each text. We extracted the top ten keywords for every text using each method:

- **KeyBERT** (Grootendorst, 2020) uses transformer-based embeddings to identify the terms most relevant to a given document's content.
- **YAKE (Campos et al., 2020)** employs an unsupervised, statistical method, ranking words based on frequency and positional features.
- **Sentence-BERT** (Reimers and Gurevych, 2019) considers semantic similarities at the sentence level, pinpointing contextually important expressions.

These keywords summarize key concepts, ensuring that an LLM model prompts remain targeted and manageable.

4.3 Few shot learning

To improve the classification accuracy for low-confidence predictions, we implemented a few-shot learning approach using ChatGPT (GPT-3.5-turbo) along with the RoBERTa classifier. We set the threshold at 0.5, corresponding to the median confidence of correct validation predictions, which strikes a balance between avoiding unnecessary LLM calls and capturing genuinely uncertain cases. Samples below this threshold are then re-evaluated by the LLM. In this case, a structured prompt is generated that includes the recall notice's title, a list of extracted keywords, and a few representative examples from the training set (selected based on cosine similarity of tf-idf embeddings). For each extraction method (KeyBERT, YAKE, Sentence-BERT), we collect only the top ten keywords returned by that method. We do not concatenate all 30 keywords into a single pool, nor do we remove duplicates across methods, since each method's output is used in a separate prompt configuration. Within each prompt, the keywords appear in the exact order provided by the extractor – reflecting their ranking – rather than as an unordered bag-of-words. This preserves the method, the specific context and ordering that proved most effective in our experiments. ChatGPT then predicts the most appropriate hazard class from a predefined list of valid classes. If ChatGPT's prediction matches one of these classes, it replaces the original RoBERTa output; otherwise, the RoBERTa prediction is retained.

All few-shot prompts follow a consistent three-part structure. First, we include a brief task description that outlines the classification objective. Next, we present N labeled examples in the format: `Title + Keywords` $\rightarrow$ `Label`. Finally, the prompt ends with the target query: `Title + Keywords` $\rightarrow$ `?`. To assess the impact of prompt design, we tested minor variations – such as ordering the examples by cosine similarity – and found that prompt ordering could change the macro F1 score by up to one point. We plan to perform a more extensive prompt-engineering study in future work.

	RoBERTa	FSL & KeyBERT	FSL & YAKE	FSL & Sentence-BERT
Without Class Balancing				
Validation Dataset				
hazard-category	0.86654	0.86077	0.86308	0.86155
product-category	0.67434	0.68555	0.68603	0.6963
Test Dataset				
hazard-category	0.77584	0.77607	0.77537	0.77948
product-category	0.67553	0.74464	0.71664	0.75418
With Class Balancing				
Validation Dataset				
hazard-category	0.88952	0.89560	0.85883	0.88107
product-category	0.70174	0.71052	0.71002	0.71084
Test Dataset				
hazard-category	0.76091	0.76644	0.75896	0.76644
product-category	0.70422	0.77889	0.74011	0.77578

Table 4: Comparison of classification methods (F1 macro scores) for hazard and product categories on the validation and test datasets. Results are shown for models built without and with class balancing.

Our implementation utilizes Huggingface Transformers (v4.49.0) (Hugging Face Inc., n.d.; Wolf et al., 2020), Optuna (v4.2.1), OpenAI (v1.60.1) (OpenAI, 2022), KeyBERT (v0.9.0), Yake (0.4.8), Sentence Transformers (v3.4.1) and other standard Python libraries (numpy, pandas, scikit-learn).

5 Results

Table 4 presents the performance of our system with and without class balancing, measured in macro F1-scores on both the validation and test datasets. Our submission to the competition used class balancing, as adding class weights improved performance for several categories. With class balancing, the few shot learning (FSL) approach combined with KeyBERT achieved the highest score for hazard-category classification (0.89560), while all few-shot learning variants improved upon the baseline RoBERTa for product-category classification, with FSL using Sentence-BERT reaching 0.71084. On the test dataset, however, the performance for hazard-category classification is notably lower, with scores ranging from 0.75896 to 0.76644, compared to 0.88952–0.89560 on the validation set. For product-category classification, the best result on the test set was 0.77889, which also represents a modest improvement over the RoBERTa baseline.

We submitted the configuration using RoBERTa with KeyBERT. However, the gap between validation and test results for hazard-category classification suggests possible overfitting, while we do not observe this for product-category classification. Notably, for product-category classification on the test set, methods using the LLM component clearly improved performance, highlighting the benefit of few-shot learning.

Our experiments show that adding few-shot learning with targeted keyword extraction improves the basic RoBERTa performance. Using class balancing, especially for product categories, effectively addresses data imbalance. Additionally, KeyBERT and Sentence-BERT work better than YAKE, providing more reliable support for the few-shot component.

The main source of errors is that underrepresented classes tend to be misclassified with high confidence. In many instances, rare hazard and product categories are incorrectly predicted with strong probabilities, indicating that the model is overly biased toward majority classes. Additionally, the few-shot learning component using ChatGPT struggles with these cases because the examples provided in the prompts are insufficient or weak, leading to more errors for rare classes. These observations suggest that both the primary model and the LLM require improved strategies, such as improved prompt design and better handling of low-frequency classes, to effectively address these issues.

5.1 Limitations

While our approach shows promise, it did not perform consistently well and seems overfitted to the training set. Here, we discuss the main challenges and possible improvements. The imbalance in category distributions can hurt model generalization, but it could be improved by data augmentation and re-sampling methods like stratified sampling. Also, using the validation set for extra training could help the model adapt better, especially in low-data scenarios. Another area to improve is selecting can-

didates for few-shot learning, where approaches like active learning or uncertainty-based sampling might help. Fixing these issues through better data handling and selection methods would make the model more robust and improve its performance.

6 Conclusion

We have developed a two-stage classification system for food hazard detection that combines the strengths of both RoBERTa and ChatGPT to tackle challenges posed by imbalanced data. Our approach employs class weighting to reduce bias toward majority classes and leverages few-shot learning to improve predictions when the model's confidence is low. Although our system ranked 17th out of 27 teams, indicating room for improvement, error analysis indicates that underrepresented classes are still frequently misclassified with high confidence. In future work, we plan to improve the prompt design and use active learning strategies to improve model adaptability. Additionally, we will explore advanced data augmentation techniques to better capture the characteristics of rare hazard categories. These improvements should make the model more robust and generalizable, improving its effectiveness in real-world food safety applications.

Abstract

Emotion detection in text plays a very crucial role in NLP applications such as sentiment analysis and feedback analysis. This study tackles two tasks: multi-label emotion detection, where the goal is to classify text based on six emotions (*joy, sadness, fear, anger, surprise*, and *disgust*) in a multilingual setting, and emotion intensity prediction, which assigns an ordinal intensity score to each of the above-given emotions.

Using the BRIGHTER dataset, a multilingual corpus spanning 28 languages, the paper addresses issues like class imbalances by treating each emotion as an independent binary classification problem. The paper first explores strategies such as static embeddings such as GloVe with logistic regression classifiers on top of it. To capture contextual nuances more effectively, we fine-tune transformer based models, such as BERT and RoBERTa. Our approach demonstrates the benefits of fine-tuning for improved emotion prediction, while also highlighting the challenges of multilingual and multi-label classification.

1 Introduction

Emotion detection in text is a fundamental task in natural language processing (NLP), which has various important applications like sentiment analysis, feedback analysis, and chatbots. Understanding the emotions present in textual data is important in digital communication, where body language and facial expressions will not available. The increased textual interactions on social media, news, and online forums have emphasized the need for accurate emotion detection systems.

Recent breakthroughs and results in NLP have significantly enhanced the performance of emotion detection models (Belay et al., 2025). Current-age transformer architecture-based models (Vaswani et al., 2017) use large-scale language representation learning to model intricate semantic and syntactic relations in the text.

In this paper, we address the task of **multi-label emotion detection** (Muhammad et al., 2025b) as part of a shared workshop challenge. The task consists of two tracks:

- **Track A: Multi-label Emotion Detection** – Given a target text snippet, the goal is to predict the perceived emotion(s) expressed by the speaker. Each of the text samples is labelled with a binary classification for six emotions: *joy, sadness, fear, anger, surprise*, and *disgust*. The model needs to determine whether each emotion is either present (1) or absent (0) for each sample.

- **Track B: Emotion Intensity Prediction** – Given both, a target text snippet and a specific emotion in the six, the objective of this task is to predict the **intensity** of the perceived emotion on a scale from 0 (no emotion) to 3 (high intensity). This task is a more challenging one as it requires fine-grained understanding and ranking of emotional expressions.

Class imbalance is a common challenge when collecting data for emotion classification, mostly due to the natural distribution of real-world occurrences. The methodology discussed in this paper tries to adequately address the class imbalance and multi- label generated nature of the data. Rather than treating the task as a multi-label classification, we split it into separate independent binary classification tasks, where one classifier is trained for each emotion. This method ensures that the model learns to classify each emotion separately, thus trying to avoid class imbalance problems. We also finetune transformer models such as as BERT (Devlin et al., 2019), RoBERTa (Conneau et al., 2019), and other such models to leverage their contextual representations and enhance prediction performance. Through the exploration of both static embeddings and transformer models fine-tuned from

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1181–1186

scratch, we want to compare the efficiency of various feature representations in multi-label emotion classification and intensity estimation.

Past studies in this area have explored the topics of sentiment analysis and emotion detection using multiple different types of approaches. (V P et al., 2023) analyzed many Malayalam YouTube comments using ML models and deep learning techniques. The methodology provided in (Talaat, 2023) proposes a hybrid BERT model for the task, which shows improved contextual understanding. (Deho et al., 2018) uses word embeddings for sentiment analysis, clearly showcasing the role of pretrained representations. These works provide some important information about the evolution of emotion detection techniques.

Further sections provide a more detailed overview of the dataset, methodology, and experimental results.

2 Dataset

The BRIGHTER (Muhammad et al., 2025a) dataset is a collection of multilabeled emotion-annotated datasets in various low-resource languages from Africa and Asia and high-resource languages such as English. BRIGHTER covers text data in 28 different languages, annotated by expert annotators and fluent speakers based on the presence of six different emotions: anger, fear, sadness, joy, surprise and disgust. Data was mainly collected from social media, news, speeches and literature. Annotation is done with the help of crowd-sourcing platforms such as Amazon Mechanical Turk for largely spoken languages and directly recruited speakers for low-resource languages. Each instance of BRIGHTER consists of a sample ID, text snippet, and labels that indicate the presence of a particular emotion. Instances are multi-labeled and are labeled from 0 to 3 depending on the intensity of the emotion present in the sentence. For the initial task, these labels are simplified to depict the presence (0) or absence (1) of a specific emotion and intensity is ignored.

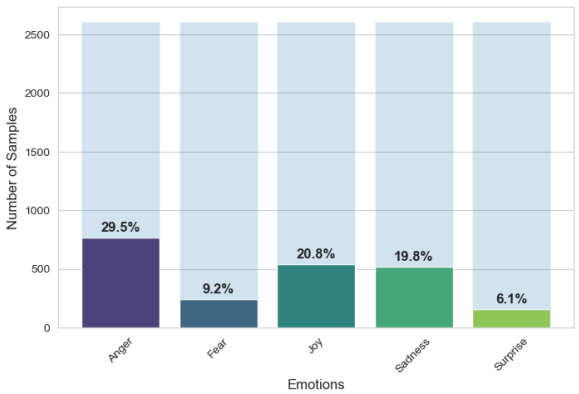

Figure 1: Percentage of positive samples in the English dataset.

We shall primarily use the English, Spanish, Russian, and Romanian datasets with the following emotions: anger, fear, joy, sadness, surprise and disgust. The English dataset does not have a label for disgust. Upon analyzing the class distribution, we observe an imbalance between positive and negative samples for nearly every emotion as depicted in Fig 1. The substantial variation in the class distribution comes from the method of choosing data from the named sources and also the amount of available data on platforms such as those. This is not only present across emotions in a language, but also across languages as expected.

3 Methodology

Due to the limited size of the dataset, it is rare to encounter samples that encompass all possible combinations of emotions across all the classes, as certain combinations may be inherently less likely to co-occur than others or may not be represented at all due to the natural distribution of real-world occurances. To address the observed class imbalances in the dataset, we split the classification task into independent binary prediction tasks to detect the presence of each emotion separately by utilizing distinct classifiers. The predictions are concatenated to obtain the final emotion representation vector.

3.1 Static and Frozen Embeddings

First, we explore static vector embeddings and frozen model embeddings to encode sentences as fixed-dimensional feature vectors. We then utilize these vectors as input data for logistic regression classifiers. A logistic regression classifier is a statistical model that predicts the probability of an input belonging to one of two classes. Here, it represents the presence or absence of a specific emotion. Two types of embeddings were tested, GloVe (Pennington et al., 2014) and BERT (Devlin et al., 2019):

- **Global Vectors for Word Representations (GloVe)**: Sentences are encoded as vectors

Model	Anger		Fear		Joy		Sadness		Surprise		Avg	
	Acc	F1	Acc	F1	Acc	F1	Acc	F1	Acc	F1	Acc	F1
GloVe	0.88	0.47	0.58	0.49	0.75	0.43	0.68	0.41	0.71	0.49	0.72	0.46
bert-base	0.89	0.69	0.77	0.76	0.83	0.76	0.80	0.76	0.80	0.75	0.82	0.74

Table 1: Performance of models using static and frozen embeddings.

Model	Anger		Fear		Joy		Sadness		Surprise		Avg	
	Acc	F1	Acc	F1	Acc	F1	Acc	F1	Acc	F1	Acc	F1
bert-base	0.89	0.76	0.76	0.76	0.86	0.80	0.81	0.76	0.81	0.78	0.83	0.79
RoBERTa	0.89	0.77	0.76	0.79	0.87	0.82	0.82	0.80	0.83	0.79	0.84	0.81
bert-large	0.90	0.77	0.80	0.80	0.83	0.79	0.84	0.81	0.84	0.80	0.84	0.82

Table 2: Performance of fine-tuned models.

by averaging the individual word vectors obtained from pre-trained GloVe representations.

- **Bidirectional Encoder Representations from Transformers (BERT - bert-base-uncased)**: Sentences are encoded using contextualized embeddings from the frozen pre-trained BERT model. Specifically, the `[CLS]` token representation from the final hidden layer is used as a fixed-dimensional sentence embedding, capturing contextual meaning and syntactic nuances more effectively than static word embeddings.

3.2 Fine-tuning Pre-trained Models

Static embeddings and pre-trained models are limited in the information they can capture. They are incapable of capturing task-specific variations. To overcome such limitations, we switch to fine-tuning models on our dataset, allowing them to adapt their representations to fit the patterns in the particular problem. We fine-tune the following models:

- **bert-base-uncased**: The base model built on the transformer architecture.
- **RoBERTa**: RoBERTa (Conneau et al., 2019) is a variant of BERT trained by eliminating the next sentence prediction task. The model has shown better performance on various NLP tasks.
- **bert-large**: bert-large-uncased is a larger model with 340 million parameters, compared to the base model with 110 million parameters. The increased number of layers allows us to capture more complex linguistic patterns.

3.3 Expanding to Multiclass Classification

To accommodate for multiclass classification, where the prediction can range from 0-3, which signifies the intensity of the emotion present, we modify the final layer of our models. Previously, we used a final layer of size 2 to represent classification between 0 and 1. Changing the size of this layer to 4 allows us to predict between classes 0-3.

3.4 Expanding to Multilingual Classification

To extend our model to multilingual classification so that it can process texts in several languages like Spanish, Russian, and Romanian along with English, we use Multilingual BERT (mBERT) also released by (Devlin et al., 2019). mBERT is a model of BERT trained on 104 languages on the basis of Wikipedia data and is thus fit for cross-lingual transfer learning. By utilizing mBERT, our model can handle text in various languages without the need for language-specific models. This is especially convenient for use cases where training data with the label is scarce in non-English languages.

3.5 Experimental Setup

The experiments were conducted using transformer-based models fine-tuned on the BRIGHTER dataset. The dataset was tokenized with a maximum sequence length of 128 using padding and truncation.

For optimization, we used the AdamW optimizer with a learning rate of 1×10^{-5}. Training was performed for 2 epochs with a batch size of 10.

4 Results

The evaluation of the models was conducted using different metrics based on the task at hand. For

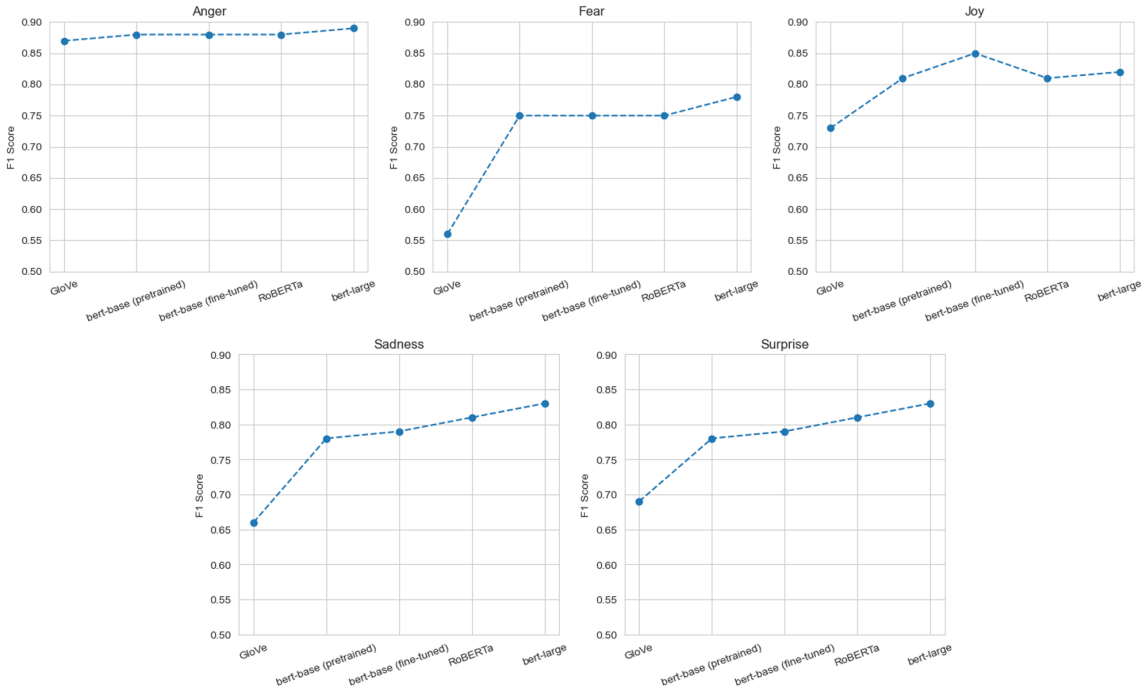

Figure 2: F1-scores across the models for each emotion.

binary emotion classification task, **accuracy** and **F1-score** were used. Accuracy provides an overall measure of the correct predictions, but since emotion classes are imbalanced in the present dataset, F1-score is a more informative metric as it takes into account both precision and recall.

For the task of emotion intensity prediction, the performance is measured using **Pearson correlation coefficient (r)**. This metric evaluates the linear relationship between the predicted values and the actual intensity values.

4.1 Binary Emotion Classification Performance

The results for binary classification are presented in Table 1 and Table 2. Results demonstrate that fine-tuning transformer-based models significantly improves performance over static or frozen embeddings. GloVe embeddings yield significantly lower F1 scores across all emotions, whereas fine-tuned BERT models achieve substantially higher F1 scores. The best-performing model, **bert-large**, attains the highest average F1 scores across all emotions, followed very closely by RoBERTa. This trend suggests that increasing model size and using contextualized embeddings contribute to better generalization in emotion classification. This can also be visualized in Fig 2.

4.2 Multiclass Emotion Intensity Prediction

For the task which involves predicting the intensity of a given emotion on a scale from 0 to 3, Table 3 presents the results for bert-large model on English. The **bert-large** model achieves the highest average Pearson correlation ($r = 0.6129$), outperforming frozen bert-base model embeddings ($r = 0.5315$). This indicates that fine-tuning enhances the model's ability to capture nuanced emotional intensity variations.

Language	Emotion	Score
English	Anger	0.2635
	Fear	0.7288
	Joy	0.6924
	Sadness	0.7457
	Surprise	0.6339
Average Pearson r		**0.6129**

Table 3: Performance of Bert Large in Track B on English Language

4.3 Multilingual Emotion Classification

The multilingual classification results, as shown in Table 4, show variations in performance across languages. Romanian and Russian data sets show

Language	Anger	Disgust	Fear	Joy	Sadness	Surprise	Micro F1	Macro F1
Russian	0.4961	0.6115	0.4031	0.6404	0.0	0.0	0.4798	0.3585
Spanish	0.1551	0.1364	0.8558	0.6824	0.8016	0.5505	0.5674	0.5303
Romanian	0.0	0.0	0.7398	0.8326	0.6223	0.0	0.5376	0.3658

Table 4: Emotion Classification Metrics for Different Languages

lower F1 scores for emotions such as surprise and anger, while the Spanish show higher scores, especially for fear and sadness. This discrepancy can be attributed to how mBERT itself is trained, particularly the quality and quantity of training data originally used for the model. Since mBERT is pre-trained on large-scale multilingual corpora, its effectiveness varies across languages depending on their representation in the training data. The macro F1 scores indicate that Spanish achieves the highest overall performance, suggesting that better model pre-training for certain languages leads to improved emotion classification results.

4.4 Overall Analysis

Across all experiments, fine-tuned transformer models evidently outperform static embeddings, reinforcing the importance of task-specific adaptation. Larger models like **bert-large** and **RoBERTa** demonstrate superior performance, benefiting from deeper contextual representations. The imbalance in dataset labels remains a challenge, particularly for low-resource languages, impacting overall classification efficacy.

5 Conclusion

The evaluation of transformer-based architecture models for the tasks of emotion detection and intensity prediction, highlights the advantages of fine-tuning over using static embeddings. BERT-based models, especially bert-large, consistently outperformed other models in both the tasks, achieving the highest F1-scores and Pearson correlations on average. RoBERTa also demonstrated competitive performance, particularly in the binary classification task, due to its optimized pre-training approach. In multilingual classification, mBERT facilitated cross-lingual generalization, though performance did vary depending on language representation in the pre-training corpus.

Across all tasks, larger models with deeper contextual representations provided the better results, reinforcing the impact of the size of models and training methods. These findings bring out the effectiveness of transformer models in emotion classification and suggest that more advancements in model architecture and quality of pre-training data could yield even better results.

Limitations

Despite the improvements achieved through fine-tuning transformer-based models, several limitations persist in our approach. One major challenge is **class imbalance** within the dataset. Certain emotions, particularly those less frequently expressed, have significantly fewer training samples. This imbalance leads to biased learning, where the model performs better on more common emotions while struggling with underrepresented ones. In future work, a more balanced dataset with uniform representation across emotions could help mitigate this issue. Additionally, techniques such as oversampling, under-sampling, and synthetic data generation could be explored to enhance model robustness.

Another limitation is that the study mainly relies on **BERT-based models**. While models like **BERT, RoBERTa**, and **bert-large** show good results, using more advanced architectures could further improve performance. Models such as **DeBERTa**, which introduces disentangled attention, and **T5 or GPT-based models**, which utilize generative learning strategies, might be better suited for capturing the complex emotional nuances.

Furthermore, the paper's current approach depends on **supervised learning** which requires labeled data. In low-resource settings, obtaining high-quality annotated datasets is quite challenging. Future research could explore semi-supervised and self-supervised learning techniques to leverage unlabeled data effectively. Pre-training on larger, diverse emotion-rich corpora before fine-tuning on task-specific data might enhance model adaptability across languages and emotional contexts.

Abstract

Machine Translation (MT) is an essential tool for communication among people across different cultures, yet Named Entity (NE) translation remains a major challenge due to its rarity in occurrence and ambiguity. Traditional approaches, like using lexicons or parallel corpora, often fail to generalize to unseen entities and, hence, do not perform well. To address this, we create a silver dataset using the Google Translate API and fine-tune the facebook/nllb-200-distilled-600M model with LoRA (Low-Rank Adaptation) to enhance translation accuracy while also maintaining efficient memory use. Evaluated with metrics such as BLEU, COMET, and M-ETA, our results show that fine-tuning a specialized MT model improves NE translation without having to rely on large-scale general-purpose models.

1 Introduction

Machine Translation (MT) has proven to be significant at enabling cross-cultural and cross-border communication. It is essential in multilingual content creation, border business interaction, and real-time translation communication services. While the contemporary Neural Machine Translation (NMT) models have achieved high fluency and accuracy, they struggle with certain aspects of translation. One of the most difficult parts is the translation of named entities (NEs) which are handled comparatively poorly. NEs include proper names of people, places, organizations and other cultural references. They pose difficulties due to their rarity in occurrence in natural language, ambiguity, and due to the language-specific variations.

Entity-Aware Machine Translation (EA-MT) seeks to resolve the complexities faced when translating sentences with named entities. Unlike generic MT that depends on the patterns of language and context, EA-MT focuses on entity recognition, retention, and accurate translation. The importance of EA-MT is very evident in real-world applications such as **news translation, medical and legal document translation, and localization of entertainment content**, where small mistakes in NE translation can lead to misinformation or loss of meaning, which would cause problems.

Handling named entities in translation is a difficult task because entities might not have direct equivalents across all languages. For example, consider the English sentence:

"*Elon Musk announced an exciting new feature for X (formerly Twitter) in an interview with CNBC today.*"

An MT model might struggle to translate the above sentence due to several possible reasons:

- "**X (formerly Twitter)**" might be translated poorly if the model fails to recognize that both "X" and “Twitter” here refer to social-media platforms.
- "**CNBC**" could be wrongly translated if the model assumes it to be a random acronym instead of recognizing it to be the media organization.
- "**Elon Musk**" should in an ideal situation remain unchanged since it is the name of an individual, but certain translation models might fail and attempt transliteration, changing the original intended meaning of the sentence.

To handle such issues as discussed above, a variety of techniques have been used in MT such as dictionary-based approaches, parallel corpus training, and using external knowledge, in addition to other approaches. Traditional approaches utilize large bilingual lexicons or pre-aligned corpora in order to guarantee the correct entity mappings. Novel techniques are now using knowledge graphs, entity linking, or explicit annotation to assist models in differentiating between named entities and regular phrases.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1187–1191

In this paper, we propose an approach that leverages a **silver dataset generated using Google Translate** and fine-tunes the **NLLB model** to enhance entity-aware translation. Such a method allows the model to learn important patterns in entity translation. The approach used in this paper also provides flexibility which helps the model to be able to generalize and tackle samples with unseen entities and still have a high accuracy.

2 Related Work

(Conia et al., 2025) is the task description article and (Conia et al., 2024) is the work that led to the creation of this task and initial dataset. Past research has explored different strategies to try and improve Named Entity translation in Neural Machine Translation. (Modrzejewski et al., 2020) uses external annotations for the NMT models, which shows that using samples which are explicitly entity labelled can enhance translation quality. The article (Li et al., 2021) proposes a unique approach which is lexicon-based to ensure consistency in the translations of the model, but such an approach would end up lacking the ability to translate any unseen entities. In contrast to this, a fine-tuning approach would learn entity mappings from the sample data rather than simply relying on predefined lexicons. (Awadallah et al., 2016) uses an alternative approach which improves translation quality by aligning entities across comparable and parallel corpora. The approach in (Jiang et al.) employs strategies such as web mining and transliteration to extract bilingual named entities in an attempt to handle unknown entities. The methodology in (Huang and Vogel, 2002) focuses on statistical NE extraction and entity disambiguation, which is similar to the goal of this paper of improving entity representation in machine translation. These studies provide some key insights into the challenges in Named Entity Machine Translation, which this paper tries to build upon by generating a silver dataset and fine-tuning a transformer model for a more adaptable and accurate entity-aware translation system.

3 Dataset

The dataset (Sen et al., 2022) provided for the task is a collection of English text data translated into various languages such as Italian, Spanish, French, etc. The data is present in the JSONL format. Fig 1 depicts a sample of evaluation data. The sample has an id, a wikidata_id, a list of entity types present in the sentence, the source language, the target language, the source text in English and the translated target sentence.

```

4 System Description

4.1 Silver Dataset Creation

As we have mentioned in the previous sections, the provided dataset contains predictions generated using GPT 4o and GPT 4o-mini. However, we

wanted to create a different dataset using an expert machine translation system as opposed to using the predictions from a general purpose large language model. This is because of the fact that GPT-4o and GPT-4o-mini are optimized for language modeling over a vast corpus rather than being trained specifically for machine translation.

To ensure we have good quality silver predictions which stem from a model specifically trained for machine translation, we made use of the Google Translate API to translate the sentences in the dataset from the source language to the target language. We call this newly created dataset our "Silver Dataset".

4.2 Model

For this task, we have decided to fine-tune a smaller pre-trained machine translation model on our newly created silver dataset. We propose using a smaller expert model as opposed to using a general-purpose large language model which fits all tasks because we believe in training smaller expert models which specialize in specific tasks instead of having generic models.

To this end, we chose to fine-tune the **Facebook / nllb-200-distilled-600M** (Costa-Jussà et al., 2022) model. This model was selected because its base pre-trained variant supports all languages present in the task dataset. We use LoRA (Low-Rank Adaptation) (Hu et al., 2022) to fine-tune the NLLB model for each language individually. LoRA was chosen because of its very minimal memory requirements compared to full fine-tuning.

After fine-tuning the base model on each language individually, we obtained the predictions for the test set. For the fine-tuning procedure, we made use of 4 RTX 3080 Ti graphics cards.

5 Results and Analysis

Our machine translation system was individually fine-tuned for each of the target languages, and its performance was evaluated using BLEU scores and the harmonic mean of COMET and M-ETA scores. The results across ten languages are summarized in Table 1 and Table 2 and can also be seen in Fig 3 and Fig 4.

5.1 BLEU Scores Analysis

BLEU (Bilingual Evaluation Understudy) is a widely used metric in machine translation that evaluates the quality of translation by comparing n-grams in the predicted translation with the N-grams in the reference translation. The BLEU scores show significant variations in performance across the different languages. The best performance was noticed in the case of Spanish (59.14), which was closely followed by Italian (54.52), French (49.17), and Turkish (49.38). Arabic, German, and Thai showed mostly moderate scores, with Arabic (47.24) and German (44.98) showing equally competitive results. However, the model seems to have struggled a lot with Japanese (1.71), Thai (4.93), and Chinese (Traditional) (0.11).

Language	BLEU Score
Arabic	47.24
German	44.98
Spanish	59.14
French	49.17
Italian	54.52
Japanese	1.71
Korean	28.19
Thai	4.93
Turkish	49.38
Chinese (Traditional)	0.11

Table 1: BLEU Scores for Different Languages

5.2 COMET and M-ETA Scores Analysis

We use a combined metric based on **COMET** (Rei et al., 2020) and **M-ETA**. **COMET (Cross-lingual Optimized Metric for Evaluation of Translation)** is a model-based metric that compares the machine translation output with a human reference translation, leveraging pre-trained embeddings to capture semantic similarity. **M-ETA (Manual Entity Translation Accuracy)**, on the other hand, measures how well named entities are translated by

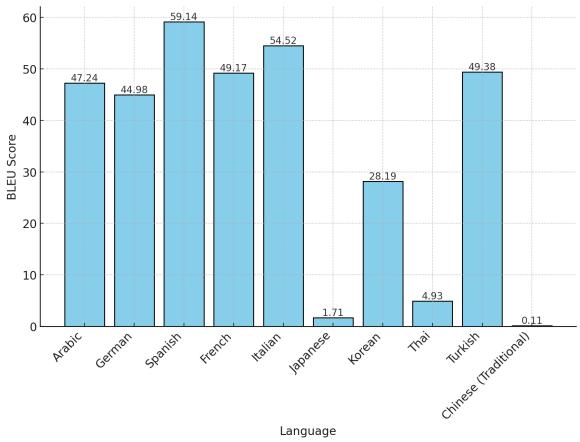

Figure 3: BLEU Scores for Different Languages.

Language	Overall Score
Arabic	37.50
German	40.32
Spanish	46.46
French	33.16
Italian	39.37
Japanese	35.28
Korean	35.97
Thai	13.75
Turkish	46.50
Chinese (Traditional)	8.41

Table 2: Harmonic mean of COMET and M-ETA Scores for Different Languages

calculating the proportion of correctly translated entities. The final **composite score** is computed as:

$$Score = 2 \times \frac{(COMET \times M-ETA)}{(COMET + M-ETA)}$$

While Spanish (46.46) and Turkish (46.50) still performed well, Japanese (35.28) and Korean (35.97) saw considerable improvement compared to their BLEU scores, which suggests that while exact word matching is poor, most of the semantic content is relatively preserved. Chinese (Traditional) (8.41) and Thai (13.75) are still the lowest-performing languages, showing the difficulty of translation in these languages.

5.3 Language-Specific Observations

- **High BLEU and M-ETA Scores:** Spanish, Italian, and Turkish performed well across both of the above metrics.

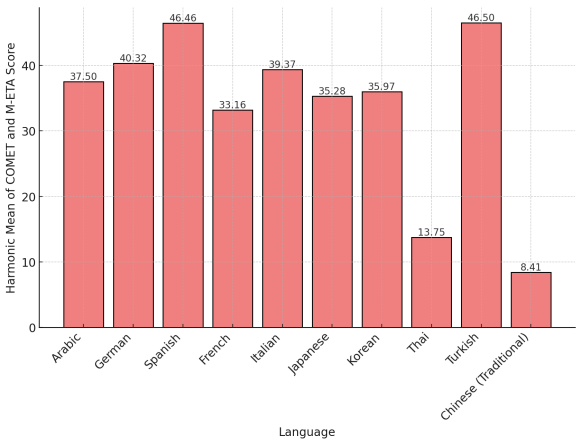

Figure 4: Harmonic mean of COMET and M-ETA Scores for Different Languages.

- **Low BLEU, Higher M-ETA:** Japanese and Korean exhibited low BLEU scores but higher M-ETA and COMET scores, suggesting that BLEU may not fully capture translation adequacy in morphologically complex languages.

- **Extremely Low Scores:** Chinese (Traditional) performed the worst across both metrics, indicating significant model limitations in handling the language's complex structure and large vocabulary space.

6 Conclusion

This paper explored the challenge of Named Entity translation in Machine Translation, a task where the generic models often fall short. To address this, we created a **silver dataset** using **Google Translate** and fine-tuned the **facebook/nllb-200-distilled-600M** model with **LoRA (Low-Rank Adaptation)**, enabling a more efficient and specialized approach to tackle the task of entity-aware translation.

Our evaluation using **BLEU, COMET, and M-ETA** metrics demonstrated the effectiveness of fine-tuning to improve NE translation quality without the need to use generalized large language models. While **Spanish and Turkish** achieved high scores across both general translation and entity accuracy, languages like **Japanese and Korean** displayed weaker BLEU scores but better semantic preservation, which can be seen from COMET and M-ETA scores. Overall, our approach shows the strengths of fine-tuning models for named entity machine translation.

Limitations

Entity Awareness in Fine-Tuning

While our approach successfully fine-tunes a specialized model for named entity translation, it does not explicitly enforce fine-tuning on the entity awareness aspect of each sample. The model learns these entity translation patterns indirectly from the silver dataset, but there is no direct, specific mechanism to ensure that these named entities are treated differently from all other words. Another key limitation of our approach is the reliance on the silver dataset as discussed above. While Google Translate usually provides high-quality translations, it might not always ensure accurate named entity translations. Some of those entities may be falsely transliterated or replaced with the wrong words, which

could introduce noise into the training data, causing the model to perform comparatively poorly.

Limitations of BLEU for Entity Translation

The BLEU score primarily measures N-gram overlap; hence it might not be a great way to measure the quality of named entity translation. It does not account for semantic accuracy and often fails to penalize incorrect entity translations effectively. The following examples illustrate these shortcomings:

Incorrect Entity Translation with a High BLEU Score

Source: Who starred in the 1972 film Taming of the Fire?
Predicted: Qui a joué dans le film Taming of the Fire de 1972 ?
Reference: Qui a joué dans le film de 1972 Dompter le feu ?
BLEU Score: 44.08

Here, even though the named entity *"Taming of the Fire"* was incorrectly translated, the BLEU score still remains considerably high because the rest of the predicted sentence aligns with the reference sentence. This shows that BLEU does not effectively penalize named entity translation errors.

Correct Entity Translation with an Average BLEU Score

Source: How old is Emmaus Monastery in Prague?
Predicted: Quel âge a le monastère d'Emmaüs à Prague ?
Reference: Quel âge a le cloître d'Emmaüs à Prague ?
BLEU Score: 43.16

In this case, the entity *"Emmaus Monastery"* is correctly translated in the predicted sentence as *"monastère d'Emmaüs"*, but still the BLEU score remains average due to small structural differences in the remaining words of the sentence. This clearly shows that BLEU alone is not sufficient for evaluating the quality of entity-aware translation and hence COMET and M-ETA scores were also used in this paper.

VerbaNexAI at SemEval-2025 Task 11: A RoBERTa-Based Approach for the Classification of Emotions in Text

Danileth Almanza Gonzalez, Edwin Puertas, Juan Carlos Martinez-Santos
Universidad Tecnológica de Bolívar
Cartagena, Colombia
{daalmanza,epuerta,cmartinezs}@utb.edu.co

Abstract

Emotion detection in text has become a highly relevant research area due to the growing interest in understanding emotional states from human interaction in the digital world. This study presents an approach for emotion detection in text using a RoBERTa-based model, optimized for multi-label classification of the emotions joy, sadness, fear, anger, and surprise in the context of the SemEval 2025 - Task 11: Bridging the Gap in Text-Based Emotion Detection competition. Advanced preprocessing strategies were incorporated, including the augmentation of the training dataset through automatic translation to improve the representativeness of less frequent emotions. Additionally, we implemented a loss function adjustment mechanism to mitigate class imbalance, enabling the model to enhance its detection capability for underrepresented categories. The experimental results reflect competitive performance, with a macro F1 of 0.6577 on the development set and 0.6266 on the test set. The model ranked 70th in the competition, demonstrating solid performance against the challenge posed.

1 Introduction

Emotion recognition in text has gained significant relevance with the rise of social networks, facing the challenge of identifying explicit and implicit emotions. The basic emotions most studied include joy, sadness, fear, anger, disgust, and surprise. Advances in NLP have driven the development of more accurate models, such as deep neural networks and pre-trained models like RoBERTa, improving emotion classification in various fields such as business, psychology, and security (Sboev et al., 2021; Faisal et al., 2024). This study addresses emotion detection in SemEval 2025 Subtask A - Task 11: Bridging the Gap in Text-Based Emotion Detection. The central problem motivating this research lies in the complexity of accurately detecting and classifying emotions in texts through multi-label prediction. The main objective of this task is to identify perceived emotions in five main categories (joy, sadness, fear, anger, and surprise) using a multi-label classification approach (Muhammad et al., 2025b). Although the competition addresses multiple languages, this study focuses exclusively on English. For this purpose, we employed the pre-trained RoBERTa model, leveraging its ability to capture advanced linguistic representations and improve emotion detection in complex texts. Furthermore, we implemented strategies to address the class imbalance, optimizing the model's overall performance and maximizing its classification accuracy. The results obtained were competitive, as our system reached the 70th position in the competition, achieving an acceptable performance. However, we identified challenges related to the representation of less frequent emotions, affecting the accuracy of minority classes. These findings highlight the importance of continuing to explore class balancing techniques and model tuning to improve emotion detection in texts. The repository is available via the following link: (available after reviewing.) [1]

2 Background

The dataset used in this task comes from BRIGHTER, a collection of multilingual datasets for text-based emotion recognition that spans 28 languages. For its construction, authors collected texts from various sources, including social media (Reddit, Twitter, YouTube, Weibo), speeches, personal narratives, literature, and news. Depending on the language, the data were obtained from specific platforms or manually generated by native speakers. Subsequently, the texts were curated and annotated by experts and collaborators through crowdsourcing platforms such as Amazon Mechanical Turk and Toloka and specialized tools like La-

[1] https://github.com/VerbaNexAI/SemEval2025

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1192–1197

belStudio and Potato. The annotation process included assigning multiple emotion labels and the intensity of each emotion on a scale from 0 to 3.

The author selected only English for this study, with data primarily extracted from Reddit. The dataset distribution is as follows: 2,768 instances for training, 116 samples for development, and 2,767 records for testing. the structured each instance into three primary columns: ID, text, and emotional labels corresponding to joy, sadness, fear, anger, and surprise. Table 1 shows the Distribution of emotions across the dataset subsets, evidencing an imbalance. It is worth noting that the emotion "disgust" was excluded from the English dataset due to its scarce representation in the collected texts. Unlike the other emotions, there were not enough examples labeled with "disgust", which prevented its inclusion and analysis within this corpus. In Figure 1, a representative sample of the training set is presented, illustrating examples of texts along with their emotional labels (Muhammad et al., 2025a).

Id	Text	Anger	Fear	Joy	Sadness	Surprise
01676	I have plenty more.	0	0	1	0	0
01903	That's messed up.	1	0	0	0	1

Figure 1: Sample of the training dataset.

Emotion	Training	Test	Development
Anger	333	322	16
Fear	1611	1544	63
Joy	674	670	31
Sadness	878	881	35
Surprise	839	799	31

Table 1: Distribution of each emotion in the training, test, and development sets.

Emotion analysis in text has been widely studied in Natural Language Processing (NLP), using approaches ranging from rule-based methods to advanced deep learning models. In particular, studies derived from Task 1 of SemEval-2018 have explored various strategies, highlighting Bi-LSTM networks with deep self-attention and transfer learning (Baziotis et al., 2018). Other works integrated the NRC VAD Lexicon, Transformer, and GRU to recognize emotions in code-mixed conversations, using techniques such as Emotion Flip Reasoning (EFR) and Emotion Recognition in Conversation (ERC) on the MELD and MaSaC datasets (Pacheco et al., 2024). Likewise, logistic regression with syntactic dependency graphs has been implemented to analyze emotional causality, although with limited results that motivate the use of more advanced models such as Transformers (Garcia et al., 2024). Finally, feature extraction techniques (TF-IDF, FastText, BERT) and predictive models (Naïve Bayes, SVM, Random Forest, Gradient Boosting, and neural networks) have been applied on the ISEAR dataset (Esfahani and Adda, 2024).

3 System Overview

The based the proposed system for emotion detection in texts on an architecture that combines the pre-trained RoBERTa model with additional classification and data balancing mechanisms (Hartmann, 2022). We designed the architecture to handle the inherent complexity of emotion classification, allowing for precise differentiation of emotions such as anger, fear, joy, sadness, and surprise. Figure 2 illustrates the system's structure, showing the processing flow from data input to prediction generation. To delve into the internal functioning of the system, we described some details of its components below.

3.1 Tokenization and DataLoader

These phases convert preprocessed texts into a numerical representation that the model can process. We used the RoBERTa tokenizer to split inputs into tokens, assign indices, and apply padding and truncation. Then, the EmotionDataset associates the encodings with emotional labels. Finally, the DataLoader creates mini-batches, optimizes efficiency, and prevents biases in training.

3.2 Model

We based the model on a pre-trained transformer (RoBERTa), which generates contextual representations for each token in the input sequence. Before selecting RoBERTa, we tested other pre-trained models during the experimentation phase, such as BERT. However, RoBERTa performed better in the task, partly due to its training providing specific advantages for emotion classification in English text. An aggregation mechanism is applied once the tokenizer segments the text and RoBERTa produces a sequence of embeddings. In this case, the

mechanism consists of computing the mean of the representations generated by RoBERTa along the sequence dimension. It serves as a way to consolidate the scattered information of each token into a single vector representing the general content of the text. We chose this technique because it can generate stable and balanced representations, avoid dependence on individual words, as occurs with max pooling, and reduce computational cost compared to more sophisticated methods such as attention pooling.

3.3 Attention Layer

We implemented an attention layer to assign specific weights to each token. This layer takes as input the vector representations for each token in the text. Subsequently, it uses an aggregation mechanism based on averaging to consolidate these representations, thus generating a single vector that summarizes the most relevant information from the entire text. Attention was indirectly implemented through this aggregation mechanism, allowing the model to automatically prioritize the most influential words in the final prediction. This approach was chosen due to its numerical stability, computational simplicity, and proven effectiveness in emotion classification tasks.

3.4 Classification Layer

We used a linear layer to transform the high-dimensional vector into a five-dimensional space. Each of these dimensions corresponds to one of the target emotions: anger, fear, joy, sadness, and surprise. The classification layer, which operates on the regularized vector, produces the logits for each emotion. These logits are subsequently interpreted through the sigmoid function in the loss computation phase (BCE With Logits Loss), transforming the results into probabilities that indicate the presence or absence of each emotion.

3.5 Class Balancing

Considering that the dataset presents an imbalanced distribution among the target emotions (anger, fear, joy, sadness, and surprise), a specific balancing strategy was incorporated into the loss function used during training. Specifically, the BCEWithLogitsLoss function from PyTorch was used with the pos_weight parameter adjusted according to the relative frequency of each emotional class in the training set. This weight was calculated by dividing the most frequent class by each of the other classes,

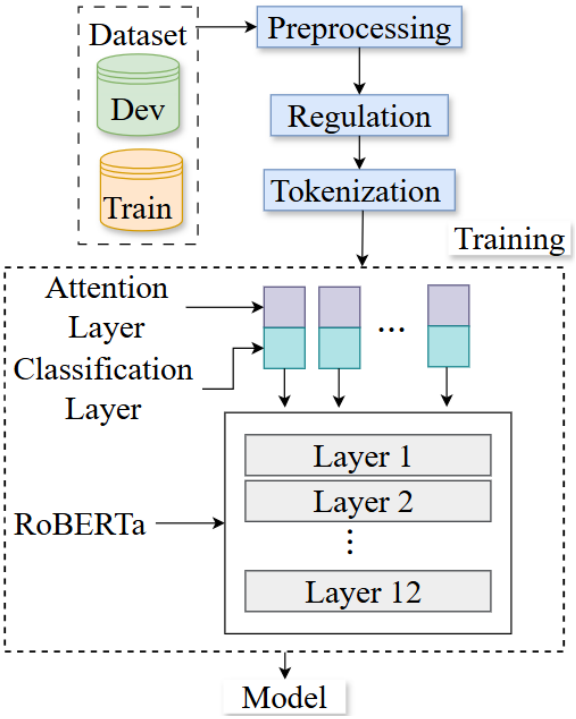

Figure 2: Architecture system.

thus ensuring that errors made on less represented emotions were penalized more heavily during training. This approach improved the model's sensitivity to minority categories and led to more balanced and accurate predictions overall. The technical implementation consisted of transforming these calculated weights into a tensor (class_weights_tensor), which was directly integrated into the loss function as a parameter during the model optimization process.

4 Experimental Setup

We designed the experimental configuration to ensure a robust and generalizable emotion detection model. The dataset was initially divided into training and testing sets, assigning 80% for training and the remaining 20% for testing. The original dataset consisted of 2,768 instances in English, which we considered insufficient to capture the complexity of emotional phenomena fully. To address this limitation, we incorporated 7,597 instances from German and Brazilian Portuguese datasets. We translated the instances into English using the DeepL Pro API (version v2), which based the learning on the Linguee service, an extensive database of phrases and text fragments translated by humans (DeepL, 2025). Thanks to this data source, the API achieves high accuracy in translations. This

strategy enriched the training set and improved the model's generalization ability across various structures and linguistic contexts. Moreover, the dataset expansion through high-quality translation not only increased data diversity but also contributed to a significant improvement in the model's performance, particularly in detecting underrepresented emotions. With the dataset duly expanded, a rigorous preprocessing procedure was applied to ensure the uniformity and quality of the textual information.

4.1 Preprocessing

This stage begins with the normalization and cleaning the text, which is fundamental to ensuring the uniformity of the corpus. First, Unicode normalization is applied, converting all characters to canonical forms and eliminating discrepancies due to different encodings and formats. This step is crucial for correctly handling accented characters and special symbols. Then, regular expressions are employed to remove undesired patterns, such as digits, redundant punctuation, and special characters that do not contribute semantic meaning. Additionally, we transformed all text to lowercase, ensuring we treated identical words in different formats uniformly, which reduces variability and noise in the data.

Once we completed the initial cleaning, we implemented a more advanced transformation pipeline, which included replacing specific text elements. We replaced URLs, mentions, and hashtags with generic tokens ([URL], [MENTION], and [HASTAG], respectively), which helps to preserve the semantic structure without overloading the model with unnecessary details. Moreover, emojis are identified and tagged by inserting a marker ([EMOJI]), allowing us to control the emotional information implicit in these symbols. Finally, this preprocessing chain is integrated in an automated fashion, ensuring that each corpus instance goes through the same cleaning and transformation steps before tokenization with the RobertaTokenizer. This standardization is essential for generating consistent and robust representations that facilitate learning and subsequent classification in the emotion detection model. This preprocessing strategy significantly contributed to improving the model's performance. These results clearly demonstrate that the implemented techniques have a direct and positive impact on the overall accuracy of the model and enhance its ability to correctly identify emotions in complex texts.

4.2 Pipeline Configuration and Hyperparameter Tuning

In this stage, we integrated preprocessing processes into a unified pipeline that prepares each input for the model. Initially, we performed tokenization using RobertaTokenizer from Hugging Face. We split the text into minimal units (tokens), which we converted into indices according to the model's predefined vocabulary. We set a maximum limit of 400 tokens per instance, ensuring the capture of relevant semantic information without introducing redundancies or excessive noise. Manual hyperparameter tuning was conducted during training to optimize the model's performance. Different learning rates ($2e-5$, $3e-5$, $4e-5$) were experimented with, as well as various batch sizes [8,16,32] and numbers of epochs (initially 10, then 50 and 100). After evaluating the performance of each configuration, we selected the values that provided the best performance: a learning rate of $2e-5$, a batch size of 8, and a total of 100 epochs. Combined with a weight decay of 0.01 and rigorous preprocessing, we made these adjustments to optimize the quality of the information provided to the model, facilitating its convergence during the training phase.

4.3 Evaluation and Performance Metrics

We evaluated the system using standardized metrics for comprehensive performance quantification. We employed accuracy, precision, recall, and F1-score measures, calculated as both micro and macro averages, providing a detailed view of the model's ability to identify each target emotion correctly.

These configurations have enabled the development of a robust and replicable emotion detection system, in which each stage, from the expansion and preprocessing of the corpus to the fine-tuning of the model, contributes significantly to improving the generalization and precision of the classification.

5 Results

In the results obtained in the different evaluation phases, as shown in Tables 3, 4, and 5 in the development and test sets, during training, the model showed a progressive improvement, reaching a micro precision of 0.9958 and a micro F1-score of 0.9917 in the last epoch. However, the average over all epochs (precision of 0.8694 and loss of

Text	Gold label					Prediction label				
	Anger	Fear	Joy	Sadness	Surprise	Anger	Fear	Joy	Sadness	Surprise
I slammed my fist against the door and yelled, Open up!	1	1	0	0	1	1	1	0	0	0
My heart dropped and I just replied “No.	0	1	0	1	0	0	1	0	0	0
Man, I can’t believe it	0	1	1	0	1	0	0	0	0	1

Table 2: Model error analysis

Metric	Development	Test
Macro F1	0.6577	0.6266
Micro F1	0.6571	0.6787

Table 3: Metrics obtained for the development and test sets.

Metric	Anger	Fear	Joy	Sadness	Surprise
F1	0.720	0.676	0.626	0.738	0.526

Table 4: Model performance on the development set

Metric	Anger	Fear	Joy	Sadness	Surprise
F1	0.495	0.787	0.6324	0.572	0.645

Table 5: Model performance on the test set

0.0962) indicates variability, suggesting the need for balancing. In the development set, the performance was lower (macro F1: 0.6577, micro F1: 0.6571), with differences among emotions, highlighting good performance in “Sadness” (0.7385) and lower in “Surprise” (0.5263). In the test set, the metrics were similar (macro F1: 0.6266, micro F1: 0.6787), with “Fear” obtaining the highest score (0.7874) and “Anger” the lowest (0.4950), suggesting difficulties in certain emotions due to data distribution.

The error analysis reveals that the model struggles to identify surprise, sadness, and fear accurately. False positives in surprise suggest that the model confuses emphatic expressions, even when they convey fear or disbelief. Similarly, false negatives in sadness indicate that the model does not adequately capture the emotional subtext when we use metaphors or figurative expressions without explicit terms like "sad" or "devastated." Additionally, the model has issues with ambiguous phrases where the emotion depends on the context, leading to omissions in detecting fear and joy. Table 2 shows that the model tends to confuse similar emotions in context, such as fear and surprise in disbelief or sadness and fear in distressing scenarios. Although the model performs better in classifying joy and anger, we also observed that it still makes errors, suggesting that it struggles to correctly interpret emotional language when it depends on contextual nuances or idiomatic expressions.

6 Conclusion

Automatic Emotion Classification in Text Analysis has applications in social networks, digital platforms, the business sector, and education. Given its relevance, it is essential to improve the accuracy and robustness of the models, ensuring their adaptability to multiple languages and domains. The proposed system has demonstrated effectiveness in detecting complex emotional nuances, achieving solid results in various categories. However, challenges persist in the identification of minority emotions such as anger and surprise. To address them, it was proposed to implement advanced class balancing strategies and automatic hyperparameter tuning techniques. Future work will consider search methods to optimize hyperparameters in several pretrained models and will explore hybrid approaches that integrate complementary architectures.

dutir914 at SemEval-2025 Task 1: An integrated approach for Multimodal Idiomaticity Representations

Yanan Wang, Dailin Li, Yicen Tian, Bo Zhang
Jian Wang*, Liang Yang
School of Computer Science and Technology, Dalian University of Technology, China
{wangyanan,ldlbest,yicentian,zhangbo1998}@mail.dlut.edu.cn
{wangjian,liang}@dlut.edu.cn

Abstract

SemEval-2025 Task 1 introduces multimodal datasets for idiomatic expression representation. Subtask A focuses on ranking images based on potentially idiomatic noun compounds in given sentences. Idiom comprehension demands the fusion of visual and auditory elements with contextual semantics, yet existing datasets exhibit phrase-image discordance and culture-specific opacity, impeding cross-modal semantic alignment. To address these challenges, we propose an integrated approach that combines data augmentation and model fine-tuning in subtask A. First, we construct two idiom datasets by generating visual metaphors for idiomatic expressions to fine-tune the CLIP model. Next, We propose a three-stage multimodal chain-of-thought method, fine-tuning Qwen2.5-VL-7B-Instruct to generate rationales and perform inference, alongside zero-shot experiments with Qwen2.5-VL-72B-Instruct. Finally, we integrate the output of different models through a voting mechanism to enhance the accuracy of multimodal semantic matching. This approach achieves **0.92** accuracy on the Portuguese test set and **0.93** on the English test set, ranking **2nd** and **2nd**, respectively. The implementation code is publicly available here[1].

1 Introduction

Idioms, as fixed expressions, are typically understood through multisensory experiences and contextual awareness of the real world, rather than by directly inferring the meaning of individual words. While multimodal learning has emerged as a critical research direction to address this limitation, current models still face challenges in reconciling literal and figurative meanings of idioms (Yosef et al., 2023).

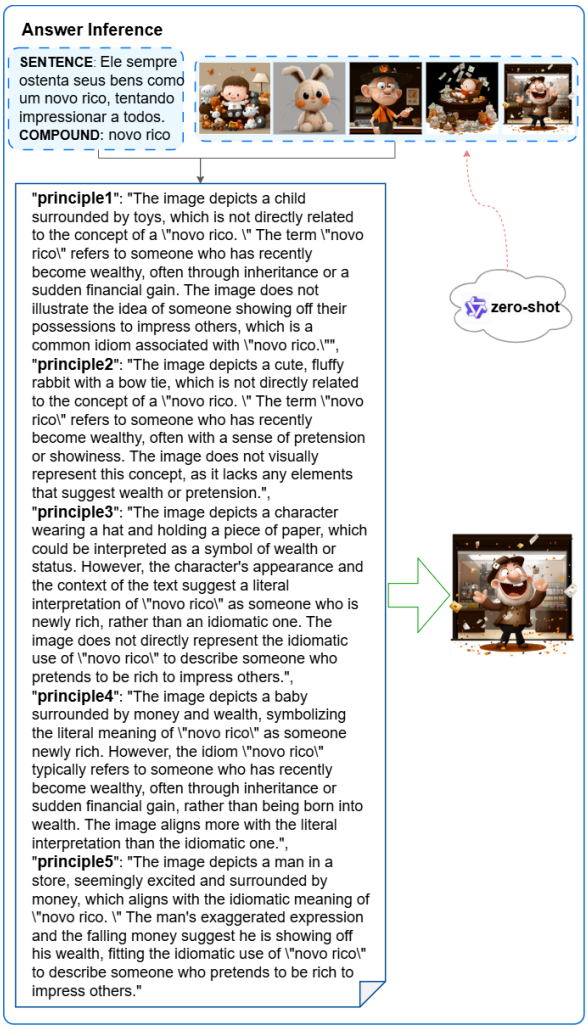

Figure 1: An example of CoT outperforming Zero-Shot Inference in selecting the top image.

Against this backdrop, SemEval-2025 Task 1 : AdMIRe (Advancing Multimodal Idiomaticity Representation) (Pickard et al., 2025) introduces a systematic evaluation framework for multimodal idiomaticity representation. This task builds on the foundation laid by SemEval-2022 Task 2 (Madabushi et al., 2022) in exploring figurative language processing and further advances visual-textual analysis of idiomatic compounds in English and Portuguese.

*Corresponding author.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1198–1203

However, the scarcity of cross-lingual multimodal training data for idiomatic compounds hinders model generalization across languages and modalities. To address this, we explore the process of multimodal idiom generation. Specifically, we generate textual explanations and images for compound idiomatic expressions using DeepSeek-V3 (Liu et al., 2024) and Flux.1-dev[2], respectively, constructing two multimodal idiom datasets. These datasets are combined with the original training set to fine-tune the CLIP model (Radford et al., 2021). This enhances its cross-language understanding, allowing it to better capture semantic relationships in multimodal idiomatic expressions.

To further mitigate overfitting risks and improve generalization, we experiment with integrating multimodal large language models. By applying the chain-of-thought principle to Qwen2.5-VL-7B-Instruct (Bai et al., 2025), we generate a step-by-step reasoning method. We integrate textual and visual information into a multi-stage framework that separates the processes of basic principle generation, fine-tuning, and answer inference (see Figure 1). Moreover, we explore the use of zero-shot inference with Qwen2.5-VL-72B-Instruct (Bai et al., 2025).

To leverage these method-specific advantages, we finally design an ensemble approach that combines the outputs of fine-tuned and zero-shot inference models through majority voting, achieving our best results.

2 Background

Recent advances in large language models, such as chain-of-thought prompting (Wei et al., 2022) and zero-shot reasoning (Kojima et al., 2022), have enhanced complex task-solving capabilities. Multimodal reasoning techniques offer new pathways for semantic disambiguation through world knowledge integration. Schwenk et al. (2022) and Zhang et al. (2023) demonstrate that cross-modal approaches surpass single-modality performance. However, the non-compositional nature of idiomatic semantics limits explicit decomposition (Phelps et al., 2024), while dataset artifacts constrain generalization (Boisson et al., 2023). Cultural adaptability solutions employ multilingual prompts (Mu et al., 2025), photorealistic diffusion (Saharia et al., 2022), and reinforcement learning (Xu et al., 2023), though metrics like CLIPScore (Hessel et al., 2021) lack semantic depth. Visual metaphor generation requires dual semantic understanding and cross-modal alignment (Chakrabarty et al., 2023; Yosef et al., 2023; Akula et al., 2023), yet conceptual-imagery inconsistencies persist.

To bridge these gaps, our work introduces multimodal data synthesis and model-scale-aware integration. By generating cross-lingual textual explanations and images, we augment training data for CLIP (Radford et al., 2021), mitigating data scarcity and enhancing cross-language alignment in idiomatic expressions. Further, we integrate multimodal large language models (Qwen2.5-VL-7B/72B (Bai et al., 2025)) through a three-stage chain-of-thought framework. By ensembling the outputs of these models via majority voting, our approach addresses prior limitations in data diversity, cultural adaptability, and model generalization, while systematically exploiting scale-dependent capabilities.

3 System Overview

As depicted in Figure 2, this paper presents a multimodal model ensemble method. First, data augmentation techniques are employed alongside binary classification fine-tuning of the CLIP model. Next, the chain-of-thought strategy is applied for staged fine-tuning and inference of the Qwen2.5-VL-7B-Instruct model while incorporating a zero-shot inference mechanism. Finally, a majority voting strategy from ensemble learning is utilized to combine predictions from multiple models, reducing the bias of individual models, and thus improving the overall system's robustness and accuracy.

3.1 Data Augmentation

Our work is inspired by visual metaphor generation techniques, specifically the combination of large language models with generative models to create visual representations of abstract concepts. This approach drives our exploration of idiomatic expressions, enhancing the understanding of compound word meanings through multimodal integration. We use the DeepSeek-V3 API to generate idiomatic explanations for compound words in English and Portuguese from the SemEval-2022 Task 2 datasets (Madabushi et al., 2022), along with five sentences representing their idiomatic meanings. These sentences are then processed by the Flux.1-dev model to generate images.

[2] https://www.modelscope.cn/models/black-forest-labs/FLUX.1-dev

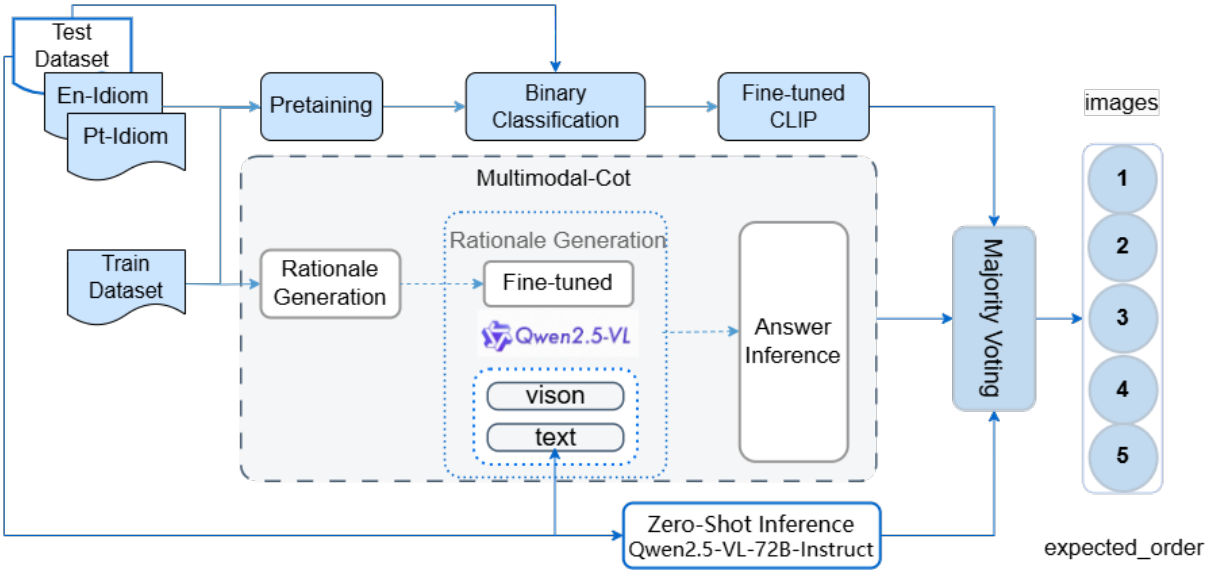

Figure 2: The overall architecture of our ensemble approach.

By pairing the idiomatic explanations with images, we create two multimodal datasets: En-Idiom, containing 243 English compound words and 1,215 images, and Pt-Idiom, consisting of 143 Portuguese compound words and 715 images. After filtering both datasets using CLIP to select image-sentence pairs with a similarity greater than 20, we obtain the Check-Idiom dataset with 1,780 data points. The similarity calculation formula is as follows:

$$s(I,T) = \frac{f_\theta(I)}{\|f_\theta(I)\|} \cdot \frac{g_\phi(T)}{\|g_\phi(T)\|} \quad (1)$$

The input image I and input text T are processed by the image encoder f_θ (using ViT-L/14-336) and the text encoder g_ϕ, respectively.

3.2 CLIP based on Binary classification

The introduction of the CLIP model has provided new perspectives for multimodal reasoning. We propose a binary classification-based fine-tuning method for CLIP, where compound usage in sentences is classified as either literal or idiomatic. This method combines binary classification with image-text pair construction and similarity sorting for more precise multimodal alignment. The steps are as follows:

Image-Text Pair Construction We augment the English and Portuguese training sets with two previously created datasets. If a compound is used idiomatically, its idiomatic meaning is paired with the correct image; if used literally, the sentence is paired with the corresponding image. This ensures that the image-text pairs accurately reflect the different semantic usage scenarios of compounds.

Binary Classification Training During fine-tuning, we select text representations based on compound usage type dynamically.

Similarity Sorting We use Qwen2.5-7B-Instruct to classify compound usage in the test set and generate idiomatic meanings. The fine-tuned CLIP model then ranks images based on the similarity to the corresponding text, considering the usage type.

3.3 Multimodal-CoT

We propose a multimodal chain-of-thought method for rationale generation to enhance the reasoning capabilities of large language models in image-text matching. The method consists of three stages:

Stage 1: Basic Rationale Generation We use Qwen2.5-VL-7B-Instruct with zero-shot chain-of-thought prompting to generate rationales for the correct answers in the English and Portuguese training sets. The model receives prompts with sentences, compounds, usage types, and questions to guide logical reasoning.

Stage 2: Fine-tuning and Rationale Generation The model is fine-tuned on a multimodal dataset of images, prompts, and rationales, enabling it to generate five rationales for each set of five images in the test set.

Stage 3: Answer Inference For each group of 5 images and their corresponding rationales and

prompts without usage types, the final inference is performed to derive the answer based on accumulated multimodal information.

Additionally, we conduct experiments on two-stage zero-shot inference on the test sets, where basic rationales are generated in the first stage, and final inference is performed in the second stage without fine-tuning. We also test zero-shot inference and two-stage zero-shot inference on LLMs with varying parameter sizes.

3.4 Ensemble

The ensemble approach consists of the following parts: (1) The fine-tuned CLIP model. (2) Multi-Modal CoT$_{72B}$: The Qwen2.5-VL-7B-Instruct model is fine-tuned in the first two stages, with the third stage utilizing the API of Qwen2.5-VL-72B-Instruct. (3) Zero-Shot Inference performed by accessing the API of Qwen2.5-VL-72B-Instruct. Specifically, for each position in the expected sequential results of these three methods on the test set and the extended evaluation set, a majority voting mechanism is applied to determine the final images ranking.

4 Experimental Setup

During CLIP training, the maximum text length was set to 77. The batch size was 16, with an initial learning rate of 5e-5 and a warm-up ratio of 0.1. The experiment ran on an RTX 4090 GPU. The CLIP model, fine-tuned on the augmented En-Idiom dataset, performed well on the English test set with 2 epochs. The Check-Idiom dataset, combined with the training set, was used for 3 epochs, achieving good results on the Portuguese test set.

During the multimodal chain-of-thought rationale generation and fine-tuning phase, Qwen2.5-VL-7B-Instruct was fine-tuned on the LLaMA-Factory platform. To ensure rationale accuracy, 127 data points from the English and Portuguese training and development sets were used. The setup involved LoRA fine-tuning with 4-bit quantization and bf16 mixed-precision training. The batch size was 2, initial learning rate 5e-5, temperature 1, top-p 0.01, and max sequence length 10240. During zero-shot inference and two-stage zero-shot inference, either local deployment of Qwen2.5-VL-7B-Instruct or the API of Qwen2.5-VL-72B-Instruct was used, with temperature set to 1 and top-p set to 1. The experiment was conducted on an A40 GPU.

5 Results

In subtask A, the task organizer creates two evaluation metrics.

- **Top Image Accuracy**: Correct identification of the most representative image. The metric presented on the leaderboard is Top 1 Accuracy.
- **Rank Correlation**: Spearman's rank correlation of model rankings with ground truth. However, the metric presented on the leaderboard is DCG Score.

$$\text{DCG} = \sum_{i=1}^{n} \frac{\text{rel}_i}{\log_2(i+1)} \tag{2}$$

where DCG (Discounted Cumulative Gain) measures ranking quality. rel_i is the relevance score of the image at position i, and n is the total number of ranked images. The denominator, $\log_2(i+1)$, serves as a discount factor, reducing the contribution of lower-ranked images to the overall score.

Our ensemble approach reaches 0.93 and 0.92 accuracy in the English and Portuguese test sets, respectively, with DCG scores of 3.46 and 3.43. It also achieves 0.79 and 0.69 accuracy on the extended evaluation sets, confirming the effectiveness of majority voting in integrating the strengths of the fine-tuned CLIP model with the generalization power of multimodal large language models.

Table 1 illustrates the performance of CLIP across different image resolutions and datasets. The results indicate that CLIP's zero-shot reasoning has limited capability for multimodal alignment of idiomatic compounds. After fine-tuning CLIP with data augmentation and binary classification, the test set accuracy is significantly improved, confirming the effectiveness of dynamically adjusting text-matching based on the usage type of compounds. However, considering both languages, the accuracy and DCG scores on the extended set are not high, likely due to the fine-tuning data being biased towards idiomatic types, which restricts generalization.

Table 2 presents the results of our different methods on Portuguese and English datasets. Compared to other methods using the 7B model, Multi-Modal CoT$_{7B}$ achieves the best accuracy and DCG Score on the Portuguese test set and extended evaluation set. This indicates that stage-wise fine-tuning is effective, although smaller models do not experience significant gain.

Model	Training Data	Accuracy(EN)	Accuracy(XE)	Accuracy(PT)	Accuracy(XP)
$CLIP_{224}$	-	0.47	0.46	0.62	0.44
$CLIP_{224}$	En-Idiom+train	0.67	0.42	0.62	0.38
$CLIP_{224}$	Check-Idiom+train	0.47	0.41	0.60	0.40
$CLIP_{336}$	-	0.47	0.46	0.69	0.40
$CLIP_{336}$	En-Idiom+train	0.93	0.46	0.54	0.40
$CLIP_{336}$	Check-Idiom+train	0.73	0.47	0.85	0.36

Table 1: Results of CLIP models on test and extended evaluation sets for different image resolutions and training data (where $CLIP_{224}$ refers to CLIP-ViT-L/14, and $CLIP_{336}$ refers to CLIP-ViT-L/14-336).

Method	Language	Accuracy	DCG Score	Accuracy (XE)	DCG Score (XP)
Zero-$Shot_{7B}$	PT	0.69	3.02	0.53	2.84
Two-$Stage_{7B}$	PT	0.62	2.91	0.51	2.80
Multi-Modal CoT_{7B}	PT	0.85	3.24	0.55	2.89
Zero-$Shot_{72B}$	PT	0.85	3.23	0.71	3.10
Two-$Stage_{72B}$	PT	0.85	3.26	0.49	2.74
Multi-Modal CoT_{72B}	PT	0.85	3.24	0.65	3.02
Ensemble	PT	**0.92**	**3.43**	**0.69**	**3.06**
Zero-$Shot_{7B}$	EN	0.53	2.80	0.56	2.84
Two-$Stage_{7B}$	EN	0.67	2.93	0.53	2.82
Multi-Modal CoT_{7B}	EN	0.53	2.77	0.55	2.87
Zero-$Shot_{72B}$	EN	0.80	3.33	0.80	3.22
Two-$Stage_{72B}$	EN	0.47	2.77	0.64	2.99
Multi-Modal CoT_{72B}	EN	0.60	2.89	0.73	3.15
Ensemble	EN	**0.93**	**3.46**	**0.79**	**3.28**

Table 2: Performance of different methods on the Portuguese and English test and extended evaluation sets.

The 72B model outperforms the 7B model on the extended evaluation set, demonstrating that the model scale has a significant impact on performance. For the 72B models, the Multimodal CoT method, which incorporates multimodal information and performs chain-of-thought reasoning with fine-tuned rationale generation, outperforms the Two-Stage method, thereby enhancing the model's reasoning capabilities. However, Zero-$Shot_{72B}$ performs well on the test set and achieves the best accuracy and DCG Scores on the extended set, validating the zero-shot generalization advantages of large-scale models.

6 Conclusion

This paper proposes an ensemble approach that integrates fine-tuned CLIP, multi-stage chain-of-thought reasoning, and zero-shot inference from large language models, focusing on enhancing the semantic and visual understanding of idiomatic nominal compounds through a multimodal integration framework. Experiments validate the effectiveness of data augmentation for fine-tuning CLIP and highlight the strong generalization capabilities of multimodal large language models. While stage-wise fine-tuning can improve performance compared to two-stage reasoning frameworks, it may still underperform relative to zero-shot inference models. Our future work will be dedicated to optimizing data generation and balancing strategies to mitigate distribution biases, further exploring the interactions between model scale and reasoning stages, and optimizing multimodal semantic understanding of idiomatic expressions.

Advacheck at SemEval-2025 Task 3: Combining NER and RAG to Spot Hallucinations in LLM Answers

Anastasia Voznyuk and **German Gritsai** and **Andrey Grabovoy**
Advacheck OÜ
{voznyuk, gritsai}@advacheck.com

Abstract

The Mu-SHROOM competition in the SemEval-2025 Task 3 aims to tackle the problem of detecting spans with hallucinations in texts, generated by Large Language Models (LLMs). Our developed system, submitted to this task, is a joint architecture that utilises Named Entity Recognition (NER), Retrieval-Augmented Generation (RAG) and LLMs to gather, compare and analyse information in the texts provided by organizers. We extract entities potentially capable of containing hallucinations with NER, aggregate relevant topics for them using RAG, then verify and provide a verdict on the extracted information using the LLMs. This approach allowed with a certain level of quality to find hallucinations not only in facts, but misspellings in names and titles, which was not always accepted by human annotators in ground truth markup. We also point out some inconsistencies within annotators spans, that perhaps affected scores of all participants.

1 Introduction

Modern advances in the field of text generation models provide artificial texts of a high quality that are hardly distinguishable from human-written texts at fluent reading. State-of-the-art instruction-tuned or reasoning Large Language Models (LLMs) are capable of generating an answer to any user query, but despite the attractiveness and conciseness of the answer, its appropriateness and accuracy often remained a controversial issue. LLMs are capable of retaining massive amounts of factual knowledge and use it to answer user queries, but they are still prone to generating hallucinations – statements that appear plausible but are factually incorrect or unverifiable (Maynez et al., 2020; Liu et al., 2023; Adlakha et al., 2024). Hallucinations pose a critical challenge in applications that demand high factual accuracy, such as medical or legal domains (Pal et al., 2023; Dahl et al., 2024). If a bit earlier we were concerned about detecting AI-generated content, nowadays with the increasing amount of the Internet being flooded with texts from LLMs, the focus on verification and validation of information is crucial (Gray, 2024; Gritsai et al., 2024). That brings us to the point where detecting and mitigating these hallucinations is essential for enhancing the reliability and trustworthiness of LLM outputs.

The SemEval 2025 Task 3 (Vázquez et al., 2025) poses a challenge in seeking hallucination within model answers on factual questions about famous people, locations or biological species. As most of these questions contain some sort of entity, we decided to employ Named Entity Recognition (NER) approach to determine for which entities there might be a relevant context. For determined entities we leverage Retrieval-Augmented Generation (RAG), as all questions from the dataset could be answered with context from Wikipedia. Relevant retrieved context together with model answer were given to LLMs that were tasked to evaluate the correctness of model's answer based on provided context and this were done twice obtain multiple opinions. After that, the final model had to edit the suggestions from LLM judges into initial answer. Through this method, we aim to detect and fix factual hallucinations from the text and thus contribute to ongoing efforts in hallucination detection and mitigation.

2 Related Work

Hallucination in LLMs refers to instances where models generate factually incorrect or unsubstantiated claims. Various methods have been proposed to detect and mitigate hallucinations, ranging from probabilistic confidence estimation (Manakul et al., 2023) to post-hoc verification using external knowledge sources. Self-consistency approaches have also been explored, where multiple model outputs

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1204–1210

are compared to detect inconsistencies. However, these approaches often struggle to identify hallucinations in complex, context-dependent settings. Hallucinations in LLMs can snowball when an initial false or misleading generation propagates through iterative interactions, reinforcing and expanding the error (Zhang et al., 2024). This happens when the model conditions future responses on its own prior outputs, amplifying inaccuracies over time. Therefore, it is important to detect hallucinations as soon as possible and abrupt model interaction with a context containing hallucinations.

2.1 Retrieval-Augmented Generation

Combining queries with additional information from sources can be valuable not only for preventing hallucinations in output, but also for recognising them. Retrieval-Augmented Generation (RAG) has emerged as a promising approach to improving factual consistency by integrating updated, relevant knowledge into the generation process (Lewis et al., 2020; Peng et al., 2023; Shuster et al., 2021). Studies have demonstrated that augmenting LLMs with structured or semi-structured data sources significantly reduces hallucination rates (Izacard et al., 2022). Nevertheless, even with RAG and other enhancements, LLMs still produce statements that are either unfounded or contradict the information provided in the retrieved references. It happens particularly when retrieval fails or retrieved documents contain inaccuracies (Gao et al., 2023). Authors of FAVA (Mishra et al., 2024) introduce a retrieval-augmented language model designed to detect and correct fine-grained hallucinations in generated text. They develop a benchmark comprising approximately one thousand human judgments across various domains, to assess hallucination detection performance. FAVA is trained using synthetic data specifically created to identify and rectify different types of hallucinations, significantly outperforming models such as ChatGPT and GPT-4 in both detection and factuality improvement tasks. In another paper authors introduce Dynamic Retrieval Augmentation (Su et al., 2024) based on hallucination Detection (DRAD) to address the posted issue. DRAD comprises two main components: Real-time Hallucination Detection (RHD), which identifies potential hallucinations during text generation without relying on external models, and Self-correction based on External Knowledge (SEK), which corrects detected inaccuracies by retrieving and incorporating relevant information from external sources. In our approach, we considered utilising RAGs in combination with LLMs as well.

2.2 Named Entity Recognition in Factual Consistency Evaluation

NER has been widely used in NLP for entity extraction and disambiguation, making it a useful tool for evaluating factual consistency in generated text (Wuehrl et al., 2023; Xie et al., 2023). Previous studies have shown that hallucinations often involve named entities being misrepresented or fabricated (Shen et al., 2023). By identifying and verifying named entities against reliable sources, NER-based methods can enhance hallucination detection.

3 Task Description

The objective of this task is to identify text spans that correspond to hallucinations in outputs, generated by LLMs. Provided data includes 14 languages and outputs from various publicly available LLMs. Participants receive an LLM-generated text in three formats:

- a raw character string
- a list of tokens
- a list of associated logits

Additionally, to determine spans more precisely, participants must assign a probability to each character or a span in the text, indicating the likelihood that it is part of a hallucination. There are two metrics: Intersection over Union (IoU) between predicted spans and ground-truth spans and Pearson correlation for evaluating how well the probability assigned by the participants' system correlates with the empirical probabilities observed by annotators. We have participated with our framework presenting approach for English, but it could be extended to other languages as well.

👴: **Which mountain range is Speichersdorf located near?**

🤖: **Speichersdorf is located in the Black Forest mountain region of Germany.**

Figure 2: Example of question and answer from the model with factual mistake (hallucination) coloured in red.

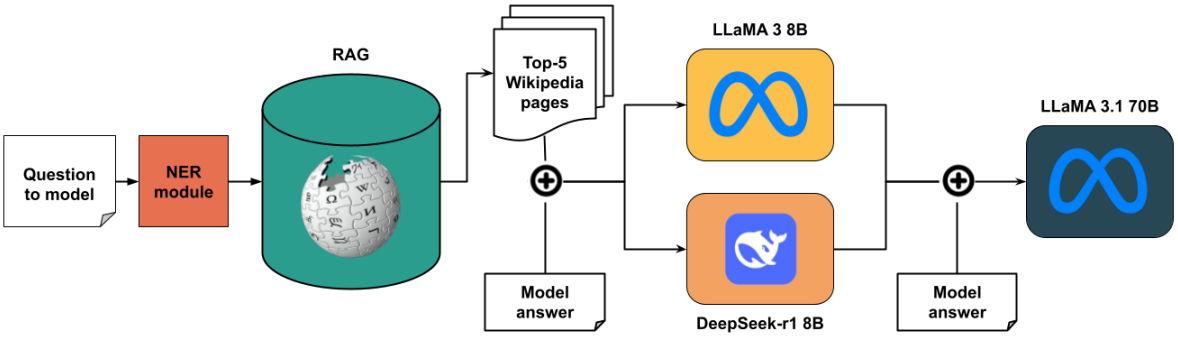

Figure 1: Our system pipeline.

4 Dataset

The dataset for the SHROOM 2025 challenge comprises a compilation of model-generated answers on factual questions. The goal is to find spans with hallucinations within model answer. Information for the data sample includes the following fields: (i) model input – the input question given to the generative language model; (ii) model id – the model used for generation; (iii) model output text – the text generated by a corresponding model; (iv) model output tokens – model output text, split to tokens; and finally (v) model output logits – logits for each generated token.

5 Proposed System

Our system employs a combination of Retrieval-Augmented Generation, Named Entity Recognition, and usage of LLMs to semi-automatically verify factual consistency and detect hallucinations in given answers. The workflow consists of the following key components:

1. NER module extracts entities from the question.

2. We find relevant to that entities Wikipedia pages through the RAG module.

3. Two small LLMs receive model answer and relevant Wikipedia context and are asked to factcheck it and output all factual mistakes.

4. Final judge LLM gets both outputs from small judges and must output the initial model answer with on-the-spot edits of factual mistakes.

5. Organisers' model answer and the answer of our system are compared to find differing spans.

It is illustrated in Figure 1.

6 Experimental Setup

We focused only on English subset, however, our system can be used for any language as long as LLMs support this language and there are knowledge sources in this language. To retrieve NER entities, we use DeepPavlov `ner_conll2003_bert` model (Savkin et al., 2024). We decided to extract sources from Wikipedia because after analysing the data provided, a significant amount of samples contain facts or references to various events. After retrieving the top-5 Wikipedia pages with the LangChain[1] loader and taking the most relevant one, we concatenate it with provided LLM answer and forward it to two LLM-judges: LLaMA3 8B (Grattafiori et al., 2024) and DeepSeek-R1 8B (DeepSeek-AI, 2025). Outputs from judges are concatenated with model answer and are given to the larger judge, LLaMA3.1 70B-Instruct. The latter judge should spot and edit the mistakes in the initial answer based on the smaller judges' opinions. Then, we check the difference between the original model answer and the edited answer. The spans that differed were stored and provided as the final answer. Additionally, we compared NER entities from the model answer and the question with cosine similarity, to find the inconsistencies and mistakes in the names.

Advacheck (our)	0.44425	0.343241
Best Leaderboard	0.650899	0.629443

Table 1: Results from the leaderboard for English subset of the task.

7 Results and Discussion

Although our system's spans do not fully overlap with spans from annotators, with 0.44425 IoU score (see Table 1), we attribute some role of lower IoU to the subjectivity of the annotation. As it involves the work of human annotators, who are asked to provide their opinion about whether some span is hallucination, there is a discrepancy between what annotators marked as hallucinations and what we marked in our system, and also some level of inconsistency between different texts from test set. We noticed that the answers from the LLMs, provided by organisers, contained a lot of typos and mistakes in the name of people from the questions. For example, the question was about *Alberto Fouillioux* and the model begins its answer with the name *Albero Foulois*. We believe it to be an input-contradicting hallucination, whereas annotators did not mark it in this way, therefore almost all such cases negatively affected the score. At the same time, there are some examples where similar typos in the names were marked as hallucinations. In some cases, annotators aimed for precision by marking hallucinations at the word level, while in others, they annotated entire sentences. We provide more examples of inconsistencies in the Table 2. Also, once the model starts to hallucinate, it is more likely that it will continue hallucinating, as stated in Zhang et al. (2024).

Also, as our system employs LLMs, it is vulnerable to hallucinations from the LLM judges when they work with the provided context. The solution is to take an ensemble of weaker judges and a more capable final judge to eradicate possible appearing hallucinations.

8 Conclusion

We presented a system that combines NER and RAG modules and after that utilises LLMs to detect spans of hallucinated output and showed how it can be used to edit factual mistakes in model answers. It can be further modified to work with several knowledge sources or employ more LLM judges to obtain more opinions and decrease the risk of hallucinations of the judges.

PALI-NLP at SemEval-2025 Task 1: Multimodal Idiom Recognition and Alignment

Runyang You* **Xinyue Mei*** **Mengyuan Zhou**
Ping An Life Insurance Company of China, Ltd.
{yourunyang013, meixinyue001, zhoumengyuan425}@ping.com.cn

Abstract

Understanding idioms in multimodal contexts poses significant challenges due to data scarcity, idiomatic ambiguity, and the need for effective alignment of visual and textual inputs. In this work, we introduce MIRA (Multimodal Idiom Recognition and Alignment), a training-free framework designed to address these challenges on the SemEval-2025 Task 1 (AdMIRe) benchmark. MIRA leverages powerful closed-source large language models (LLMs) and integrates three key innovations: bias correction via in-context learning, multi-step semantic-visual fusion, and a self-revision mechanism that iteratively refines its outputs through backward verification. By systematically processing and fusing multimodal inputs, MIRA generates high-quality, fine-grained image-text representations that enhance idiom comprehension across different languages and cultural contexts. Experimental evaluations in both English and Portuguese demonstrate that our approach achieves robust performance without the need for additional training, setting a new standard for multimodal idiom recognition.

1 Introduction

The SemEval-2025 Task 1 (AdMIRe) (Pickard et al., 2025) presents a new benchmark for understanding idioms in both visual and textual forms. It poses three main challenges: 1. Data Scarcity: With limited data (102 samples for Subtask A and 20 for Subtask B), traditional training methods won't work, so we need more efficient solutions. 2. Idiomatic Ambiguity: Phrases like "panda car" can mean different things (e.g., a police car or a toy) depending on context, making classification difficult. This is further complicated by cultural and domain-specific differences. 3. Multimodal Alignment: Combining visual and textual information requires new ways to integrate these different types of data, beyond just merging features.

To address these challenges, we propose **MIRA** (**M**ultimodal **I**diom **R**ecognition and **A**lignment), a training-free framework that leverages powerful closed-source large language models (LLMs). MIRA is built on three key innovations: Bias Correction via In-Context Learning – employing diverse in-context learning techniques to mitigate biases inherent in the closed-source LLM; Multi-Step Semantic-Visual Fusion – to ensure the retention of fine-grained visual details without excessive computational overhead; Self-Revision Mechanism – leveraging a backward verification process that diagnoses discrepancies, reconstructs justification chains for reliable outputs.

Our novel pipeline is designed to support cross-lingual and cross-modal idiom comprehension by systematic processing of multimodal inputs, with code available[1]. In addition to the core system, our contributions include:

- By first extracting image information and step-by-step fusing it with textual data, we can effectively obtain high-quality, fine-grained image-text representations not only enhance the performance of downstream tasks.
- Synergies in-context learning with in-domain knowledge, LLM can interpret semantics in accordance with the data distribution, yielding robust and accurate results without the need for additional training.
- Through combination of advanced test-time-scaling approaches and casual inference pipeline, MIRA can accurately interpret cross-lingual, cross-modal semantics in cross-cultural contexts, ultimately securing top rankings in both English and Portuguese evaluations.

* Equal contribution.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1211–1216

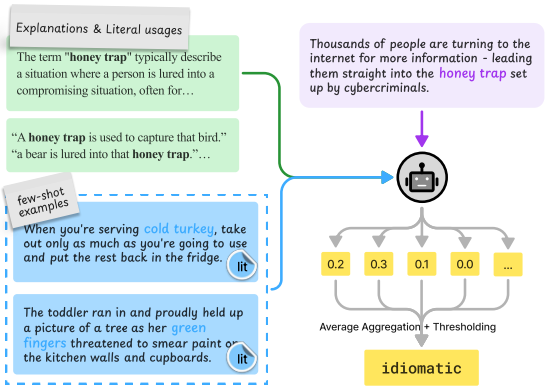

Figure 1: Pipeline for Sentence type interpolation

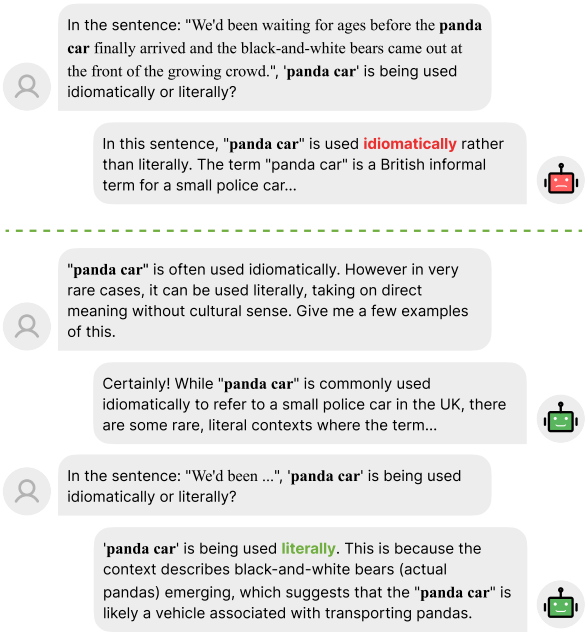

Figure 2: Case study on idiomatic bias of Zero-shot Inference

2 Subtask A System overview

In Subtask A, given a sentence containing a potentially idiomatic nominal compound (NC), the task is to rank five candidate images based on their relevance to the NC's meaning in context. This requires both accurate interpretation of the NC's sense (literal or idiomatic) and an effective ranking mechanism that aligns images with the intended meaning.

We introduce a bi-step approach to address this challenge: (1) Sentence Interpolation, and (2) Image Understanding and Ranking. This structured decomposition ensures that the system first establishes a clear understanding of the NC's meaning before attempting image ranking, allowing for more reliable alignment between textual interpretation and visual selection.

2.1 Sentence Interpolation

2.1.1 In-context Learning

Training-free methods face inherent limitations due to their unfamiliarity with dataset-specific statistical patterns and label distributions when applied outside domain-adapted fine-tuning (Li et al., 2025; Snell et al., 2024).

Idiomatic Bias Our analysis (see Figure 2) reveals that LLMs are systematically biased toward figurative interpretations of NCs, often failing to accurately identify their literal usage. This shortcoming can be attributed to a training data bias that emphasizes prevalent figurative instantiations over the less frequent literal ones, thereby impairing the models' ability to capture nuanced semantic distinctions in contextually ambiguous cases. We address this limitation through 2 in-context learning strategies – by providing additional exemplars and by offering literal explanations of the NC, which (1) align model reasoning with domain-specific label distributions and (2) enforce output format compliance via syntactic templates.

Literal Exemplars We prompt the LLM for literal use cases before classification to counteract LLM's figurative bias. This simple addition boosts accuracy from 91.4% to 98.6% on the English dataset, demonstrating the power of contextual exemplars.

Challenging Cases Using diagnostic sampling on the training data without exemplars, we identified 15 misclassified cases as challenging examples. At inference, we include literal cases, their explanations, and a random selection (0–2 examples) from this set to guide ambiguous predictions. Additionally, if a compound appears only once in training, its instance is added as an extra exemplar.

2.1.2 Self-Consistency Reasoning

To secure robustness and reduce prompt sensitivity, we employ self-consistency reasoning (SCR) (Wang et al., 2023), which generates multiple divergent reasoning paths with varied prompt formulations, then selects the most coherent classification via majority voting, as illustrated in Figure 1. This approach leverages the principle that diverse problem-solving trajectories often converge on the

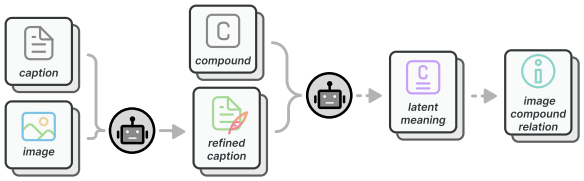

Figure 3: Multi-step image understanding pipeline

correct answer, enhancing robustness and reducing the impact of local minima.

2.2 Image Understanding

We introduce a unified pipeline that enhances compound-image relevance assessment through a 3-step pipeline – enabling fine-grained interpretation of multimedia content through interconnected stages (see Figure 3).

Cross-Modal Caption Refinement Given an image I and its associated textual caption T_I, we refine the caption by integrating both visual and textual features. Specifically, an LLM is prompted to generate an enriched caption $\hat{T}_I = \text{LLM}(T_I, f(I))$ where $f(I)$ denotes the extracted visual features of I. This multimodal alignment ensures that the refined caption $\hat{T}_I$ captures intricate semantic details beyond the original textual description.

Latent Meaning Inference To infer deeper semantic intent, the refined caption $\hat{T}_I$ is further analyzed to determine implicit or non-literal meanings regarding the compound C. The LLM processes $\hat{T}_I$ and outputs a latent interpretation L: $L = \text{LLM}(C, \hat{T}_I)$, which incorporates idiomatic, metaphorical, or culturally specific insights essential for downstream classification and ranking.

Relation Scoring Leveraging the previous output L, the LLM is prompted to estimate ternary relation probabilities over three categories: *Literal* (L), *Idiomatic* (I), and *N/A* (N). The probability distribution is denoted as:$P = \{p_L, p_I, p_N\} = \text{LLM}(L)$. These probabilities serve as fine-grained relational signals, enriching the final ranking process with nuanced semantic information.

2.3 Reliable Ranking

Let $\mathbf{E}_i = \{P_{ij}, L_{ij}\}_{j=1}^{5}$ denote the evidence tuples for data instance i, where P_{ij} and L_{ij} represent relation probabilities and latent interpretations for the j-th candidate image. These tuples are fed into an LLM via a unified prompt to generate an initial ranking. To enhance stability, we adopt a simple verification step inspired by (Weng et al., 2023), in which K independent forward passes are performed, follwed by diagnosing ranking discrepancies, reconstructing justification chains. Finally output the refined ranking.

3 Subtask B System overview

The goal is twofold: to extend a visual narrative by selecting the most appropriate candidate image from a set of four, and to classify the NC usage as either idiomatic or literal. We address this through a two-stage pipeline: multimodal story analysis followed by usage classification. Similar to Subtask A, we also include literal use cases to tackle idiomatic bias, as described in Section 2.1.1.

Target Image Selection The LLM is prompted to describe and continue the story. Based on this continuation, the system scores the candidate images based on their likelihood to fit the narrative. SCR (explained in Section 2.1.2) is used along with average probability aggregation to enhance the robustness of the image selection process.

Sense Classification After selecting the most appropriate image, the system classifies the NC usage as idiomatic or literal, providing probability scores for both interpretations. SCR and average probability aggregation are applied to ensure accurate and robust classification.

4 Experiment

In this section, we perform a series of experiments to address the following research questions:

- How does in-context learning optimize results?
- How does visual information enhance textual features?
- How does Self-Consistency Reasoning work?

4.1 Experimental Settings

In this work, we utilize training data to conduct experiments and fine-tune our models, while also exploring a training-free framework that employs GPT-o1 as the underlying large language model (LLM) for inference.

To evaluate the performance of our approaches, we adopt a comprehensive set of metrics, including top-1 accuracy, Discounted Cumulative Gain (DCG), Normalized Discounted Cumulative Gain (NDCG), ensuring a robust assessment across both subtasks and experimental settings.

4.2 Primary Results

Subtask	Modality	Metric	Test Set	Extended Eval Set
A	English	Top 1 Acc	**0.9333**	**0.83**
		DCG Score	3.522991	**3.425982**
	Portuguese	Top 1 Acc	0.6923	**0.7636**
		DCG Score	3.207992	**3.225982**
B	English	Image Acc	0.6	**0.9333**
		Sentence Type Acc	0.8	**1.0**

Table 1: Performance Results for Subtask A and B

The main results of task A and B are presented in Table 1. Our approach demonstrates strong performance across both tasks, particularly in the extended evaluation set, which has a larger data volume, making the improvements even more significant. For Subtask A, our method achieved first-place rankings in all three extended evaluations. Notably, the performance for Subtask B also secured the top position, with an accuracy of 1.0 on sentence type classification task.

4.3 How does in-context learning optimize results?

Dataset	FewShot	Idiomatic	Literal	Overall
Train	None	89.7% (35/39)	64.5% (20/31)	78.6%
	+ Hard	87.2% (34/39)	87.1% (27/31)	87.1%
	+ + Same	N/A		N/A
Eval (ex)	None	87.0% (40/46)	64.8% (35/54)	75.0%
	+ Hard	89.1% (41/46)	81.5% (44/54)	85.00%
	+ + Same	93.5% (43/46)	87.0% (47/54)	90.0%

Table 2: Result on In-Context Learning Variants for Sentence Classification. Binary classification accuracy results, with the specific number of correct predictions indicated in parentheses. "None": no example, "Hard": the include hard example, and "Same": using data instance with identical NC as detailed in Section 2.1.1.

To explore optimal in-context learning strategies for this task and assess the impact of few-shot exemplars as discussed in Section 2.1.1, we examine three configurations of the in-context approach: (1) exclusion of all examples, (2) inclusion of exclusively hard examples, and (3) additional integration of training-set examples with identical NC values. Throughout all experimental conditions, the quantity of "Hard" instances remains fixed at one (serving as single-shot exemplars).

Table 2 reveals that incorporating hard examples consistently enhances overall performance across all metrics. Notably, the "Hard" configuration demonstrates greater improvements compared to baseline (+26%), indicating that hard examples sharing distributional characteristics with the training data yield superior contextual learning benefits.

A pronounced distinction emerges in performance gains between literal and idiomatic classification accuracy. This phenomenon correlates with fundamental principles of in-context learning mechanisms - LLMs unfamiliar with the dataset's distribution exhibit inherent discrepancies in interpreting idiomatic NCs, which typically function semantically differently than their literal counterparts. The strategic provision of representative examples addresses this representational gap by aligning the model's contextual reasoning with the target data distribution's statistical properties.

4.4 How does visual information enhance textual features?

To evaluate the contribution of visual information in enriching textual features, we assess the impact of Cross-Modal Caption Refinement and Latent Meaning Inference in Section sec: self-consistency through controlled experiments, where each ablation progressively removes a key processing step. The compared variants are:

- ***w/o* refine & latent**: directly ranks candidate images based only on their captions and the given compound, bypassing both caption refinement and latent meaning inference.
- ***w/o* refine**: Instead of Cross-Modal Caption Refinement, the model performs latent meaning inference using raw captions without multimodal enhancement.
- ***w/o* latent**: Excludes Latent Meaning Inference, directly using the refined caption and compound for Relation Scoring.

As shown in Figure 4, incorporating visual information significantly enhances the quality of textual features. Specifically, Cross-Modal Caption Refinement leads to substantial improvements in Acc@1, with gains of 15.8% and 13.0% for English and Portuguese, respectively. This highlights the limitations of raw captions and the necessity of integrating image-based enhancements.

While Latent Meaning Inference does not yield substantial improvements in Acc@1, it plays a crucial role in optimizing the overall ranking quality. By leveraging compound semantics for deeper interpretation, this step improves the DCG score by 3.0% and 4.0% in English and Portuguese, respectively. These findings suggest that multimodal

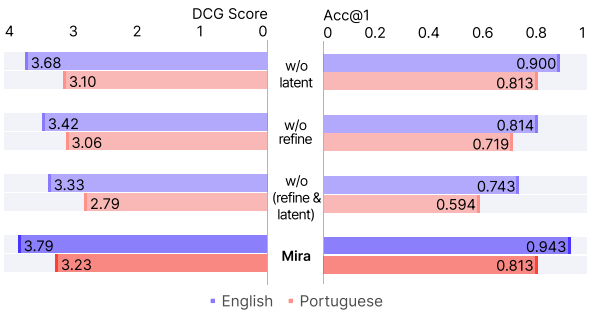

Figure 4: Impact of visual information on ranking performance. The left plot shows DCG Score, and the right plot shows Acc@1. Purple represents English, while red represents Portuguese. Incorporating visual features significantly improves Acc@1, while latent meaning inference enhances overall ranking quality (DCG Score).

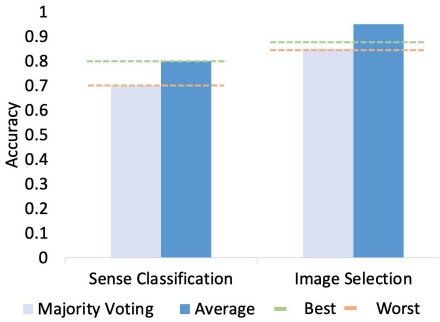

Figure 5: Comparison of Majority Voting and Mean Aggregation for task 1: sense classification and task 2: image selection accuracy. The red line represents the worst performance among individual results before aggregation, while the green line highlights the best performance.

alignment enhances both direct selection accuracy and the ranking consistency of candidate images.

4.5 How does Self-Consistency Reasoning work?

Table 5 below presents a comparison of the performance of Majority Voting and Mean Aggregation for 2 tasks in Subtask B.

From the results, we observe that Average Aggregation consistently outperforms Majority Voting across both tasks. For Sense Classification, Average Aggregation achieves a mean score of 0.8, compared to Majority Voting's 0.7. Similarly, in the Image Selection task, Average Aggregation shows a stronger performance, with a mean of 0.95 versus Majority Voting's 0.85. Additionally, the Worst and Best values for both tasks reflect the relative stability of Average Aggregation.

5 Conclusion

This work presents MIRA, a training-free framework for multimodal idiom comprehension. Leveraging powerful closed-source language models, MIRA overcomes data scarcity, idiomatic ambiguity, and multimodal alignment challenges through three core components: visual-text fusion, in-context learning, and self-consistency reasoning. Visual-text fusion extracts fine-grained visual details and integrates them with text to create high-quality representations. In-context learning leverages in-domain knowledge to ensure semantic interpretations align with the data distribution, while self-consistency reasoning aggregates multiple reasoning paths to mitigate errors and enhance reliability. Together, these components form a robust causal inference pipeline that has achieved top rankings in both English and Portuguese evaluations and adapts efficiently to low-resource multilingual scenarios. Future work will explore enhanced chain-of-thought reasoning and zero-shot debiasing to further expand its applicability.

6 Related Work

Multi-modal Understanding Multimodal understanding, the integration of visual and textual data, faces significant challenges in alignment issues, noise resilience, and disparities in feature representation (Masry et al., 2025; Li and Tang, 2024). While studies have highlighted the importance of leveraging complementary information across modalities for accuracy and applicability, training-free methods remain limited (Chen et al., 2025). This framework have explored a pipeline path-way to tackle these challenges through multi-steps thinking, thus dynamically align semantic features without fine-tuning.

Test-time scaling and LLM Reasoners The concept of test-time scaling, where increased compute at test time leads to better results, has gained traction in the context of LLMs (Xu et al., 2025). Recent work using models like OpenAI's o1 and Deepseek-r1 (Sui et al., 2025) demonstrated superior performance through scaled test-time computation. Our work leverages these insights by employing self-consistency reasoning (Wang et al., 2023; Yao et al., 2023) to enhance performance without fine-tuning, aligning with the goal of efficient and scalable reasoning in LLMs.

Abstract

Emotion intensity prediction is crucial in affective computing, allowing for a more precise understanding of how emotions are conveyed in text. This study proposes a system that estimates the levels of intensity of emotions by integrating contextual language representations with numerical emotion-based characteristics derived from Valence, Arousal, and Dominance (VAD). The methodology combines BERT embeddings, predefined VAD values per emotion, and machine learning techniques to enhance emotion detection without relying on external lexicons. The system was evaluated on the SemEval-2025 Task 11 Track B dataset, predicting five emotions (anger, fear, joy, sadness, and surprise) on an ordinal scale.

The results highlight the effectiveness of integrating contextual representations with predefined VAD values, allowing a more nuanced representation of emotional intensity. However, challenges arose in distinguishing intermediate intensity levels, which affected the classification accuracy for specific emotions. Despite these limitations, the study provides insight into the strengths and weaknesses of combining deep learning with numerical emotion modeling. It contributes to developing more robust emotion prediction systems. Future research will explore advanced architectures and additional linguistic features to enhance model generalization across various textual domains.

1 Introduction

Emotions are essential in language and vary in intensity depending on the context. Understanding which emotions we express in a conversation and why they occur is crucial for improving the quality of human interactions (Wang et al., 2023). Given a text and a perceived emotion, the system must estimate its level within a predefined scale, considering the language and its variations, thereby enabling a precise analysis of affective language (Cuadrado et al., 2023). This article presents a system to predict the intensity of a set of emotions in a text fragment. This analysis builds upon previous models that have contributed to the identification of emotions present in textual comments. Some emotions are more fundamental in physiological and cognitive terms, allowing them to manifest at different intensity levels (Hsu et al., 2025). Their significance lies in enhancing the automatic understanding of emotions in artificial intelligence and affective language analysis.

To address this task, we proposed a system that relies on contextual language representations and emotional features that capture language representations and emotion-specific VAD values, quantifying valence, arousal, and dominance (Ghosh et al., 2023).

Participation in this task allowed for the evaluation of the system's performance in detecting the intensity of perceived emotions compared to other approaches. Although the system's performance was below the average, it successfully captured relevant patterns in emotional intensity variation. We observed that integrating contextual representations with VAD-based emotional features enabled an approximation to the objective despite limitations in classifying certain emotions. The primary challenges arose in differentiating intermediate intensity levels, which affected accuracy in some categories. Despite these challenges, the experience provided valuable insights for improving the modeling of emotional intensity in future studies. The code developed in this study is available for researchers and developers to access, analyze the implemented approaches, and replicate the experiments. By sharing the code, this work promotes the reproducibility of results. It fosters continuous improvement in the detection of perceived emotion intensity. [1]

2 Background

Emotion recognition in text is an area of growing interest due to the rise of digital communication and the inherent complexity of language in these environments. Previous research has approached this challenge from various perspectives, achieving significant advances in the semantic and syntactic understanding of texts and improving language representation across multiple languages (Suresh et al., 2024; Mohammad and Kiritchenko, 2018). Additionally, authors highlighted the importance of context, sentiment consistency, and common-sense knowledge to accurately detect emotions in such texts (Tu et al., 2022). These approaches emphasize the need for sophisticated models to capture the emotional richness of diverse digital interactions.

Emotion recognition models have evolved considerably, shifting from rule-based approaches to more adaptive methods, allowing a more precise and flexible interpretation of emotional language (Bhati et al., 2024). These advancements have enhanced the ability of models to capture linguistic nuances, recognize context, and handle variations in emotional expression, which is crucial for practical applications in various domains.

In this work, we participated in Track 2 of Task 11, which focuses on detecting and predicting emotion intensity in English text. The task consisted of identifying the perceived emotion in a text fragment and assigning it an intensity level based on a predefined ordinal scale. This approach allows a single comment to contain multiple emotions, each with an intensity level, enriching data analysis and interpretation.

The dataset used for this task consisted of 117 developing samples, 2768 training samples, and test validation samples, in which we analyzed five specific emotions: joy, sadness, fear, anger, and surprise. The ordinal scale assigns the following values: 0 for no emotion, 1 for low intensity, 2 for moderate intensity, and 3 for high intensity. For example, in the sentence "None of us has mentioned the incident since", the system assigned the following intensities: joy (0), fear (1), anger (0), sadness (2), and surprise (1), illustrating the data structure and the model’s response generation, which has been explored in previous studies Table 1 (Muhammad et al., 2025)

We reviewed prior sentiment and emotion analysis research to support this approach, providing a solid theoretical and methodological foundation (Garcia et al., 2024). Integrating advanced natural language processing techniques with emotion prediction models has opened new possibilities for a deeper understanding of written communication. These approaches enhance accuracy in emotion detection and facilitate their application in customer service, mental health, and trend analysis on social media. As these models evolve, we expect future research to expand and refine emotion analysis methods, offering increasingly robust and efficient solutions for automatic language processing.

3 System Overview

Analyzing and predicting emotions from text follows a structured approach based on multiple stages. The methodology begins with data loading and preprocessing, followed by text representation using embeddings, fine-tuning a BERT-based model, predicting valence, arousal, and dominance (VAD) values, and finally converting these values into discrete emotion intensities. We evaluated the model using metrics that compare predictions with reference values to measure its accuracy and reliability, as shown in Figure 1.

In the preprocessing stage, textual data undergoes thorough cleaning and normalization to ensure a standardized representation. First, the dataset is loaded, ensuring its structure is consistent and suitable for the model. Then, text normalization techniques are applied, including lowercase conversion, removal of special characters, punctuation, and non-alphabetic elements, and expansion of contractions to enhance semantic coherence. We also removed stopwords to optimize text representation. Additionally, we computed VAD values to represent the emotion labels.

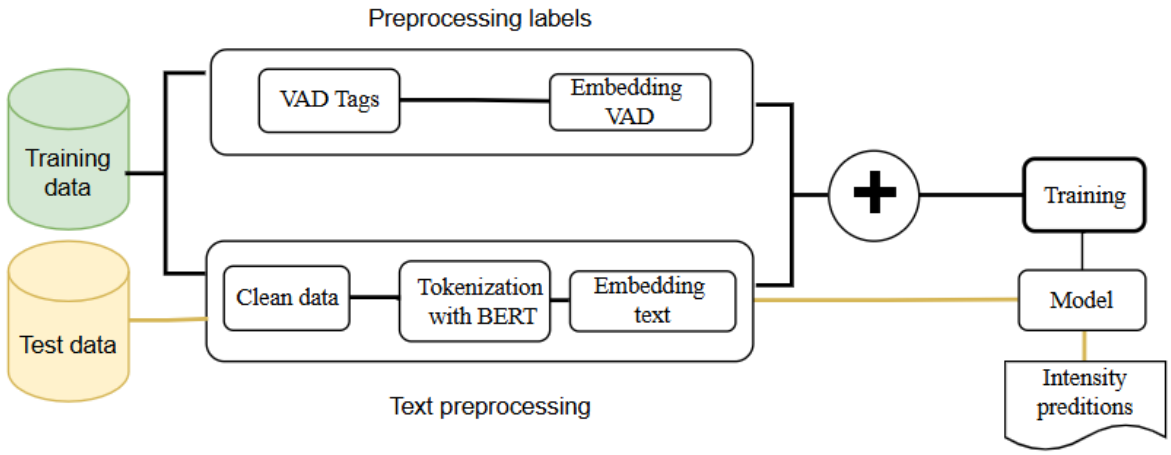

Figure 1: General pipeline system.

Once the text is processed, it is tokenized and represented using a pre-trained language model. In this case, BERT (Devlin et al., 2018) is employed to convert the text into token sequences and attention masks. These numerical representations capture semantic and contextual relationships within the text, enabling a deeper analysis of expressed emotions.

The next step involves training the model. We fine-tuned a BERT-based model for predicting continuous VAD values, and we adapted a pre-trained model specialized in language comprehension through a fine-tuning process. During this phase, the model learns to associate textual patterns with corresponding VAD values, optimizing its weights via a gradient descent algorithm and using a regression loss function.

We trained the model using standard hyperparameters to fine-tune BERT in classification tasks. We used a learning rate 2e-5 and three epochs to ensure convergence without overfitting. We set a batch size of 8 to optimize memory usage when processing long sequences. We employed AdamW as the optimizer. A learning rate scheduler with an initial warm-up phase and linear decay was also applied to improve training stability and convergence. We selected these values based on best practices for emotional intensity prediction.

After training, the model generates VAD predictions for new data. These predictions provide a continuous estimation of the emotion present in each sentence, offering insights into the emotional intensity of the text. However, we converted these VAD values into discrete emotional intensities to facilitate result interpretation. We achieved this through a mapping mechanism based on Euclidean distances. In this process, we compared the predicted VAD values with predefined reference values for each emotion, and we assigned the closest intensity on a scale from 0 to 3.

Finally, we evaluated the model using performance metrics. We calculated the Pearson correlation to measure the relationship between predicted and reference VAD values, assessing the model's capability to correctly identify emotional intensities. The results of these metrics help identify strengths and limitations, guiding future improvements in the emotion prediction system.

The proposed methodology integrates advanced natural language processing techniques with deep learning models to predict emotions in text. By leveraging BERT for language representation and a conversion system for mapping VAD values to discrete intensities, a robust and efficient model is developed for analyzing emotions in textual conversations.

4 Experimental Setup

We got three datasets: training, development, and testing, ensuring that the model is trained and evaluated on entirely independent data. We applied techniques such as normalization, contraction expansion, pattern removal, and stopword elimination during preprocessing. We used tools like spaCy and the contractions library to clean and standardize the text before using BertTokenizer. Hyperparameter tuning, including adjustments to the learning rate and number of epochs, is performed on the training set. In contrast, we used the development set for it-

erative validation and model selection. Finally, the Pearson correlation coefficient is calculated individually for each dimension of the VAD space, which is then transformed into emotional intensities to assess the quality of the predictions.

5 Result

In our experiments, we evaluated the model over three training epochs, where we monitored the Pearson correlation coefficient for each dimension of the VAD space (Valence, Arousal, and Dominance). During the first epoch, a global accuracy of 0.6552 was obtained, with Pearson's r values of 0.5133, 0.5467, and 0.6429 for V, A, and D, respectively. In the second epoch, the metrics improved significantly, reaching a precision of 0.7726 and Pearson coefficients of 0.5765, 0.5898, and 0.6910 for V, A, and D, demonstrating an increased ability of the model to capture emotional intensity at this stage. In the third epoch, the accuracy stabilized at 0.7455, and the Pearson coefficients were 0.5609, 0.5874, and 0.6821, respectively. The final average metrics in all epochs showed a precision of 0.7244 and average Pearson values of 0.5502 (V), 0.5746 (A) and 0.6720 (D), as shown in Table 2. These results suggest that the model more accurately captures perceived intensity regarding control and authority, whereas positivity (Valence) and emotional activation (Arousal) exhibit more significant variability in predictions.

The performance of the model varied significantly between emotions. As shown in Table 3, the model achieved better predictions for emotions such as Anger (0.6418) and Sadness (0.55), suggesting that these emotions exhibit more distinct patterns in the VAD space. In contrast, Fear obtained the lowest score (0.0514), indicating difficulties in accurately identifying this emotion. Joy and Surprise showed intermediate values, with scores of 0.5408 and 0.1782, respectively. In particular, the low score for Surprise suggests that this emotion presents an additional challenge, possibly due to the subjectivity and implicit contextual cues required for proper interpretation.

Furthermore, Table 5 presents the comparison of validation metrics between the baseline model, without VAD information integration, and the improved model that incorporates these affective features. Although the precision of the micrometrics, the recall, F1 and the overall accuracy (0.7437) remained constant, the macrometrics showed substantial improvements: the macro precision increased from 0.5959 to 0.7494, the macro recall from 0.5535 to 0.7528, and macro F1 from 0.5715 to 0.7434. These results demonstrate a more balanced performance between classes, indicating that the incorporation of VAD information significantly improved the quality and fairness of the model.

When analyzing the development set, the Pearson coefficients for each emotion reflect a more significant discrepancy between predicted and actual intensities. Anger (-0.0617), Fear (0.0141), Joy (-0.0023), Sadness (-0.0252), and Surprise (-0.1307), with an average of -0.0412 (Table 4). This significant difference in correlation at the emotional level suggests that, while the model captures some coherence in the VAD space, the conversion to emotional intensities still presents inconsistencies. Furthermore, the negative correlation in some emotions indicates that the model may be predicting intensities in opposite directions to those expected, highlighting the need for refinement in transforming VAD into discrete emotional categories.

A key finding in our analysis is that integrating VAD values improved the detection of emotions with well-defined characteristics in valence, arousal, and dominance. However, for emotions with less distinct distributions in this space, such as Fear and Surprise, the model tended to predict values closer to neutrality, which may explain the lower scores for these categories. The difference in performance between emotions could be attributed to an imbalance in the distribution of the class within the training set, limiting the model's ability to learn appropriate representations for less frequent or more ambiguous emotions Table 6.

While the model demonstrates promising performance in predicting certain emotions, the results suggest that additional adjustments are needed to improve its generalization capability. Techniques such as class balancing, loss function adjustments, or incorporating additional linguistic features—such as deep semantic analysis or multimodal models integrating supplementary signals—could be explored to address these limitations. Additionally, evaluating the model on more diverse datasets would allow for assessing its robustness across domains and contexts.

6 Conclusions

This study presented a system for predicting the intensity of perceived emotions in a text by inte-

	Pearson r Score
Valence	0.5502
Arousal	0.5746
Dominance	0.6720

Table 2: Pearson r VAD Assessment Score.

Emotion	Pearson r
Anger	-0.0617
Fear	0.0141
Joy	-0.0022
Sadness	-0.0252
Surprise	-0.1307
Average	-0.0412

Table 3: Development model evaluation.

Emotion	Pearson r
Anger	0.6418
Fear	0.0514
Joy	0.5408
Sadness	0.55
Surprise	0.1782
Average	0.40

Metric	Without VAD	With VAD
Accuracy	0.7437	0.7437
Precision (Micro)	0.7437	0.7437
Precision (Macro)	0.5959	0.7494
Recall (Micro)	0.7437	0.7437
Recall (Macro)	0.5535	0.7528
F1 (Micro)	0.7437	0.7437
F1 (Macro)	0.5715	0.7434

Table 5: Validation results comparison without and with VAD.

Text	Gold Label					Prediction Label				
	Joy	Fear	Anger	Sadness	Surprise	Joy	Fear	Anger	Sadness	Surprise
So... for reasons unknown...	0	1	0	0	2	1	1	0	0	1
None of us has mentioned the incident since.	0	1	0	2	1	0	1	0	1	0
I stopped a couple times to stretch out my calves and quads.	0	0	0	0	0	1	1	0	0	1

Table 6: Comparison of gold and predicted emotion labels.

grating contextual linguistic representations with a numerical modeling approach based on predefined VAD values. By combining BERT embeddings and machine learning techniques, the system successfully captured relevant patterns in emotional intensity variation, achieving acceptable performance in predicting certain emotions such as anger and sadness.

The results highlight the impact of integrating VAD values into emotional representation, allowing for a more nuanced capture of emotion intensity compared to discrete classification approaches. However, the system encountered difficulties distinguishing intermediate intensity levels, particularly in emotions such as fear and surprise, suggesting further refinement to improve its accuracy in these categories.

Despite these limitations, the applied methodology offers a promising approach to text-based emotion analysis, emphasizing the importance of continuous representations in emotion modeling. This study provides a solid foundation for future research, underscoring the need to explore advanced techniques further to enhance the prediction of emotional intensity.

7 Future Work

Future research should focus on optimizing the integration of VAD values within BERT's attention mechanism, dynamically adjusting them based on semantic context to better capture subtle emotional nuances. Calibration techniques like ordinal regression and isotonic calibration could also improve the accuracy of intermediate intensity classifications. Additionally, enhancing text preprocessing through efficient tokenization and embedding strategies that merge semantic and affective information could further strengthen predictive performance. A detailed error analysis is recommended to refine the model based on misclassification patterns. Finally, applying interpretability methods such as SHAP and LIME would provide greater transparency and insights into the model's decision-making in affective computing.

Acknowledgments

Abstract

Question answering using Large Language Models has gained significant popularity in both everyday communication and at the workplace. However, certain tasks, such as querying tables, still pose challenges for commercial and open-source chatbots powered by advanced deep learning models. Addressing these challenges requires specialized approaches.
During the SemEval-2025 Task 8 competition focused on tabular data, our solution achieved 86.21% accuracy and took 2nd place out of 100 teams. In this paper we present ten methods that significantly improve the baseline solution. Our code is available as open-source software at the link: https://github.com/samsungnlp/semeval2025-task8.

1 Introduction

In recent years, Large Language Models (LLMs) have made significant advancements, emerging as powerful tools for extracting, interpreting, and generating insights from textual data. One of their most significant applications is Question Answering (QA), where LLMs provide contextually relevant responses to user queries. Although LLMs excel in natural language understanding, they still face challenges in processing and reasoning over tabular data, particularly in understanding relationships, identifying relevant columns, and answering complex queries. With a substantial amount of real-world data stored in tabular formats, the ability to efficiently interpret and utilize structured information seems more critical than ever.

1.1 Related methods

Tabular QA has gained significant attention in recent years, with various approaches being explored. Ye et al. (2024) generated pandas queries using only column names. Giang et al. (2024) introduced The Plan-of-SQL (POS), which enhances transparency by breaking down questions into SQL sub-queries. Zhang et al. (2023) proposed ReAcTable, which iteratively generates intermediate tables (through SQL or Python code) for step-by-step reasoning. Abhyankar et al. (2024) presented H-STAR, which extracts relevant table rows and columns before reasoning, reducing noise but risking error propagation if key columns are missed.

1.2 System overview

Our solution is based on an ensemble of carefully prompted models built around generative LLMs, where each model contributes to the prompt or verifies the result. Each of these models votes on the final answer. The system overview is illustrated in Figure 1a.

Although the models differ significantly – which is essential to leverage voting – they share a common structure composed of essential blocks, as shown in Figure 1b. Key components include table preprocessing and summary, identifying necessary columns and answer types, question paraphrases, few-shot learning and a correction loop.

2 Data

The training and test data we used was DataBench, a benchmark dataset for tabular data (Osés Grijalba et al., 2024; Os'es Grijalba et al., 2025). The authors of DataBench emphasised their intention to create a benchmark using "real-life" datasets, which also resulted in challenges in interpretation. The issues related to tables involved two areas (please refer to Table 10 in Appendix D for examples): (1) Multiple types of values within a single column (e.g. integers, floats and NaNs), (2) Unclear column names – acronyms or shortened words.

The analysis of the questions also showed that some posed greater challenges than others, which corresponded to the models' performance. We identified the following groups of issues: (1) The need

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1223–1232

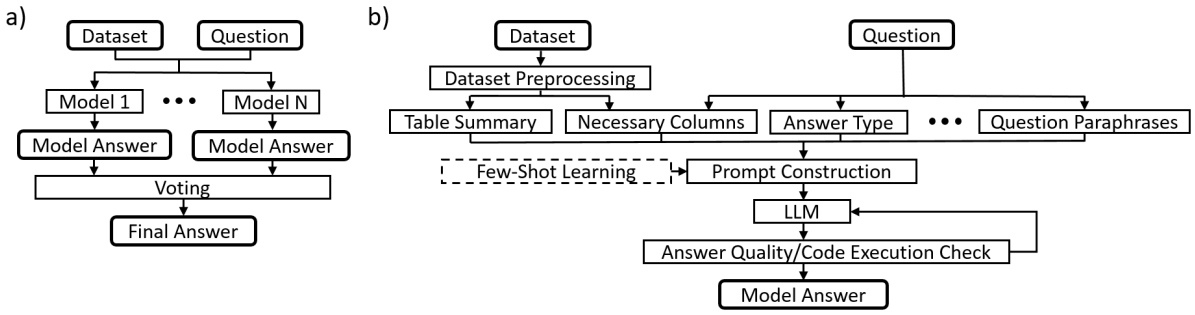

Figure 1: System overview. a) Top level overview of the system – multiple models are used to produce answers further used for voting. b) Overview of elements building a single model.

for external knowledge not present in the table, (2) The necessity to operate on substrings/altered strings, (3) Ambiguity in question phrasing that allows for multiple interpretations, (4) Multiple possible answers that are equally correct, (5) The need to convert units, such as weight or currency, (6) Complex phrasing or language mistakes. See examples in Table 11 in Appendix D.

3 Methods

3.1 Prompt Construction

During our experimentation we found that the following approaches significantly enhanced system performance and proved effective on our tasks:

Data preprocessing: LLM's performance declines without preprocessing due to issues like emojis in column names and table content interfering with code execution. We discuss it in Section 3.2.

Table summary: As LLMs struggle with numerical data, and passing an entire table would require a large context window, we included only a summary of the table in the prompt (see Section 3.4.)

Detecting necessary columns: To simplify the LLM tasks, we include only essential column names in the prompt. The detection process is detailed in Section 3.3.

Question paraphrases: We used question paraphrases in the prompts (see details in Section 3.8).

Code output: Our LLMs return code for answerers, as this solution works well with tables (Osés Grijalba et al., 2024). See Section 3.7 for details.

Output formatting: To ensure compatibility with the validation function, we specify the required answer formatting in the prompt for each question. We determine the necessary formatting by analyzing the questions with a separate model, as described in Section 3.6.

Few-shot learning: To enhance prompting, for some models, we used around 10 carefully selected QA examples.

3.2 Data preprocessing

We encountered irregularities in column names and issues when reading datasets with *pandas* `read_csv`, particularly with advanced data types, such as lists or dictionaries, which were incorrectly converted to strings. We implemented a multi-stage preprocessing pipeline involving:

(1) **Column name cleanup**: Removing emojis, HTML tags, and excess whitespaces.

(2) **Value Parsing**: At first we attempted literal evaluation. If this approach failed, we then parsed values as JSON objects. Finally, we transformed list-like values (those lacking quotation marks or containing extra brackets) into valid lists.

These steps improved data parsing for effective operations.

3.3 Detecting necessary columns

To reduce dimensionality, we used LLMs to identify the essential columns for specific questions. Through several experiments and iterative prompt engineering, we discovered that the best results were achieved by breaking down the task of extracting the appropriate pandas query into three steps:

1. Filtering the dataset with relevant columns (time-based, categorical, or entity-related filters).
2. Sorting, ranking, or aggregating data based on specific columns.
3. Returning the final answer by selecting the necessary columns.

We provided the LLM with a list of dataset columns, including data types and three random example values for each.

To ensure that the model returned only original column names from the dataset, the prompt restricted outputs to the provided column list. However, a postprocessing loop was added as a fallback, where each proposed column was checked against the input list. If a column was missing, preprocessing steps like removing double spaces, trimming underscores, and eliminating trailing whitespace were applied, followed by a re-check.

Ultimately, Llama 3.3 achieved approximately 95% accuracy[1] on this task, where accuracy was defined as the inclusion of *at least* all required columns for a given query.

3.4 Table summary

In order to provide LLM with additional knowledge about a given table, we created a script that extracts key information about the table, including column names, variable types, empty values, and statistics for numeric columns (standard deviation, mean, min and max).

We also checked whether each row of the column is unique and what are the most common values. The generated report, passed to the prompt, helped inform the LLM about the table's structure and potential difficulties in the analysis.

3.5 Raw data in markdown format

We found it valuable to include both the column headers and a sample of row data in markdown format. Typically, we fed the prompt with 20 rows.

3.6 Answer type prediction

To achieve balance between classification task metrics and GPU usage we utilized paraphrase-albert-small-v2 ALBERT based model (Lan et al., 2019) from the Sentence BERT model family (Reimers and Gurevych, 2019). The model was first fine-tuned on DataBench dataset. Given a query tokenized into subwords using ALBERT's tokenizer, the model then processed the text through the transformers layer, allowing its neural network to classify the given query into one of the answer types.

ALBERT' accuracy on the training set was approximately 96%, exceeding Llama 3.3's performance of 86% on the same task. See Appendix A for more ALBERT's result details.

To further improve the classification, a voting system incorporating Llama 3.3 and Qwen 2.5 was deployed. In case of ALBERT and Llama disagreeing, Qwen is inferenced. Thanks to this voting, the overall accuracy of answer type prediction increased to 98.28%.

3.7 Python pandas and SQL code generation

Our approach involved generating single, one-line commands in pandas and SQL. At first, we prompted LLM to generate pandas code answering a question. We constructed our prompts iteratively, as described in Section 3.9 It was specified that the model should generate a plain command, without any additional explanation. Tests revealed that for some questions LLM continued to make similar mistakes in pandas commands.

For stronger contribution to the ensemble of models, we asked LLM to write SQL queries. The prompt construction mirrored that written in pandas case, introducing as an add-on SQL schema of a table. For generating and executing SQL code we used SQLite and DuckDB.

3.8 Question paraphrasess

Using paraphrase generation as an auxiliary method to increase accuracy is a common approach applied in various AI systems, e.g.: text style transfer (Bujnowski et al., 2020) or open domain question answering (Siriwardhana et al., 2023). In our experiments we generated paraphrases of questions using Qwen 2.5 and used them in various answerer models. Input to the model was a prompt with a task to return 5 paraphrases of a question (in a JSON format) and included the table headline and a few examples (e.g. 3 rows) from the dataset in a markdown format.

Question paraphrases seem to be beneficial for LLMs in case of ambiguous questions, e.g. by using column names directly or reformulating a question in a less complex way.

3.9 Loops for code correction

We employed an LLM for QA tasks by generating pandas or SQL code iteratively. The process involved querying the LLM to propose a code snippet within a loop, which was set to a maximum number of iterations (max_iter). Each proposed code was then executed to evaluate its response. If the code was executed without errors, the response was accepted. If an error occurred, the information about the error was fed back into the LLM as feedback, allowing it to refine the next proposed code snippet. This iterative process continued until either

[1]This result is nontrivial to calculate precisely, as the task is inherently nondeterministic, and some questions may have multiple valid solutions.

executable code was generated or the max_iter limit was reached.

The next stage of our pipeline focused on improving the generated queries. Common errors included the absence of methods such as `.to_list()`, `.any()`, `.iloc[0]`, `.item()`, `.index.to_list()` at the end of a query, problems with redundant or missing brackets, as well as unnecessary artifacts of LLM's responses such as ```` ```python ````. The auxiliary LLM received input that included a pre-generated pandas query along with details about possible issues, and was tasked with generating a corrected version of the query based on this information.

3.10 Limiting inference tokens

Many questions demanded thorough understanding of both the question and dataset, prompting us to use reasoning models. We adhered to established prompt structures and temperature recommendations (Guo et al., 2025). However, for ambiguous or highyly dataset-specific questions, reasoning models often generated excessively long thinking processes without arriving at correct solutions. We addressed this by implementing a token cap for the thinking process, which forced the models to provide final answers after reaching a predetermined token limit.

3.11 Ensemble models

To improve predictions we used ensemble models, selecting the best-performing ones based on training set results. For each question we took answers inferred by selected models and removed these flagged as invalid. If there was a single answer left, it was returned as the ensemble result. Otherwise, we next applied simple majority voting. The vote was considered conclusive if more than the half of the answers were consistent. If not, we used Qwen 2.5 for arbitration. Its input included: the question text, column names, inferred necessary columns (Section 3.3), table summary (Section 3.4), predicted answer type (Section 3.6), and valid model results. Additionally, we assessed the complexity of pandas queries where applicable, based on factors such as the number of executable functions in a query, occurrence of a custom function like `lambda` or `.apply()`, and presence of data type conversions. For each criterion the query received a penalty, which was then added up to the final score and fed to the LLM to support voting.

4 Results

4.1 Experimental setup

Model name	Model size
Llama-3-Instruct	70B
Llama-3.3	70B
Qwen-2.5-Instruct	72B
DeepSeek-R1-Distill-Qwen	32B
DeepSeek-R1-Distill-Llama	70B
DeepSeek-R1	671B

Table 1: LLMs: models used in experiments and for final predictions, with their respective parameter counts.

We evaluated various LLMs and selected them based on their high scores on coding and reasoning benchmarks (Dubey et al., 2024; Guo et al., 2025; Yang et al., 2025). The specific models that we used are detailed in Table 1. All models were implemented in 4-bit quantized versions due to hardware limitations, and executed on GPUs via the llama.cpp interface (further details provided in the Appendix in Table 7).

4.2 Results of separate and ensemble models

In Table 2 we present our results for single and ensemble models for "FULL" task. Our top-performing system achieved an accuracy of 86.21% and consisted of 8 various models using combinations of the methods outlined in Section 3.

In Table 8 in Appendix D we present examples of the most challenging questions from the test dataset, which none of our models with accuracy over 80% could answer correctly. Additionally, the Lite task results are shown in Appendix C.2.

4.3 Ablation studies for "FULL" task

To better understand how various methods presented in Section 3 impact the final results, we conducted an ablation study using Qwen 2.5 model. We changed the parameters of one model, starting with the base methods and progressively adding more sophisticated ones. While the choice of methods was somewhat arbitrary, calculating the full permutation of methods was difficult. The results for two types of code generation queries – Python pandas and SQL – are shown in Table 3.

The baseline method consisted of a simple prompt with a single code generation attempt. The original pandas and SQL prompts used in the ablation studies are presented in Appendix B. To this simple prompt we added just three sentences (we

Experiment	Accuracy	Description
Voting	**0.8621** (0.8736)	Voting from models S10, S8, S9, S11, S7, S6, S4, S1. The winning model submitted to the competition
Voting	**0.8602** (0.8716)	Voting from models S12, S10, S8, S9, S11. The better single model (S12) added after submission
Voting	**0.8563** (0.8678)	Voting from models S12, S10, S8, S9, S11, S7, S6, S4, S1. Long list of models to vote from (9 models)
Voting	**0.8506** (0.8621)	Voting from models S12, S10, S8, S9, S11, S7, S6, S4, S1. Only LLM voting, majority voting not used
S12	**0.8333** (0.8448)	Qwen 2.5; generation of pandas code using methods 3.1 – 3.9
S11	**0.8161** (0.8276)	Qwen 2.5; generation of SQL code using methods 3.1 – 3.9
S10	**0.8161** (0.8276)	Qwen 2.5; generation of pandas code using methods 3.1 – 3.9; shorter prompt
S9	**0.8142** (0.8276)	Qwen 2.5; generation of SQLite code using methods 3.5, 3.8
S8	**0.8123** (0.8238)	Llama 3.3; generation of pandas code using methods 3.1 – 3.9
S7	**0.8084** (0.8199)	DeepSeek R1; generation of pandas code; 3.1 – 3.7, 3.9, 3.10 (inference limit: 3000 tokens)
S6	**0.7950** (0.8065)	Qwen 2.5; generation of pandas code using methods 3.1 – 3.4 and 3.6 – 3.9; shorter prompt
S5	**0.7893** (0.8008)	Qwen 2.5; generation of pandas code using methods 3.3, 3.4, 3.6
S4	**0.7874** (0.7989)	Llama 3.3; generation of pandas code using methods 3.1 – 3.9; shorter prompt
S3	**0.7510** (0.7625)	Llama 3.3; generation of pandas code using methods 3.3, 3.4, 3.6
S2	**0.7356** (0.7471)	DeepSeek R1; generation of pandas code; 3.1 – 3.4, 3.6, 3.7, 3.10 (inference limit: 1200 tokens)
S1	**0.729**9 (0.7395)	Qwen 2.5; generation of DuckDB code instead of pandas

Table 2: Performance of single models and their ensembles on the test set.
In brackets: results with the final evaluation function updated by the task organizers.

Methods of one model for FULL testset	Accuracy (pandas)	Accuracy (SQL)
Simple prompt, 1 LLM request	0.4770	0.6743
Extended prompt, 1 LLM request	0.6782	0.6897
... + up to 3 LLM requests (3.9)	0.6801	0.7050
... + up to 10 LLM requests (3.9)	0.6877	0.7088
... + added 20 table rows in markdown (3.5)	0.7759	0.7682
... + added table summary (3.4)	0.7893	0.7510
... + answer type classifier (3.6)	0.8218	0.8199
... + necessary column detector (3.3)	0.8238	0.8046
... + LLM-gen. 5 paraphrases of question (3.8)	0.8333	0.8218
... + LLM-gen. 5 paraph. of question w/o column detector	0.8429	0.8314

Table 3: Ablation studies: the impact of methods on one-model results: Python pandas or SQL query generation.

call it "the complex prompt"), achieving a 20% increase in the performance of the pandas code model. Next, we increased the number of LLM inferences, up to 3 or 10 when necessary (described in Section 3.9), resulting in a performance gain of between 1% and 1.9% (for 10 loops).

Two factors had the greatest impact on accuracy in the later stages: (1) Adding the number of table rows in markdown format (+8.8% for pandas and +5.9% for SQL), (2) Including answer type prediction (described in Section 3.6; +3.3% for pandas and +6.9% for SQL).

The necessary columns selector, presented in Section 3.3, slightly improved the pandas code results and worsened the SQL results.

Finally, using paraphrases (Section 3.8) improved outcomes by +1% for SQL and 1.9% for pandas (with the column selector removed).

Interestingly, both pandas and SQL models reached similar maximum accuracy of 84.3% and 83.1% respectively, with larger differences when applying various methods in the earlier stages.

5 Limitations

Our system was built and fine-tuned using the DataBench dataset. Although it includes a diverse set of tables and questions, our experiments were conducted on a limited sample of real data. Additional research is necessary to determine how well the proposed methods generalize to other domains.

6 Conclusion

Despite the availability of verified open-source LLMs, answering questions over massive tabular data is still a challenging task. Designing an effective prompt is undoubtedly a crucial method, but can be difficult to control. Interestingly, simple feature and system engineering, combined with common classifiers, continue to be valuable and can significantly improve QA accuracy. Through our experiments in the SemEval Task 8, we demonstrated that using multiple models and smart voting

can result in creating an effective, general-purpose tabular QA system.

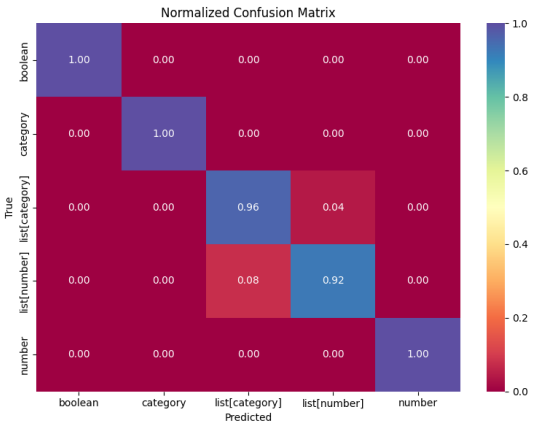

Figure 2: ALBERT Confusion Matrix.

Figure 2 visualizes the correctness of predictions made by the ALBERT model, pretrained on the questions from the dev and train sets. The matrix has been normalized to simplify analysis.

Table 6 compares the accuracy of ALBERT, Llama 3.3 and Qwen 2.5 on the DataBench training set.

Model	Accuracy
ALBERT	0.9618
Llama 3.3	0.8624
Qwen 2.5	0.9067

Table 6: Classification accuracy.

B Ablations study – supplement

We present both a simple and a complex prompt (the latter with added purple sentences) for pandas and SQL generation output. The red color indicates string variables that were added. Some sentences contain syntax errors (such as the repetition of the word "executable" in the last sentence). However, this version worked better compared to the correct version, where "executable" was used only once.

pandas_question_prompt = f"""{You are given a pandas DataFrame named 'df' which contains the following columns: {*all_column_names*}. Based on this information, generate a query in Python Pandas to answer the question: {*question_text*}. Specify only the code needed to calculate the answer using pandas (don't write anything else and do not write anything else. Also, return the code as a string, without any characters marking that this is code. Make sure it is an executable command, not a print statement. Be attentive to units of measurement, currencies, and notation systems, as data can be represented in various ways (using numbers, words, abbreviations, or symbols). Verify if conversion is needed. For a currency column it could be better to transform values into floats (on fly) and answer using it. Finally, make sure the code you produce will return an answer in the proper format – it should never be a DataFrame, a dictionary or a series. Make sure the answer is an executable one line executable command!!!} """

sql_question_prompt = f"""{You are given a pandas DataFrame named 'df' created from famous dataset: {*dataset_name*} with columns: {*all_column_names*}. In the next step 'df' DataFrame is converted to SQLite table with schema: {*schema*}. Please generate a query in SQLite answering the question: {*question_text*}. Specify only SQL query. Don't write anything else and do not write any explanation! Also, return the query as a string, without any characters marking that this is code. Be attentive to units of measurement, currencies, and notation systems, as data can be represented in various ways (using numbers, words, abbreviations, or symbols). Verify if conversion is needed. For a currency column it could be better to transform values into floats (on fly) and answer using it. Query should be as simple as possible, avoid nested queries and joins whenever possible! """

C Results

C.1 The most challenging questions

Out of the 522 question in the test set, 21 turned out to be the most difficult. It emerges that none of our models with accuracy exceeding 80% managed to return the correct answers to them. Table 8 depicts 5 examples from this set.

C.2 Results on the DataBench Lite QA subtask

We applied the same methods as for the full version subtask, and received results presented in Table 9.

D Data

Table 10 illustrates challenges in table interpretation based on columns (either their names or the type of values). Table 11 provides examples of potentially problematic questions, followed by a short discussion of the applicable issue.

Model name	Parameters	Quantization	Hardware	Source
Llama-3-Instruct	70B	Q4_K_M	2 x Quadro RTX 8000	bartowski
Llama-3.3	70B	Q4_K_M	2 x NVIDIA RTX A6000	unsloth
Qwen-2.5-Instruct	72B	Q4_K_M	2 x NVIDIA L20	bartowski
DeepSeek-R1-Distill-Qwen	32B	Q4_K_M	NVIDIA L20	unsloth
DeepSeek-R1-Distill-Llama	70B	Q4_K_M	2 x Quadro RTX 8000	unsloth
DeepSeek-R1	671B	Q4_K_M	8 x NVIDIA H100	unsloth

Table 7: LLMs: specifications of the models used, the hardware they were deployed on, and the source of quantized weights.

Question	Comment	Challenge
What is the name of the animal involved in the production of the most expensive coffee-related product that we offer? Answer with a value present in a cell of the database.	It was impossible to create a valid query to search for an unspecified animal within the column values.	external knowledge
How many suns were there in the title of Hosseinis' novel? Answer with a number	The book title is *A Thousand Splendid Suns*. The number in this cell is a string, but an integer is required as the answer. An additional difficulty is that the models must search for an unspecified number.	substring/altered string
List the first (by number of appearance) 3 different values in the highest tier of the dataset. If there are less than 3 list as many as there are.	The expression "highest tier of the dataset" was confusing for the models – the majority of them chose the column named "Tier 4" instead of "Tier 1", as the former name include the highest number.	ambiguity
Is Barbados considered overall more expensive than the country ranked in the 10th place?	"Overall more expensive" refers to the most general index, i.e. "Cost of Living Plus Rent Index". Meanwhile, models took various approaches, e.g. they tried to sum several random indices and compare these sums.	ambiguity
Is the average age of all lifting records in the weight class of someone who weights 103000 grams above 40?	Converting weight units turned out to be an issue.	converting units

Table 8: Examples of questions to which none of the models answered correctly.

Experiment	Accuracy	Description

SL2	**0.6897** (0.6973)	Llama 3.3; generation of pandas code using methods 3.5 and few-shot learning
SL1	**0.6743** (0.6839)	Llama 3.3; generation of pandas code using methods 3.5

Table 9: Performance of single models and their ensembles on the test set for the DataBench Lite QA subtask. In brackets: results with the final evaluation function updated by the task organizers.

Dataset	Column name	Meaning	Question	Comment
069_Taxonomy	Parent	The Parent ID number.	*List the 3 Parent values associated with the 3 highest number of descendants (direct or otherwise).*	The column contains both integers (e.g. "483") and strings (e.g. "SPSHQ5").
072_Admissions	Research	Indicates if a candidate has any research experience.	*Do most students have some research experience prior to the application?*	The answer contains integers (0 and 1), not strings ("yes", "no").
072_Admissions	LOR	The score for Letter of Recommendation (a statement given by a university or college.).	*What is the score for the recommendation letters presented by the student with the lowest English score?*	In the column name, there is an abbreviation, whereas in the question the term is paraphrased.
023_Climate	racha	The maximum wind speed.	*Did any day with maximum wind speed above 15 also have average wind speed below 5?*	The column name is in Spanish.
022_Airbnbs	host_total_listings_count	The number of properties owned by a host.	*Are there any hosts who have listed more than 10 properties?*	The wording in the column name differs from the phrasing used in the question.

Table 10: Examples of challenging columns. The first two concern value types and the following three illustrate unclear column names.

Challenge	Dataset	Question	Comment
External knowledge	058_US	*How many respondents have a high school degree or less as their highest level of education?*	Knowledge about the US education system is necessary.
External knowledge	074_Lift	*Are there more than 100 lifters in the weight class someone that weighs 82kg would compete in?*	The model needs to understand that weight categories are fixed weight ranges and then find the closest weight category.
Substring/altered string	018_Staff	*Were there any employees hired in 2019?*	The content of the applicable cell is a date from which the year must be extracted.
Substring/altered string	080_Books	*How much stock (in number of books) of Ben Graham's work is there in this store?*	There is "Benjamin Graham" in the dataset, not "Ben".
Ambiguous questions	017_Hacker	*List the top 4 most frequent terms in the "Clusters II" column.*	An exemplary value for the "Clusters II" column is "year, work, new". It is unclear whether to list 4 most frequent sets of terms or 4 single-word terms.
Ambiguous question	077_Gestational	*How many teen pregnancies are there in this dataset?*	The name of the applicable column is "Pregnancy No", which may refer to either cardinal or ordinal numbers.
Ambiguous question	078_Fires	*What is the name of the month that recorded the driest day when a fire took place?*	There are three columns with dryness metrics: RH (relative humidity), DC (Drought Code), and DMC (Duff Moisture Code).
Multiple possible answers	074_Lift	*List 5 lifters from the "74 kg" weight class.*	There are 10 lifters in this weight class.
Multiple possible answers	076_NBA	*List the 5 players with the least games played.*	There are 26 players who played just 1 game.
Converting units	074_Lift	*Is the biggest lift performed greater than 880 pounds?*	The content of the applicable column is in kilograms, so conversion is necessary.
Converting units	077_Gestational	*List the weights of women with a height of exactly 1m and 45cm.*	The numbers in the "Height" column range from 135 to 196, so they are in centimeters (though not specified).
Language mistakes	020_Real	*What are the 2 types of properties which are listed more frequently?*	It is not specified what "more frequently" refers to, leading one to assume the question is about the "most frequently" listed properties.
Language mistakes	077_Gestational	*What is the most value of the status marking hereditary diabetes risk in the dataset?*	It is unclear whether the question refers to "the highest value" or "the most common value" (the dataset authors admit a word is missing, indicating that it is the latter).
Lexically challenging	072_Admissions	*List the best 2 graduate record scores of applicants whose stated motivation to enter got a rating better than 4.*	The phrase "graduate record scores" refers to "GRE Score" (Graduate Record Examinations), and "stated motivation to enter" refers to "SOP" (statement of purpose).

OPI-DRO-HEL at SemEval-2025 Task 11: Few-shot prompting for Text-based Emotion Recognition

Daniel Karaś and Martyna Śpiewak
National Information Processing Institute
Warsaw, Poland
{dkaras, mspiewak}@opi.org.pl

Abstract

This paper presents our system, developed as our contribution to SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection task (Muhammad et al., 2025b), in particular track A, Multi-label Emotion Detection subtask. Our approach relies on two distinct components: semantic search for top N most similar inputs from training set and an interface to pretrained LLM being prompted using the found examples. We examine several prompting strategies and their impact on overall performance of the proposed solution.

1 Introduction

Emotions are inherently complex and multifaceted, influencing daily interactions while often remaining challenging to articulate and interpret. Individuals employ language in intricate and nuanced ways to convey emotions, with expression and perception varying across linguistic and cultural contexts, as well as within the same societal or social group. This paper presents our system proposed as a solution to Task 11, track A of Semeval-2025 competition, which focuses on detecting perceived emotions, i.e., what emotion most people think the speaker might have felt given a sentence or a short text snippet (Muhammad et al., 2025a).

The recognition of emotions by machine learning (ML) systems has been an active area of research for several decades, with approaches evolving from rule-based models to neural networks such as Long Short-Term Memory (LSTM) (Gupta et al., 2024).

The advent of large language models (LLMs) has introduced significantly more complex architectures, which demonstrated efficacy in classical natural language processing downstream tasks but also phenomenons such as emergent abilities (Wei et al., 2022). The effectiveness of LLMs in emotion detection is further supported by benchmarks such as SemEval-2024 Task 10, where LLMs were widely adopted by participants (Kumar et al., 2024). Given their demonstrated performance, LLMs are now regarded as state-of-the-art solutions in this domain. Consequently, this study leverages 70B variant of Deepsek R1 LLM to solve given task using several prompting strategies such as chain-of-thought and few-shot-prompting with examples for in-context-learning being provided by an information retrieval subsystem based on embeddings generated by a fine-tuned RoBERTa encoder (Liu et al., 2019).

2 Task and dataset

The task at hand is an instance of classical multi-labeled text classification task with the set of labels spanning six categories of perceived emotions: anger, sadness, fear, disgust, joy, surprise, which align with Ekman's six basic emotions. Text snippets were mostly extracted from social media webpages such as Reddit, Youtube and Twitter among others.

For instance, the sentence "That was the last time anyone saw her." was annotated with "fear" and "sadness".

The organizers provided a separate dataset for each of 28 different languages from 7 language families, each dataset was further divided into train, dev and test splits. In this study, we focused on developing a solution for the English subset of the Track A dataset, which consists of 2,768 training examples, 116 development examples, and 2,767 test examples.

An analysis of the label distribution, as presented in the task dataset description paper (Muhammad et al., 2025a), suggests that class imbalance may introduce additional challenges. Specifically, the most frequent class, fear, appears in 3,218 instances, whereas the least frequent class, anger, is present in only 671 examples. Additionally, only

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1233–1240

545 instances do not belong to any of the six predefined emotion categories, classifying them as neutral.

The official evaluation metric selected by the organizers was the macro-averaged F1-score, computed based on the predicted and gold-standard labels.

3 Experiments

In the following section, we present results exclusively on the test dataset to ensure a consistent and reliable point of reference, which most closely aligns with the final ranking. All reported results are based on the official macro-averaged F1-score; therefore, unless otherwise specified, this metric should be assumed by default.

3.1 Baseline

At the time of developing our system, the baseline results provided by the organizers had not yet been published in the task ranking. Consequently, we sought an appropriate off-the-shelf candidate to serve as a baseline upon which improvements could be made. In our preliminary study, we identified the pretrained RoBERTa-based model, *j-hartmann/emotion-english-roberta-large* (Hartmann, 2022), as a suitable candidate. This decision was based on the fact that the model was pretrained on the same set of emotion labels as those used in this task, with the addition of a "neutral" category, which could be interpreted as the absence of any assigned emotion label. Furthermore, the training data for this model predominantly consisted of social media posts (e.g., Reddit, YouTube, Twitter), which closely resemble the characteristics of the dataset used in this task. Given these factors, we hypothesized that the model would generalize effectively to previously unseen data of a similar nature.

We employed the pretrained model using the Hugging Face text-classification pipeline (Hug, accessed February 27, 2024) and applied a fixed threshold to convert the obtained softmax probability distribution into the expected binary classification format. The final threshold value of 0.26 was determined through a basic grid search.

Upon obtaining the performance results of the official baseline solution, which was based on RemBERT and achieved a macro-averaged F1-score of 0.7083, it became evident that our selected baseline was significantly weaker, reaching only 0.4472.

3.2 RoBERTa fine-tuning

To determine whether the poor performance stemmed from the pretrained model's inability to generalize to unseen data from a different distribution or from inherent limitations of its architecture, we proceeded with fine-tuning the model on the training split of this task.

The model was trained for two epochs using the AdamW optimizer, a learning rate of 5.49e-05 and a batch size of 8, with hyperparameters optimized using the Optuna framework (Akiba et al., 2019). Adapting the competition dataset to the format expected by the pretrained model was relatively straightforward; the primary modification involved mapping instances without assigned labels to the "neutral" category. Additionaly, model's vocabulary was extended with unseen words present in task's dataset.

Fine-tuning the model led to a substantial improvement, yielding a macro-averaged F1-score of 0.6915.

3.3 Large language models

We hypothesized that the fine-tuned RoBERTa model had reached its performance limits and that further improvements would not be achievable without the introduction of additional data, likely through augmentation techniques. Given this constraint, we opted to explore the performance of large language models (LLMs) in a zero-shot or few-shot setting to assess their "out-of-the-box" effectiveness on the task.

We conducted an evaluation of several smaller large language models within the 8B–14B parameter range using the development dataset. Additionally, we assumed that the performance of these smaller models could serve as an indicator of their larger counterparts' capabilities. This approach enabled rapid iteration in a local environment. Additionally, the integration of tools such as Ollama (oll, accessed February 27, 2024) and LangChain (Lan, accessed February 27, 2024) streamlined the interaction with the models, allowing us to focus on experimental evaluations rather than addressing technical implementation challenges.

The evaluated models included Teuken-7B (Ali et al., 2024), Vicuna-13B (Chiang et al., 2023), LLaMA 3.1-8B (Grattafiori et al., 2024), and DeepSeek-R1-14B (DeepSeek-AI, 2025). However, these smaller models frequently exhibited issues such as hallucination of labels, failure to

Model	Prompt	N-shot	Chain-of-thought	F1-score
emotion-english-roberta-large (baseline)	-	-	-	0.4472
emotion-english-roberta-large (fine-tuned)	-	-	-	0.6915
RemBERT (official baseline)	-	-	-	0.7083
Deepseek-R1	unstructured	Zero	No	0.7307
Deepseek-R1	unstructured	Few	No	0.7356
Deepseek-R1	structured	Few	No	0.7159
Deepseek-R1	structured	Few	Yes	0.7039

Table 1: Results on test dataset for english language. N-shot denotes number of examples in the prompt and chain-of-thought marks the usage of said prompting technique, where "-" that it's not relevant for given model, see example prompts in Appendix

adhere to the task as specified in the prompt, or generation of outputs that did not conform to the expected format. Among the evaluated models, DeepSeek-R1 demonstrated the most promising results. Consequently, we proceeded with further evaluation of its larger variant, DeepSeek-R1-70B.

Initially, we aimed to assess the model's performance in a zero-shot setting using an unstructured prompt, which was primarily a paraphrased version of the task formulation. We hypothesized that this approach would serve as a strong baseline for further improvements. This evaluation yielded a promising macro-averaged F1-score of 0.7307. See Figure 1 for example prompt of this type.

3.4 Few-shot prompting

To further enhance this promising result, we implemented well-established prompting techniques, including few-shot prompting (FSP) and chain-of-thought (CoT) reasoning . Both techniques are widely recognized for their ability to potentially improve the performance of LLMs.

To select examples for few-shot learning, we repurposed our fine-tuned RoBERTa-based classifier. While this approach is not necessarily optimal—given that our model was not explicitly trained for metric learning tasks—it provided a practical means of example selection. We identified the top N examples by computing the cosine similarity between embeddings generated through mean pooling. Our underlying assumption was that this method would allow us to retrieve examples that are not only semantically similar but also aligned in terms of emotional labeling (i.e., associated with the same or similar sets of emotions) to the query embedding. The selected examples were drawn from the training set.

The few-shot prompting approach resulted in only a marginal improvement in performance compared to the zero-shot method, achieving an F1-score of 0.7356. While we did not conduct extensive benchmarking on the example selection process, a qualitative assessment suggests that the selected examples were generally relevant to the query. Therefore, we hypothesize that the limited performance gain is not primarily due to deficiencies in the example selection pipeline. Instead, we attribute this outcome to either a suboptimal choice of the number of shots or an insufficient model size.

The authors of (Brown et al., 2020) demonstrate that model performance tends to improve with increasing model scale, with the FSP approach exhibiting a more rapid performance gain compared to the zero-shot method. This suggests that increasing the parameter count of the prompted LLM could still have a significant impact on performance. Furthermore, a similar trend is observed with the number of examples: except for very small models (fewer than 2 billion parameters), performance generally improves as the number of shots increases. An example prompt is provided in Figure 2.

However, as highlighted in (Brown et al., 2020), the effectiveness of FSP is also dependent on the specific characteristics of the task. Therefore, it is possible that the task under investigation does not benefit substantially from few-shot prompting.

3.5 Prompt structuring

Additionally, we investigated the impact of structuring and formatting the prompt. Previous studies, such as (Wei et al., 2023) and (He et al., 2024), indicate that large language models (LLMs) can be highly sensitive to prompt formulation, with factors such as the order of few-shot examples and even capitalization influencing performance. An

example is provided in Figure 3.

Enhancing the previously described unstructured prompt with additional structure and formatting led to a decrease in performance, yielding an F1-score of 0.7159. This finding is consistent with the observations reported in (He et al., 2024), where markdown formatting resulted in lower performance compared to plain text. However, given the inherent variability in how LLMs respond to prompt formulation, it remains possible that the opposite effect could occur under different downstream task.

3.6 Chain-of-thought

Unfortunately, the use of chain-of-thought prompting proved detrimental to overall performance, yielding an F1-score of 0.7039, which was lower than that of the zero-shot approach. This outcome is not entirely unexpected, as prior research (Wei et al., 2023) has demonstrated that the effectiveness of CoT prompting is highly dependent on model size. Notably, performance can improve significantly when scaling from a 62B model (which is relatively close in scale to our 70B model) to a 540B model.

Moreover, the robustness of CoT prompting is largely task-dependent. While CoT can outperform standard prompting in models as small as 8B for certain tasks, in other cases, a significant performance shift occurs around the 62B model threshold, or the performance of CoT prompting remains comparable to that of non-CoT prompting, regardless of model size. An example CoT prompt is provided in Figure 4.

4 Conclusions and limitations

Consequently, we selected the unstructured few-shot approach with RoBERTa-based semantic search as our final submission. This approach achieved a macro-averaged F1-score of 0.7356, ranking 32nd out of 75 teams and outperforming the official baseline solution, which scored 0.7083.

As discussed in the previous section, we believe that this ranking could be improved with minimal modifications to the overall system while maintaining the existing framework. Specifically, replacing DeepSeek-R1-70B with a larger model, optimizing the number and potentially the order of few-shot examples, and further fine-tuning RoBERTa for the metric learning task could yield performance gains. Furthermore, given the sensitivity of large language models (LLMs) to prompt formulation, refining prompt design presents an additional avenue for optimization and future research.

A Example prompts

Unstructured zero-shot prompt

Given a target text snippet: "/ o So today I went in for a new exam with Dr. Polvi today, I had to file new paperwork for the automobile accident case which is being done differently then the scoliosis stuff. So he comes in and starts talking about insurance stuff and how this look bad since I was getting treatment on my neck and stuff already blah blah.", predict the perceived emotion(s) of the speaker, knowing that target text comes from twitter. Specifically, select whether each of the following emotions apply: joy, sadness, fear, anger or surprise.
In other words, label the text snippet with: joy (1) or no joy (0), sadness (1) or no sadness (0), anger (1) or no anger (0), surprise (1) or no surprise (0).
Output only labels and their corresponding scores (0 or 1) in following format: "Label":Score.

Figure 1: Example unstructured (written in plain, natural language, no formatting) zero-shot (no examples) prompt

Unstructured few-shot prompt

Given a target text snippet: "/ o So today I went in for a new exam with Dr. Polvi today, I had to file new paperwork for the automobile accident case which is being done differently then the scoliosis stuff.So he comes in and starts talking about insurance stuff and how this look bad since I was getting treatment on my neck and stuff already blah blah.", predict the perceived emotion(s) of the speaker, knowing that target text comes from twitter.
Specifically, select whether each of the following emotions apply: joy, sadness, fear, anger or surprise.
In other words, label the text snippet with: joy (1) or no joy (0), sadness (1) or no sadness (0), anger (1) or no anger (0), surprise (1) or no surprise (0).
Output only labels and their corresponding scores (0 or 1) in following format: {"Label":Score}.
Following are examples of similar sentences with assigned labels to help you with labeling:
"i have major headache, just want to sleep all day, and the worst part when i look in the mirror my lips is swollen to like two times the size." has following scores
{ "anger":0,"fear":1,"joy":0,"sadness":1,"surprise":0 }
(...)

Figure 2: Example unstructured (written in plain, natural language, no formatting) few-shot (examples present) prompt. Only one example is included for clarity and brevity.

Structured few-shot prompt

Role:
You are a multilabel classifier predicting the perceived emotion(s) of the author, knowing that text comes from twitter.
Label the text snippet with: joy (1) or no joy (0), sadness (1) or no sadness (0), anger (1) or no anger (0), surprise (1) or no surprise (0), fear (1) or no fear (0).

Pointers:
- Remember that you are predicting emotions of author, not the reader.
- Carefully consider each possible emotion(label).

Constraints:
- Classify text snippet provided in Input section
- Output only labels and their corresponding scores in following format: {"Label":Score}.
- Scores can only be either 0 or 1
- Use same format as provided by examples

Examples:

Example 1

Input:
"i have major headache, just want to sleep all day, and the worst part when i look in the mirror my lips is swollen to like two times the size."

Labels:
{ "anger":0,"fear":1,"joy":0,"sadness":1,"surprise":0 }

Input
"/ o So today I went in for a new exam with Dr. Polvi today, I had to file new paperwork for the automobile accident case which is being done differently then the scoliosis stuff.So he comes in and starts talking about insurance stuff and how this look bad since I was getting treatment on my neck and stuff already blah blah."

Figure 3: Example structured (formatting, clear constraints and instructions) few-shot (examples present) prompt. Only one example is included for clarity and brevity.

Structured few-shot prompt with chain-of-thought

##Role:
You are a multilabel classifier predicting the perceived emotion(s) of the author, knowing that text comes from twitter.
Label the text snippet with: joy (1) or no joy (0), sadness (1) or no sadness (0), anger (1) or no anger (0), surprise (1) or no surprise (0), fear (1) or no fear (0).

##Pointers:
- Remember that you are predicting emotions of author, not the reader.
- Carefully consider each possible emotion(label).

##Constraints:
- Classify text snippet provided in ##Input section
- Output only labels and their corresponding scores in following format: {"Label":Score}.
- Scores can only be either 0 or 1
- Use same format as provided by examples

##Examples:

Example #1

Input:
"i have major headache, just want to sleep all day, and the worst part when i look in the mirror my lips is swollen to like two times the size."

Reasoning:
Was author feeling anger? No.
Was author feeling fear? Yes.
Was author feeling joy? No.
Was author feeling sadness? Yes.
Was author feeling surprise? No.

Labels:
{ "anger":0,"fear":1,"joy":0,"sadness":1,"surprise":0 }

##Input
"/ o So today I went in for a new exam with Dr. Polvi today, I had to file new paperwork for the automobile accident case which is being done differently then the scoliosis stuff.So he comes in and starts talking about insurance stuff and how this look bad since I was getting treatment on my neck and stuff already blah blah."

Figure 4: Example structured (using formatting and additional isntructions), few-shot, chain-of-thought prompt. Only one example is included for clarity and brevity.

Saama Technologies at SemEval-2025 Task 8: Few-shot prompting with LLM-generated examples for question answering on tabular data

Hwanmun Kim, Kamal Raj Kanakarajan, Malaikannan Sankarasubbu
Saama Technologies
{hwan.kim, kamal.raj, malaikannan.sankarasubbu}@saama.com

Abstract

For SemEval 2025 Task 8, addressing tabular data question answering, we introduce a novel few-shot prompting system that guides large language models (LLMs) to generate Python code representing the reasoning process. Our system automatically creates a library of exemplar code snippets from training data, which are then used for few-shot prompting. Crucially, we incorporate a selection prompt to choose the best candidate code from multiple LLM-generated options, improving robustness and accuracy. Our system achieved competitive results, ranking 17th in the Open Model track and 25th overall. Ablation studies demonstrate the effectiveness of our exemplar generation and code selection strategies. We conclude with a discussion of limitations and promising avenues for future research.

1 Introduction

Recent rapid advancement of Large Language Models (LLMs) has innovated a wide range of natural language processing (NLP) tasks Zhao et al. (2023); Hadi et al. (2023), as the extended context size enables LLMs to handle much more complicated tasks. Yet, question answering on tabular data requires more strategic approaches as even extended context size cannot handle full size of large tables effectively. SemEval 2025 Task 8[1] Os'es Grijalba et al. (2025) deals with this problem by providing the challenge for the recently developed DataBench dataset. Through this dataset, SemEval 2025 Task 8 provides hundreds of questions and associated tables written in English along with answers and related information.

In this paper, we explain our approach to SemEval 2025 Task 8 in detail. To provide LLMs guides to steps to deduce the answer from the table, we generated example python codes out of the provided questions and tables in the training data. With these examples, we performed few-shot prompting followed by a selection prompt to choose the most proper code to answer the question among multiple candidate codes.

We applied our optimal approach, identified through extensive experimentation, to the competition test set. Our submitted system achieved a rank of 17th in the Open Model track and 25th overall on the SemEval 2025 Task 8 leaderboard. Ablation studies were conducted to evaluate the contribution of each system component. Further analysis of our example generation method revealed a need for improvement in handling boolean-type questions. Finally, we propose several directions for future research to enhance system performance.

2 Background

As in many other NLP tasks, question answering using LLMs has shown notable progress recently thanks to a variety of approaches including such as chain-of-thought prompting Wang et al. (2023), retrieval-augmented-generation Fan et al. (2024), knowledge distillation Sutanto and Santoso (2024), and hybrid approaches Daull et al. (2023).

Among different kinds of question answering tasks, question answering on tabular data is distinguished from other question answering tasks by the fact that its provided tabular data are structured and can be arbitrarily long. To deal with these problems, most approaches rely on non-natural languages such as SQL or Python to represent logical steps deducing a subtable or an answer from the given table Jin et al. (2022); Zhang et al. (2023); Cao et al. (2023); Kong et al. (2024); Zhang et al. (2024); Lu et al. (2024); Zhu et al. (2024). To utilize the most relevant information from the table, many systems adopt mechanisms to select relevant subtables Zhang et al. (2023); Kong et al. (2024); Sun et al. (2016). As there are multiple approaches with different advantages, selection agents that choose the

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1241–1247

best approach among multiple candidates are often used to increase the performance of the system Gao et al. (2024); Pourreza et al. (2024).

2.1 Task description

SemEval 2025 Task 8 aims to develop a question answering system for tabular data. The challenge provides multiple datasets and questions about these datasets where each question only deals with a single dataset at a time. The challenge is composed of two subtasks; the subtask 1 can provide datasets of any size and the subtask 2 provides tables of maximum 20 rows each.

2.1.1 Dataset

SemEval 2025 Task 8 uses the DataBench dataset Grijalba et al. (2024) for development and evaluation. DataBench datset used for this challenge is composed of 3 splits: train, dev, and test.

- **Train split**: 988 questions over 49 tables
- **Dev split**: 320 questions over 16 tables
- **Test split**: 522 questions over 15 tables. Participants submit the results on this split.

There is no overlap of tables between different splits. Each question belongs to one of 5 types: boolean, number, list of number, category, list of category. In the train split and the dev split, this type information and the columns used to answer each question are included. For the test split, only the question and the table are provided.

2.1.2 Evaluation Metric

The evaluation metric for SemEval 2025 Task 8 is the accuracy of the result, which is defined as the ratio of the results matching with answers over the total number of questions. When determining whether a result matches with the answer, the order within the list is ignored. For numeric results, each number is rounded up to the second decimal.

3 System overview

Our approach is consisted of three steps. First, we generate example python codes using zero-shot prompting on the LLM with the training data. Second, we do few-shot prompting on the LLM using the example codes generated in the first step to generate candidate python codes for the input question. Finally, we run a selection prompt to select the most suitable code to answer the given question.

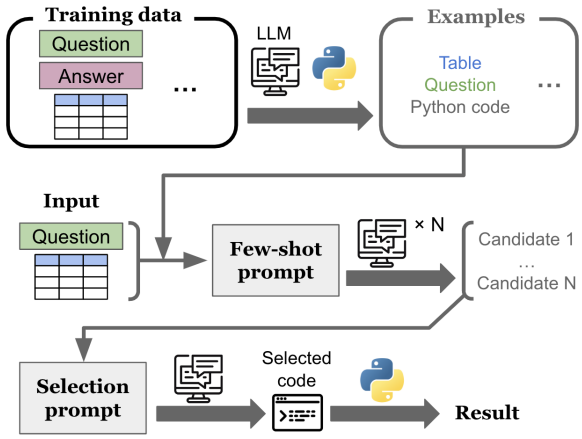

Figure 1: Overview of our few-shot prompting system.

By executing this selected code, we obtain the final result for the given question. This entire process is summarized in Fig. 1.

3.1 Example generation with LLM

To guide the LLM to properly answer the question based on the given training data, the most straightforward way is to utilize in-context learning via few-shot prompts. While one may try a few-shot prompt composed of the question and answer pairs given in the training data, such prompt lacks any detailed explanation how one can reach to the result. Moreover, it may be almost impossible to present all the information in the table if the table size is too large compared to the context size of the LLM. Therefore, one should use example logical steps to guide LLM to replicate its own logical steps to deduce the result from the table. In our approach, we used python codes as our logical steps.

To turn the entire training split into example codes to be used in few-shot prompting, we first performed zero-shot prompting on the training data along with a simplified table. The zero-shot prompt we used can be found in Appendix B. For the simplified table, we randomly sampled 10 rows from the original table and presented them as in Appendix A. Our table presentation is inspired by Zhang et al. (2023). Once the python code is generated, we executed it and compare the execution result with the given answer of the training data, then accepted it as a valid example if the result matches with the answer. To collect as much examples as possible, we repeated the zero-shot prompting 10 times per each different temperature $T = 0.2, 0.3, 0.4, 0.5$ and aggregated all the valid examples. As a result, we collected the example set of 839 examples out of 988 questions in the train-

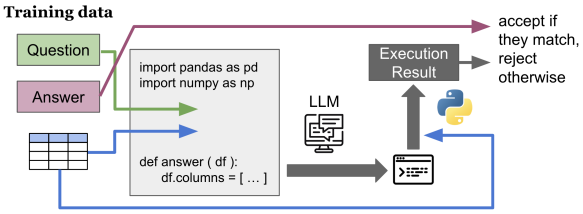

Figure 2: Example generation process.

ing data. The entire example generation process is illustrated in Fig. 2.

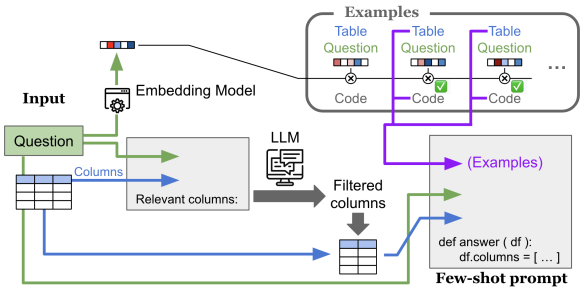

Figure 3: Few-shot prompt for candidate code generation.

3.2 Few-shot prompting

Once example python codes are generated, we perform few-shot prompting on the LLM to generate candidate python codes to answer the input questions. For that, we sample a few examples from the example set for each prompt. To choose the closest examples to the given question, we evaluate 1536-dimensional embedding vectors of the given question and all questions in the example set using `gte-Qwen2-1.5B-instruct` model[2]. Then we select examples based on the cosine similarity between these embedding vectors.

For succinct presentation of tables, we filtered the columns of the given table so that only columns relevant to the given input question can be presented. For this process, we utilized another few-shot prompts, inspired by Talaei et al. (2024), to select relevant columns for the given question. Details of this process is described in Appendix D.

With the chosen examples and the input data, we created few-shot prompt as presented in Appendix C. The over process is summarized in Fig. 3.

3.3 Selection prompt

Although we guide the LLM with our few-shot prompt, there is always some fluctuation of generated results for the stochastic nature of the LLM. To regularize this, we generate multiple candidate python codes for each input question using the prompts in Section 3.2, and run another prompt to select which candidate code is most appropriate to answer the given question. Our selection prompt is inspired by Gao et al. (2024), and a template is presented in Appendix E.

4 Experimental setup

4.1 Hardware

All of our text generation and embedding evaluation on LLMs were performed on a 4× Quadra RTX 8000 (48GB VRAM) card.

4.2 LLMs used for prompting

`Qwen2.5-72B-Instruct` model[3] was used to run the zero-shot prompts for example generation. `Qwen2.5-coder-32B-Instruct` model[4] was used to run the few-shot prompts for candidate code generation. `Qwen2.5-coder-7B` model[5] was used to run the column filtering prompts for the input questions and the selection prompts. All prompts were run with temperature $T = 0$ unless otherwise noted.

5 Results

We present the results of our experiments in Table 1. All experiments were performed at temperature $T = 0$. Here we report the average performance of 10 repeated experiments. For the challenge competition, we submitted the results from Exp 8.

6 Discussions

To see how effective each component of our approach is, we may compare different experiment results listed in Table 1.

- Comparison of Exp 1 ∼ Exp 3 shows that `Qwen2.5-coder-32B-Instruct` performed the best in our setting. This code-specific model outperformed a generic-purposed model with more parameters.
- Comparison of Exp 2 and Exp 4 shows that the table presentation improves the accuracy by the margion of 12.5 %p.

[3]https://huggingface.co/Qwen/Qwen2.5-72B-Instruct

[4]https://huggingface.co/Qwen/Qwen2.5-Coder-32B-Instruct

[5]https://huggingface.co/Qwen/Qwen2.5-Coder-7B

Exp #	Experiment	Model size	Split	Accuracy (%)
1	Zero-shot	7B	dev	61.0
2	Zero-shot	32B	dev	78.8
3	Zero-shot	72B	dev	77.5
4	Zero-shot, without table presentation	32B	dev	66.3
5	Few-shot ($n_{\text{ex}} = 5$)	32B	dev	81.9
6	Few-shot ($n_{\text{ex}} = 5$), without column filtering	32B	dev	81.2
7	Few-shot ($n_{\text{ex}} = 5$) with selection prompt ($n_{\text{cand}} = 3$)	32B	dev	**82.1**
8	Few-shot ($n_{\text{ex}} = 5$) with selection prompt ($n_{\text{cand}} = 3$)	32B	test	**78.35**

Table 1: Experiment results. All accuracies are average value of 10 repeated experiments except Exp 8. Model size 7B / 32B / 72B indicates the model `Qwen2.5-coder-7B` / `Qwen2.5-coder-32B-Instruct` / `Qwen2.5-72B-Instruct`, respectively.

- Comparison of Exp 2 and Exp 6 indicates that the few-shot approach is better than the zero-shot approach by the accuracy margin of 2.4 %p.
- Comparison of Exp 5 and Exp 6 shows that column filtering increases the accuracy by the margin of 0.7 %p.
- Comparison of Exp 5 and Exp 7 implies that selection prompt can slightly boost the accuracy by the margin of 0.2 %p.

n_{ex}	Accuracy (%)
3	81.7
4	80.9
5	**81.9**
6	81.6

Table 2: Accuracy of the system for different n_{ex}. All other conditions of the experiment is identical to Exp 4.

n_{cand}	Accuracy (%)
2	81.4
3	**82.1**
4	81.6
5	82.0
6	81.8
7	81.9

Table 3: Accuracy of the system for different n_{cand}. All other conditions of the experiment is identical to Exp 5.

Moreover, Table 2 and Table 3 shows how the accuracy of the system changes as the number of few-shot examples (n_{ex}) and the number of candidates for the selection prompt (n_{cand}) change. Based on these experiments, we selected $n_{\text{ex}} = 5$ and $n_{\text{cand}} = 3$ for our best performing system.

Question type	Exp 2	Exp 7
Boolean	85.2	85.3
Category	86.7	90.6
Category, list	67.2	71.4
Number	80.6	84.2
Number, list	74.2	78.6

Table 4: Accuracy (%) of each question type

To see how our few-shot prompting approach performs on each question type, we compared the accuracies of each question type on Exp 2 and Exp 7. This comparison shows that our approach outperforms the baseline zero-shot approach by the accuracy margin of $3.6 \sim 4.4$%p in all other question types except the boolean type. For the boolean type, our approach shows similar performance (accuracy margin of 0.1%p) with the baseline approach. We believe this behavior is related to how we generate and collect examples for the few-shot prompts. In cases of numerical and text fields, it is very rare to produce the right answer from the example code with wrong logic. However, example codes for the boolean type intrinsically has the danger of having wrong logic while giving the right answer as there are only two possible outcomes (true of false) for this type.

7 Conclusion

We presented a novel few-shot prompting system for tabular data question answering in SemEval 2025 Task 8. Our approach leverages LLM-

generated Python code as reasoning guides and incorporates a selection prompt to enhance output quality. This system achieved a 17th-place ranking in the Open Model track and 25th overall. Our analysis highlighted the contributions of individual components and identified key areas for future research, particularly in handling boolean queries.

Limitations

As discussed in Section 6, our method for the generation and collection of example codes shows limited performance on boolean-type questions, and improving this limitation would be an interesting subject for the future research. While our approach entirely relied on the python codes, many other approaches in the literature uses SQL as the means to convey the logic of question answering for the tabular data. To utilize the full capacity of both approaches, one may combine python codes and SQL queries in a single system for better performance. It is also noteworthy that our selection prompt is the simplest zero-shot prompt. Therefore, there is some room to improve this selection process by providing examples, introducing some logical reasoning for selection, or fine-tuning with synthesized training data.

A Table presentation

In our prompts, we presented sampled tables several times. To demonstrate how we presented them, a sample m-row, n-column table is presented in Prompt 1. Note that any field over 27 characters are truncated up to first 27 characters and followed by "...". Also, any NaN field is replaced to NULL.

```
Input table (df):
[HEAD]: col_1 | ... | col_n
---
[ROW] 1: field_1_1 | ... | field_1_n
...
[ROW] m: field_m_1 | ... | field_m_n
```

Prompt 1: Table presentation

B Zero-shot prompt template

```
import pandas as pd
import numpy as np

"""
For the following input table, write a function
    to answer the question: (question)
(table presentation)
"""

def answer ( df ) -> (question type) :
    """
    Returns: (question)
    """
    df.columns = [(list of columns of the table)]
```

Prompt 2: Zero-shot prompt for code generation. Note that "-> (question type)" part is skipped if question type is not provided.

C Few-shot prompt template

```
import pandas as pd
import numpy as np

(zero-shot prompt from the first example)
(generated code from the first example)

...

(zero-shot prompt from the last example)
(generated code from the last example)

(zero-shot prompt from the input question, table)
```

Prompt 3: Few-shot prompt for code generation. Note that all zero-shot prompts in this template skip the lines importing packages. For the brevity of the example codes, comments added in the same line of actual code are omitted from the generated codes of examples.

D Column filtering

To filter the relevant columns for the input question from the input table, we used the few-shot prompts (Prompt 4) where the randomly sampled training data were used as examples. We set the number of examples to 6. We utilized the fact that the training data contain the information on the columns used to answer each question.

```
### You are a detail-oriented data scientist
    tasked with selecting relevant columns from
    a given database to answer the given
    question.

Database: (database name for table 1)
Columns: [(list of columns of table 1)]
Question: (question 1)
Relevant columns: [
    (used columns to answer question 1)]

...

Database: (database name for table 6)
Columns: [(list of columns of table 6)]
Question: (question 6)
Relevant columns: [
    (used columns to answer question 6)]

Database: (database name for input table)
Columns: [(list of columns of input table)]
Question: (input question)
Relevant columns:
```

Prompt 4: Few-shot prompt for column selection.

To regularize the fluctuating responses from the LLM and the bias of randomly sampled examples, we repeated the experiments 20 times (10 times at temperature 0.0 and 10 times at temperature 0.2) and aggregated all columns selected in the responses.

For column filtering of example data, we directly extracted column names from the generated codes instead of running LLMs for column selection.

In both cases of the example data and the input data, we manually added any column name that

contains "id" or "name". We also added any column name that contains any selected column or the other way around.

E Selection prompt template

Prompt 5 is a template of our selection prompt in the case of $n_{\text{cand}} = 4$. Note that we have already excluded examples that cannot be executed without errors before feeding the examples for the prompt.

```
You are a data science expert.
For a given input table below and a question
    regarding this table, there are 4 candidate
    python functions to answer the question.
Your task is to compare these candidates and
    select the correct and reasonable candidate
    to answer the question.

(table presentation)

Question: (question)

[Candidate A]
import numpy as np
import pandas as pd
def candidate_A_solution(df: pd.DataFrame):
(python code for candidate 1)

...

[Candidate D]
import numpy as np
import pandas as pd
def candidate_D_solution(df: pd.DataFrame):
(python code for candidate 4)

Please output the selected candidate as "A" or "
    B" or "C" or "D".

Selected canddiate:
```

Prompt 5: Selection prompt. In this template prompt, number of candiates are set to 4.

Tuebingen at SemEval-2025 Task 10: Class Weighting, External Knowledge and Data Augmentation in BERT Models

Özlem Karabulut, Ali Gharaee, Soudabeh Eslami, Matthew Kirk Andrews
University of Tübingen Tübingen, Germany
name.surname@student.uni-tuebingen.de

Abstract

The spread of disinformation and propaganda in online news presents a significant challenge to information integrity. As part of SemEval 2025 Task 10 on Multilingual Characterization and Extraction of Narratives from Online News, this study focuses on Subtask 1: Entity Framing, which involves assigning roles to named entities within news articles across multiple languages.

We investigate techniques such as data augmentation, external knowledge integration, and class weighting to improve classification performance. Our findings indicate that data augmentation was more effective than other approaches.

1 Introduction

The internet has opened new ways for communication but has also made consumers more vulnerable to misleading content and manipulation (SemEval2025-Task-10 (2025)). Recognizing propaganda strategies is crucial for combating disinformation, particularly in media analysis, politics, and online discussions. The SemEval 2025 Multilingual Characterization and Extraction of Narratives from Online News Task aims to automate the identification and classification of narratives, assisting analysts in addressing disinformation. This task comprises three subtasks: entity characterization, narrative classification, and narrative extraction. It is available in five languages: Bulgarian, English, Hindi, Portuguese, and Russian. More information can be found in the Task Description Document (Jakub Piskorski (2025)).

This paper discusses our experimental approach in Subtask 1. We evaluated several transformer-based models with minimal hyperparameter tuning. We experimented with data augmentation, external knowledge integration, and class weighting to improve performance.

Our model performed better than the baseline, ranking 21st out of 32 participants in the final submission. However, our results from the development set were better, suggesting that our models were likely overfitting and leading to overly optimistic results. Our code and setup are available at: https://github.com/cicl-iscl/SemEval25-Task10.

2 Background

The task covers news articles from two domains: the Ukraine- Russia War and Climate Change (SemEval2025-Task-10 (2025)). In this paper, we focus on Subtask 1, Entity-Framing. The goal is to assign one main role and one or more sub-roles to a pre-identified Named Entity (NE) in a news article, using a fine-grained entity role taxonomy (Stefanovitch et al. (2025)). The task is formulated as a multi-label, multi-class text-span classification problem and does not require Named Entity Recognition (NER) (Marrero et al. (2013)). An example of a system response to a news article is provided in Appendix A.

2.1 Related Work

Detecting frames in news articles has been a challenging task. Foundational studies by Card et al. (2015) and Boydstun et al. (2018) developed annotations for framed articles. A supervised approach by Naderi and Hirst (2017) applied deep neural networks to classify sentence-level frames using the Media Frames Corpus.

Our task builds on previous SemEval media analysis tasks. Da San Martino et al. (2020) in SemEval 2020 Task 11 focused on detecting propaganda techniques, where transformer-based models and ensembles performed well, particularly with contextual information. Similarly, Piskorski et al. (2023) in SemEval 2023 Task 3 addressed news categorization, framing, and persuasion techniques across nine languages. The multilingual aspect of their task aligns closely with our study. Our research extends these previous works by exploring various approaches to similar challenges.

2.2 Dataset

The input data comprises news and web articles. Details on the gold label and submission format are in Appendix B.
We used a training set, a development set without annotations to train and evaluate our models, and a test set for final submission. Initially, we trained our models on an English dataset with 328 training set articles. Thus, the results in Sections 4.1 and 4.2, as well as the class distribution in Table 2, are derived from this dataset. We later expanded the dataset through data augmentation on the multilingual dataset. The final data set, shown in Table 1, is used to augment the training data detailed in Section 3.5.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1248–1254

Language	Training Set	Development Set
English	399	27
Bulgarian	401	15
Hindi	366	35
Portuguese	400	31
Russian	133	28
Total	1,699	136

Table 1: Final dataset distribution (used in data augmentation)

The official evaluation metric is the exact match ratio, a metric that ignores partially correct results by considering them incorrect:

$$MR = \frac{1}{n}\sum_{i=1}^{n} I(y_i = \hat{y}_i)$$

where I is the indicator function (Sorower (2010)).

3 System Overview and Experimental Setup

This study evaluated transformer-based models with minimal hyperparameter tuning. We adopted a non-hierarchical approach, first classifying sub-labels and then assigning the main label within the algorithm. We employed BERT-family models, specifically RoBERTa (Liu et al. (2019)) and DistilBERT (Sanh et al. (2019)).

3.1 Model Training

Data Preprocessing . The raw data were restructured to align with the gold label and submission format. The English training data were split into 80% training and 20% validation. In data augmentation, this ratio was maintained while the dataset was modified. To preserve label distributions, we applied iterative stratification during the split.

Hyperparameter Tuning . Key hyperparameters tuned for optimal model performance included a batch size of 8 per device, an epoch count of 25 (based on epoch-based performance evaluation), and an overridden loss function parameter for class weighting.

Model Training . We fine-tuned models `distilbert-base-uncased` and `roberta-base` for multi-label classification using Hugging Face's API (HuggingFace, 2025a) on the tokenized data. Threshold was reduced from 30% to 20% to improve the recall of underrepresented labels, ensuring that entities with multiple roles were correctly classified. Also, binary cross-entropy loss was used to optimize multi-label predictions to handle overlapping labels.

3.2 Multi-label Classification

A sigmoid activation is applied to logits and threshold probabilities to generate binary predictions.

Evaluation Metrics . The system's training performance was evaluated using Exact Match Ratio, Hamming Loss, and F1-Score (Murat Arat (2020)).

3.3 Challenges and Experiments

The key challenge was underrepresentation (Chakraborty and Dey (2024)) of specific classes, namely the class imbalance. The class frequencies in the English dataset are presented as in the "Before" column of Table 2.

Most machine learning methods struggle with imbalanced datasets as they tend to favor majority-class samples, leading to lower accuracy for the minority class. There are two main approaches to address this problem (Chakraborty and Dey (2024)):

- **Algorithm Level Approach:** Class Weighting Algorithms
- **Data Level Approach:** Data Augmentation and External Knowledge

3.4 Class Weighting

We explored two weighting strategies: scikit-learn[1] and logarithmic weighting.

3.4.1 Pre-defined Class Weighting With Scikit Library

Many algorithms in scikit-learn support class weight adjustments (Chakraborty and Dey (2024)). We applied class weighting using `scikit-learn's compute_class_weight`[2] function, assigning weights inversely proportional to class frequencies. The computed weights are integrated into PyTorch's `BCEWithLogitsLoss` by extending HuggingFace's `Trainer`(HuggingFace (2025b)) class via modifying the `compute_loss` function to ensure that misclassifications in minority classes receive higher penalties.

3.4.2 Logarithmic Weighting

An alternative approach computes class weights using a logarithmic transformation relative to the most frequent class:

$$\text{class\_weights} = \log\left(1 + \frac{\max\_count}{\text{label\_counts} + \epsilon}\right)$$

where ϵ ensures numerical stability. This method smooths extreme weight differences, preventing biasing rare classes. The weights are applied via the `pos_weight` parameter in `BCEWithLogitsLoss`, offering a more gradual adjustment than traditional frequency-based weighting.

3.5 Data Augmentation

We leveraged data augmentation to enhance data diversity and model performance. Data augmentation is a general term used to increase robustness and accuracy

[1] https://scikit-learn.org/stable/whats_new/v1.2.html

[2] https://scikit-learn.org/stable/modules/generated/sklearn.utils.class_weight.compute_class_weight.html

by allowing them to perform well on small, poorly representative data, according to (Mumuni and Mumuni (2022)). Specifically, we applied back translation and pivot translation to generate additional training samples for minority and moderate classes. The augmented dataset was then used for the models we mentioned earlier.

3.5.1 Dataset

Augmented data for minority classes (fewer than 200 instances) was stored separately, containing only back-translated examples and not initially merged with the original dataset. For moderate classes (200–500 instances), augmentation involved direct concatenation with the original data. This augmented dataset comprised 7,991 stratified instances (6,390 for training, 1,601 for validation). Validation data was incorporated into training to mitigate overfitting. The latest model we submitted was trained on 12,450 multilingual samples with a 20% validation split (10,731 training, 2,694 validation). The final sublabel distributions are detailed in Tables 2

Role	Before	After	
	Train	Train	Validation
Instigator	49	792	198
Guardian	40	822	206
Conspirator	38	565	141
Incompetent	35	658	165
Foreign Adversary	35	874	219
Victim	33	886	221
Tyrant	29	690	173
Deceiver	26	570	143
Saboteur	20	347	87
Virtuous	19	644	161
Corrupt	17	662	165
Peacemaker	15	474	118
Terrorist	14	558	139
Underdog	12	485	121
Rebel	11	566	142
Martyr	11	407	102
Bigot	9	375	94
Traitor	8	397	99
Scapegoat	8	428	107
Exploited	6	314	78
Spy	3	472	118
Forgotten	1	464	116

Table 2: Comparison of sub-label distributions before augmentation (train) and after augmentation (train and validation)

3.5.2 Dataset Preprocessing

The dataset augmentation pipeline follows these steps:

Back Translation and Pivot Translation: Sentences were translated to an intermediary language and back to the original language to introduce variability. The backtranslated texts are stored in a directory as separate files, one column including the modified text.

Entity Preservation: Placeholder tokens (`_[ENTITY_]`) were replaced with entity mentions in their respective languages. If the entity mention was altered during translation, contextual modifications were applied.

Duplicate Removal and Data Cleaning: Excessive augmentation and duplicate entries were removed.

Dataset Splitting and Stratifying

3.5.3 Model Training

The dataset was used in training models, notably the BERT family. Previous experimentation with the T5 (Raffel et al. (2019)) model on data showed minimal performance improvements.

3.6 External Knowledge

Incorporating external knowledge enhances model performance by providing additional context beyond the training data, improving generalization, robustness, and accuracy.((Jegierski and Saganowski (2019))). The key sources of external knowledge include:

- **Wikipedia / Wikidata**: Offers entity and factual knowledge, enriching the model's understanding of entities and relationships.
- **ConceptNet**: Provides commonsense knowledge and relationships between concepts, improving contextual relevance(Speer et al. (2017)).
- **Domain-Specific Knowledge Graphs**: Specialized databases such as medical, legal, or scientific knowledge graphs contribute domain-specific insights.

3.6.1 Implementation

In our system, the process of integrating external knowledge followed these key steps:

Data Preprocessing: We extracted relevant knowledge on entities from Wikidata and merged it with unstructured data.

Feature Engineering: We created knowledge-aware embeddings and augmented input representations with external data to enhance model features.

Model Training: We used our input data with DistilBERT.

4 Results

4.1 Initial Results

Table 3 summarizes the training evaluation results for DistilBERT and RoBERTa. Both models showed promising results, and RoBERTa significantly outperformed DistilBERT, also demonstrating a more consistent decline with better stability and lower validation loss.

Model	Exact Match Ratio	Hamming Loss	F1-score
DistilBERT	0.186	0.046	0.173
RoBERTa	0.300	0.041	0.256

Table 3: Training performance evaluation for different models

Threshold Adjustment Effect: Adjusting the classification threshold from 30% to 20% improved the Exact Match Ratio by 6% for DistilBERT, demonstrating the importance of dynamic threshold optimization.

4.2 Results for Class Weighting

4.2.1 RoBERTa

The following results belong to RoBERTa with different class-weighting methods on the initial English dataset consisting of 328 samples. The model is trained for 25 epochs. Table 4 summarizes the training evaluation results, and Table 5 illustrates the submission results.

Method	Exact Match Ratio	Hamming Loss	F1-score
Built-in Weighting	0.2093	0.0761	0.2693
Logaritmic Weighting	0.3139	0.0618	0.3113

Table 4: Training performance evaluation for different class-weighting methods

Method	EMR[1]	Micro P	Micro R	Micro F1	Acc[2]
Built-in weighting	0.10990	0.17480	0.18000	0.17730	0.67030
Logarithmic Weighting[3]	0.15384	0.96842	0.19000	0.98385	0.70329

Table 5: Submission results on development set for different class-weighting methods
[1] Exact Match Ratio, the official metric in evaluation, [2] Accuracy in main roles
[3] Not the official submission results, these are calculated by our code after the official leaderboard closed

The results of our experiments after the closing of the official submission leaderboard are presented in Table 16 in Appendix C. Surprisingly, this method performed better than our official submission results, which may be due to the reasons mentioned in Section 5.

4.2.2 DistilBERT

All the experiments on DistilBERT has been made after the closing of the official submission leaderboard. Tables 13 and 14 present the results in Appendix C.

4.3 Results for Data Augmentation

Table 6 summarizes the training evaluation results for DistilBERT and XLM-RoBERTa (Conneau et al. (2020)). Although our officially submitted model DistilBERT performed better in model training evaluation, XLM-RoBERTa outperformed DistilBERT in post-submission test set results. (See Table 7 and Table 15 in Appendix C).

Model	Exact Match Ratio	Hamming Loss	F1-score
DistilBERT	0.7112	0.0240	0.8157
XLM-RoBERTa	0.6911	0.0247	0.8189

Table 6: Training performance evaluation with augmented multilingual data

Prediction Set	EMR	Micro P	Micro R	Micro F1	Acc
Test set	0.13190	0.20580	0.21510	0.21030	0.74040
Development set	0.21980	0.29290	0.29000	0.29150	0.75820

Table 7: Submission result on different datasets with DistilBERT trained on augmented data

4.4 Results for External Knowledge

The training logs show a significant drop in training loss from 0.8024 to 0.0008 by Epochs 7-8, while validation loss decreases initially but then peaks at around 1.0679, indicating overfitting (Table 8). Despite this, the model achieves a validation accuracy of 0.8036 and a weighted score of 0.7885, and an exact match ratio of 0.8036 on the validation set, demonstrating some capability in identifying key features of the classification task (Table 9).
However, these metrics are based on our training performance evaluation, so they cannot be directly compared with the performance metrics of other methods, as those come from different code. Also, it cannot be compared to official submission results because this experiment has been submitted for official evaluation only once, which showed relatively poor results, though it did notably outperform other models in main role accuracy (Table 10).

Epoch	Training Loss	Validation Loss
1	0.802400	0.970969
2	0.534900	0.541840
3	0.311900	0.605355
4	0.074800	0.765731
5	0.073900	0.947722
6	0.001700	1.031157
7	0.000800	1.054733
8	0.000800	1.067893

Table 8: Training and Validation Loss per Epoch

Model	Exact Match Ratio	Hamming Loss	F1-score
DistilBERT	0.8036	0.1964	0.7457

Table 9: Evaluation performance metrics

Prediction Set	EMR	Micro P	Micro R	Micro F1	Acc
Development set[4]	0.05490	0.06590	0.0600	0.06280	0.80220

Table 10: Submission result on development dataset with DistilBERT

However, the increasing validation loss suggests poor generalization due to the small training dataset. To mitigate overfitting, strategies like regularization and early stopping are recommended, and incorporating external knowledge sources could improve the model's generalization ability by enhancing data representation.

5 Conclusion

Our results demonstrate the effectiveness of various approaches for entity role classification in multilingual

data. The Exact Match Ratio shows that while our models performed competitively, there is room for improvement. Before the closing of the official submission leaderboard, augmented data combined with RoBERTa achieved the highest EMR (0.13190). Data augmentation significantly enhanced performance for underrepresented classes, as seen in F1 scores. However, its failure to boost the EMR could be caused by back-translation-label noise, loss of contextual integrity, or inconsistencies in entity role assignments. Especially thinking our best results came from an intermediate data augmentation, in which we did not "over-augment" the data. However, a key oversight in our process was that we did not record the submission results at various stages. In short, the complexity of this task may require a more refined augmentation technique to reduce noisy data.

Another observation is that the validation results were likely inflated due to the similarity of training and validation data, leading to overly optimistic performance estimates. Test results revealed that our models were likely overfitted.

Also, the results of external knowledge also indicate potential overfitting, shown by high main role accuracy but low metrics. Other factors could be differences in dataset distribution, improved feature representation, or random initialization effects. Further examination with additional models is needed.

Beyond these, we explored prompting techniques at the entry level, which showed some promise in improving accuracy. However, due to time constraints, we could not further investigate prompting.

In closing, classifying with imbalanced datasets remains crucial. Future research should explore alternative models, such as GPT-based architectures, prompting or ensemble learning techniques (Jia et al. (2024)), as they combine multiple models to leverage their strengths.

Acknowledgments

We would like to express our heartfelt gratitude to Dr. Çağrı Çöltekin for his continuous guidance, insightful feedback, and support throughout this task.

A Appendix: Example of Entity Roles for a given Article

Below is an example of how a system processes a news article for Subtask 1:

Met Office Should Put 2.5°C 'Uncertainties' Warning on All Future Temperature Claims

"It is "abundantly clear" that the Met Office cannot scientifically claim to know the current average temperature of the U.K. to a hundredth of a degree centigrade, given that it is using data that has a margin of error of up to 2.5°C, notes the climate journalist Paul Homewood. His comments follow recent disclosures in the Daily Sceptic that nearly eight out of ten of the Met's 380 measuring stations come with official 'uncertainties' of between 2-5°C. In addition, given the poor siting of the stations now and possibly in the past, the Met Office has no means of knowing whether it is comparing like with like when it publishes temperature trends going back to 1884.

There are five classes of measuring stations identified by the World Meteorological Office (WMO). Classes 4 and 5 come with uncertainties of 2°C and 5°C respectively and account for an astonishing 77% of the Met Office station total. Class 3 has an uncertainty rating of 1°C and accounts for another 8.4% of the total. The Class ratings identify potential corruptions in recordings caused by both human and natural involvement. Homewood calculates that the average uncertainty across the entire database is 2.5°C. In the graph below, he then calculates the range of annual U.K. temperatures going back to 2010 incorporating the margins of error.

The blue blocks show the annual temperature announced by the Met Office, while the red bars take account of the WMO uncertainties. It is highly unlikely that the red bars show the more accurate temperature, and there is much evidence to suggest temperatures are nearer the blue trend. But the point of the exercise is to note that the Met Office, in the interests of scientific exactitude, should disclose what could be large measurement inaccuracies. This is particularly important when it is making highly politicised statements using rising temperatures to promote the Net Zero fantasy. As Homewood observes, the Met Office "cannot say with any degree of scientific certainty that the last two years were the warmest on record, nor quantify how much, if any, the climate has warmed since 1884".

The U.K. figures are of course an important component of the Met Office's global temperature dataset known as HadCRUT. As we noted recently, there is ongoing concern about the accuracy of HadCRUT with large retrospective adjustments of warming in recent times and cooling further back in the record. In fact, this concern has been ongoing for some time. The late Christopher Booker was a great champion of climate scepticism and in February 2015 he suggested that the "fiddling" with temperature data "is the biggest science scandal ever". Writing in the Telegraph, he noted: "When future generations look back on the global warming scare of the past 30 years, nothing will shock them more than the extent to which official temperatures records – on which the entire panic rested – were systematically 'adjusted' to show the Earth as having warmed more than the actual data justified."

A.1 Entity Role Classification

This example illustrates how our system classifies entities and assigns their roles:

Entity	Role(s)
Met Office	Antagonist-[Deceiver]
Paul Homewood	Protagonist-[Guardian]
Daily Sceptic	Protagonist-[Guardian]
Christopher Booker	Protagonist-[Guardian, Virtuous]

Table 11: Entity roles assigned by the system for the given example.

B Gold Labels and Submission Format

B.1 Subtask 1 - Entity Framing

The format of a tab-separated line of the gold label and the submission files for Subtask 1 is:

article_id	entity_mention	start_offset	end_offset	main_role	fine_grained_roles
EN_10001.txt	Martin Luther King Jr.	10	32	Protagonist	Martyr
EN_10002.txt	Mahatma Gandhi	12	27	Protagonist	Martyr, Rebel
EN_10003.txt	ISIS	4	8	Antagonist	Terrorist, Deceiver

Table 12: Partial view of a gold label file for Subtask 1

The columns are defined as follows:

- **article_id**: The file name of the input article.
- **entity_mention**: The string representing the entity mention.
- **start_offset** and **end_offset**: Start and end position of the mention.
- **main_role**: A string representing the main entity role.
- **fine_grained_roles**: A tab-separated list of strings representing the fine-grained role(s).

Important Notes:

- For creating the submission file, a list of all entity mentions and their corresponding offsets for all the articles will be provided.
- The leaderboard evaluates predictions for both *main_role* and *fine_grained_roles*, but the official evaluation metric is based on the *fine_grained_roles*.
- *main_role* should take only one of three values from the 1st level of the taxonomy.
- *fine_grained_roles* should take one or more values from the 2nd level of the taxonomy.
- If you do not train a model to predict *main_role*, you must still provide a valid value under *main_role* to pass the format checker in the scorer.

C Post-Submission Results

DistilBERT All the experiments on DistilBERT has been made after the closing of the official submission. Tables 13 and 14 present the results.

Method	Exact Match Ratio	Hamming Loss	F1-score
Built-in Weighting	0.2906	0.0692	0.2410
Logaritmic Weighting	0.3372	0.0634	0.2931

Edwin Puertas
Universidad Tecnológica de Bolívar, Cartagena, Colombia
dgnecco@utb.edu.co jcmartinezs@utb.edu.co epuerta@utb.edu.co

Abstract

This paper presents the VerbaNexAi Lab system for SemEval-2025 Task 2: Entity-Aware Machine Translation (EA-MT), focusing on translating named entities from English to Spanish across categories such as musical works, foods, and landmarks. Our approach integrates detailed data preprocessing, enrichment with 240,432 Wikidata entity pairs, and fine-tuning of the MarianMT model to enhance entity translation accuracy. Official results reveal a COMET score of 87.09, indicating high fluency, an M-ETA score of 24.62, highlighting challenges in entity precision, and an Overall Score of 38.38, ranking last among 34 systems. While Wikidata improved translations for familiar entities like "Águila de San Juan," our static methodology underperformed compared to dynamic LLM-based approaches (Yuksel et al., 2025).

1 Introduction

Translating named entities such as proper nouns, geographic locations, and culturally significant references across languages remains a persistent challenge in natural language processing (NLP). This difficulty is particularly evident in the English-to-Spanish language pair, where lexical and cultural disparities often hinder accurate translation (Conia et al., 2025). For instance, a literal translation of "The Shawshank Redemption" as "La redención de Shawshank" fails to convey its identity as a well-known film, potentially confusing Spanish-speaking audiences. Similarly, "Eagle of St. John" requires translation to "Águila de San Juan" to retain its cultural and religious significance rather than an erroneous "Águila de Jhon." These examples underscore the importance of entity-aware machine translation (EA-MT), the focus of SemEval-2025 Task 2, which seeks to enhance precision in translating such entities for applications, including content localization, cross-cultural communication, and user-facing services.

Human translators excel at navigating these nuances by leveraging cultural knowledge and external resources, such as glossaries, to adapt entities appropriately (Vishwakarma, 2023). For example, rendering "Thanksgiving" as "Día de Acción de Gracias" demands understanding its North American cultural context. This task challenges automation without advanced systems. Neural machine translation (NMT) has markedly improved fluency in general translation tasks. Yet, it often struggles with named entities due to insufficient training data for rare or culturally specific terms and the absence of real-time contextual adaptation (Zeng et al., 2023). These shortcomings motivated our participation in SemEval-2025 Task 2, aiming to improve entity translation accuracy.

We propose an EA-MT system that combines MarianMT, an efficient model for English-to-Spanish translation, with enrichment of 240,432 bilingual entity pairs from Wikidata. This approach balances computational scalability, suitable for resource-constrained environments, with precision for culturally significant entities such as movie titles, foods, and landmarks. MarianMT's lightweight architecture facilitates fine-tuning with limited resources, while Wikidata's structured data addresses data scarcity challenges (Hu et al., 2022). We aim to narrow the divide between human-like cultural adaptation and automated scalability, addressing a pressing need in contemporary NLP.

Our contributions are threefold: (1) a scalable pipeline for data integration using Wikidata, adaptable to various languages and domains; (2) an empirical analysis comparing our static approach to dynamic LLM-based systems (Yuksel et al., 2025); and (3) insights into the limitations of static EA-MT and the demand for real-time, culturally sensitive adaptation. We intend to release our code and enriched dataset to support further research. This paper is structured as follows: Section 2 reviews related work, Section 3 details our methodology,

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1255–1262

Section 4 evaluates performance, and Section 5 summarizes findings and outlines future directions.

2 Related Work

Entity-Aware Machine Translation (EA-MT) has emerged as a critical subfield in NLP, addressing the limitations of traditional Neural Machine Translation (NMT) in handling named entities that require cultural and contextual precision (Conia et al., 2025). Recent advancements, such as SemEval-2025 Task 2, introduce specialized metrics like M-ETA for entity-specific accuracy and COMET for overall translation quality. These developments build upon approaches like Yuksel et al.'s dynamic LLM-based methods (Yuksel et al., 2025). Unlike these dynamic strategies, our system leverages Wikidata as a static knowledge base for entity enrichment.

Machine translation has evolved significantly over the years. Early rule-based systems relied on manually crafted linguistic rules, offering limited scalability and adaptability. Statistical machine translation (SMT), exemplified by tools like Moses, improved upon this by leveraging parallel corpora. However, it struggled with rare entities and context-dependent translations due to their reliance on statistical alignments rather than semantic understanding. The advent of transformer-based NMT models (Yang et al., 2020) marked a significant leap in translation quality. Yet, limitations persist in entity translation, as traditional approaches often lack mechanisms for cultural adaptation and real-time knowledge integration. Modern neural approaches like CroCoAlign (Molfese et al., 2024) refine sentence alignment, optimizing training data for NMT systems.

Introducing models like BERT (Devlin et al., 2018) brought pre-trained language representations, further enhancing NMT capabilities. However, challenges persist, particularly in translating rare named entities (Saadany et al., 2024). Efforts such as MOSAICo (Conia et al., 2024) address data scarcity by providing large-scale, multilingual, semantically annotated corpora. Other techniques have contributed to improved entity translation, including entity projection via MT (Jain et al., 2019) and denoising pre-training with monolingual data (Hu et al., 2022). Our system builds on these advancements by integrating entity enrichment through Wikidata.

Handling named entities remains a significant challenge in NMT. Zeng et al.'s Extract-and-Attend method dynamically extracts entity candidates, reducing errors by up to 35% (Zeng et al., 2023). Similarly, Lee et al. (Lee et al., 2021) employ NER post-processing to refine translation outputs, an approach we adapt statically via fine-tuning. Our system enhances entity translation by leveraging Wikidata to ensure contextual accuracy across languages.

Cultural adaptation is a crucial aspect of EA-MT. Challenges such as preserving culturally significant titles (e.g., Breaking Bad) align with our focus on entities like Águila de San Juan (Vishwakarma, 2023). Wang et al. (Wang et al., 2024) highlight the issue of cultural dominance in LLMs, which we mitigate through the integration of multilingual data in Wikidata. Named Entity Recognition (NER) plays a foundational role in this effort, with surveys like Li et al. (Li et al., 2022) guiding our enrichment strategy.

Evaluation remains a significant challenge in EA-MT. Traditional metrics like BLEU fail to capture entity accuracy, leading to the adoption of M-ETA, which reflects the limitations of our static approach. Jung et al. (Jung et al., 2023) propose fine-grained error analysis for deeper quality assessment. This approach could further refine our evaluation.

Our work aims to address existing gaps in EA-MT by incorporating structured knowledge bases and static entity enrichment, enhancing translation accuracy and cultural relevance.

3 System Description

Our EA-MT system enhances English-to-Spanish entity translation through a three-stage process tailored for scalability and precision in SemEval-2025 Task 2. As detailed below, our methodology adapts a static approach using MarianMT and Wikidata, explicitly discarding dynamic alternatives due to resource constraints.

3.1 Data Preprocessing

We preprocessed the EA-MT dataset to remove noise and standardize text, ensuring semantic focus. It involved (1) removing emojis, URLs, mentions (e.g., @username), and hashtags (e.g., #tag); (2) eliminating non-standard special characters (retaining ., !, ?); and (3) replacing accented characters in general text (e.g., "Á" to "A") while preserving entity names with accents to maintain integrity (e.g., "Águila" unchanged). We preserved the original

case to avoid obscuring entity boundaries (Jurafsky and Martin, 2025). Accent replacement in non-entity text risked degrading contextual translation (Naveen and Trojovský, 2024), but entity preservation ensured outputs like "Águila de San Juan" remained accurate.

3.2 Wikidata Enrichment

To address entity data scarcity, we enriched training with 240,432 Wikidata pairs across categories like musical works (Q2188189, 3766 labels; Q105543609, 70176 labels), foods (Q2095, 2575 labels; Q25403900, 445 labels), plants (Q756, 15037 labels), books (Q571, 2396 labels), book series (Q1667921, 750 labels), fictional entities (Q14897293, 17865 labels), landmarks (Q570116, 6157 labels; Q2319498, 620 labels), movies (Q11424, 67293 labels), places of worship (Q24398318, 12275 labels), natural places (Q1286517, 18387 labels), and TV series (Q5398426, 16282 labels). These pairs, extracted via Wikidata API queries, enhanced coverage for familiar entities like "Águila de San Juan," though rare entity representation remained limited.

While our enrichment improved precision for frequent entities, the static nature of this approach limits its effectiveness for rare or emerging entities. A more curated version of Wikidata, focusing on task-specific entities, could further enhance M-ETA scores, though the inherent limitation of static systems' incapability to adapt to new or context-specific entities absent from pre-enriched data would persist, underscoring the need for dynamic retrieval methods.

3.3 MarianMT Fine-Tuning

We selected MarianMT (`Helsinki-NLP/opus-mt-en-es`) for its efficiency and suitability for English-to-Spanish translation. Unlike larger models like NLLB-200 and M2M-100, which are designed for broad multilingual coverage and require significantly more computational resources, MarianMT offers a balanced trade-off between performance and resource efficiency. Given our hardware constraints (NVIDIA RTX 3050 GPU, 4GB), fine-tuning a larger model would have been impractical.

While NLLB-200 and M2M-100 may outperform in general multilingual translation, their advantage in entity-specific tasks remains uncertain, particularly in combination with our entity enrichment strategy. We fine-tuned MarianMT on our dataset using a learning rate of 3×10^{-5}, a batch size of 4 with gradient accumulation, and four epochs, optimizing with AdamW ($\beta_1 = 0.9$, $\beta_2 = 0.999$) (Yang et al., 2020). With more significant computational resources, increasing the number of epochs could further improve entity translation accuracy. Hardware limitations dictated this static approach, as dynamic LLM-based methods, such as recovery-augmented generation (RAG), required more VRAM, impractical for our setup. See Appendix 6 (Table 4) for a comparison of the EA-MT approaches considered.

Additionally, we explicitly discarded dynamic LLM-based approaches, such as retrieval-augmented generation (RAG), due to their high computational demands. Instead, we prioritized a static, resource-efficient solution better suited to our constraints. See Appendix 6 (Table 4) for a comparison of EA-MT approaches considered.

3.4 Prediction Generation

Predictions used the fine-tuned MarianMT statically, applying identical preprocessing steps. We formatted outputs as JSONL per SemEval requirements. Unlike dynamic LLM-based systems (Yuksel et al., 2025), our approach prioritized efficiency over adaptability.

4 Results and Analysis

We assess performance using SemEval-2025 Task 2 metrics: COMET (general quality), M-ETA (entity accuracy), and Overall Score:

$$\text{Overall Score} = 2 \times \frac{\text{COMET} \times \text{M-ETA}}{\text{COMET} + \text{M-ETA}}$$

All scores range from 0 to 100.

4.1 Performance Metrics

Our system achieved a COMET of 87.09, M-ETA of 24.62, and an Overall Score of 38.38, ranking 34th out of 34 systems. The high COMET reflects fluency, but the low M-ETA indicates struggles with rare entities (Naveen and Trojovský, 2024).

Metric	Validation	Test
COMET	87.24	87.09
M-ETA	27.74	24.62
Overall Score	45.12	38.38

Table 1: Validation vs. test metrics.

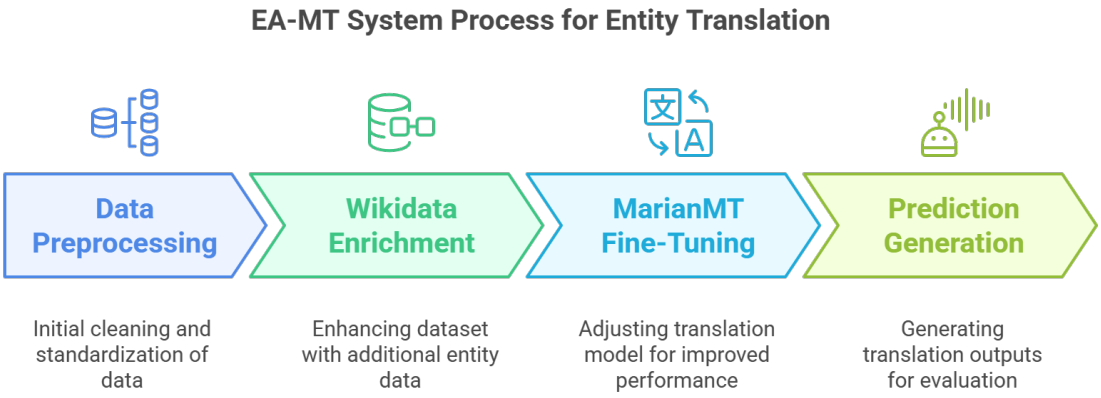

Figure 1: Pipeline diagram of the EA-MT system, illustrating data preprocessing, Wikidata enrichment, MarianMT fine-tuning, and prediction generation.

4.2 Comparison with Top Systems

We now compare our system's performance against top-performing models in the SemEval-2025 Task 2 leaderboard across Overall, M-ETA, and COMET metrics. Leading systems, such as Qwen2.5-Max (Overall: 92.63), Llama-3.3-70B-Instruct + DeepSeek-R1 (M-ETA: 90.50), and GPT-4o (COMET: 95.31), leverage large-scale LLMs, significantly outperforming our static MarianMT-based approach. Table 2 summarizes these results.

System	Overall	M-ETA	COMET
GPT-4o	92.42	89.88	95.31
Qwen2.5-Max	92.63	90.26	95.09
Qwen2.5-72B	92.54	90.13	95.09
Phi-4	92.50	90.09	95.04
Llama-3.3-70B-Instruct	91.72	88.42	95.28
Qwen2.5-32B	91.72	88.42	92.77
Llama-3.3-70B-Instruct + DeepSeek-R1	92.17	90.50	93.91
Ours	38.38	24.62	87.09

Table 2: Comparison of our system with top-performing systems in SemEval-2025 Task 2 across Overall, M-ETA, and COMET metrics

The top Overall scores, led by Qwen2.5-Max at 92.63, reflect a balanced performance in fluency and entity accuracy, far surpassing our 38.38. In M-ETA, systems like Llama-3.3-70B-Instruct + DeepSeek-R1 (90.50) and Qwen2.5-Max (90.26) demonstrate exceptional entity precision, while our 24.62 highlights a significant gap in handling named entities. For COMET, GPT-4o (95.31) and Llama-3.3-70B-Instruct (95.28) set the benchmark for fluency. Yet, our 87.09 remains competitive, indicating that our system's strength lies in general translation quality rather than entity-specific accuracy. These leading systems utilize large language models (LLMs) with retrieval-augmented generation (RAG) techniques, enabling them to access and incorporate external knowledge during translation dynamically. This dynamic approach allows models to handle a range of entities, including rare or domain-specific ones, by retrieving relevant information in real time. In contrast, our reliance on static Wikidata enrichment, while effective for familiar entities, fails to adapt to new or less frequent entities, explaining our low M-ETA score. It underscores the advantage of dynamic methods, as discussed in recent work on RAG in machine translation, such as Yuksel et al. (2025) (Yuksel et al., 2025).

4.3 Qualitative Analysis

The M-ETA metric, an exact-match evaluation for named entity translation accuracy, considers a translation correct only if it precisely matches the reference, offering no partial credit for approximate matches. This strict standard penalizes any deviation, be it a mistranslation, typographical error, or cultural misinterpretation. Our system's low M-ETA score of 24.62 indicates that many named entities were not translated accurately under this metric, reflecting challenges with rare entities and context-specific adaptations.

Successes included "Eagle of St. John" as "Águila de San Juan," showcasing Wikidata's strength with well-documented entities. However, frequent failures reveal cultural and contextual deficits (Saadany et al., 2024). Examples include "Breaking Bad," which was mistranslated as "Rompiendo Malo" instead of retaining its title, "Star Wars" as "Guerras Estelares" rather than "La Guerra de las Galaxias," and "Empire State Building" as "Edificio del Estado del Imperio" instead of preserving its name. These errors highlight limitations in handling culturally significant titles and landmarks, penalized heavily by M-ETA's exact match requirement. See Appendix 6 (Table 5) for a detailed list of translation examples with error types.

5 Conclusion

Despite Neural Machine Translation (NMT) advancements, our results highlight fundamental shortcomings in entity-aware translation when relying solely on static knowledge sources. While our system achieved a COMET score of 87.09, demonstrating strong fluency, its M-ETA score of 24.62 exposed severe deficiencies in entity precision, ultimately leading to an Overall Score of 38.38, the lowest among competing systems. These results confirm that a static enrichment approach, even when incorporating a large-scale structured knowledge base like Wikidata, is insufficient for handling the complexity of named entity translation. Static methods offer scalability and efficiency in low-resource settings (e.g., 4GB GPU) compared to RAG's demands, but the COMET-M-ETA gap shows fluency prioritization over precision, misaligned with EA-MT goals.

One of the main issues observed was the rigid dependency on Wikidata, which, while useful for well-documented entities, failed to capture emerging terms, domain-specific references, and subtle cultural nuances. The absence of real-time retrieval mechanisms also resulted in translation errors for ambiguous or context-sensitive entities. Compared to retrieval-augmented systems (Yuksel et al., 2025), our approach could not dynamically adjust translations, leading to cases where named entities were either mistranslated or omitted entirely. Exploring more curated or updated versions of structured knowledge bases like Wikidata could enhance entity translation accuracy. However, the fundamental limitation of static approaches' inability to adapt to new or context-specific entities would remain, reinforcing the need for dynamic retrieval methods.

Another critical limitation was our preprocessing pipeline, which, although effective in text normalization, introduced unintended side effects. For example, the replacement of accented characters (e.g., "Águila" to "Aguila") compromised entity integrity, further reducing translation accuracy (Naveen and Trojovský, 2024). Moreover, our constrained hardware (NVIDIA RTX 3050, 4GB) restricted fine-tuning to only four epochs, potentially limiting the model's ability to leverage the enriched dataset effectively (Yang et al., 2020). Traditional approaches, such as rule-based systems and statistical machine translation (e.g., Moses), suffer from similar limitations, poor scalability, lack of semantic understanding, and inadequate entity handling, rendering them obsolete for modern EA-MT tasks.

Our metrics provide clear evidence for the need for alternative solutions. The stark contrast between our M-ETA score 24.62 and the top systems' scores (e.g., 90.50 for Llama-3.3-70B-Instruct + DeepSeek-R1) indicates a significant gap in entity translation accuracy. In contrast, our competitive COMET score (87.09 vs. 95.31 for GPT-4o) suggests fluency is less of a bottleneck. This disparity underscores the inadequacy of static methods for entity-specific tasks. It justifies the adoption of dynamic, retrieval-augmented approaches capable of addressing rare and context-dependent entities. A hybrid approach, like lightweight RAG caching frequent entities, could balance efficiency and adaptability.

5.1 Limitations

Our approach revealed several constraints affecting performance:

1. **Over-reliance on Wikidata:** While structured knowledge bases offer valuable entity translations, their static nature prevents adaptation to emerging or domain-specific terms, reducing overall system robustness (Li et al., 2022).

2. **Lack of Contextual Adaptation:** Unlike retrieval-augmented LLM-based approaches, our system could not adjust entity translations dynamically, leading to rigid and often incorrect outputs (Yuksel et al., 2025).

3. **Preprocessing-induced Errors:** The aggressive normalization of text removed diacritics, impacting the accuracy of culturally significant named entities and altering their intended meaning (Naveen and Trojovský, 2024).

4. **Computational Constraints:** Limited hardware resources severely restricted the fine-tuning depth, potentially capping the model's ability to leverage the enriched dataset (Yang et al., 2020) fully.

5.2 Future Work

Our results strongly indicate that static knowledge bases alone are insufficient for robust entity translation. Future work must focus on integrating retrieval-augmented generation (RAG) (Yuksel et al., 2025) and adaptive entity-linking techniques to incorporate contextual information dynamically. Additionally, improving preprocessing strategies to preserve linguistic integrity (Jurafsky and Martin, 2025) and increasing computational resources to enable deeper fine-tuning (Yang et al., 2020) will be critical in overcoming current limitations. Finally, exploring meta-learning (Deb et al., 2022) and heuristic reasoning (Aoki et al., 2024) could enhance adaptability, reducing errors in domain-specific and low-resource entity translations.

6 Acknowledgments

We dedicate this work to the master's degree scholarship program in Engineering at the Universidad Tecnológica de Bolívar (UTB) in Cartagena, Colombia. We extend our deepest gratitude to the VerbaNex AI Lab team for their dedication, collaboration, and continuous support of our research endeavors.

Appendix

This appendix provides supplementary tables and details about the VerbaNexAI system for SemEval-2025 Task 2, which we removed from the main paper to comply with the 5-page limit.

A. Comparison of EA-MT Approaches

The following table, originally in Section 3, summarizes the primary EA-MT approaches considered in our methodology:

Our static approach leverages MarianMT and Wikidata for scalability under resource constraints. At the same time, we discarded dynamic RAG systems due to hardware limitations. Traditional SMT methods, like Moses, were not considered due to their obsolescence and poor performance on entity translation tasks.

B. Translation Examples with Error Types

The following table, originally in Section 4, provides examples of entity translations with identified error types:

These examples illustrate both successes (e.g., "Eagle of St. John") and frequent failures (e.g., "Breaking Bad"), highlighting limitations in cultural adaptation and entity precision.

C. Hardware Constraints

Our experiments were conducted on an NVIDIA RTX 3050 GPU with 4GB VRAM, which limited batch sizes and fine-tuned epochs. This constraint likely impacted our ability to fully leverage the enriched dataset, suggesting that future work with higher-capacity hardware could yield improved results.

Approach	Advantages	Limitations	Adaptation/Discard
Static (Ours)	Efficient, scalable	Low M-ETA, no adaptability	Adapted with MarianMT/Wikidata
Dynamic (RAG)	High M-ETA, adaptable	Resource-intensive	Discarded due to hardware
Traditional (SMT)	Simple alignment	Poor entity accuracy	Discarded, outdated

Table 3: Comparison of relevant EA-MT approaches, highlighting adaptation or discard decisions in our system.

Approach	Advantages	Limitations	Adaptation/Discard
Static (Ours)	Efficient, scalable	Low M-ETA, no adaptability	Adapted with MarianMT/Wikidata
Dynamic (RAG)	High M-ETA, adaptable	Resource-intensive	Discarded due to hardware
Traditional (SMT)	Simple alignment	Poor entity accuracy	Discarded, outdated

Table 4: Comparison of relevant EA-MT approaches, highlighting adaptation or discard decisions in our system.

Entity	Correct Translation	Our Output	Error Type
Eagle of St. John	Águila de San Juan	Águila de San Juan	Correct
Breaking Bad	Breaking Bad	Rompiendo Malo	Mistranslation
The Room	La Habitación	La Sala	Cultural Error
Darth Vader	Darth Vader	Dar Vader	Typographical
Star Wars	La guerra de las galaxias	Guerras Estelares	Mistranslation
Sushi	sushi	Sushí	Typographical

Abstract

Food contamination and associated illnesses represent significant global health challenges, leading to thousands of deaths worldwide. As the volume of food-related incident reports on web platforms continues to grow, there is a pressing demand for systems capable of detecting food hazards effectively. Furthermore, explainability in food risk detection is crucial for building trust in automated systems, allowing humans to validate predictions. SemEval-2025 Task 9 proposes a food hazard detection challenge to address this issue, utilizing content extracted from websites. This task is divided into two sub-tasks. Sub-task 1 involves classifying the type of hazard and product, while sub-task 2 focuses on identifying precise hazard and product "vectors" to offer detailed explanations for the predictions. This paper presents our participation in this task, where we introduce a transformer-based method. We fine-tune an enhanced version of the BERT transformer to process lengthy food incident reports. Additionally, we combine the transformer's contextual embeddings to enhance its contextual representation for hazard and product "vectors" prediction. The experimental results reveal the competitive performance of our proposed method in this task, which achieved 7th place in both sub-tasks. We have released our code at https://github.com/AhmadMonir-CSECU/SemEval-2025_Task9.

1 Introduction

Ensuring food safety is a growing concern; identifying and explaining food risks from online text-based sources could help mitigate this issue. However, the explainability of decision mechanisms related to food risk classification remains underexplored. Enhancing this understanding could help humans quickly assess the validity of predictions and utilize meta-learning approaches, such as clustering or pre-sorting examples. To address these challenges, SemEval-2025 Task 9 (Randl et al., 2025) proposed two sub-tasks: i) Text classification for predicting food hazards, which predicts the type of hazard and product, and ii) Detection of food hazards and product "vectors", which aims to identify the specific hazard and product. To demonstrate a clear view of the task definition, we articulate an example in Table 1.

Prior research (de Noordhout et al., 2014; Marvin et al., 2017) showed that developing early detection methods through compiling epidemiological data and evaluating cases may help us prevent foodborne illness outbreaks. To automate food safety detection, Maharana et al. (2019) investigated several machine learning (ML) models, including linear support vector machines, multinomial Naive Bayes, and weighted logistic regression along with over-sampling and under-sampling techniques on Amazon.com food reviews and FDA food recalls linked data. However, ML-based approaches are being limited to learning complex global contextual information resulting in poor performance. To address this limitation, several studies have explored probabilistic models (Wang et al., 2023) and transformer-based approaches (Xiong et al., 2023; Randl et al., 2024). Nevertheless, transformer-based models exhibit superior performance compared to other methods.

In this work, we have proposed a method based on an enhanced Bidirectional Encoder Representations from Transformers (BERT). We utilize the contextual embedding from the transformer for downstream purposes. To predict hazard and product "vectors", we duplicate and concatenate the embedding, then pass the combined representation into a classifier for final predictions.

We organize the rest of the paper as follows: Section 2 describes our proposed system for the SemEval-2025 food hazard detection task. In Section 3, we detail the system design, including parameter configurations, and present the experimental results along with a performance analysis. Fi-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1263–1268

nally, we conclude with potential future directions and the limitations of our system in Section 4.

2 Food Hazard Detection Framework

In this section, we introduce our proposed framework for the food hazard detection task. The task consists of two distinct sub-tasks. Sub-task 1 involves predicting the categories of food hazards and products. The sub-task 2 focuses on predicting the exact hazards and products. Both of these are structured as multi-class classification problems. Figure 1 illustrates the overview diagram of our proposed framework.

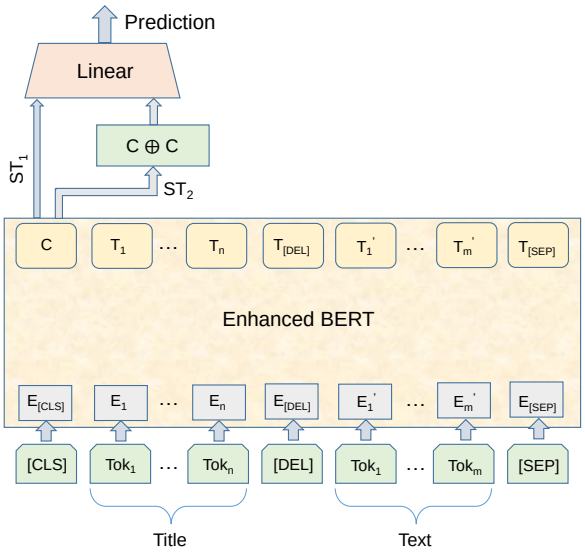

Figure 1: Overview diagram for our proposed method for SemEval-2025 Task 9: Food Hazard Detection Challenge. Here ⊕ indicates concatenation operation.

Our approach incorporates the "Title" and "Text" fields from the dataset. We represent the sequence as: "Title" + [DEL] + "Text" as the input to the transformer where [DEL] indicates a delimiter. We embed a '#' token between "Title" and "Text" as [DEL] to mark the boundary between them. Following (Zhou et al., 2021), we leverage the Enhanced BERT transformer to capture contextual embedding of the sequence. For sub-task 1, the [CLS] token representation is directly fed into the classification layer. For sub-task 2, we replicate the [CLS] representation, concatenate the copies, and then pass the aggregated embedding to the classifier. Finally, the model predicts based on the unnormalized scores (logits) computed by the Linear layer (Paszke et al., 2019).

2.1 Encoder Model

Unlike traditional sequence-based models such as LSTM (Schuster and Paliwal, 1997) and CNN (Goodfellow et al., 2016), transformer models can capture long-term dependencies and enhance the relationships between tokens in a sequence by leveraging multi-head attention and positional embedding mechanisms. To obtain contextualized feature representations of food hazard contexts, we fine-tuned the BERT transformer model as the encoder.

2.1.1 BERT

BERT (Bidirectional Encoder Representations from Transformers) (Devlin et al., 2018), developed by Google's research team in 2018, is a language model that leverages the transformer (Vaswani et al., 2017) architecture. It was pre-trained using passages from BooksCorpus (Zhu et al., 2015) and English Wikipedia. Unlike traditional unidirectional models, BERT performs bidirectional training of transformers, allowing it to understand the context of sentences more deeply. This two-way method has allowed BERT to attain top performance on different natural language processing (NLP) tasks. BERT's pre-training involves two tasks. The first one is Masked Language Modeling (MLM). In this task, BERT randomly masks certain tokens in the input and trains the model to predict these masked tokens using the surrounding context. The second one is the Next Sentence Prediction (NSP). Here, BERT determines whether a pair of sentences are consecutive in the original text.

We utilize the base uncased version of BERT[1] in

[1] https://huggingface.co/google-bert/bert-base-uncased

our task. It comprises 12 transformer blocks (i.e., hidden layers) with 12 attention heads and contains 110M parameters. The hidden size is 768 and the vocabulary size is 30,522.

2.1.2 Extension of BERT

The original BERT encoder supports up to 512 sequence lengths. To handle longer sequences, we utilize the implementation by (Zhou et al., 2021) of Enhanced BERT. Unlike other transformer models that support longer sequences like ModernBERT (Warner et al., 2024), Longformer (Beltagy et al., 2020), it keep the original architecture of the BERT encoder. Let L be the sequence length that is greater than 512, the Enhanced BERT segments the sequence into two overlapping sub-segments which can be represented as follows:

- **Segment 1**: [CLS] Token_1, Token_2, ..., Token_{510}, [SEP]
- **Segment 2**: [CLS] Token_{L-511}, Token_{L-510}, ..., Token_{L-1}, [SEP]

Both of them are then forward-passed to the original BERT encoder. Then we obtain a merged representation of the sub-segments by:

$$
\begin{aligned}
H_1 &= \text{Pad}(\text{BERT}(\text{Segment}_1), \text{bottom padding}) \\
H_2 &= \text{Pad}(\text{BERT}(\text{Segment}_2), \text{top padding}) \\
T &= [T_0, T_1, ..., T_{L-1}] = \frac{H_1 + H_2}{M_1 + M_2 + \epsilon}
\end{aligned} \tag{1}
$$

Here, $H_1, H_2, T \in \mathbb{R}^{L \times d}$. M_1 and M_2 are attention masks for segment 1 and segment 2 respectively. The d indicates the hidden size of the encoder (e.g., 768 for $\text{BERT}_{\text{BASE}}$). ϵ is a small constant to prevent division by zero.

2.2 Classification

We utilize the [CLS] token embedding, c, which corresponds to T_0 in Equation 1, from the transformer for classification purposes. For sub-task 1, we directly feed the embedding into a linear feed-forward layer. For sub-task 2, we duplicate and concatenate the embedding before passing the concatenated embedding into the linear layer. The logits, y, are obtained as follows:

$$y = cW^T + b, \tag{2}$$

Here, $W \in \mathbb{R}^{n \times d}$, $b \in \mathbb{R}^n$ are the model's parameters. n indicates the number of classes to be predicted. Finally, the model predicts the class corresponding to the maximum logit.

3 Experiments and Evaluation

3.1 Dataset Overview

To assess the performance of the proposed methods, the organizers of SemEval-2025 Task 9 introduced a benchmark dataset (Randl et al., 2025), derived from CICLe (Randl et al., 2024). This dataset comprises manually annotated English food recall reports sourced from official food agency websites, such as the FDA. Each instance includes six attributes: "year", "month", "day", "country", "title", and "text". The dataset is partitioned into three subsets, as detailed in Table 2.

The competition is structured into two sub-tasks. In sub-task 1, a model is expected to predict the hazard category and product category associated with a given instance. Sub-task 2 extends this challenge by requiring the identification of the exact hazard and product labels. The dataset covers 1,142 distinct products (e.g., "ice cream," "chicken-based products," "cakes"), which are grouped into 22 product categories (e.g., "meat, egg, and dairy products," "cereals and bakery products," "fruits and vegetables"). Additionally, the dataset contains 128 unique hazard labels (e.g., "salmonella," "listeria monocytogenes," "milk and products thereof"), categorized into 10 broader hazard categories. Notably, the dataset exhibits a significant class imbalance (Randl et al., 2024). In the evaluation phase, we merge the train and validation set to train our model and evaluate it with the unseen test set in the CodaLab competition[2].

Fold	Samples
Train	5082
Validation	565
Test	997
Total	6644

Table 2: The statistics of the SemEval-2025 Task 9 dataset.

3.2 Evaluation Measures

To evaluate the performance of the participant's proposed system, the organizers use the macro-averaged F1 score (Sokolova and Lapalme, 2009), which is essential for datasets with a long tail distribution problem. Given a set of true labels y

[2] https://codalab.lisn.upsaclay.fr/competitions/19955

and predicted labels $\hat{y}$, the performance score for a sub-task aggregates the performance on two classification tasks by:

$$F1_h = F1_{\text{macro}}(y_h, \hat{y}_h) \quad (3)$$

$$F1_p = F1_{\text{macro}}(y_p \mid \hat{y}_h = y_h, \hat{y}_p) \quad (4)$$

$$S = \frac{F1_h + F1_p}{2} \quad (5)$$

Where $F1_h$ is the macro F1-score for hazard labels and $F1_p$ is the macro F1-score for product labels, conditioned on correct hazard classification. The evaluation considers both hazard and product classifications, ensuring a balanced assessment across different levels of granularity.

3.3 Parameter Settings

In this section, we outline the parameter configurations for our proposed method. Our model is implemented using PyTorch (Paszke et al., 2019) and the Hugging Face Transformers library (Wolf et al., 2019). We fine-tune the uncased $\text{BERT}_{\text{BASE}}$ pre-trained language model, employing mixed-precision training (Micikevicius et al., 2017) through the Apex library[3] to enhance computational efficiency. Optimization is performed using the AdamW optimizer (Loshchilov and Hutter, 2017). The maximum sequence length is fixed at 1024 tokens. The optimal hyperparameters, as determined by validation set performance, are detailed in Table 3, while default values are maintained for all other parameters. Training is carried out on a T4 GPU utilizing Google Colab (Bisong, 2019).

Hyper-parameters	Optimal Value
Training batch size	8
Encoder learning rate	3e-5
Classifier learning rate	1e-4
Number of epochs	7
Manual seed	66

Table 3: Hyperparameter settings for our method.

3.4 Results and Analysis

In this section, we present a comparative analysis of our proposed system against selected methods for food hazard detection. Following the benchmark set by SemEval-2025 Task 9, system rankings are determined based on the macro-F1 score. Tables 4 and 5 summarize the performance comparisons for sub-task 1 and sub-task 2, respectively. Our system demonstrates competitive performance across both sub-tasks, highlighting its effectiveness in identifying food hazard categories, product categories, specific hazards, and specific products. Upon analyzing Tables 4 and 5, it is evident that sub-task 2 presents greater challenges compared to sub-task 1. This is primarily due to the increased number of target classes and the pronounced class imbalance, making accurate predictions more complex.

Team	Macro-F_1	Features
Baseline (BERT)	0.6670	title
Baseline (TFIDF + LR)	0.4980	title
Anastasia (1st)	0.8223	year, month, day, country, title, text
MyMy (2nd)	0.8112	year, month, day, country, title, text
HU (5th)	0.7882	title, text
BitsAndBites (6th)	0.7873	title, text
CSECU-Learners (7th)	0.7863	title, text
ABCD (8th)	0.7860	title, text
MINDS (9th)	0.7857	title, text
Habib University (26th)	0.4482	N/A
Howard University-AI4PC (27th)	0.1426	text

3.5 Ablation Study

In this section, we evaluate the contribution of various components in our model by selectively turning off them. Our findings indicate that each component plays a crucial role in overall performance. The "text" feature, in particular, has a significant impact, as removing it leads to a performance drop

[3] https://github.com/NVIDIA/apex

Team	Macro-F_1	Features
Baseline (BERT)	0.1650	title
Baseline (TFIDF + LR)	0.1830	title
SRCB (1st)	0.5473	title, text
MyMy (2nd)	0.5278	year, month, day, country, title, text

Fossils (6th)	0.4848	title, text
CSECU-Learners (7th)	0.4797	title, text
PuerAI (8th)	0.4783	N/A
Zuifeng (9th)	0.4712	N/A
JU-NLP (25th)	0.0126	title, text
Anaselka (26th)	0.0049	title, text

Table 5: Performance comparison of our proposed method (Team CSECU-Learners) with other selected participants' methods for sub-task 2.

of 6.59% and 8.95% in macro-F1 scores on the test set for sub-task 1 and sub-task 2, respectively. Additionally, the "title" feature also proves beneficial, with its removal resulting in a slight decrease in performance 0.21% for sub-task 1 and 0.18% for sub-task 2. For sub-task 2, we observe that concatenating the [CLS] token embedding enhances the macro-F1 score by 2.12%. In contrast, that strategy reduces the macro-F1 by 0.96% for the sub-task 1. This might be because of the larger number of classes to be predicted for sub-task 2 (128 hazards and 1142 products) than for sub-task 1 (10 hazard categories and 22 product categories).

Method	ST-1	ST-2
CSECU-Learners	0.7863	0.4797
- Title	0.7842	0.4779
- ($c \oplus c$)	-	0.4585
- Text	0.7204	0.3902
+ ($c \oplus c$)	0.7767	-

Table 6: Ablation study results for sub-task 1 and sub-task 2.

Therefore, we can hypothesize that the impact of feature concatenation on model performance is not universal; it depends heavily on the scale and nature of the classification problem. This approach tends to be advantageous in tasks involving a large number of classes, where greater representational power is beneficial. However, in tasks with relatively few classes, increasing the input dimensionality may introduce unnecessary complexity, potentially leading to overfitting. In such cases, the model may learn to rely on spurious patterns in the data rather than focusing on the core discriminative features.

4 Conclusion and Future Direction

In this work, we addressed the challenge of food hazard detection by participating in SemEval-2025 Task 9. We proposed a transformer-based approach, leveraging an enhanced version of the BERT model to handle the complexities of lengthy food incident reports. By combining the transformer's embeddings, our method enhances contextual representations for accurate hazard and product vector prediction. Our approach demonstrated competitive performance in this task, highlighting its effectiveness in classifying hazards and providing precise explanations for predictions.

In the future, we intend to explore other state-of-the-art transformer models pre-trained on biomedical datasets, as they may offer enhanced performance for this task. Due to the imbalanced nature of the dataset, we also aim to apply augmentation techniques that could improve learning across all classes.

Limitations

Our system can process sequences with a maximum length of 1024 tokens. However, many food incident reports exceed this limit, and incorporating the full text could improve the model's contextual understanding. Furthermore, while we utilized the base version of transformer models, their larger variants have shown superior performance in various downstream tasks, an aspect not explored in this study. Additionally, the issue of class imbalance remains unaddressed, which may limit the model's ability to generalize effectively across underrepresented classes, potentially impacting overall prediction accuracy.

{abdullaharean2613@gmail.com}

Abstract

This paper describes NLP-DU's entry to SemEval-2025 Task 11 on multi-label emotion detection. We investigated the efficacy of transformer-based models and propose an ensemble approach that combines multiple models. Our experiments demonstrate that the ensemble outperforms individual models under the dataset constraints, yielding superior performance on key evaluation metrics. These findings underscore the potential of ensemble techniques in enhancing multi-label emotion detection and contribute to the broader understanding of emotion analysis in natural language processing.

1 Introduction

Emotion detection seeks to identify and categorize emotions conveyed in textual data. This task presents significant challenges due to the inherently complex and overlapping nature of human emotions, as well as the difficulty associated with acquiring high-quality labeled datasets. Muhammad et al. (2025a) introduce the BRIGHTER dataset, which aims to bridge the gaps in textual emotion recognition across 28 languages and further enriched their semantic evaluation work in Muhammad et al. (2025b). Furthermore Belay et al. (2025) introduce Evaluating the Capabilities of Large Language Models for Multi-label Emotion Understanding. Recent research by Zhang et al. (2020) underscores the necessity of modeling both label dependence and modality dependence in multi-modal, multi-label emotion detection, further highlighting the intricacies involved in this domain.

In our approach, we first explored CNN and LSTM-based solutions and checked for baseline performance after training. Then we chose to explore transformer-based models for multi-label emotion detection. We experimented with ModernBERT Warner et al. (2024), DeBERTa He et al. (2021), ALBERT Lan et al. (2020), XLM-RoBERTa Conneau et al. (2020), DistilBERT Sanh et al. (2020), and XLNet Yang et al. (2020), some state-of-the-art transformer models known for their strong contextual understanding and generalization capabilities. To address the challenges posed by a compact dataset Muhammad et al. (2025a) with sensitive labeling and emotion context added to each sentence, we employed data augmentation techniques and leveraged multiple dataset splitting techniques such as balanced stratified K-fold splitting, tree-based splitting, k-means splitting, and balanced stratified splitting for robust evaluation. Additionally, we propose an ensemble approach that combines multiple transformer-based models, for example, ModernBERT and DeBERTa, via weighted averaging, improving overall performance. To encourage reproducibility, we have released our code and models, which can be accessed at: https://github.com/ssadman887/SEMEVAL-TASK-2025.

2 System Overview

2.1 Data Description

The dataset consists of text samples labeled with multiple emotional categories: Anger, Fear, Joy, Sadness, and Surprise. The analysis of text length distribution reveals that most samples contain between 5 to 25 words, with a right-skewed distribution indicating that shorter texts are more common. In terms of class distribution, the dataset is imbalanced, with Fear and Anger appearing more frequently than Surprise and Joy.

The correlation analysis between emotions shows notable relationships, such as a strong negative correlation between Joy and Fear (-0.49), while Fear and Sadness exhibit a moderate positive correlation (0.27). These findings provide insights into the dataset's structure, which is essential for guiding preprocessing steps and model training.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1269–1275

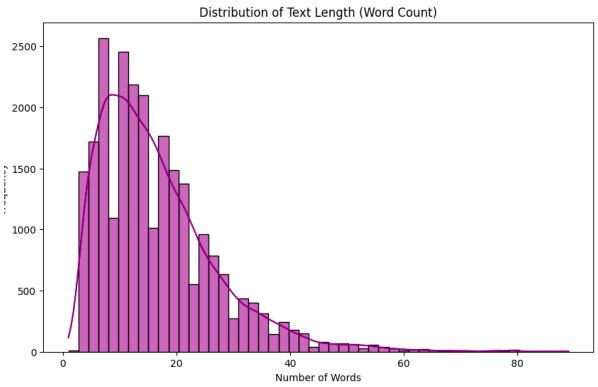

Figure 1: Distribution of Text Length

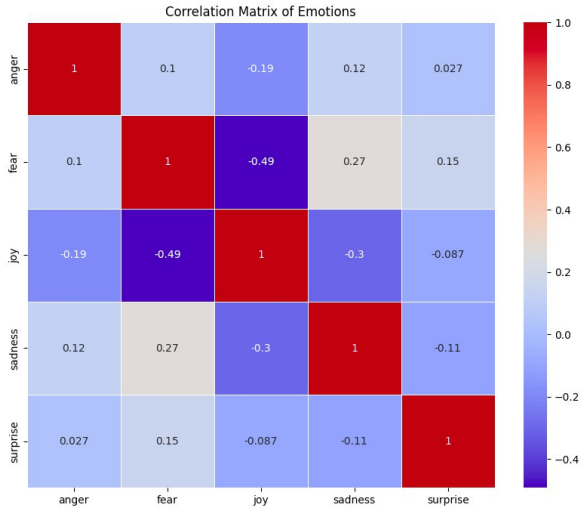

Figure 2: Correlation Matrix of Emotions

2.2 Key Algorithms and Modeling Decisions

Our system for multi-label emotion detection is based on a transformer-based architecture. The system follows a sequence classification approach where each input text is encoded into contextual embeddings and passed through a multi-label classification head.

2.2.1 Data Augmentation

To improve dataset diversity and robustness, a sentence rewriting data augmentation strategy was utilized. This method rephrased sentences while preserving original emotion labels. By creating various versions of the same text, the dataset expanded, enhancing the model's capacity to generalize across diverse linguistic emotion expressions. This technique increased training data volume and introduced more syntactic and lexical variety, thereby boosting the model's ability to recognize nuanced emotional expressions. We used Meta LLaMA 3.1

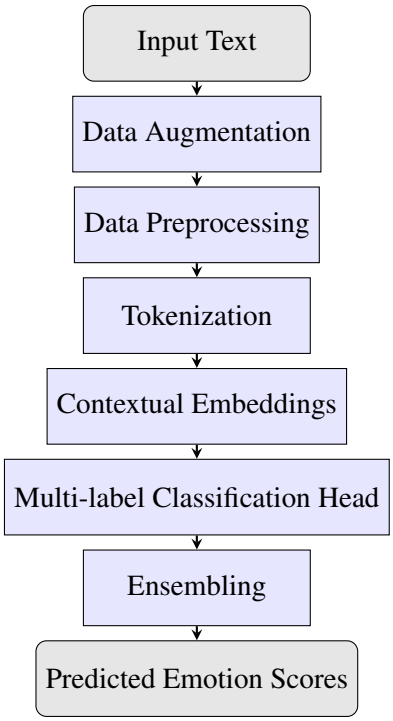

Figure 3: Pipeline for multi-label emotion classification

AI (2025) from the Ollama platform on a local device using an RTX 4050 GPU. We employed multiple augmentation techniques, discussed in Table 1. We checked each data row for discrepancies and modified accordingly.

2.2.2 Preprocessing Steps

The preprocessing phase aimed to preserve the data's textual integrity while aligning it with model architectures. Minimal text cleaning was conducted to maintain the original semantic meaning. This method retained critical linguistic structures, avoiding the unintended loss of emotional nuances. Next, tokenization was performed using the tokenizers specific to ModernBERT, DistilBERT, and DeBERTa, capping sequence length at 512 tokens. This converted raw text into structured tokens for transformer-based model processing. Lastly, label representation used binary encoding for each emotion category, enabling the model to predict multiple emotions per input, thus reflecting the complex interdependencies of human emotional expressions.

2.3 Model Architecture

The model architecture consists of ModernBERT, DistilBERT, and DeBERTa as the base models. A classification head is applied on top, which includes a fully connected layer with a 0.01 dropout rate to

Augmentation Technique	Original Sentence	Augmented Sentence
Synonym Replacement	They were dancing to Bolero.	They were performing to Bolero.
Perspective Transformation	I moved my arms, stretching the muscles.	He moved his arms, stretching the muscles.
Voice Transformation	The cop tells him to have a nice day.	He was told to have a nice day by the cop.
Tone Adjustment	We ordered some food at McDonald's instead of buying food at the theatre because of the ridiculous prices the theatre has.	We opted for McDonald's rather than purchasing food at the theatre due to its exorbitant prices.
Tense Consistency	About 2 weeks ago I thought I pulled a muscle in my calf.	About 2 weeks ago I had thought I had pulled a muscle in my calf.
Tag Question Addition	The room was small but brightly lit.	The room was small but brightly lit, wasn't it?
Neutral Modifier Insertion	I still cannot explain this.	I still cannot quite explain this.

Table 1: Examples of Data Augmentation Techniques Applied Using Meta LLaMA

prevent overfitting. The output layer uses a sigmoid activation function to predict multi-label probabilities. The model is trained using the Binary Cross Entropy with Logits loss function, optimized with AdamW at a learning rate of 2e-5.

2.4 Training Strategy

The training strategy was designed to optimize model performance for multi-label emotion classification while ensuring robustness and generalization across diverse data subsets. We employed a 5-fold Multilabel Stratified Cross-Validation (MSCV) approach, which preserves the label distribution across folds in a multi-label setting. For a dataset D with N samples and $K = 5$ labels (Anger, Fear, Joy, Sadness, Surprise), MSCV partitions D into 5 folds $\{D_1, D_2, \ldots, D_5\}$, where each fold D_i maintains the proportion of positive instances for each label k:

$$\text{prop}_{k,i} \approx \frac{1}{N} \sum_{n=1}^{N} y_{n,k}, \quad \forall i \in \{1, 2, \ldots, 5\}, \quad (1)$$

where $y_{n,k} \in \{0, 1\}$ is the k-th label for the n-th sample, and $\text{prop}_{k,i}$ is the proportion of positive instances for label k in fold D_i. This stratification ensures that the model is trained and evaluated on representative subsets, mitigating bias due to label imbalance.

To prevent overfitting and optimize training efficiency, early stopping was applied based on the change in macro F1 score between epochs. Let $\text{F1}^{(e)}_{\text{macro}}$ denote the macro F1 score on the validation set at epoch e. Early stopping was triggered if the improvement in F1 score was below a threshold:

$$\Delta\text{F1} = \text{F1}^{(e)}_{\text{macro}} - \text{F1}^{(e-1)}_{\text{macro}} < 0.01, \quad (2)$$

halting training to retain the model weights from the epoch with the highest validation performance. Table 2 summarizes the training hyperparameters.

Training Parameter	Value
Batch Size	16
Epochs	5
Early Stopping Threshold	$\Delta\text{F1} < 0.01$
Optimizer	AdamW
Learning Rate	2×10^{-5}

Table 2: Training hyperparameters for model optimization.

2.5 Ensembling Strategy

To enhance prediction robustness, we employed Weighted Ensembling, where predictions were combined based on model confidence:

$$\hat{y}_{\text{ensemble}} = w_A \cdot \hat{y}_A + w_B \cdot \hat{y}_B \quad (3)$$

where $w_A, w_B \in [0, 1]$ and typically $w_A + w_B = 1$ to ensure normalized weighting. Furthermore, we tested both the best model among the folds and, in other cases, used all folds to predict results. In a multi-label classification setting with M models and K labels, majority voting aggregates binary predictions to produce a consensus prediction. For the n-th sample and k-th label, let $\hat{y}_{m,n,k} \in \{0, 1\}$ represent the binary prediction

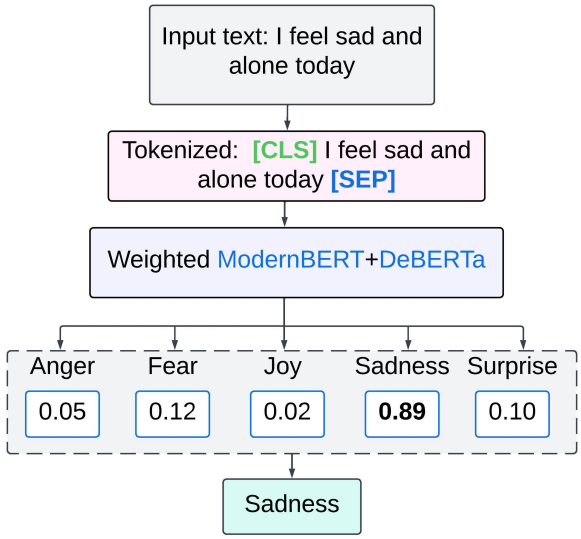

Figure 4: An example of emotion classification of an input text

from the m-th model. The ensemble prediction $\hat{y}_{n,k}$ is determined by majority voting:

$$\hat{y}_{n,k} = \mathbb{1}\left(\sum_{m=1}^{M} \hat{y}_{m,n,k} \geq \left\lceil \frac{M}{2} \right\rceil\right), \quad (4)$$

where $\mathbb{1}(\cdot)$ is the indicator function, returning 1 if the condition is true and 0 otherwise, and $\lceil x \rceil$ denotes the ceiling function.

2.6 Example Walkthrough

Figure 4 shows an example of emotion classification of an input text. We have taken a sample data from our dataset to show the workflow.

2.7 Addressing Key Challenges

To mitigate the effects of class imbalance, particularly for underrepresented emotions such as Surprise, we implemented a weighted loss function. In a multi-label classification setting, the weighted binary cross-entropy loss adjusts for class imbalance across labels. For the n-th sample with K labels, the loss $\mathcal{L}_n$ is defined as:

$$\mathcal{L}_n = -\frac{1}{K}\sum_{k=1}^{K} w_k \cdot \big[y_{n,k} \cdot \log(\sigma(\hat{z}_{n,k})) + (1 - y_{n,k}) \cdot \log(1 - \sigma(\hat{z}_{n,k}))\big], \quad (5)$$

where $w_k \geq 0$ is the weight for the k-th label, $y_{n,k} \in \{0, 1\}$ is the ground truth, and $\sigma(\hat{z}_{n,k})$ is the sigmoid activation of the logit $\hat{z}_{n,k}$. The total loss over a batch of N samples is:

$$\mathcal{L}_{\text{batch}} = -\frac{1}{N \cdot K}\sum_{n=1}^{N}\sum_{k=1}^{K} w_k \cdot \big[y_{n,k} \cdot \log(\sigma(\hat{z}_{n,k})) + (1 - y_{n,k}) \cdot \log(1 - \sigma(\hat{z}_{n,k}))\big]. \quad (6)$$

To address class imbalance, oversampling balances the dataset by increasing the representation of underrepresented labels. For a dataset D with N samples and K labels, let $y_{n,k} \in \{0, 1\}$ denote the k-th label for the n-th sample. The frequency of positive instances for the k-th label is:

$$f_k = \sum_{n=1}^{N} y_{n,k}. \quad (7)$$

The maximum frequency across all labels is $f_{\text{max}} = \max_k\{f_k\}$. The oversampling ratio for the k-th label is:

$$r_k = \frac{f_{\text{max}}}{f_k}. \quad (8)$$

For each sample (x_n, y_n) where $y_{n,k} = 1$, approximately $\lfloor r_k \rfloor$ duplicates are created to balance the dataset.

3 Experimental Setup

3.1 Data Preparation

We applied data augmentation by altering sentence structures while preserving the original emotions, increasing dataset diversity. Standard data cleaning techniques, including special character removal, and tokenization, were used for preprocessing.

3.2 Data Splitting Strategy

To identify the optimal data partitioning method, we evaluated four strategies. Tree-based splitting utilized hierarchical clustering to group similar data points prior to division. K-Means clustering generated diverse data clusters for balanced splits. Balanced splitting preserved label distribution across partitions. Finally, Multilabel Stratified K-Fold Cross-Validation with five folds maintained label consistency in each fold. These methods were assessed for both training and prediction to determine the most effective solution.

3.3 Training Procedure

Models were trained using a batch size of 16 for up to 5 epochs, with early stopping applied if the improvement in F1 score was below 0.01. The optimizer used was AdamW with a learning rate of 2×10^{-5}.

3.4 Hardware and Software

All experiments were conducted on the Kaggle platform using a GPU P100 and a local Ollama platform using an RTX 4050. The implementation was done using PyTorch, Transformers (Hugging Face), and Scikit-learn.

4 Experimental Results and Analysis

We evaluated both individual transformer-based models and ensemble strategies, using the development (Dev) and test datasets. Performance is assessed through F1 scores (macro and micro) and accuracy, providing a comprehensive view of model effectiveness in this multi-label setting.

4.1 Individual Model Performance

Table 3 summarizes individual model performance. ModernBERT leads on the Dev

dataset with an F1 score of 0.7842 and accuracy of 85.65%, outperforming DistilBERT (F1 = 0.6970, accuracy = 80.17%), XLM-R_{Base} (F1 = 0.6470, accuracy = 77.70%), and XLNet (F1 = 0.6140, accuracy = 71.9%). DeBERTa follows with an F1 score of 0.7324 and accuracy of 84.48%. On the Test dataset, ModernBERT and DeBERTa achieve macro F1 scores of 0.6805 and 0.6930, and micro F1 scores of 0.7212 and 0.7232, respectively. Conversely, XLNet, XLM-R_{Large} (Dev F1 = 0.6342, Test macro F1 = 0.5762), and ALBERT underperform, likely due to pretraining misalignment with emotional text. The LSTM baseline (Dev F1 = 0.4278, Test macro F1 = 0.3805) highlights transformers' superiority.

4.2 Ensemble Model Performance

Ensemble methods enhance performance by combining model predictions. The weighted averaging strategy combines logits as:

$$\hat{z}_{n,k}^{\text{ensemble}} = w_A \cdot \hat{z}_{n,k}^{A} + w_B \cdot \hat{z}_{n,k}^{B}, \qquad (9)$$

with $w_A + w_B = 1$, yielding a prediction $\hat{y}_{n,k} = \sigma(\hat{z}_{n,k}^{\text{ensemble}})$. For ModernBERT+DeBERTa ($w = 0.5, 0.5$), this achieves the highest Dev F1 score (0.7886) and Test macro F1 score (0.7086). Majority voting, defined as:

$$\hat{y}_{n,k}^{\text{majority}} = \mathbb{1}\left(\sum_{m=1}^{M} \hat{y}_{m,n,k} \geq \left\lceil \frac{M}{2} \right\rceil\right), \qquad (10)$$

reaches a Test micro F1 of 0.7457. The best-fold weighted ensemble, with weights:

$$w_m = \frac{\text{F1}_m^{\text{best-fold}}}{\sum_{m'=1}^{M} \text{F1}_{m'}^{\text{best-fold}}}, \qquad (11)$$

achieves the highest Test micro F1 (0.7467), while best-fold voting yields 0.7432. DeBERTa+DistilBERT ensembles underperform (e.g., weighted Dev F1 = 0.7261, Test micro F1 = 0.7418 for best-fold weighted) due to DistilBERT's lower capacity.

4.3 Result Table

Table 3 provides a detailed comparison of all models and ensembles, highlighting the superiority of the ModernBERT+DeBERTa combinations across most metrics.

4.4 Discussion

Transformer-based models outperform traditional architectures like LSTM, with ModernBERT (Dev F1 = 0.7842, accuracy = 85.65%) and DeBERTa (Dev F1 = 0.7324, Test macro F1 = 0.6930) leading due to their advanced pretraining and attention mechanisms. Ensemble methods enhance performance, with ModernBERT+DeBERTa weighted averaging (Equation 3) achieving the highest Dev F1 (0.7886) and Test macro F1 (0.7086), while majority voting (Equation 4) excels in Test micro F1 (0.7457). The best-fold weighted ensemble (Equation 5) yields the top Test micro F1 (0.7467). DeBERTa+DistilBERT ensembles underperform due to DistilBERT's lower capacity (Dev F1 = 0.6970). The poor performance of XLNet, XLM-R_{Large}, and ALBERT suggests their pretraining may not suit emotional text. These results highlight the efficacy of ensemble learning for multi-label emotion classification, with future work potentially exploring dynamic weighting or analyzing underperforming models for architectural improvements.

5 Conclusion

We employed various data splitting techniques and augmentation strategies to enhance the robustness of our training process. One of the key challenges

Model Name	Dev Data		Test Data	
	F1 Score	Accuracy	F1 Score (Macro)	F1 Score (Micro)
LSTM	0.4278	64.20%	0.3805	0.4022
DistilBERT	0.6970	80.17%	0.6521	0.7001
ModernBERT	0.7842	85.65%	0.6805	0.7212
DeBERTa	0.7324	84.48%	0.6930	0.7232
XLM-R_{Base}	0.6470	77.70%	0.5804	0.6234
XLM-R_{Large}	0.6342	76.33%	0.5762	0.6300
XLNet	0.6140	71.90%	0.5742	0.6265
ALBERT	0.5872	72.20%	0.5659	0.6282
Ensemble Models				
ModernBERT+DeBERTa$_{0.5+0.5\ weight}$	0.7886	85.30%	0.7086	0.7443
ModernBERT+DeBERTa$_{majority\ voting}$	0.7639	85.42%	0.7034	0.7457
ModernBERT+DeBERTa$_{best\ fold\ weighted}$	0.7399	86.20%	0.7056	0.7467
ModernBERT+DeBERTa$_{best\ fold\ voting}$	0.7528	86.90%	0.7044	0.7432
DeBERTa+DistilBERT$_{0.5+0.5\ weight}$	0.7261	85.17%	0.7004	0.7322
DeBERTa+DistilBERT$_{majority\ voting}$	0.7128	84.31%	0.6947	0.7212
DeBERTa+DistilBERT$_{best\ fold\ weighted}$	0.7318	85.00%	0.6925	0.7418
DeBERTa+DistilBERT$_{best\ fold\ voting}$	0.7324	84.48%	0.6943	0.7422

Table 3: Performance of individual and ensemble models on Dev and Test datasets. The best ensemble performance is underlined.

we encountered was the inherent imbalance in the dataset, with certain emotions being overrepresented. Additionally, we identified instances of mislabeling within the training data, which introduced noise into the learning process. Despite these challenges, our approach enabled us to achieve a competitive F1 score, demonstrating the effectiveness of our data handling strategies and model optimization techniques.

6 Ethical Considerations

Due to the sensitivity of the training data, there is a risk of misclassification in sentence predictions, potentially leading to incorrect label assignments. This is particularly concerning for emotionally charged content, where misinterpretation could have significant implications. To mitigate such risks, we implemented data augmentation and rigorous evaluation strategies to enhance model robustness. Additionally, we emphasize the importance of human oversight in critical applications to ensure ethical and responsible deployment of our system.

Abstract

This paper presents the WordWiz team's submissions for Task 10 of SemEval 2025: Multilingual Characterization and Extraction of Narratives from Online News. The Narrative Extraction subtask focuses on generating concise explanations that support dominant narratives identified in multilingual news articles. We employ two complementary approaches: supervised fine-tuning and direct preference optimization of large language models. To enhance training data quality, we develop a preprocessing pipeline. Additionally, we implement a multi-temperature inference strategy, which generates three candidate explanations using varying temperature parameters and selects the most relevant one through semantic similarity scoring. Our final system[1] secured first place in Portuguese and second place in English, Russian, Bulgarian, and Hindi, consistently outperforming baseline systems across all languages.

1 Introduction

The democratization of information on the internet has posed significant challenges in discerning and interpreting manipulative content. News ecosystems, particularly during crises, often serve as contested spaces where disinformation and propaganda narratives vie for public credibility and attention. Consequently, the automated identification and characterization of narratives in multilingual news sources constitute a vital endeavor for content moderators, fact-checkers, and media literacy initiatives. The SemEval 2025 Task on Multilingual Characterization and Extraction of Narratives from Online News addresses this issue through three subtasks spanning five languages English, Bulgarian, Hindi, Portuguese, and Russian Piskorski et al. (2025) Stefanovitch et al. (2025).

Our research centers on Subtask 3: Narrative Extraction, which entails producing a concise explanation (maximum 80 words) that substantiates a given dominant narrative using textual evidence from a news article. This text-to-text generation task necessitates both the precise detection of pertinent evidence and a coherent summary that aligns with the narrative classification. Our methodology leverages recent advancements in large language models, employing two complementary approaches. First, we utilized Supervised Fine-Tuning (SFT) Lee (2024) on pre-trained models, including Phi-3.5, Llama-3, and Llama-3.1-8B. Second, we applied Direct Preference Optimization (DPO) Rafailov et al. (2023) to enhance model outputs by incorporating human preference data. To optimize performance across diverse linguistic contexts, we developed a robust preprocessing pipeline that eliminates duplicate sentences, standardizes text, and augments training examples with narrative-specific details. During inference, our system generates multiple candidate explanations by varying temperature parameters and selects the most apt one via semantic similarity scoring.

Experimental findings reveal that, although larger models frequently exhibit robust performance, the meticulously fine-tuned Phi-3.5 model consistently yielded superior results across most languages. We delineate critical factors for effective narrative extraction, including the identification of relevant evidential sentences, the preservation of cross-lingual consistency in explanation structure, and the equilibrium between textual fidelity and succinct summarization. Our system markedly outperforms baseline models across all evaluated languages.

2 Background

SemEval 2025 Task 10 posed a complex information extraction challenge across five languages: English, Bulgarian, Hindi, Portuguese, and Russian. The dataset comprised news articles primarily covering two domains climate change (CC) and the

[1] https://github.com/roohix/WordWiz

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1276–1281

Ukraine-Russia war (UA) with each article annotated for its dominant narrative and, when applicable, sub-narrative classifications. The training set contained a substantial number of multilingual examples, while the development set was comparatively smaller. Both adhered to the same data structure: article text, narrative label, sub-narrative label, and gold-standard explanations. The task presented significant challenges in identifying evidence supporting the assigned narratives, particularly given the substantial variation in article length. The gold-standard explanations highlighted key textual evidence aligning with the assigned narrative without explicitly referencing its classification. Our dataset analysis indicated that effective explanations required capturing the rhetorical strategies, entities, and argumentation patterns characteristic of each narrative type while maintaining linguistic and structural appropriateness for each language.

The task organizers provided a baseline system utilizing zero-shot prompting with the Microsoft Phi-3-small-8k-instruct model. This approach relied exclusively on the model's pre-trained capabilities to interpret prompts and generate explanations, without any fine-tuning.

Research on information and event extraction from news articles remains in its early stages. Sentence-level methods, frequently falling under the umbrella of Timeline Summarization (TLS), typically generate linear sequences representing a single story's progression. Recent variations on TLS aim to capture more complexity, such as comparative timelines highlighting contrasting events between datasets Duan et al. (2020) or Multi-Timeline Summarization (MTLS) which extracts distinct parallel storylines from a corpus Yu et al. (2021). Alternative paradigms like Summarize Dates First reverse the typical TLS pipeline by summarizing individual dates before selecting relevant ones Quatra et al. (2021). Document and cluster-level methods often employ more complex graph structures to represent interactions between multiple storylines and events, moving beyond simple linearity to capture convergences and divergences.

Recent advancements have incorporated diverse techniques and representations. For sentence-level extraction, methods like WILSON utilize PageRank and BERT embeddings within a divide-and-conquer framework for date selection and summarization Liao et al. (2021), while specialized approaches like TexSL construct spatio-temporal storylines for disaster events using neural embeddings and integer linear programming Yuan et al. (2019). At the document level, optimization techniques continue to be refined, building upon earlier 'Connect the Dots' concepts to maximize coherence and other criteria, sometimes incorporating entity information and temporal decay factors Barranco et al. (2019). Cluster-level approaches represent events as groups of documents, using techniques like Temporal Event Maps (TEMs) based on LDA and mutual information metrics Cai et al. (2019), Event Phase Oriented News Summarization (EPONS) using structural clustering and random walks Wang et al. (2018), or the iterative construction of Story Forests using classifiers and tree-based operations Liu et al. (2020).

3 Methodology

Our approach to narrative extraction integrates two complementary methodologies. These methodologies leverage the strengths of large language models (LLMs) while addressing their limitations in generating concise, evidence-based explanations.

3.1 Supervised Fine-Tuning

For our SFT approach, we fine-tuned multiple LLMs on the training dataset using the Unsloth framework (Daniel Han and team, 2023), which facilitates efficient fine-tuning. The models were trained to generate explanations aligned with the provided dataset and corresponding narrative labels. To ensure clarity and consistency, we structured our prompts to emphasize task requirements, incorporating explicit instructions on output format and content constraints. The prompt template comprised sections for instructions, input documents, narrative information, task specifications, and response areas. This structured format guided the model toward producing focused explanations that directly addressed the assigned narrative within the specified character limits. Additionally, adding language-specific tokens enabled the model to adapt its responses to the target language, a critical feature for multilingual applications.

3.2 Direct Preference Optimization

We employed DPO, a technique that fine-tunes models using preference data. DPO allows the model to learn from human preferences between output pairs, aligning its generations more closely with human judgments of quality and relevance. Unlike traditional reinforcement learning methods, DPO optimizes the model without explicit reward

modeling, instead training it to produce outputs preferred by human evaluators. This approach is particularly valuable for our task, where explanation quality is inherently subjective and difficult to quantify using standard metrics. By leveraging preference data derived from human annotations, we guided the model toward generating explanations that were factually accurate and stylistically aligned with human expectations for narrative justification. Specifically, the model was trained using annotated explanations as preferred responses, while its zero-shot outputs served as rejected explanations, facilitating more effective preference-based learning.

3.3 Inference Strategy

We implemented a multi-candidate generation strategy during inference to address variability in language model outputs. For each article-narrative pair, we generated three candidate explanations using temperature values of 0.5, 0.7, and 0.9, exploring a spectrum from conservative to more diverse outputs.

To select the optimal explanation, our selection algorithm focused on two key components:

1. **Keyword Matching**: We extracted all unique words from the narrative text (after lowercasing) to create a set of narrative-specific keywords. These keywords represented the core concepts that should appear in a relevant explanation. For example, for climate-related narratives, keywords might include `temperature`, `measurement`, `uncertainty`, or `scientific`. Our algorithm measured the overlap between these narrative keywords and the words in each candidate explanation, giving preference to explanations incorporating more narrative-specific terminology.

2. **Length Scoring**: We implemented a normalized length scoring mechanism that awarded maximum points (1.0) to explanations containing approximately 80 words (the task's upper limit), with diminishing returns for shorter explanations, ensuring that explanations were substantial enough to convey necessary information without being overly verbose or truncated.

These scores were combined using a weighted formula: $(\text{keyword\_overlap} \times 2) + \text{length\_score}$, with keyword overlap weighted more heavily to prioritize content relevance over length. This prioritization ensured that even slightly shorter explanations with strong narrative alignment would be selected over longer explanations with weaker relevance.

3.4 Preprocessing Strategies

Our preprocessing pipeline incorporated advanced techniques to improve data quality and model performance. We removed extraneous elements such as emojis, URLs, hashtags, and email addresses to reduce noise and standardized punctuation and whitespace across all five languages. Case normalization minimized variability, and narrative enhancement expanded abbreviated codes into full expressions, enriching semantic context. Additionally, content filtering eliminated the redundant sentences commonly found in news articles, sharpening the model's focus on relevant information. Collectively, these preprocessing techniques produced cleaner, more consistent training examples, enhancing the model's ability to discern narrative patterns and maintain cross-lingual consistency across different approaches and outputs.

4 Experimental Setup

Our experimental framework was designed to evaluate the effectiveness of our approach across multiple languages and model architectures.

4.1 Dataset and Evaluation Metrics

Our system exclusively utilizes the official dataset provided for the task, adhering to the default training-development split. We use the development set solely to assess various experimental configurations during the development phase. The language model is fine-tuned on the training and development sets for the final submission. Performance is evaluated using the F1 macro score, the standard metric for this subtask, despite its tendency to favor majority classes over minority ones.

4.2 Training Strategy

We selected the pre-trained language models employed in our system from those available on Hugging Face. We utilized the PyTorch deep learning framework (version 2.5). For the SFT approach, we employed a batch size of 2 and a learning rate of 2e-4, with five warm-up steps and training for 60 steps. To optimize memory usage on consumer-grade hardware, we applied 4-bit quantization, which reduced memory requirements significantly while

maintaining model performance. For DPO, we further refined our SFT models using preference data derived from the development set, aligning the model outputs more closely with human judgments of explanation quality and relevance.

4.3 Models

We experimented with several pre-trained models from different architectural families and parameter scales. Our primary models included Phi-3.5-mini, Meta-Llama-3.1-8B, and Mistral-7B. All models were fine-tuned using Low-Rank Adaptation (LoRA) with a rank of 16, targeting key parameter matrices (q_proj, k_proj, v_proj, o_proj, gate_proj, up_proj, down_proj) with a LoRA alpha of 16. This parameter-efficient fine-tuning approach enabled us to adapt large models to our specific task while minimizing computational costs and mitigating the risk of catastrophic forgetting.

5 Results

The experimental results demonstrate the effectiveness of our approach across multiple languages and model architectures, consistently outperforming baseline systems.

5.1 Overall Performance

We evaluated multiple language models to identify the most effective architecture for narrative extraction, with Phi-3.5 emerging as the top-performing model. Table 1 provides a comparative analysis of different models across five languages, reporting F1 macro scores alongside baseline performance on the validation set.

Based on our findings, we highlight the following key observations:

- **Model Size vs. Performance**: The smaller Phi-3.5 model consistently outperformed the larger Llama-3.1-8B across most languages. This suggests that model architecture and fine-tuning strategies may play a more critical role than parameter count in optimizing performance for this task.

- **Language-Specific Performance**: Llama-3.1-8B demonstrated superior performance in Hindi, significantly surpassing Phi-3.5 (0.7375 vs. 0.6801). This discrepancy may stem from differences in pre-training corpora, indicating that certain models are inherently better suited for specific languages.

- **Baseline Comparison**: Our top-performing model, Phi-3.5, exceeded baseline performance across all languages, with the most notable gains observed in English (+8.05%) and Russian (+6.98%).

- **Mistral Performance**: The Mistral-7B model consistently underperformed relative to other models and even the baseline, particularly in Portuguese, where it achieved an F1 macro score of only 0.4252.

5.2 Final Submission Results

Our final submission to the SemEval 2025 Narrative Extraction task employed the Phi-3.5 model, incorporating our enhanced preprocessing pipeline and multi-temperature inference strategy. Table 2 presents the official evaluation results across all five languages, ranked by F1 macro score.

Our system consistently outperformed the baseline across all five languages, demonstrating strong performance in Portuguese and English. The lowest improvement was observed in Bulgarian (+4.96%), which nonetheless represented a significant advancement.

The model's robust performance across typologically diverse languages highlights the effectiveness of our approach. We attribute these improvements to several key factors:

- **Effective Preprocessing**: Our preprocessing pipeline which included duplicate sentence removal, text normalization across languages, and targeted evidence filtering ensured cleaner, more relevant inputs for model training and inference.

- **Multi-Temperature Inference**: By generating multiple candidate explanations with varying temperature settings and selecting the most relevant one based on narrative alignment, we achieved significant improvements over single-temperature inference strategies.

- **Model Selection**: Despite having fewer parameters than some alternative architectures, Phi-3.5 exhibited strong instruction-following capabilities and demonstrated superior performance when fine-tuned for narrative extraction.

These results validate our approach, illustrating that carefully designed preprocessing and inference strategies can yield significant performance gains, even when leveraging smaller language models.

Table 1: F1 macro scores for each model across different languages using the SFT approach. Bold values indicate the highest performance per language. The baseline results presented in this table correspond to those provided by the shared task organizers.

Language	Baseline	Microsoft PHI-3.5	Meta-Llama-3.1-8B	Mistral-7B	Improve (%)
Portuguese	0.6804	**0.7487**	0.6627	0.4252	10.04%
English	0.6671	**0.7477**	0.6924	0.5497	12.09%
Russian	0.6442	**0.7141**	0.6447	0.5095	10.84%
Hindi	0.6697	0.6801	**0.7374**	0.6731	10.11%
Bulgaria	0.6343	**0.6853**	0.6613	0.5010	8.04%

Table 2: Evaluation of the WordWiz system across five languages using the F1 macro score.

Language	F1 macro	Rank	Improve(%)
Portuguese	0.7486	1	+10.0%
English	0.7455	2	+11.8%
Russian	0.7040	2	+9.3%
Hindi	0.7336	2	+9.5%
Bulgarian	0.6839	2	+7.8%

Table 3: Comparison of Phi-3.5 SFT and DPO on the English Dataset

Model	Precision	Recall	F1 macro
Phi-3.5 SFT	0.7683	**0.7287**	**0.7477**
Phi-3.5 DPO	**0.7756**	0.6798	0.7243
Baseline	0.6554	0.6796	0.6672

5.3 Direct Preference Optimization

To further enhance our narrative extraction capabilities, we implemented DPO as an additional fine-tuning approach for the English language track. Compared to standard SFT, DPO provides a more sophisticated alignment technique by directly optimizing model outputs based on human preferences without requiring explicit reward modeling.

Our DPO implementation utilized the Phi-3.5 model, previously fine-tuned with SFT, as the reference model. To construct preference pairs, we designated human-annotated explanations from the training set as the chosen responses, while outputs from the non-fine-tuned model served as the rejected explanations. This approach enabled the model to distinguish high-quality narrative justifications from suboptimal ones.

As shown in Table 3, the DPO-tuned model exhibited higher precision (+0.73%) compared to SFT but at the expense of lower recall (-4.89%), resulting in a slightly lower F1 macro score. This experiment suggests that DPO encourages selectivity, prioritizing high-confidence explanations while potentially omitting some valid ones.

5.4 Qualitative Analysis

A qualitative assessment of the DPO-generated outputs reveals a tendency toward more nuanced, contextually aligned justifications. For instance, given article `EN_CC_200040.txt`, the DPO model produced:

> "The article critiques the climate movement, highlighting instances of vandalism and disruption by protesters. It questions the effectiveness of their methods and the public sentiment towards the climate change narrative."

In contrast, the SFT output was:

> "The text criticizes the climate movement for being disruptive and for targeting cultural heritage sites."

The DPO-generated response provides a more comprehensive and contextually enriched explanation, capturing both the criticism and its underlying rationale.

6 Conclusion

This paper presents the WordWiz team's solution for extracting narrative explanations from multilingual news articles. By combining advanced preprocessing techniques with two complementary fine-tuning strategies (SFT and DPO) our system demonstrates substantial improvements over the baseline model across all five competition languages.

The success of our approach underscores the effectiveness of targeted text preprocessing, which facilitates cleaner, more focused input for model training. Our structured prompting strategy effectively guided model generation toward task-relevant outputs. The multi-candidate generation with temperature-based sampling enabled the exploration of diverse response possibilities, while

the selection of candidates based on narrative relevance ensured that final explanations were well-aligned with the intended narrative characterization. Furthermore, our results suggest that, for specialized applications, model architecture and pre-training approach can be more critical than model size.

Future research could explore the extraction of evidence from news text to support narrative extraction. Incorporating more advanced evidence extraction techniques could further enhance the grounding of explanations in the source material. Extending our system's multilingual capabilities to encompass low-resource languages and investigating cross-lingual transfer learning may also expand the system's applicability to a broader range of global contexts.

Abstract

This paper describes our participation in SemEval 2025 Task 8, focused on Tabular Question Answering. We developed a zero-shot pipeline that leverages an Large Language Model to generate functional code capable of extracting the relevant information from tabular data based on an input question. Our approach consists of a modular pipeline where the main code generator module is supported by additional components that identify the most relevant columns and analyze their data types to improve extraction accuracy. In the event that the generated code fails, an iterative refinement process is triggered, incorporating the error feedback into a new generation prompt to enhance robustness. Our results show that zero-shot code generation is a valid approach for Tabular QA, achieving rank 33 of 53 in the test phase despite the lack of task-specific fine-tuning.

1 Introduction

Tabular Question Answering (Tabular QA) has huge potential in real-world applications such as financial analysis, business intelligence, and scientific data exploration, where structured databases serve as the primary source of information. Unlike traditional text-based Question Answering (QA), which primarily deals with unstructured data, Tabular QA requires extracting information from structured tables to be able to answer the input questions, thus involving reasoning about diverse table schemas, column relationships, and heterogeneous data types.

Complex supervised systems have been proposed to deal with the structured nature of Tabular QA, either leveraging structured prediction with language representations (Herzig et al., 2020; Yin et al., 2020) or by formulating the task as a sequence-to-sequence problem (Zhong et al., 2017; Yu et al., 2018; Pal et al., 2023). However, with the rise of instruction-based Large Language Models (LLM) (Brown et al., 2020), recent approaches have shifted away from reliance on large annotated datasets, instead reframing the task as a zero-shot generation problem (Cao et al., 2023).

In this work, we further explore instruction-based LLMs to dynamically generate code functions capable of retrieving relevant data from tables based on the input question in a zero-shot manner. To enhance accuracy and reliability, we developed a modular three-staged pipeline that includes: (i) a column selection mechanism to determine the most relevant columns and their data-type, (ii) a code generation module responsible for producing executable code and (iii) an iterative error handling module that, in case the initial code execution fails, tries to fix the generated code accordingly.

Our group tested this approach within the SemEval 2025 Task 8 event (Osés Grijalba et al., 2025), which provided a diverse dataset featuring real-world tabular data.[1] The competition required models to produce answers in multiple formats, including boolean, categorical, numerical, and list-based outputs. Our model was designed to generalize across different table structures, making it adaptable to various datasets beyond the shared task, ensuring robustness and broad applicability. Although our approach demonstrated strong performance in code generation and execution, subsequent analysis revealed that the model struggles with columns containing complex data types (lists, dictionaries, etc.) and ambiguous queries, particularly for list-based responses.

2 Background

Question Answering (QA) has been gaining significant attention in recent years, driven by the need for models capable of reasoning over structured data.

[1] Our implementation is fully available at https://github.com/adrian-gude/Tabular_QA (Feb. 2025).

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1282–1288

Early tasks in QA mainly focused on retrieving information from unstructured text sources (Rajpurkar et al., 2016; Yang et al., 2018), but the increasing availability of structured datasets has led to new challenges in understanding and querying tabular data. Unlike classic text-based QA, where answers are retrieved from free-form text, Tabular QA requires a higher level of interpretation and robustness to map questions to relevant columns and rows, handle missing values, and compute statistics when necessary.

In parallel, several datasets have been introduced to benchmark Tabular QA models, including WikiTableQuestions (Pasupat and Liang, 2015), SQA (Iyyer et al., 2017), and the more recent DataBench dataset (Osés Grijalba et al., 2024), which provides real-world tabular data for evaluating models in different scenarios.

Structured Tabular QA Most state-of-the-art approaches for Tabular QA leverage a pretrained language model —equipped with an specialized encoding module to represent tabular information— tailored for structured prediction. For example, TAPAS (Herzig et al., 2020) feeds both the input question and the flattened table into BERT (Devlin et al., 2019) as a single sequence, and finetunes the architecture to select relevant columns and predict an aggregation function. Similarly, TACUBE (Zhou et al., 2022) combines a cube constructor with BART (Lewis et al., 2020) to predict the real answers based on the input question and the results of the cube operations.

Generative Tabular QA To address the rigidity of structured approaches, recent works have explored generative models for program synthesis, where an LLM is finetuned to generate executable programs or instructions (in the form of SQL queries, for example) to be applied against tabular sources. Zhong et al. (2017) proposed SEQ2SQL, a sequence-to-sequence model to translate natural language into SQL syntax, incorporating query-space pruning to significantly simplify and enhance the generative task. Later, Yin et al. (2020) joined both concepts by optimizing tabular embeddings that fit both generative and structured purposes.

Zero-Shot Code Generation More recently, advancements in code generation have enabled a paradigm shift in Tabular QA, driven by powerful multipurpose LLMs with strong coding capabilities, such as Qwen (Bai et al., 2023) and Mistral's Codestral (Jiang et al., 2023). These models facilitate a zero-shot approach to program synthesis, eliminating the need for predefined templates or large annotated datasets. Instead, zero-shot generation allows the system to dynamically adapt to different schemes without explicit prior knowledge of the table structure (Cao et al., 2023), thus providing flexibility and scalability.

Despite its potential, zero-shot code generation models still face big challenges, particularly in error handling, runtime execution failures, and schema variability. Building on this approach, our work extends an instruction-based model with error awareness, enabling it to detect and recover from execution failures in an iterative error-recovery mechanism, where the model dynamically analyzes execution failures and regenerates code based on error feedback.

3 System Overview

Our approach for the SemEval 2025 Task 8 iterates upon the code generation approaches for Tabular QA, where the core component is a pretrained LLM responsible of generating executable code to extract the answer from the tables. To build upon prior works (Herzig et al., 2020), we incorporated a module that helps selecting the columns relevant to the question, while also identifying the data types of their content. Moreover, we incorporate an error-fixing module that attempts to catch runtime errors and integrates them as part of a new prompt, guiding the LLM to refine its code generation.

Figure 1 shows an schematic view of the architecture of our system. We have designed a modular pipeline that features three main components, which we describe below: (i) a column selector, (ii) an answer generator and (iii) a code fixer.

Column Selector Instead of relying on manually crafted heuristics or embedding similarity measures, the first component of our system leverages an instruction-based LLM tasked to identify the most relevant columns of a tabular source from an input question in natural language form. Our template provides the list of column names and instructs the model to return only those that are essential for answering the query.[2]

[2]All our prompts are available in the code publicly available at GitHub.

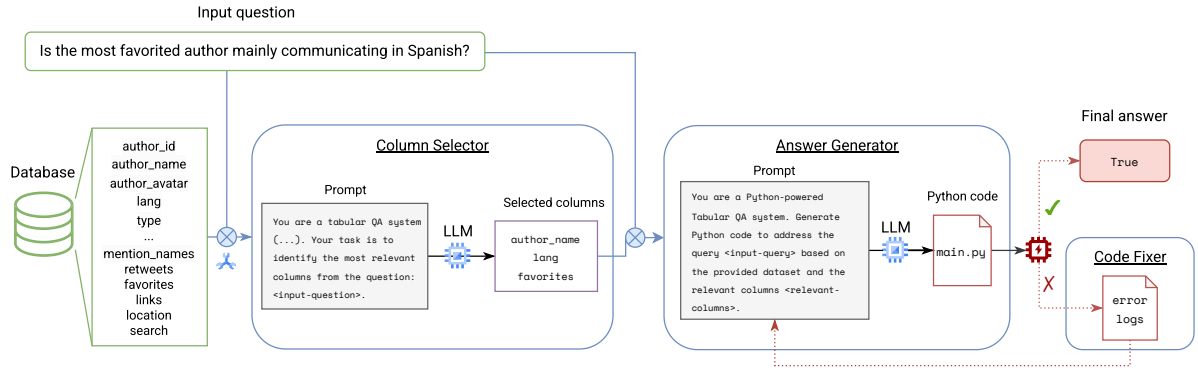

Figure 1: Architecture of our system. Different symbols are used to represent different elements of our pipeline: ⊗ merges information in a prompting-like form, represents a preprocessing step, indicates LLM inference (with optional post-processing steps), and runs Python code and catches error logs. Solid lines are used to indicate fixed pipeline steps while dotted lines indicate optional steps that are executed depending on partial results of the system. Green boxes represent elements provided in the task.

Answer Generator Once the relevant columns are identified, the second component of our pipeline is instructed to generate executable code that retrieves the answers from the tabular source using both the input query and the relevant columns extracted in the previous step. As part of our prompt, we guided the LLM to generate Python programming code and postprocessed the output to ensure that only Python lines were passed throught the next module. Python language was chosen since it is widely used in data analysis and has extensive support for tabular data processing through libraries such as Pandas.

Code Fixer The final component of our pipeline captures execution errors that might occur due to incorrect syntax, schema mismatches, or runtime exceptions. This module captures the error messages and re-generates a corrected function by feeding the error context back into the LLM. To achieve this, we used a structured prompt that includes the code that causes an error with the corresponding error description.

Preprocessing Since our system strongly relies on a well-formatted prompt, we manually designed a preprocessing step to ensure a consistent format to feed our system. We standardized column names for simplified versions (removing emoji and all non-alphanumerical characters except punctuation symbols) to prevent possible errors in the Answer Generator caused by mismatches between the table structure and the generated code. We identified enum-like column types, such as the case of categorical attributes with a finite amount of strings as a value (e.g. a "*Survey*" column that only contains "*Yes*", "*No*" or "*Maybe*"), and inferred a common scheme so to ensure consistency across different attributes, thus reducing errors related to unexpected variations in categorical values.

4 Experimental Setup

Our system relies on open-source LLMs for zero-shot code generation. This way, no explicit training nor finetuning was conducted. Instead, we used the available training phase datasets to validate different LLMs and select the best performing one for the final test phase.

Dataset The dataset provided for the task is divided into three sets: *training*, *development* (aka *dev*), and *test*. In our case, since we had opted for a zero-shot approach, the training set remained unused during the development phase, using only the dev set for our experiments. During this stage we tried different LLMs to compare their ability to generate the adequate Python code to answer the input questions. To do that, we analyzed the accuracy obtained with respect to the ground truth of the validation set, together with manual checks to assess the quality of the generated code.

Evaluation The official evaluation consists of two subtasks, where *Subtask 1* uses all available data sources to answer the input question, while *Subtask 2* operates on a limited database, sampling a maximum of 20 rows per table to perform queries.

System Setup We conducted experiments with different open-source LLMs adjusted to our hardware limitations, specifically pretrained for

instruction-based code generation: Qwen-2.5-Coder (Bai et al., 2023) (with 7B and 32B versions), Mistral-7B and Codestral-22B —the later two from Mistral (Jiang et al., 2023).

To run the generated code we relied on Python 3.10.12 with Pandas 2.2.3 as a requirement. Due to VRAM constraints, all models were executed with 4-bit quantization, using a greedy generation strategy with a temperature of 0.7.

5 Analysis of Results

In this section, we present the evaluation of our system on the task. We first report performance during the development phase (§5.1), where we experimented with different models on the validation dataset, followed by the final test phase (§5.2), where our system was evaluated on the test dataset through CodaBench submissions.[3]

5.1 Development Phase

As explained before, during the development phase we focused on selecting the best performing LLM just using the dev set; that is, dismissing the training set. At this first stage, our pipeline was conformed by only the Answer Generator module.

The results obtained for this original setup, presented in Table 1, show that larger models such as Qwen-2.5-Coder^{32B} significantly outperform smaller models, with accuracy gains of over 20 points compared to Qwen2.5-Coder^{7B}. Regardless of the selected model, our zero-shot approach consistently outperforms the baseline system (Osés Grijalba et al., 2025) in both subtasks. Evaluation metrics indicate higher scores for Subtask 2 than for Subtask 1, likely due to the smaller input size, which reduces the amount of information introduced in the prompt and minimizes potential ambiguities when execution the generated code. We also notice a performance drop when breaking down the accuracy by the datatype, where even the best LLM struggles when generating answers for categorical list-like attributes.

Ablation Study We relied on the results displayed in Table 1 to select the best performing LLM, which served as the foundation for integrating the additional modules that could further enhance performance (see Figure 1). Table 2 shows the results when varying the components of the pipeline while maintaining Qwen-2.5-Coder^{32B} as backbone. The AG (Answer Generator only) setup corresponds to the result displayed in Table 1, from which the extra components of our pipeline where compared to see if there was an actual improvement when introducing error-awareness and column preselection. The AG+CS (AG with Column Selector) setup shows a clear improvement of 3 and 2 points in each subtask with respect to the AG-only model, outlining the importance of first asking the LLM to filter the relevance of the input attributes. Lastly, when integrating the Code Fixer (CF) with an enhanced column selection (ECS) to feed richer information about feature variations to the prompt, our final system setup (AG+ECS+CF) maintains almost the same performance over Subtask 2 but improves 7 points in Subtask 1, proving that integrating error feedback to the model assists the LLM for better querying larger databases. Specifically, the largest performance boost is obtained in categorical list-like attributes, where the accuracy increases 10 points with respect to the AG+CS model.

5.2 Final Test Phase

The best performing configuration (AG+ECS+CF) was selected to participate in the competition. Our zero-shot approach reached 65 points of accuracy in Subtask 1 and 68 points in Subtask 2. So, we ranked in the 32th (Subtask 1) and 31th (Subtask 2) positions out of 49 participants in the *General* category, and 23th (Subtask 1) and 21th (Subtask 2) positions out of 35 participants in the *Open models* category.

Our results during the development phase (84 and 85 points for Subtasks 1 and 2, respectively) suffered a significant drop of 20 points (approx.) in accuracy with respect to the validation results, likely due to the greater complexity of datatypes presented in the test tables. For instance, the test set presents multiple columns with lists that are not enclosed by square brackets, or that have variable separators for their elements (commas or semicolons); and dictionaries with a variable amount of keys.[4] Tables 1 and 2 show a clear difference in terms of accuracy when considering more complex datatypes: boolean accuracy reaches more than 80 points, while list-like types do not surpass 75 points. This might indicate that the LLM is not able to infer these complex schemes on the test

set, producing errors that are propagated from the Column Selector module to the Answer Generator.

6 Conclusions and Future Work

In this work we propose a zero-shot approach for Tabular QA that demonstrated a strong performance for the SemEval 2025 Task 8, ranking among the best systems in the development phase, although suffering from a performance drop in the test phase. Still, our system shows that an instruction-based approach allows to dynamically adapt to different dataset schemes without requiring additional training or finetuning, surpassing the baseline model even with limited hardware resources available.

Future work will focus on further refining prompt templates, improving schema adaptation, optimizing execution efficiency or incorporating a voting system with different LLMs. Improving the detection of these complex datatypes is also critical, as they allow the model to answer questions on less structured tables —which constitute the majority of online data—, ultimately making the system more generalizable.

Hardware Setup

Our hardware resources are somewhat limited by today's standards. We had shared access to an Intel Core i9-10920X at 3.50 GHz with 258 GiB RAM and two integrated NVIDIA RTX 3090, so we opted to perform zero-shot instead of finetuning the LLMs.

A Prompts used

A.1 Answer Generator

```
Role and Context
You are a Python-powered Tabular Data Question-Answering
      System. Your core expertise lies in understanding
      tabular datasets and crafting Python scripts to
      generate precise solutions to user queries.

Task Description:
Generate Python code to address a query based on the
      provided dataset. The output must:

- Use the dataset and query as given, avoiding any external
      assumptions.
- Adhere to strict syntax rules for Python, ensuring the
      code runs flawlessly without external modifications.
- Retain the original column names of the dataset in your
      script.

Input Specification
    dataset: A Pandas DataFrame containing the data to be
          analyzed.
    question: A string outlining the specific query.

Output Specification
    Return only the Python code that solves the query in the
          function, excluding any introductory explanations
          or comments. The function must:
        Include all essential imports.
        Be concise and functional, ensuring the script can
              be executed without additional modifications.
        Use the dataset and return a result of type number,
              categorical value, boolean value, or a list of
              values.

Code Template
    Below is a reusable code structure for reference:
    Return only the code inside the function, without any
          outer indentation.
    Complete the function with your solution, ensuring the
          code is functional and concise.

import pandas as pd
def answer(df: pd.DataFrame) -> None:
    df.columns = {list(df.columns)} # Retain original column
          names
    # The columns used in the solution : {selected_columns}
    {columns_unique}
    # Your solution goes here
    ...
    >>>{row["question"]}
```

A.2 Column Selector

```
You are a tabular QA system specialized in understanding and
      analyzing datasets. Your task is to identify the most
      relevant columns from a given dataset that can answer a
      specific question.

You will be provided with a list of column names from the
      dataset.
Based on the question, analyze the provided column names and
      determine which ones are likely to contain the
      information required to answer the question. You only
      have to answer the question based on the provided
      column names in the formmating described below.

Input Format:
    column_names: A list of column names from the dataset.
          Each column name is enclosed in single quotes and
          separated by commas. The column names may contain
          spaces and special characters.
    question: A string containing the question to be
          answered.

Output Format:
    A list of the relevant column names. The output should
          be a subset of the provided column names. Maintain
          the names EXACTLY as provided, special characters
          and all, for example < or >. If no columns are
          relevant, return an empty list.
    Only the relevant column names should be returned in
          list format, without any additional information or
          formatting.

Example:
    column_names: ['Name', 'Age', 'Email', 'Purchase Date',
          'Product']
    question: 'Which product was purchased?'
    Output: ['Product']

Input:
    column_names: {column_names}
    question: {question}
```

A.3 Code Fixer

```
Role and Context
You are a Python-powered Tabular Data Question-Answering
      System. Your core expertise lies in understanding
      tabular datasets and crafting Python scripts to
      generate precise solutions to user queries.

Task Description:
Fix the Python code to address a query based on the provided
      dataset. The output must:

- Use the dataset and query as given, avoiding any external
      assumptions.
- Adhere to strict syntax rules for Python, ensuring the
      code runs flawlessly without external modifications.
- Retain the original column names of the dataset in your
      script.

Input Specification
    code: The Python code that needs to be fixed.
    error: The error message that results from running the
          code.

Output Specification
    Return only the Python code that solves the query in the
          function, excluding any introductory explanations
          or comments. The function must:
        Include all essential imports.
        Be concise and functional, ensuring the script can
              be executed without additional modifications.
        Use the dataset and return a result of type number,
              categorical value, boolean value, or a list of
              values.
Code:
    Below is the piece of code that needs to be fixed, along
          with the error message that results from running
          the code:
    {response}

Error: {error}
```

AILS-NTUA at SemEval-2025 Task 3: Leveraging Large Language Models and Translation Strategies for Multilingual Hallucination Detection

Abstract

Multilingual hallucination detection stands as an underexplored challenge, which the Mu-SHROOM shared task seeks to address. In this work, we propose an efficient, training-free LLM prompting strategy that enhances detection by translating multilingual text spans into English. Our approach achieves competitive rankings across multiple languages, securing two first positions in low-resource languages. The consistency of our results highlights the effectiveness of our translation strategy for hallucination detection, demonstrating its applicability regardless of the source language.

1 Introduction

Hallucinations in Large Language Models (LLMs) pose a significant challenge, as they can generate fluent yet factually incorrect or misleading content (Zhang et al., 2023; Huang et al., 2025). Several detection techniques have been developed, either by accessing the LLM's internals (Azaria and Mitchell, 2023; Sriramanan et al., 2024; Chen et al., 2024), probing generation inconsistencies (Manakul et al., 2023a; Mündler et al., 2023) or exploiting token-based classification (Quevedo et al., 2024).

While hallucination detection has been widely studied in monolingual contexts, multilingual settings are severely underexplored and accompanied by additional complexities. Variations in linguistic structure, resource availability, and training data distribution can lead to uneven model reliability across languages. Low-resource languages, in particular, are more susceptible to hallucinations due to limited high-quality training data, making factual consistency a critical issue. Recent works in multilingual hallucinations detection verify faithfulness shortcomings (Qiu et al., 2023a; Shen et al., 2024), shift the focus on data rather than model capacity (Guerreiro et al., 2023a) while also pinpointing evaluation concerns (Kang et al., 2024).

To this end, the Mu-SHROOM shared task is proposed in order to fill this gap by providing high-quality data on 14 languages, including low-resource languages such as Farsi, Czech, Finnish, Swedish and Basque. This effort is accompanied by annotations on hallucinated data spans within given sentences, which participants have to automatically detect.

In our work, we leverage LLM prompting and translation strategies to address hallucination detection without designing independent systems per language. Particularly, we combine two LLMs, Llama 3 (Grattafiori et al., 2024) and Claude (AI), prompting them in a few-shot manner to detect hallucinatory spans. Our language-adaptive system is proven efficient and successful in both high- and low-resource languages *without any training or fine-tuning*. As a result, we achieve first position in the low-resource Farsi and Czech languages, second position in the high-resource Italian language and among the top 15% positions in English, Spanish, German, Hindi and Basque.

2 Background

2.1 Task description

Mu-SHROOM (Vázquez et al., 2025) is a multilingual extension of SHROOM (Mickus et al., 2024) comprising 14 languages: Arabic (Modern standard)-*AR*, Basque-*EU*, Catalan-*CA*, Chinese (Mandarin)-*ZH*, Czech-*CS*, English-*EN*, Farsi-*FA*, Finnish-*FI*, French-*FR*, German-*DE*, Hindi-*HI*, Italian-*IT*, Spanish-*ES*, and Swedish-*SV*. Participants are tasked to detect hallucinatory spans within generated text as accurately as possible, so that if the span was omitted the hallucination would be removed.

2.2 Related work

Multilingual NLP Hallucinations. While hallucination detection has been actively researched in

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1289–1305

monolingual contexts across various fields (Dhuliawala et al., 2023; Manakul et al., 2023b; Min et al., 2023; Fabbri et al., 2022; Maynez et al., 2020; Scialom et al., 2021), its multi-lingual counterpart has primarily focused on identifying hallucinations in machine translation, where such hallucinations are defined as translations containing information completely unrelated to the input (Guerreiro et al., 2023b). Machine translation also has established benchmarks (Dale et al., 2023), as well as metrics (Kang et al., 2024), for evaluating model performance in cross-lingual generation and transfer. Multilingual hallucinations are also extensively studied in text summarization applications. In low-resource languages, summaries are often translated into high-resource languages, such as English, to utilize more reliable evaluation metrics (Qiu et al., 2023b). Mu-SHROOM (Vázquez et al., 2025), based on last year's SHROOM challenge (Mickus et al., 2024), is the inaugural benchmark for multilingual hallucination detection, addressing a significant gap in low-resource language research due to the absence of established benchmarks.

3 System Overview

We focus on LLM prompting and translation strategies to tackle hallucination detection challenges in a language-agnostic manner. Due to the prompt-heavy nature of our approach, no further training is required to attain high scores in either high- or low-resource languages. Specifically, we combine two LLMs, Llama 3.1 405B[1] and Claude 3.5 Sonnet[2], prompting them in a few-shot (FS) way to detect hallucination spans. To improve detection performance in low-resource languages, we also experiment with incorporating a translation tool to translate original input-output data to English. Finally, given the inputs of each MuSHROOM instance, we instruct Llama and Claude to generate the corresponding output and incorporate it as a *hypothesis* to facilitate hallucination detection.

Based on the results of our preliminary experiments presented in App.C, our final system consists of three components, i.e. three experiments:

Component 1 We prompt Claude to detect hallucination spans given the input text, the output text in the original language and their translations in English, as well as the outputs produced by Llama as hypothesis.

[1]meta.llama3-1-405b-instruct-v1:0

[2]anthropic.claude-3-5-sonnet-20241022-v2:0

Component 2 We prompt Llama to detect hallucination spans given the input text, the output text in the original language and their translations in English, as well as the outputs produced by Claude as hypothesis.

Component 3 We prompt Llama to detect hallucination spans given the input text, the output text in the original language and their translations in English *without* providing extra generated answers as hypothesis. We adopt this approach since generated hypotheses can themselves contain hallucinations, resulting in misleading outcomes. Moreover, the LLMs sometimes place undue emphasis on the provided generated hypothesis rather than relying on their internal knowledge, causing them to miss hallucinatory spans in the outputs.

Each component produces a list of hallucination spans and then the three lists are combined as follows: for each produced span, the assigned probability is calculated as the ratio of the experiments that characterize it as hallucination over the total number of experiments (three).

4 Methods

Hallucination categorization To initiate the hallucination detection process, we begin by defining what constitutes a hallucination. This initial categorization allows us to effectively handle data from various tasks and domains. Drawing on Huang et al. (2025) and our exploratory analysis of both the task's sample and validation data, we identify four distinct types of hallucinations:

(1) **Input-Output inconsistency**: The produced output is inconsistent with the input, i.e. it does not satisfy the input query or is irrelevant to it.

(2) **Factual inconsistency**: The output contains information that is factually inconsistent in a sense that it cannot be associated with verifiable real-world facts.

(3) **Internal output inconsistency**: The output contains contradictory facts, i.e.c—c- in the generated text span there is inconsistent information.

(4) **Misspellings**: The output contains misspelled words.

Output Format After defining hallucinations, we specify the expected output format to effectively process LLM outputs. For that purpose we attempt two approaches: In our first approach, in order to make the procedure simpler, we split the output text in parts and prompt the LLMs given the input, the output and a specific part of the output to

decide whether that specific part contains a hallucination. This technique is not successful as shown in Tables 1, 2 in the preliminary column. In the second approach, which we ultimately adopt, we prompt the LLM with both the input and output to detect hallucination spans while also encouraging chain-of-thought (CoT) reasoning.

Prompting strategies After initializing the process of hallucination detection by providing the hallucination definition and the expected output format, we experiment in both a **zero-shot (ZS)** and a **few-shot(FS)** way. In the FS scenario we present an example for each aforementioned category, together with the expected output format. For the main process, we adopt the system/user prompt. After consolidating the system prompts, we experiment with the user prompts and specifically the data given as input to the LLMs. For the simplest approach, we just provide the input-output pair to the LLM. Then, we attempt to enhance performance by also demonstrating the *translations* of inputs and outputs. To deploy our final system, as explained above, we also supply a *hypothesis* generated by the LLMs. To show how each of the steps of the procedure we propose improves the final results we present the following experiments:

1. Standalone prompting We prompt Claude or Llama at a time in either a ZS or a FS manner without translating in English or leveraging hypotheses.

2. Prompting + Translation We prompt Llama and Claude to detect hallucination spans using the input and output texts in the original language, as well as their English translations, without providing additional generated hypotheses; then, we combine the two lists of produced hallucination spans.

3. Prompting + Translation + Hypothesis We prompt Claude to detect hallucination spans using the input and output text in the original language, their English translations, and the outputs produced by Llama as hypotheses. Conversely, we prompt Llama with the same inputs but use Claude's outputs as hypotheses. Additionally, we incorporate the results from Llama's previous experiment, combining the three produced hallucination span lists.

Translation Given the disparity in linguistic resources across different languages and our objective of developing a system that performs robustly across multilingual settings, we investigate various strategies to address this challenge. Specifically, we examine the following key questions in the context of multilingual hallucination detection: *"Is it more effective to provide both the input and output in their original languages and allow the LLM to detect hallucinations, or should we instead supply their English translations?"* Furthermore, *"If input-output pairs are provided in their original language, should the prompt also be in the same language, or is it preferable to present it in English?"*. Conversely, *"If we supplement the detection process with translated input-output pairs, is it more effective for the LLM itself to handle the translation before the detection step, or should an external translation system be employed?"*

To explore these questions, we conduct the following experiments. Firstly, we experimented with the impact of the language of the prompt given the input-output pairs in their original languages. In this direction, the following ***Original Input-Output Pairs*** experiments are conducted.

No translator The simplest approach is to provide the definition of hallucination, along with the examples per category and instructions for the output format in English, and then present the input-output pairs in their original language.

External translator - original language Given the input-output pairs in their original language, we translate the prompts—which include the hallucination definition and output format instructions—into the original language. To achieve this, we use the Google Translate API for Python[3].

For the second part of our experiments, we translate the input-output pairs into English, the highest-resource language, and then use the translated pairs to detect hallucinations, while the prompt remains in English. The LLM is exposed to both the original language (before translation), as well as with its English version to ensure fairness. The experiments we conduct belong to the ***Translated Input-Output Pairs*** category.

External translator - English We translate the input-output pairs into English using Google Translate and then prompt the LLMs (providing *both* the original and English versions of data) to generate a CoT for hallucination detection in English.

LLM as the translator We prompt the LLMs to perform the analysis in two steps: Firstly to translate input-output pairs into English when the text is in another language, and then based on that to detect hallucinations in the same chat, thus ensuring that the LLM is exposed in both languages before concluding to the hallucination spans identified.

Table 2: Prompting scenario comparison – Correlation. The three baselines are: neural/ mark-all/ mark-none.The best-performing method per language is in **bold**. This Table considers the best translation strategy.

5 Experimental setup

Dataset For the results presented, the test set provided by the task organizers is used. The test set is presented in detail in Appendix A.

Baselines presented by the organizers comprise a neural-based model, and the edge cases of mark-all and a mark-none.

Evaluation comprises two character-level metrics: first, Intersection-over-Union **(IoU)** of characters marked as hallucinations in the gold reference vs. characters predicted as such; second, the **correlation** between the hallucination probabilities occurring from the detection system and the gold reference probabilities provided by the annotators.

Computational resources All our experiments are executed in Amazon Bedrock using Google Colab platform for the API calls.

6 Results

The results of our experiments are shown in detail in Tables 1, 2 for prompting experiments (IoU and correlation metrics respectively) and in Table 3 regarding translation experiments. In the prompting experiments, the FS approach for both hallucination definition and expected output format significantly improves the results: The detected hallucination spans are more accurate and the output format is strictly followed, which is fundamental in order to automatically handle the answers and extract the feedback provided by the LLMs. Furthermore, incorporating the English translation of the texts appears to enhance the LLM's performance. A similar effect is observed when integrating the hypothesis from the other LLM. In this case, the LLM is able to compare the hypothesis with the actual output provided to determine more effectively the presence of hallucinations and identify their respective spans. Notably, these patterns remain consistent across all languages, *regardless of whether they are low-resource or high-resource*. However, the addition of translations and hypotheses has *a more pronounced impact on low-resource* languages compared to high-resource ones. Regarding the translation experiments, interesting insights emerge. On one hand, in the simplest approach—where prompts are given in English while pairs remain in their original language—the English language score is not the highest. This suggests that translation aids in hallucination detec-

Table 4: Qualitative results in various languages. The detected hallucination span is highlighted.

tion and partially addresses the challenges of low-resource languages. However, the reverse process, translating into the language of the pairs, does not appear to offer the same benefits. Additionally, the use of the Google Translator is more effective compared to the end-to-end system where the LLMs are prompted to translate the input and output texts themselves. Thus, the most effective approach for identifying multilingual hallucinations is to provide *both the prompt and the input-output pairs in English*, using an *external translation system* rather than incorporating translation as a step within the LLM pipeline. This finding holds consistently across all languages in the dataset.

The results tables also show that for high-resource languages such as Spanish, Chinese, and German, the FS scenario and the incorporation of the generated hypothesis contribute the most towards performance improvements. In contrast, *for low-resource languages, translation is a crucial component* in achieving similar results. The prompts are detailed in App. D.

As a demonstration of our system, in Table 4 we present some qualitative results from our system which achieve a perfect score of IoU=1.

7 Conclusion

In this work, we detect multilingual hallucination spans in the outputs from the SemEval 2025-Task 3 MuSHROOM dataset using LLM prompting and translation techniques. We showcase the merits of converting all data in English, especially for low-resource languages, achieving highly-ranked results in a language-agnostic manner overall.

A Exploratory data analysis

1.1 Sample set

In the preliminary phase of the competition, a small sample set is released to allow participants to acclimate to the task. The sample set consists of a total of 8 samples in 3 different languages (3 samples in English, 3 samples in Spanish and 2 samples in French). The features of each samples are:

- 'id': a unique number of the sample.
- 'lang': the id of the language of the participating text.
- 'model_input': the input prompt given to the model.
- 'model_output_text: the output text the model generated.
- 'model_id ': the id of the model that produced the output.
- 'soft_labels': spans that include a start and end character number, together with an assigned probability to the span constrained by these two characters.
- 'hard_labels': spans for which the assigned soft label probability is more than 0.5.

Models producing hallucinations to be detected are the following: The different models used are:

- Model id: TheBloke/Mistral-7B-Instruct-v0.2-GGUF (4 annotated samples).

- Model id:meta-llama/Meta-Llama-3-8B-Instruct (1 annotated sample).
- Model id:Iker/Llama-3-Instruct-Neurona-8b-v2 (3 annotated samples).

Since we propose a model-agnostic approach, information regarding the model from which hallucination occurs is overlooked in practice.

1.2 Validation set

The validation set consists of 10 subsets of 50 samples each, separated by language, comprising 500 samples in total. The different languages are: arabic, german, english, spanish, finnish, french, hindi, italian, swedish and chinese. The features of the samples were the same as the ones of the sample set in version 1, with the extension of:

- model_output_tokens: the tokens of the output of the model
- model_output_logits: the logits of the output of the model

in version 2 that was released after the evaluation phase.

Since the data were of different tasks and domains, the exploratory analysis contained an effort to categorize the hallucinations found in the data.

Based on the definition of hallucinations and overgeneration mistakes, we distinguish the following types of hallucinations:

A hallucination is the production of fluent but incorrect output of an LLM. The definition of incorrect output falls in four categories:

1. The *output is inconsistent with the input*, so the produced answer does not answer the input query or is irrelevant to it.

2. The *output contains a factual inconsistency*, so contains something that is not a validated fact or is wrong.

3. The *output contains contradictory facts*, so in the output there are things that cannot be true at the same time.

4. The *output contains misspelled words*.

Based on these categories, in an attempt to understand better the annotation procedure, we conducted manually a categorization of the hallucinations marked in the outputs:

- Input-Output Inconsistency: 10
- Factual Inconsistency: 31
- Output conflicts: 6
- Misspelled words: 8

1.3 Test set

The number of annotated samples per language in the test set are presented in Figure 1. Most languages contain around 150 samples, with the exception of Basque (EU), Farsi (FA), Catalan (CA) and Czech (CS) that contain around 100 samples each.

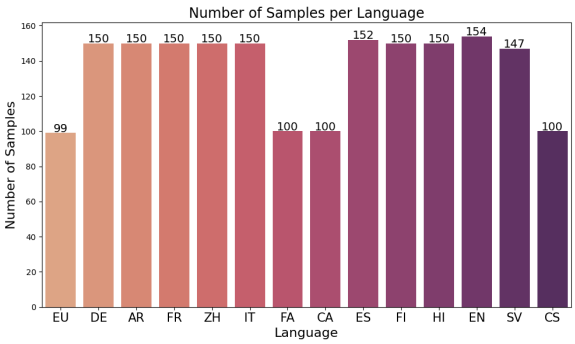

Figure 1: Number of annotated test data samples per language.

Input & Output sentence length In the following Figures, we present the length distribution regarding the input and output sentences per language on the test set.

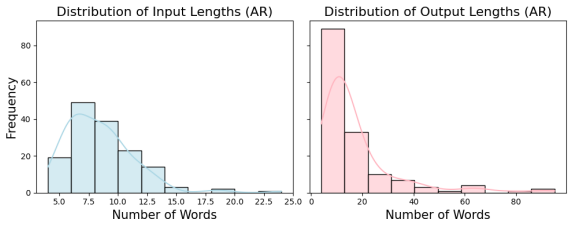

Figure 2: Input/Output length distribution for Arabic.

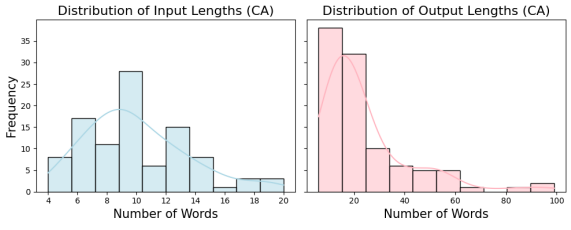

Figure 3: Input/Output length distribution for Catalan.

C Preliminary experiments

In order to deploy our LLM-based system, we conduct some exploratory experiments with Llama and Claude. For that purpose we initially employ the labeled test set from the SHROOM-shared task of 2024 (Mickus et al., 2024), due to its larger

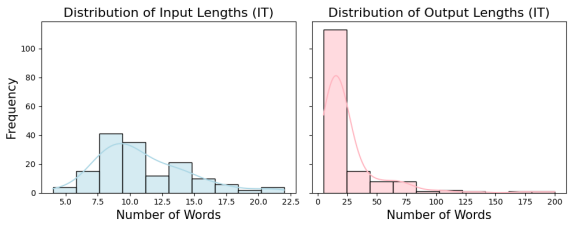

Figure 13: Input/Output length distribution for Italian.

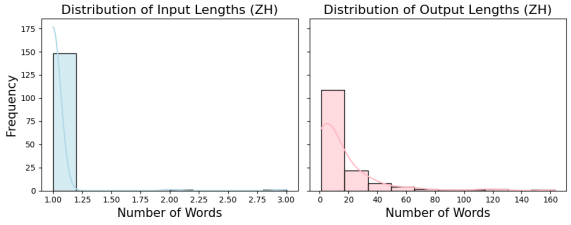

Figure 14: Input/Output length distribution for Chinese.

amount of labeled examples. This dataset contains instances with the following features: *Source - src* is the input given to a model, *hypothesis - hyp* is the output generated by the model, *target - tgt* comprises the ground truth output for this specific model, *reference - ref* indicates whether target, source or both of these fields contain the semantic information necessary to establish whether a datapoint is a hallucination, *task* refers to the task being solved and *model* to the model being used (in the model-agnostic case the model entry remains empty).

In this task, the participants were asked to classify the output of the LLM as hallucination or not based on the meaning of the target output that the LLM should have produced. Each instance also contains the tag *Hallucination/Not Hallucination* and a *probability* expressing the ratio of the annotators that marked the output as Hallucination over all the annotator that participated.

In order to explore the capabilities of Llama and Claude in hallucination detection, we manipulate the SHROOM-2024 dataset by bringing it to the format of this year's dataset. To perform that we create the feature 'model input' by combining the source and the task feature that has three distinct values (MT - Machine Translation, PG - Paraphrase Generation, D - Definition Modeling) as described in the Table 6.

Preliminary experiments involve probing the hallucination detection capabilities of Llama and Claude models. More specifically we conduct the following four experiments:

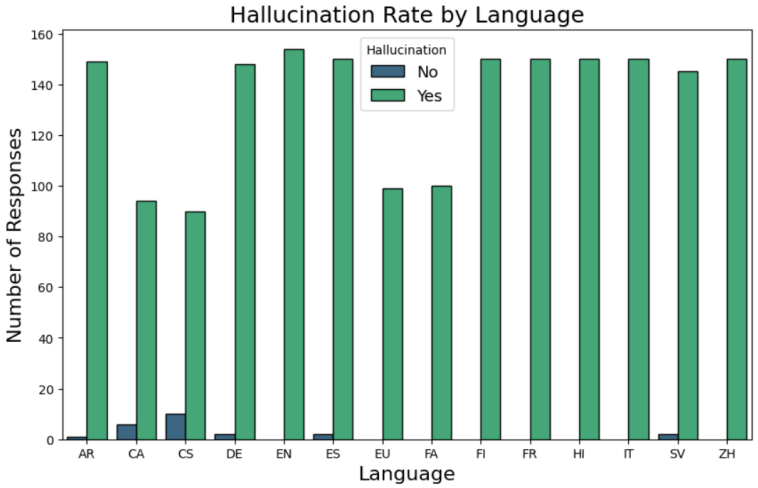

Figure 15: Hallucination rate per language according to 'soft label' annotations.

Task	Source	Model Input
Machine Translation (MT)	src	Translate the following sentence in English : {src}
Definition Modelling (DM)	src	{src}
Paraphrase Generation (PG)	src	Paraphrase the following sentence : {src}

Table 6: Combination of task identifier and source text to create model input feature

1. Zero-shot (ZS) We use a simple zero-shot prompt that questions in the form: *"Given the {input} and the {output}, is the output a hallucination? Reply with Yes/No"*.

2. ZS + Hypothesis To further boost this, we also leverage the *hypothesis* provided, transforming the prompt as: *"Given the input, the output and the hypothesis, is the output a hallucination? Reply with Yes/No"*.

3. CoT + Hypothesis Since the results' accuracy was close to randomly assigning a Hallucination/not Hallucination tag, instead of prompting the LLMs to simply respond with a binary Yes/No label, we prompt them to develop their thoughts; then, based on this and the hypothesis, we generate the final Yes/No label. The prompt used in this case is: *"Given the {input}, {output} and the {hypothesis} is the output a hallucination? Firstly, explain your thought and in the end write the word Yes or No if it is or it is not a hallucination respectively."*

4. Hypothesis generation and similarity Since the Mu-SHROOM dataset does not contain ground truth hypotheses, we prompt the LLMs to generate those by replying to the input query, so that we can assess the hypothesis similarity with the generated output using Natural Language Inference (NLI) models, similar to Grigoriadou et al. (2024). The results are presented in Table 7.

After these experiments, we manually observe the false negatives, and conclude the following:

1. Even though Claude performs better than Llama in general, there are cases where Llama is able to detect some hallucinations that Claude could not.

2. Even though providing a hypothesis improves the results, there are cases that the LLM (either of the two) focuses more on the hypothesis than its internal knowledge and therefore it fails to recognize a hallucinated part.

On the second part of the preliminary experiments, we tried combining different components in order to benefit from the extra information that the combinations provide and then choose the best strategy for the development of our final system. Those experiments were conducted with the validation set in order to gain some insight on the performance of the models with the multilingual texts and are the following:

1. No Hypothesis In the first experiment we prompt Claude and Llama to detect hallucination spans without providing a hypothesis.

2. Model + Hypothesis from the same model In the second experiment we prompt Claude and Llama to generate answers for the input texts, and then prompt them to detect hallucination spans on the output text given the answers each model produced, i.e. prompt Llama given as hypothesis the answers that Llama produced and Claude given as

Model	ZS	ZS + Hypothesis	CoT + Hypothesis	Hypothesis Generation
Llama	0.52	0.55	0.62	0.79
Claude	0.51	0.55	0.63	0.83

Table 7: Results of preliminary experiments: Columns ZS, ZS + Hypothesis, CoT + Hypothesis refer to the accuracy of the classification task (Hallucination/Not Hallucination) and the Hypothesis Generation refer to the similarity of the produced answers with the ground truth provided

hypothesis the answers that Claude produced.

3. Model + Hypothesis from the other Model In the third experiment we prompt Claude and Llama to generate answers for the input texts, and then prompt them to detect hallucination spans on the output text given the answers the other model produced, i.e. prompt Llama given as hypothesis the answers that Claude produced and Claude given as hypothesis the answers that Llama produced.

4. Combinations of two of the above For the fourth experiment we examine how the combinations of the results of two of the components above improve the performance.

To measure these results we used the evaluation metrics of the task (IoU and Cor) but we prioritized the IoU to choose the dominant components.

In Tables 8 , 9 we present the results for each experiment in english in detail and then we present the results for the top-3 strategies for every other language.

For the last experiment, we calculated the IoU of the predictions that occurred from the different experiments and we came to the conclusion that even though the IoU between predictions with and without hypothesis are lower than these of prediction with hypothesis from different sources, the combination of predictions with and without hypothesis reached better scores. After carefully inspecting the results, we found that reasonable because the lack of hypothesis led the LLM to emphasize on more parts that might contain hallucinations rather than the factual inconsistencies that were more often inspected when the hypothesis was provided. An example is provided for English in Table 11.

Language id	**Experiment, IoU**
ar	Claude, Llama Hypothesis: 0.53 Llama, Claude Hypothesis: 0.52 Claude, no Hypothesis: 0.49
de	Llama, Claude Hypothesis: 0.56 Claude, Llama Hypothesis: 0.55 Llama, no Hypothesis: 0.54
es	Llama, Claude Hypothesis: 0.42 Llama, no Hypothesis: 0.41 Claude, Llama Hypothesis: 0.49
fi	Llama, Claude Hypothesis: 0.61 Claude, Llama Hypothesis: 0.59 Llama, no Hypothesis: 0.56
fr	Claude, Claude Hypothesis: 0.58 Claude, Llama Hypothesis: 0.57 Claude, no Hypothesis: 0.56
hi	Llama, Claude Hypothesis: 0.57 Claude, Llama Hypothesis: 0.55 Llama, no Hypothesis: 0.52
it	Llama, Claude Hypothesis: 0.60 Claude, Llama Hypothesis: 0.59 Llama, Llama Hypothesis: 0.59
sv	Claude, Llama Hypothesis: 0.51 Llama, Claude Hypothesis: 0.47 Llama, Llama Hypothesis: 0.44
zh	Claude, Llama Hypothesis: 0.35 Claude, Claude Hypothesis: 0.33 Llama, Llama Hypothesis: 0.30

Table 10: Best Components for each language

Based on these findings showing how the LLMs benefit from the answers provided by the other LLM, we design the prompting experiments presented in the main paper (Section 3 - Prompting

Components	IoU1	IoU2	IoU3	IoU4
Claude, no Hypothesis + Claude, Llama Hypothesis	0.47	0.52	0.465	**0.53**
Claude, Llama Hypothesis + Claude, Claude Hypothesis	0.52	0.48	0.87	0.50

Table 11: For combinations of components, we calculate the IoU of each separate component with the reference values (IoU1, IoU2), the IoU between the predictions of different components (IoU3) and the IoU between the predictions of the combined components and the reference values (IoU4)

strategies).

D Prompts

The prompts to initialize the hallucination detection and the answer generation processes are presented in Tables 12, 13. The system and user prompts designed for our approaches are presented in Tables 14, 15.

Description	Prompt
	Zero-Shot Scenario
Hallucination Definition	You are a hallucination detector. A hallucination is the production of fluent but incorrect output of an LLM.The definition of incorrect output falls in four categories: a. The output is inconsistent with the input, so the produced answer does not answer the input query or is irrelevant to it., b. The output contains a factual inconsistency, so contains something that is not a validated fact or is wrong. c. The output contains contradictory facts so in the output there are things that cannot be true at the same time. d. The output contains mispelled words
Output Format Instruction	I will provide some examples for you to find hallucinations based on the given definition of hallucination. Although there might be several parts where hallucinations of probably different types occur, the answer should only end with the phrase 'So the hallucinations are: ' followed by the hallucinations exactly as they are written in the sentence given, inside "" and separated by commas
	Few-Shot Scenario
One example for each hallucination type	**Example 1(input-output conflict)**:The input is: Where did the Olympic Games of 2004 take place? The output is: The Olympic Games of 2020 took place in London.As a hallucination detector you should point out that there is a hallucination here because the output replies the answer where did the Olympic Games of 2020 take place. So the hallucinations are:"2020". **Example 2 (factual inconsistency)**:The input is: Where did the Olympic Games of 2004 take place? The output is: The Olympic Games of 2004 took place in Florida.As a hallucination detector you should point out that there is a hallucination here because the Olympic Games of 2004 took place in Athens, so there is a factual inconsistency in the word "Florida".So the hallucinations are: "Florida" **Example 3(internal output conflict)**:The input is: Where did the Olympic Games of 2004 take place and what was the biggest Stadium used? The output is: The Olympic Games of 2004 took place in Athens, Greece. All stadiums were designed for that purpose but the biggest was Olympic Stadium of Athens "Spyros Louis" that was built in 1982.As a hallucination detector you should point out that there is a hallucination here because the output states that all stadiums were created for that purpose but the Olympic Stadium of Athens "Spyros Louis" was built in 1982 so much earlier than the Olympic Games, So the hallucinations are: "All stadiums were designed for that purpose".

Table 12: Prompts used to initialize the hallucination detection or the answer generation process.

Description	Prompt
Few-Shot Scenario	
One example for each hallucination type	**Example 4(misspelling)**:The input is: Where did the Olympic Games of 2004 take place? The output is: The OLympooooc Games of 2004 took place in Athens, Greece. As a hallucination detector you should point out that there is a hallucination here because the OLympooooooc Games are a misspelling of the Olympic Games So the hallucinations are: "OLympooooc".
One example for the expected output format	**Example(output format)** The input is: What is the biggest church in Greece? The output is: The biggest church in Greece is Saint George located in the center of Athens. It has a maximum length of 73 m and width 48 m and it is the biggest church of Greece.The church is in the downtown of the modern city of Athens, close to the high-traffic Acharnon Avenue.The foundations of the church were laid on 12 September 1910 by King George I of Greece and it was consecrated on 10 JUly 1935. The expected output is: There are several hallucinations. The name of the biggest church is Saint Panteleimon of Acharnai and is indeed located in the center of Athens but has a maximum length of 63 m and was consecrated on 22 June 1930. So the hallucinations are: "saint George","73","10 JUly 1935".
Answer generation	
Answer Generation	I will provide a question and you will provide the answer

Table 13: Continuation of table 12. Prompts used to initialize the hallucination detection or the answer generation process.

Approach	System Prompt	User Prompt
Preliminary Test: input-output pair +specific part of the output to assign a Hallucination/not Hallucination tag	You are a hallucination detector. I will provide some input-output pairs and a specific part of the output and you have to decide whether the specific part is a hallucination as it was defined, based on your sources of knowledge. Write 'Hallucination' or 'Not Hallucination' if it is a hallucination or not respectively. The tag 'Hallucination' or 'Not Hallucination' should be the only words in your answer.	The input is:*input*, the output is : *output* and the part that might contain hallucination is: *part*
Input-output pair	You are a hallucination detector. I will provide some input-output pairs that represent inputs given to LLMs and the outputs they produced.Define the specific words or parts of the outputs that are hallucinations based on your sources of knowledge.Try to specify as much as possible the parts that are a hallucination even if it is just one word and put those parts in "".Inside "" include only parts in the exact way they are written in the given sentence.In your answer explain your thought and then provide the parts seperated with commas in the end of your answer after the sentence 'So the hallucinations are:.After this sentence include only parts of the output in the exact way they are written and nothing more	The input is:*input* and the output that might contain hallucination is: *output*
Input-output pair + Hypothesis	You are a hallucination detector. I will provide some input-output pairs that represent inputs given to LLMs and the outputs they produced and a hypothesis. Define the specific words or parts of the outputs that are hallucinations based on your sources of knowledge and the hypothesis.Try to specify as much as possible the parts that are a hallucination even if it is just one word and put those parts in "".Inside "" include only parts in the exact way they are written in the given sentence. In your answer explain your thought and then provide the parts seperated with commas in the end of your answer after the sentence "So the hallucinations are:" After this sentence include only parts of the output in the exact way they are written and nothing more	The input is:*input*, the output that might contain hallucination is: *output* and the hypothesis is *hypothesis*

Table 14: Prompts (system and user) regarding our various prompting and translation approaches.

Approach	System Prompt	User Prompt
Input-output pair + English Translations	You are a hallucination detector. I will provide some input-output pairs that represent inputs given to LLMs and the outputs they produced. The task is to define the specific words or parts of the outputs that are hallucinations based on your sources of knowledge. The given input-output pairs are in different languages.If they are not in english I will also provide a translation in English. The process you should follow includes some steps: 1. Examine the translation if provided or the original sentence if it is in english 2. Try to specify as much as possible the parts that are a hallucination even if it is just one word. 3. Explain your thoughts in English and then put the parts of the original sentence in the original language that correspond to the hallucinated parts you detected in English in "". Inside "" include only parts in the exact way they are written in the original sentence. So in your answer explain your thought in english and then provide the parts in the original language, separated with commas in the end of your answer after the sentence 'So the hallucinations are:. After this sentence include only parts of the output in the exact way they are written and nothing more.	The input is:*input* and the output that might contain hallucination is: *output*. The english translation of the input is *input translation* and the english translation of the output is *output translation*.
Input-output pair + English Translations + Hypothesis	You are a hallucination detector. I will provide some input-output pairs that represent inputs given to LLMs and the outputs they produced. The task is to define the specific words or parts of the outputs that are hallucinations based on your sources of knowledge and a provided hypothesis. The given input-output pairs are in different languages.If they are not in english I will also provide a translation in English. The process you should follow includes some steps: 1. Examine the translation if provided or the original sentence if it is in english. 2. Try to specify as much as possible the parts that are a hallucination even if it is just one word. 3. Explain your thought in english and then put the parts of the original sentence in the original language that correspond to the hallucinated parts you detected in english in "". Inside "" include only parts in the exact way they are written in the original sentence. So in your answer explain your thought in english and then provide the parts in the original language, seperated with commas in the end of your answer after the sentence 'So the hallucinations are:. After this sentence include only parts of the output in the exact way they are written and nothing more.	The input is:*input* and the output that might contain hallucination is: *output*. The english translation of the input is *input translation* and the english translation of the output is *output translation* and the hypothesis is *hypothesis*.
Input-output pairs + LLM Translation	You are a hallucination detector. I will provide some input-output pairs that represent inputs given to LLMs and the outputs they produced. The task is to define the specific words or parts of the outputs that are hallucinations based on your sources of knowledge. The given input-output pairs are in different languages. So the process you should follow includes some steps: 1. Translate the input and output in English 2. Try to specify as much as possible the parts that are a hallucination even if it is just one word 3. Explain your thought in english and then put the parts of the original sentence in the original language that correspond to the hallucinated parts you detected in english in "". Inside "" include only parts in the exact way they are written in the given sentence. So in your answer explain your thought in english and then provide the parts in the original language, separated with commas in the end of your answer after the sentence 'So the hallucinations are:'.After this sentence include only parts of the output in the exact way they are written and nothing more. If the given input-output pairs are in english do not do the translation step.'	The input is:*input* and the output that might contain hallucination is: *output*.

Abstract

We present our submission to SemEval 2025 Task 8: Question Answering on Tabular Data, which challenges participants to develop systems capable of answering natural language questions on real-world tabular datasets. Our approach aims at generating Pandas code that can be run on such datasets to produce the desired answer. The approach consists in fine-tuning a Small Language Model (SLM) through Preference Optimization on both positive and negative examples generated by a teacher model. A base SLM is first elicited to produce the code to compute the answer to a question through a Chain of Thought (CoT) prompt. We performed extensive testing on the DataBench development set, exploring a variety of prompts, eventually settling on a detailed instruction prompt, followed by two-shot examples. Due to hardware constraints, the base model was an SLM with $\leq$ 8 billion parameters. We then fine-tuned the model through Odds Ratio Preference Optimization (ORPO) using as training data the code produced by a teacher model on the DataBench training set. The teacher model was GPT-4o, whose code was labeled preferred, while the code generated by the base model was rejected. This increased the accuracy on the development set from 71% to 85%. Our method demonstrated robust performance in answering complex questions across diverse datasets, highlighting the effectiveness of combining small LLMs with supervised fine-tuning and automated code execution for tabular question answering.

1 Introduction

The ability of Large Language Models (LLMs) to process structured data and generate meaningful responses has become an increasingly important area of research. The SemEval 2025 Task 8: Question Answering on Tabular Data (Osés Grijalba et al., 2025) focuses on assessing the capacity of LLMs to perform question answering (QA) over tabular datasets using the newly developed DataBench benchmark (Osés Grijalba et al., 2024). Unlike traditional QA tasks that operate on unstructured text, this task requires models to interpret structured data, extract relevant information, and generate precise answers. The challenge lies in the complexity of real-world tabular datasets, which contain diverse column types, varying structures, and sometimes millions of rows. The DataBench benchmark was designed to evaluate LLM performance on this task, featuring 65 real-world datasets spanning multiple domains, with 1300 hand-crafted questions and answers.

Our approach to solving this problem relies on code generation rather than in-context learning. Instead of answering questions directly in natural language, our system generates executable Python code that extracts the relevant information from the dataset to compute the answer. The approach consists of fine-tuning a Small Language Model (SLM) through Reinforcement Learning on both positive and negative examples produced by a teacher model. A base SLM is first elicited to produce the Pandas code to compute the answer to a question through a Chain of Thought (CoT) (Wei et al., 2022) prompt consisting of a detailed instruction and two-shot examples (Brown et al., 2020), which helps guide the model through a step-by-step reasoning process. Due to hardware constraints, we had to resort to a small LLM ($\leq$ 8B parameters). We selected *deepseek-coder-6.7b-instruct* as our base model by comparing several models on the DataBench development set. The supervised fine-tuning (SFT) step uses data generated by a teacher model. In our case the teacher model GPT-o4 was used to generate code on the DataBench training set. We used the Odds Ratio Preference Optimization (ORPO) algorithm (Hong et al., 2024) , supplying to it the responses from our base SLM labeled rejected, while the GPT-4o generated responses labeled preferred.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1306–1312

To promote transparency and reproducibility, we released our code and fine-tuned model on GitHub: https://github.com/daniele-sartiano/semeval_2025_task_8. This resource includes our prompt templates, code execution script, and fine-tuning scripts enabling further research into improving LLMs for tabular question answering.

Our findings suggest that combining code generation with preference-based fine-tuning offers a promising direction for enhancing LLM capabilities on tabular QA tasks. Future work may explore hybrid approaches, integrating in-context learning with code generation to leverage the strengths of both methodologies.

2 System Overview

The system is designed to generate Python code using the Pandas[1] library to extract information from real-world datasets. We initially used the baseline[2] example provided by the task organizers and then extended the software by integrating prompt engineering, including Chain of Thought (CoT) reasoning and two-shot learning, model selection, supervised fine-tuning, and automated code execution to effectively solve the challenge task.

2.1 Prompt engineering

We designed a structured prompt incorporating Chain of Thought (CoT) instructions and two-shot learning to guide LLMs in generating accurate Python code for data extraction and analysis. The CoT approach encourages step-by-step reasoning in the generated code, improving the model's ability to handle complex queries. Two-shot learning provides the model with two examples of correctly generated code, which helps it infer the proper structure and logic when tackling new questions. Listing 1 shows an example, although the "list of columns" and the "head of the DataFrame in JSON format" of the two-shot examples are omitted for brevity.

2.2 Model Selection

We conducted empirical experiments to find the best model for code generation. We experimented with small models, with a maximum of 30 billion parameters, including general-purpose and code-specific models. The selection of models was guided by the top-ranked entries on Hugging Face's Big Code Models Leaderboard[3], allowing us to focus on state-of-the-art small language models (SLMs) relevant to our task. Table 1 lists some of the models evaluated.

We assessed their performance on the development set from the DataBench dataset, using similar prompts as described in Section 2.1. The model that achieved the highest accuracy was *deepseek-coder-6.7b-instruct*, which we selected as the baseline for our next experiments, without applying fine-tuning.

2.3 Supervised Fine-Tuning with ORPO

To enhance the performance of the baseline model, we applied supervised fine-tuning (SFT) using the Odds Ratio Preference Optimization (ORPO) algorithm. ORPO introduces a loss function that combines the standard negative log-likelihood (NLL) loss with a term based on the log odds ratio. This term effectively contrasts preferred (chosen) responses with less preferred (rejected) ones, guiding the model toward generating outputs that align more closely with human preferences. Unlike Proximal Policy Optimization (PPO) (Schulman et al., 2017), which requires a multi-stage pipeline involving reward modeling and reinforcement learning, ORPO simplifies the process by integrating preference optimization directly into the fine-tuning phase. Similarly, while Direct Preference Optimization (DPO) (Rafailov et al., 2023) aligns preferences with a reference model, ORPO completely eliminates the need for such a model. This streamlined approach reduces computational complexity while also enhancing both the quality and relevance of the generated responses.

Initially, we attempted to generate a fine-tuning dataset by pairing correct answers from the baseline model with incorrect answers, which were generated via a structured prompt. To generate incorrect responses, we exploited the prompt shown in Listing 2.

```
Your task is to generate code using pandas to answer a question on a table of data.
You will be provided with a list of table columns, a dataframe in json format and a question.
Choose the relevant information from the table columns and complete the code of function `answer`
    below.
Ensure using compatible types in aggregate comparisons.
Ensure to close expressions before applying further operators.
Use empty to check if there are columns that do not contain any elements.
The output must be concise and directly solve the problem.

Table columns: <list of columns>
Dataframe: <head of the dataframe in json format>
Question: Is the most favorited author mainly communicating in Spanish?
Function:
def answer(df: pd.DataFrame):
    return df[df['author_id'] == df.groupby('author_id')['favorites'].sum().idxmax()]['lang'].mode()
        [0] == 'es'

Table columns: <list of columns>
Dataframe: <head of the dataframe in json format>
Question: Is there a patent containing the word 'method in the title?
Function:
def answer(df: pd.DataFrame):
    return df['title'].str.lower().str.contains('method').any()

Table columns: {{df.columns.to_list()}}
Dataframe: {{df.head().to_json(orient='records')}}
Question: {{question}}
Function:
def answer(df: pd.DataFrame):
```

Listing 1: An example of the prompt where the "list of columns" and the "head of the DataFrame in JSON format" for the two-shot examples are omitted for brevity.

Model	**DataBench**	**DataBench lite**
Mistral-7B-Instruct-v0.3	0.496875	0.528125
Nxcode-CQ-7B-orpo	0.6	0.596875
CodeQwen1.5-7B-Chat	0.625	0.615625
Qwen2.5-Coder-32B-Instruct	0.68125 2	0.68125
OpenCodeInterpreter-DS-6.7B	0.625	0.59375
deepseek-coder-6.7b-instruct	**0.7125**	**0.703125**
DeepSeek-R1-Distill-Llama-8B	0.321875	0.371875

Table 1: Model selection using base SML (without fine tuning).

```
Modify the following Python instruction to
    return an incorrect value for the question:
    '{question}'.
Create an alternative version with the main
    instruction altered, so that it returns an
    incorrect value.
The error can be simple or non-trivial, but must
     remain in one line. Only use pandas and
    numpy.
Do not include any additional text or
    explanations. Write minimum 5 samples.
Respond with only the modified code in the
    following format:

<code>{instruction}</code>
```

Listing 2: The prompt used to create rejected samples.

However, this approach resulted in limited diversity and effectiveness of the fine-tuning dataset. Consequently, we adopted an alternative strategy that leverages GPT-4o (OpenAI, 2024) as a teacher to generate possibly better code as preferred examples. In this revised approach, responses from the baseline LLM were labeled as "rejected," while GPT-4o outputs were labeled as "chosen". This process led to the creation of a preference dataset consisting of 1,079 triples in JSON format: prompt, rejected, and chosen.

This preference-based fine-tuning significantly improved the model's ability to generate more accurate and contextually appropriate code. After fine-tuning, we observed a notable improvement in accuracy on the development set, demonstrat-

ing the effectiveness of ORPO in enhancing small LLMs for code generation tasks. Specifically, the fine-tuning process led to an approximate 6% improvement as detailed in the Experimental Setup Section 3.

2.4 Automated code Execution and Error Handling

Our script automatically extracts the Python function from the response generated by the LLM and executes it on the test dataset. The result of this function is our system's answer to the question. Whenever an error occurs during execution, the system catches the error and submits an extended prompt to the model that includes the wrong generated code and info about the error it caused. This iterative error-handling mechanism enables the model to correct its mistakes.

The overall workflow of the system, also shown in Figure 1, is as follows:

- **Input**: The system retrieves the question and loads the corresponding DataFrame.
- **Prompt**: The prompt is generated using the question and the head of the dataset.
- **LLM**: The SLM is invoked with the generated prompt, and the answer function is extracted from the response.
- **Execution**: The answer function is run on the DataFrame to obtain the answer.
- **Error Handling**: If the execution fails, the error is caught, and the LLM is prompted again, including the error details.
- **Output**: The final output is the answer to the initial question.

This approach enhances our system's ability to reduce errors and improve overall accuracy.

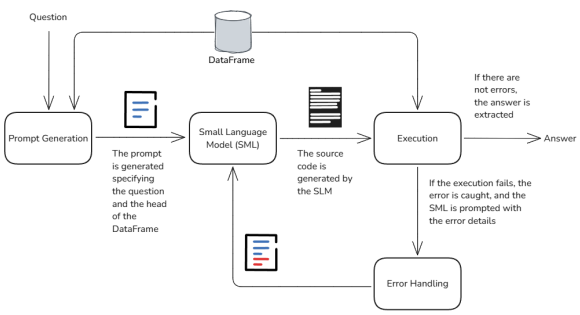

Figure 1: The overall workflow of the system.

3 Experimental Setup

We conducted our experiments on a machine equipped with a single NVIDIA A100 GPU with 80GB VRAM, only suitable to run Small Language Models. We used the Hugging Face Transformers library to interact with the models, retrieving all models from the HuggingFace Hub.

For evaluation, we used the *databench_eval*[4] library provided by the task organizers. The DataBench QA dataset, specifically the development split, which consists of 320 questions, was used in our experiments to validate and optimize our system, measuring the accuracy of several variants and refining the models iteratively.

To fine-tune the models, we used the train split of the DataBench QA dataset, which consists of 988 questions. This dataset was leveraged to generate a preference-based fine-tuning dataset by invoking the GPT-4o model via the OpenAI API. Using the prompt specified in Listing 2, we generated answers, executed the Python functions, and compared their outputs with the ground truth answers from the trainset.

To construct the fine-tuning dataset, we identified the correctly executed answers and paired them with responses generated by the base model selected for fine-tuning. The best performing model at that stage, *deepseek-coder-6.7b-instruct*, was chosen for this process (as shown in Table 1). This process resulted in a fine-tuning dataset containing 805 samples, formatted as JSON records with the structure shown in Listing 3.

```
{
  "prompt": "You are a pandas code generator...
      Question: What's the rank of the
      wealthiest non-self-made billionaire?\
      nFunction:\ndef answer(df: pd.DataFrame):\
      n"",
  "rejected": "import pandas as pd\nimport numpy
       as np\n\ndef answer(df): \treturn df[(df
      ['selfMade'] == False) & (df['finalWorth']
       >= 10**9)]['rank'].min()",
  "chosen": "def answer(df: pd.DataFrame):\n
      return df[df['selfMade'] == False].
      nlargest(1, 'finalWorth')['rank'].iloc[0]"
}
```

Listing 3: An example of one entry of the fine tuning dataset.

ORPO fine-tuning was performed using its implementation from the HuggingFace libraries TRL - Transformer Reinforcement Learning[5] and the

[4] https://github.com/jorses/databench_eval
[5] https://huggingface.co/docs/trl/index

PEFT Parameter-Efficient Fine-Tuning.[6] The hyperparameters used are those listed in the Table 2. We obtained the best results with a maximum of 1000 steps. We also experimented with higher step counts, such as 10,000 and 30,000, but the results on the development set were worse.

Hyperparameter	Value
Batch Size (per device)	2
Max Steps	1,000
Learning Rate	8e-5
Gradient Accumulation Steps	1
Evaluation Steps	500
Optimizer	RMSProp
Warmup Steps	150
LoRA Rank ($lora\_r$)	16
LoRA Alpha ($lora\_alpha$)	16
Max Prompt Length	320

Table 2: Hyperparameters Used in Fine-Tuning

The fine-tuning process, combined with the CoT two-shot prompt resulted in a significant performance improvement. Specifically, accuracy increased from 71.25% to 85.00% on the DataBench QA development dataset and from 70.31% to 80.31% on DataBench Lite QA development dataset. These improvements show the effectiveness of distillation through SFT with a teacher model and Preference Optimization. It was this configuration that we used in our best final submission.

4 Results

Our submission was evaluated by the SemEval 2025 Task 8 organizers using the official *databench_eval* Python script. The final test set originally contained 522 questions, but after identifying errors in the ground truth, corrections were made, and 5 ambiguous questions were removed. These questions were excluded from the final evaluation resulting in a final evaluation set of 517 questions.

In the General ranking, which includes both large and small LMs, as well as both proprietary and open-source models, our submission achieved 31st place in the DataBench QA subtask with an accuracy of 68.97% and 29th place in DataBench Lite QA subtask with an accuracy of 69.35%. This represents an improvement of approximately 43 percentage points over the baseline. In the separate ranking category for Small models ($\leq$ 8B parameters), we achieved second place in both subtasks as shown in Table 3 and in Table 4.

Ranking	Team Name	Score
1	ScottyPoseidon	76.63
2	**Dataground**	**68.97**
3	NexGenius	65.64
4	Tree-Search	64.56
5	Basharat Ali	43.10
-	Baseline	26.00

Table 3: Top 5 final ranking results for DataBench in the small category.

Ranking	Team Name	Score (Lite)
1	ScottyPoseidon	74.71
2	**Dataground**	**69.35**
3	NexGenius	66.22
4	Tree-Search	64.94
5	Basharat Ali	43.87
-	Baseline	27.00

Table 4: Top 5 final ranking results for DataBench Lite in the small category.

After the end of the challenge, we experimented also with a larger model, *deepseek-coder-33b-instruct*, and achieved an accuracy of 72.4% on the test set, using the same prompt as our submission but without SFT.

5 Conclusion

In this paper, we described our submission to SemEval-2025 Task 8: Question Answering on Tabular Data, using a code generation approach, rather than in-context learning with a LLM. We exploit and tune a SML to generate code that extracts the answers from structured datasets. By leveraging a small LLM ($\leq$8B parameters), prompt engineering, and supervised fine-tuning from a teacher model with the Odds Ratio Preference Optimization (ORPO) algorithm, we significantly improved on the baseline model accuracy.

Our experimental results show that:

- Fine-tuning from a large teacher model using ORPO alone improved accuracy by approximately 6%, highlighting the effectiveness of preference optimization.
- Prompt engineering played a crucial role, with structured two-shot learning and Chain of

[6] https://huggingface.co/docs/peft/index

Thought (CoT) reasoning yielding significant performance gains.

- Error handling mechanisms helped refine model outputs, reducing execution failures and increasing robustness.
- Compared to the challenge baseline, our model improved performance by over 43 percentage points on the official test set.

In the official evaluation, our system achieved second place in both tasks, in the category Small Models ($\leq$8B parameters), demonstrating the effectiveness of fine-tuning through preference optimization. Despite the hardware limitations that constrained our experiments, we were able to achieve competitive results. Our results confirm in particular the benefits of distilling the knowledge of a LLM into a smaller model, as reported for the reasoning capabilities of DeepSeek R1 in (DeepSeek-AI et al., 2025) We hope to be able to further explore the distillation technique using a LLM more specialized on coding than the one we could use.

Team Core Intelligence at SemEval-2025 Task 8: Multi-hop LLM Agent for Tabular Question Answering

Maryna Chernyshevich
Accuris
Marina.Chernyshevich@accuristech.com

Abstract

Tabular Question Answering (Tabular QA) is a challenging task requiring models to extract, interpret, and reason over structured data. While Large Language Models (LLMs) have demonstrated strong performance in natural language tasks, their ability to process and query tabular data remains inconsistent, particularly in multi-column reasoning and structured output generation. To address these challenges, we propose a multi-hop LLM agent that enhances Tabular QA by analyzing table structure, building step-by-step plan, generating code to extract relevant data, and verifying outputs. Our approach combines proprietary LLM (ChatGPT-3.5-turbo) for code generation and open source LLM (Llama-3.2-3B) for answer validation. We evaluate our method on the SemEval-2025 Task 8 and were ranked 6-th with 87.16% accuracy.

1 Introduction

Retrieval-Augmented Generation (RAG) is an efficient technique for incorporating enterprise knowledge into Large Language Models (LLMs), improving factual accuracy and reducing hallucinations – a persistent problem, when LLMs operate in unfamiliar domains. The RAG system retrieves relevant information from external knowledge bases and provides it as context for LLM for reasoning and answer generation. This approach has been widely adopted for handling unstructured textual data, where relevant documents are stored in vector databases and traditional search engines.

However, a significant portion of public and proprietary knowledge is stored in structured formats, such as Excel spreadsheets or databases. Semantic chunking, a well-established method for retrieval of unstructured information, is not suitable for tables, as structured data is inherently relational, meaning that cells, rows, and columns must be interpreted together to get meaningful insights. RAG systems today primarily focus on text-based retrieval and struggle with structured data integration due to several limitations:

1. Database tables can be too large to process directly. Real-world tables often contain millions of rows and hundreds of columns, which makes passing the whole table into LLM costly and inefficient. A traditional chunking approach (e.g., breaking text into meaningful text chunks of fixed size) does not work well for structured data, as different questions might require different subsets of rows and columns rather than a table fragment.

2. Tabular question answering often requires computation. Unlike text-based question answering, which involves retrieval of relevant information, tabular QA requires sorting, filtering, grouping, aggregations, and mathematical operations. A system working with structured data must be capable of query execution rather than just retrieval.

3. Data inconsistencies and schema mismatches complicate the answer extraction. Data stored in tables or databases often follow inconsistent schemas, contain abbreviations, missing values, diverse types of data such as numbers, strings, categories, timestamps, etc. A robust Tabular QA system must handle these inconsistencies automatically and ensure semantic consistency between queries and table structure.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1313–1317

To overcome these challenges, we propose a multi-step LLM agent designed to serve as a structured data reasoning component of an advanced multi-agent RAG system. Our approach combines four main stages: 1) table exploration to extract data schema and metadata; 2) execution planning to decompose complex question into simpler steps; 3) code generation and execution to extract, transform and summarize tabular data; 4) answer validation to verify the correctness and consistency of the answer.

Our multi-step agent framework enables efficient reasoning over large, structured knowledge sources, while minimizing hallucinations, code execution errors, and ensuring accurate answer generation. The solution was evaluated in the SemEval-2025 Task 8 Question Answering over Tabular Data (Grijalba et al., 2025), where it was ranked 6th with 87.16% accuracy on the test dataset, demonstrating the effectiveness of our structured retrieval and reasoning approach.

2 Task and Dataset Description

Tabular Question Answering (Tabular QA) task involves answering natural language questions based on structured tabular data. Given an input query Q and a table T with N rows and M named columns, the goal is to produce an accurate answer A.

The SemEval-2025 Task 8 organizers offer the DataBench dataset, a large benchmark for the task of question answering on structured or tabular data (Grijalba et al., 2024). This dataset consists of 1300 questions and each question is accompanied by a related tabular dataset. Overall, 65 datasets are presented from 5 different domains, such as business, health, social, sports and travel. The average number of rows in table is 50,300, while maximum is 713,107 rows per table. Average number of columns is 25 per table, and maximum is 123.

The questions are split into different categories depending on the type of expected answer:

Question Type	Example Question	Reasoning Type
Boolean (Yes/No)	*Are all transactions IDs unique?*	Lookup
Category Selection	*Which organization has the patent with the highest number of claims?*	Sorting & comparison
Numerical Value	*How many borrowers have more than 1 existing loan?*	Aggregation
List Output	*Which 5 states have the most number of job listings?*	Filtering & grouping

3 Related Work

Early approaches of Tabular QA relied on semantic parsing, where natural language questions were transformed into SQL-like commands (Zhong et al., 2017; Yu et al., 2018). These methods require extensive training on domain-specific schemas and struggle with generalization across unseen tables.

Recent advances in Large Language Models (LLMs) have enabled zero-shot Tabular QA by leveraging in-context learning (Brown et al., 2020), supervised LLM finetuning (Zha et al., 2023) and code generation (Cao et al., 2023). Models such as GPT-4 and Llama, and CodeLLama can dynamically generate SQL queries or code instructions to retrieve answers from structured data. However, these methods suffer from hallucinations, logical inconsistencies, and execution failures.

To address these limitations, researchers have explored multi-agent systems, where different LLMs specialize in code generation, execution verification, and logical consistency checks (Zhu et al., 2024, Zhou et al, 2024). Our work builds upon this trend and introduces a structured LLM agent, that dynamically plans, executes, and validates tabular queries, ensuring high reliability and accuracy.

4 System overview

We introduce a multi-hop LLM agentic system, that performs tabular QA by decomposing reasoning and execution into separate stages. In contrast to single-pass prompting approaches, which often struggle with multi-column queries, schema inconsistencies, and logical errors, our system follows an iterative process that includes table exploration, execution planning, code generation, and answer validation. The architecture

of the agent relies on LangGraph[1], a framework that organizes nodes execution as a directed acyclic graph (DAG), which ensures modularity, reusability, and observability.

Our system orchestrates multiple LLM-based agents, each having a distinct role and underlying implementation, including ChatGPT-3.5-turbo for Python code generation and Llama-3.2-3B-Instruct (fine-tuned) for answer validation and consistency checks. This multi-model collaboration improves both accuracy and efficiency and allows specialized models to handle tasks suited to their strengths. If answer consistency check fails, the system revisits previous reasoning steps, refines queries and execution plans dynamically.

4.1 Table exploration

The system begins processing questions and tables with analyzing the table structure and extracting metadata to establish an accurate understanding of the dataset before attempting to answer a query.
At this stage, the agent executes automatically generated Python code and identifies column names, data types, missing values, and summary statistics and other information.

This step ensures the agent has an accurate understanding of the dataset. For example, it can detect that a "height" column contains values in inches, while the question asks for values in centimeters. It also can recognize that "IBM" in the query refers to "International Business Machines Corp." in the table, preventing incorrect lookups.

The discovered information is stored in memory and passed to the subsequent stages. If the initial metadata extraction is incomplete or inaccurate, the system refines its analysis and re-executes exploration queries before proceeding (Fig 1).

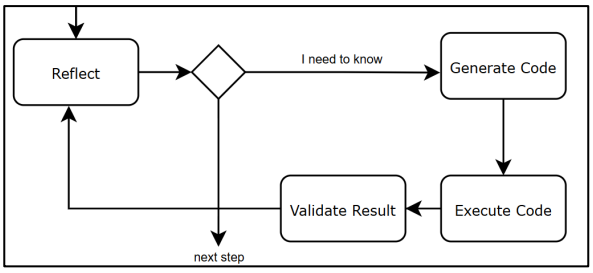

Figure 1: Table Exploration step flow

4.2 Execution planning

Once the table has been analyzed, the agent moves to execution planning, where the question is decomposed into structured subqueries described in natural language and a step-by-step plan is built. This prevents column misinterpretation and ensures proper sequencing of operations such as direct lookup, filtering, aggregation, and mathematical operation.

For example, given the question:

"What are the word counts of the 3 longest posts?"

The agent generates the following plan:

```
1. Create a new column 'word_count' in the
DataFrame by splitting the 'text' column by
spaces and counting the number of resulting
words for each post.
2. Sort the DataFrame by the length of the
'text' column in descending order to find
the longest posts.
3. Select the top 3 rows from the sorted
DataFrame, which correspond to the 3 longest
posts.
4. Extract the 'word_count' values from
these top 3 rows to get the word counts of
the 3 longest posts.
```

In another case, when asked:

"Which salary level has the least number of employees who had an accident at work?"

The agent produces:

```
1. Filter the table to keep only rows where
'Work Accident' is 'Yes'.
2. Group this filtered table by the 'salary'
column and count how many employees in each
salary level had an accident.,
3. Identify the salary level(s) with the
minimum count from this grouped result.
```

By explicitly identifying the retrieval strategy, the system avoids common errors such as extracting data from irrelevant columns or applying incorrect operations.

4.3 Code generation and execution

Based on the structured execution plan, the agent generates Python (pandas) code to extract the answer from the dataset. The code is executed in a controlled environment to prevent uncontrolled command execution. If an error occurs, such as a KeyError due to an incorrect column name or a TypeError caused by a mismatched data type, the system analyzes the failure and acts accordingly. To mitigate the consequences, each code execution

[1] https://www.langchain.com/langgraph

call is accompanied by a result validation step (Fig. 2), that takes one of the following:

1. If execution succeeds, the system forwards the answer to the validation step.
2. If a recoverable error occurs, it regenerates the Python code with corrections.
3. If the error persists, it replans the execution strategy, modifying the approach before generating new code.

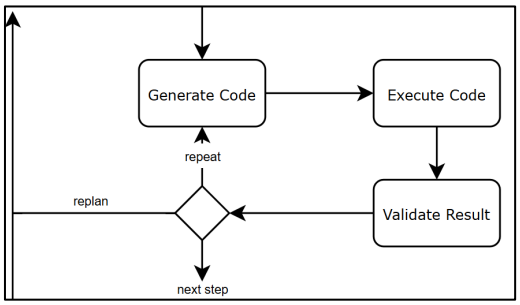

Figure 2: Code Generation & Execution diagram

This iterative code execution reduces overall failure rates and ensures robust handling of schema inconsistencies and dynamic table structures.
Figure 3 demonstrates the code generated according to a plan to answer the question: "What are the bottom 4 class types with the least combined total legs?"

```
def execute_plan(df):
    # 1. Group the df by 'class_type' and sum the 'legs' for each class type
    class_legs_sum = df.groupby('class_type')'legs'].sum().reset_index()
    # 2. Sort the resulting DataFrame by the sum of legs in ascending order
    sorted_class_legs = class_legs_sum.sort_values(by='legs')
    # 3. Select the bottom 4 class types with the least combined total legs
     bottom_4_classes = sorted_class_legs.head(4)
    # 4. Return the list of class types
    return bottom_4_classes['class_type'].tolist()
```

Figure 3: Generated code

4.4 Validation and refinement

Even when the code is executed without exceptions, the answer may still contain errors, for example due to incorrect column selection or semantic mismatch with the question. To address this, the extracted response is passed through a verification step, where a fine-tuned Llama-3.2-3B model acts as a supervising agent and checks answer's correctness.

The validation process includes the following checklist:

1. Do the involved table columns match the question?
2. Is the output type (boolean, numeric, categorical, list) consistent with the question?
3. Does the answer logically align with the original question?
4. Does the answer output contain the expected number of elements?

If the validation model detects an issue, it generates a short explanation describing why the answer is potentially incorrect. This feedback is sent back to the execution planning stage for refinement (Fig. 4). This feedback loop enhances accuracy by incorporating self-correction mechanisms.

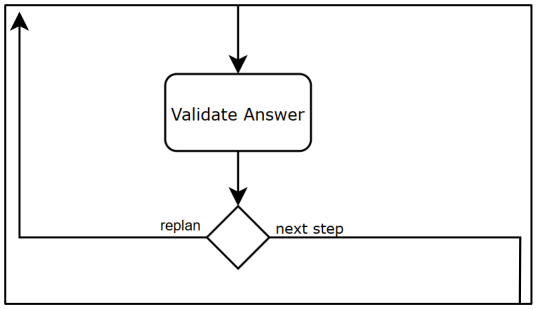

Figure 4: Answer validation diagram

For example, the validation model is generating based on the inputs: "What are the stock codes of the bottom 5 transactions with the lowest quantities ordered? If there is a tie go with numerical order." (question) and "[556690.0, 556691.0, NaN, NaN]" (answer) following validation message:

```
The answer contains several issues:
1.  'nan' values which are not valid stock
    codes
2.  The answer contains 4 elements, but the
    expected number of elements should be 5.
I suggest to replan the execution.
```

This step catches the incorrect table or question understanding and forces the agent to replan and generate a corrected answer.

To enhance instruction-following and validation capabilities, we leveraged the Low-Rank Adaptation (LoRA), originally introduced in (Hu et al., 2021), to fine-tune the Llama-3.2-3B instruction model on about 1,000 synthetic instructions, generated based on DataBench training question-answer pairs.

This validation step improved the overall quality of the agent, but also introduced a high false positive rate, flagging over 18% of correct answers as incorrect. This led to unnecessary recomputation

in some cases but also forced the agent to re-examine its reasoning.

4.5 Conclusion

We evaluated our system on the SemEval-2025 Task 8: Question-Answering over Tabular Data, where it was ranked 6th with 87.16% accuracy, demonstrating its effectiveness compared to other approaches.

Our experiments also proved that the structured agent-based approach significantly outperforms the single-pass LLM prompting approaches. Decomposition of the tabular question answering task into exploration, planning, execution, and validation steps allows handling very complex multi-column tables with millions of records, reducing hallucination and increasing reliability compared to traditional approaches.

While the proposed agent-based solution is showing its efficiency, it also, also highlights areas for further research and improvements, such as evaluating other open models such as Llama-70B or Qwen-72B in zero-shot as well as instruct-tuning settings to execute some of the agent functions. Our findings suggest that distributing reasoning tasks across multiple specialized models is a promising direction, as it allows for more cost-efficient computation while improving answer reliability.

The combination of code-based reasoning, automatic verification, and iterative refinement make a multi-hop LLM agent an effective way to get information from structured data.

MALTO at SemEval-2025 Task 3: Detecting Hallucinations in LLMs via Uncertainty Quantification and Larger Model Validation

Claudio Savelli and Alkis Koudounas and Flavio Giobergia
Politecnico di Torino, Italy
Turin, Italy
{firstname.lastname}@polito.it

Abstract

Large language models (LLMs) often produce *hallucinations* —factually incorrect statements that appear highly persuasive. These errors pose risks in fields like healthcare, law, and journalism. This paper presents our approach to the Mu-SHROOM shared task at SemEval 2025, which challenges researchers to detect hallucination spans in LLM outputs. We introduce a new method that combines probability-based analysis with Natural Language Inference to evaluate hallucinations at the word level. Our technique aims to better align with human judgments while working independently of the underlying model. Our experimental results demonstrate the effectiveness of this method compared to existing baselines.

1 Introduction

Large language models (LLMs) are widely used for various NLP tasks, such as information retrieval (Dai et al., 2024), medical queries (Singhal et al., 2025), and content generation (Coppolillo et al., 2024). Their ability to generate coherent and contextually relevant text has led to an increasing reliance on them as primary information sources, sometimes surpassing traditional methods like search engines, expert consultations, or structured databases (Dwivedi et al., 2023). This shift reflects the growing trust in LLMs for fast and accessible information.

However, a major challenge is their tendency to produce *hallucinations* — factually incorrect but highly persuasive outputs (Ji et al., 2023; Bertetto et al., 2024). These errors can take various forms, including false claims (D'Amico et al., 2023), fabricated references (La Quatra et al., 2021), and made-up biographies (Yuan et al., 2021), often presented in a way that makes them difficult to distinguish from accurate information. Since LLMs generate text based on patterns in their training data rather than direct verification of facts, they may confidently assert misinformation, leading to potential risks in sensitive domains such as healthcare (Bélisle-Pipon, 2024; La Quatra et al., 2025), law (Benedetto et al., 2024), and journalism (Spangher et al., 2024; Giobergia et al., 2024).

The problem is further amplified by the fact that hallucinations are often blended with accurate, truthful statements, making them harder to detect (Lewis et al., 2020; Borra et al., 2024). A model may produce a largely correct passage with only a few inaccurate details, increasing the likelihood that users will accept the entire output as trustworthy. Moreover, the possibility that models have to generate and deal with multiple languages (Huang et al., 2024; Savelli and Giobergia, 2024) can make evaluating these outputs even more complex. As LLMs become more advanced and widely deployed, addressing their tendency to hallucinate is critical to ensuring their reliability and safe integration into real-world applications.

To bring more attention to this issue, the **Mu**ltilingual **S**hared-task on **H**allucinations and **R**elated **O**bservable **O**vergeneration **M**istakes (*Mu-SHROOM*) has been introduced at SemEval 2025 (Vázquez et al., 2025). Mu-SHROOM invites researchers to detect hallucination spans in LLM outputs across multiple languages and models. The task specifically focuses on identifying which parts of a generated text contain hallucinations. Participants are provided with LLM outputs in different formats, including raw text, token lists, and logit values, and are tasked with predicting hallucination probabilities at the character level.

This work introduces a novel approach that operates at the word level to evaluate hallucinations[1]. By leveraging probability-based analysis and a Natural Language Inference (NLI) model, we compare each generated token to the most likely alternatives

[1]The code to replicate the experiments can be found at https://github.com/MAL-TO/Mu-SHROOM

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1318–1324

from a larger model, identifying potential hallucinations based on inconsistencies in predicted outputs. Our method aims to improve alignment with human annotations while remaining model-independent.

1.1 Mu-SHROOM

The objective of this task (Vázquez et al., 2025) is to identify spans of text within model-generated responses that represent hallucinations. Participants must determine which parts of a response produced by LLMs contain factual inaccuracies. The task is multilingual and multi-model, as it includes data from various languages[2] and outputs generated by different publicly available LLMs[3].

Dataset. The dataset consists of multiple fields that capture both the model-generated responses and the corresponding factuality annotations. Each data entry includes an *ID* for identification, a *language code* indicating the language of the query, and the *model input*, which represents the original question posed to the LLM. The *model output* contains the generated response, and the specific model that produced it is recorded under a *model ID*.

Two types of annotations are provided to assess the factual reliability of the model output: *soft labels* and *hard labels*. Soft labels represent a continuous evaluation of factual accuracy by assigning probability values to specific spans of text. These probabilities, ranging from 0 to 1, indicate the likelihood that a given segment is hallucinated. A lower probability suggests a higher likelihood of correctness, whereas a higher probability signals greater uncertainty or fabrication. Hard labels, on the other hand, offer a binary assessment of factual errors. They identify definitive hallucinations by marking specific spans of text that have been verified as incorrect. Each hard label is recorded as a pair of indices representing the start (inclusive) and end (exclusive) positions of the hallucinated text. For evaluation, hard labels are used to measure accuracy based on intersection-over-union (IoU), while soft labels are analyzed through Pearson correlation between system outputs and human ratings.

Each language has three different splits: an *unlabeled training set* containing raw samples without labels, a *labeled validation set* including soft and hard labels from the annotators, and the *test set* used for evaluation purposes. The three sets have 809, 50, and 154 samples, respectively.

[2]While the dataset covers 14 languages (Arabic (Modern standard), Basque, Catalan, Chinese (Mandarin), Czech, English, Farsi, Finnish, French, German, Hindi, Italian, Spanish, and Swedish), we only focus on English.

[3]For the English task, the models considered are: `TheBloke/Mistral-7B-Instruct-v0.2-GGUF`, `tiiuae/falcon-7b-instruct` (Almazrouei et al., 2023), and `togethercomputer/Pythia-Chat-Base-7B`.

2 Related Works

Fact-checking is a common approach to mitigate hallucinations in LLM outputs (Nakov et al., 2021; Guo et al., 2022). However, it typically depends on external knowledge sources such as databases, search engines, or pre-verified information repositories. These sources, while useful, are often incomplete, domain-specific, and require continuous updates to remain relevant (Cheng et al., 2024). Additionally, integrating them into real-time LLM applications introduces significant computational overhead, making the process inefficient and sometimes impractical at scale.

To overcome these limitations, this work proposes an alternative approach based on *uncertainty quantification* (UQ), which detects hallucinations directly from the model's own outputs without relying on external verification (Kotelevskii et al., 2022; Vazhentsev et al., 2022). Our methodology provides a way to assess how confident an LLM is in its generated text, offering a built-in mechanism for identifying potentially unreliable information.

Detecting hallucinations at the claim level is a challenging task (Fadeeva et al., 2024), as a single output may contain both accurate and inaccurate information, requiring finer-grained uncertainty measurement to highlight specific false or misleading claims. Our work addresses this challenge by expanding upon previous research in this direction (Fadeeva et al., 2024), which introduced a new token-level uncertainty score by aggregating token uncertainties into claim-level scores. We adapt their method for word-level detection and introduce a larger model to verify the smaller model's output, leveraging its broader knowledge. Additionally, we enhance the hallucination score by factoring in the uncertainty of both the NLI model and the LLM.

3 Methodology

To detect hallucinated content in a sentence generated by a model m, we compare it to a larger model M, which we assume has better general knowledge. The goal is to check if each word in m's output is consistent with what M would generate. Our method analyzes words individually, using

both probability scores and an NLI model[4].

Word probability from model M. For each word in m's output, we provide its preceding context to M. We then extract the most likely tokens from M's probability distribution until (i) their combined probability reaches a threshold k, or (ii) a single token has a probability lower than ρ[5]. Therefore, the number of selected tokens N varies depending on the word. Given the selected tokens, we determine the probability of the full word w by summing the probabilities of its tokens: $p(w) = \sum_{t_j \in w} p_j$, where t_j are the tokens forming w and p_j are their probabilities.

Checking semantic consistency with NLI. We assess whether each word aligns with the original sentence's meaning using an NLI model. Such model determines whether replacing one word with another changes the meaning of the sentence. If the sentence is too long, we truncate it around the word to fit the model's context window.

The NLI model assigns probabilities for three possible relationships: *Entailment* ($\mathrm{P}_+(w)$), i.e., the word fits naturally in the sentence; *Neutral* ($\mathrm{P}_=(w)$), i.e., the word has a different meaning but does not contradict the original sentence; *Contradiction* ($\mathrm{P}_-(w)$), i.e., the word changes the meaning of the sentence.

Computing the hallucination score. To measure hallucination at the word level, we start from the original approach proposed by Fadeeva et al. (2024). They compute the hallucination score (HS) at the claim level as follows:

$$HS = 1 - \frac{\sum p(c_i|e^+)}{\sum p(c_i|e^+) + \sum p(c_i|e^-)} \quad (1)$$

where $p(c_i|e^+)$ represents the probability of a claim having positive entailment, and $p(c_i|e^-)$ corresponds to the probability of a claim having negative entailment.

We extend their method by forcing it to operate at the word level and integrating NLI uncertainty:

$$HS = 1 - \frac{\sum_{i=1}^{N} (p_i(w) \cdot p_i^{nli}(w))}{\sum_{i=1}^{N} p_i(w)} \quad (2)$$

where $p_i(w)$ represents the probability assigned by the model to word w in position i, and $p^{nli}(w)$ is the sum of the probabilities for entailment and neutrality, defined as follows:

$$p^{nli}(w) = P_+(w) + P_=(w) \quad (3)$$

We incorporate neutral entailment alongside positive entailment, unlike (Fadeeva et al., 2024), as it empirically improved results on the validation set.

This formulation in Eq. 2 effectively captures the inverse relationship between word confidence and hallucination likelihood while accounting for semantic coherence through the NLI component.

The baseline methodology operates independently of human-annotated ratings, ensuring applicability in scenarios where labeled data is scarce or unavailable. However, to enhance alignment with human perception of hallucinations, we introduce a calibration mechanism through a multiplicative factor η:

$$HS^* = \eta \cdot HS \quad (4)$$

The parameter η serves as an alignment coefficient that is empirically determined using the validation dataset to maximize the correlation between our computed scores and the soft labels provided by human reviewers. This calibration process allows to fine-tune the sensitivity of the hallucination detection system to better match human judgment thresholds.

In our experimental framework, we systematically evaluate two distinct configurations: (1) a label-agnostic variant (`LAV`) where $\eta = 1$, which preserves the model's inherent hallucination detection capabilities without reliance on human feedback, and (2) a reviewer-aligned variant (`RAV`) where η is optimally selected based on validation data to maximize correlation with human annotations. The former configuration is particularly valuable in zero-shot deployment scenarios or when consistent detection criteria are required across diverse domains, while the latter configuration offers enhanced performance in applications where human perception of hallucinations is the primary evaluation metric.

4 Experimental Setup

This section outlines the various methods implemented, which will be evaluated in Section 5 using the metrics detailed below.

[4]We used `Qwen/QwQ-32B-Preview` (Yang et al., 2024) as M, and `cross-encoder/nli-deberta-v3-large` (He et al., 2020) for the NLI task.

[5]We set k to 0.9 and ρ to 0.005 in our experiments.

4.1 Methods

To evaluate the effectiveness of our proposed approach, we compare it against the baseline methods proposed by Vázquez et al. (2025).

Mark-None (-All). Trivial baselines where no (all) the words are considered as hallucinations. This serves as a lower bound for detection performance.

RoBERTA. We fine-tune a RoBERTA model (Liu et al., 2019) on the labeled validation set for all the 14 available languages to classify words as hallucinations or not. The model was trained for five epochs with a learning rate of 2e-5 and weight decay of 0.01.

Fadeeva et al. (2024) We adapt the scoring mechanism described in Eq.1 within our pipeline to evaluate hallucinations at the word level. This allows us to compare their formulation with ours, remaining consistent with the purpose of the challenge.

Ours. We evaluate our proposed hallucination detection method with two variants: (1) LAV, which applies our detection framework without any alignment to human annotations and uses only the test set, and (2) RAV, where we introduce the multiplicative factor η to adjust the hallucination scores based on the grading patterns of the human reviewers. For the latter, we use the value that maximizes the correlation with the soft labels, which is $\eta = 1.48$, as shown in Figure 1.

4.2 Evaluation Metrics

We employ two character-level evaluation metrics proposed by (Vázquez et al., 2025) to measure the performance of the different methods.

Intersection over Union (IoU) with Hard Labels to evaluate the overlap between the characters predicted as hallucinations and the hard labels.

Pearson Correlation with Soft Labels to measure how well the predicted probability of a character being part of a hallucination correlates with the empirical probabilities derived from annotator judgments.

5 Results

Table 1 compares the performance of different methods based on the two evaluation metrics described above.

As expected, the Mark-None method performs the worst. Its scores are close to zero for both metrics, showing that it fails to capture hallucinated content. On the other hand, the Mark-All method achieves a relatively high IoU. This is likely because large portions of the text in this task are hallucinated. However, its correlation score is very low ($\rho = 0.000$), meaning it does not align well with human judgments.

Method	η	ρ	IoU
Mark-None	-	.000	.032
Mark-All	-	.000	**.349**
RoBERTa	-	.119	.031
Fadeeva et al. (2024)	-	<u>.309</u>	.283
Ours-LAV	1	.300	.310
Ours-RAV	1.48	**.324**	<u>.311</u>

Table 1: Comparison of the different methods. Best results in **bold**, second-best <u>underlined</u>.

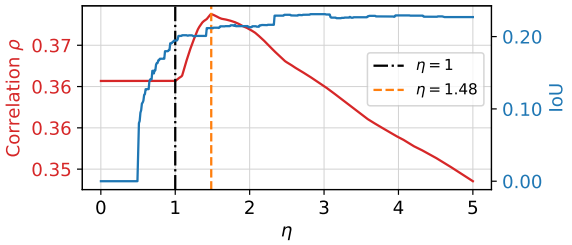

Figure 1: Analysis of ρ and IoU as η changes on the validation set. In this case, ρ is maximized for $\eta = 1.48$.

The RoBERTa-based model performs slightly better. It improves correlation ($\rho = 0.119$), meaning it captures some alignment with annotator probabilities. However, it has a low IoU, indicating that it struggles with precise localization.

Our proposed method significantly outperforms these baselines. We test it in two configurations described in Section 4. Both variants of our method achieve the highest overall performance as they provide the best balance between the two considered metrics. The label-agnostic model (LAV) reaches a correlation of $\rho = 0.300$ and an IoU of 0.310. This surpasses in IoU the scoring method proposed in (Fadeeva et al., 2024) and adapted to our scenario while maintaining a similar correlation. The reviewer-aligned version (RAV) further improves correlation ($\rho = 0.324$) while keeping a strong IoU (0.311). This result shows that our approach effectively identifies hallucinated content. When properly calibrated, it also aligns well with human judgments, thus providing a strong balance between accurate hallucination detection and agreement with human perception.

Impact of η. Figure 1 shows how IoU and correla-

tion change as η varies from 0 to 5. When $\eta = 1$, the method is label-agnostic. The highest Pearson correlation (0.324) occurs at $\eta = 1.48$ (yellow dotted line), indicating the best alignment with human soft labels. IoU remains stable across different η values, as expected. Even after applying the correction factor, hallucination failure detection (HS = 0) stays unchanged. These results confirm that tuning our hallucination scores using the validation set improves performance. The reviewer-aligned method ($\eta = 1.48$) better matches human perception of hallucinations while still performing well on the hard label detection task.

5.1 Limitation of the Proposed Method

Our method is effective at detecting hallucinations, but it has a key limitation. The model generates text step by step, using all previous tokens as context. If a hallucination appears early, it becomes part of this context. The model then builds on the false information, creating more text that fits the hallucination. This makes it difficult to spot later hallucinations that seem consistent with the first one. As a result, the model may correctly detect the initial false statement but fail to identify the ones that follow. This creates a propagation effect, where one mistake leads to more undetected errors.

For example, consider the following case from the test set:

Sentence: *What is the dry boiling point of DOT 5 brake fluid?*
`The dry boil point for DOT5 Brake Fluid is 212°F (100°C).`
Ground Truth: 212°F (100°C)
Our detection: 212°F

Here, our method correctly identifies the first hallucination (the temperature *"212°F"*) but fails to mark the Celsius conversion *"(100°C)"* as part of the hallucination. This occurs because once the model has incorporated the incorrect Fahrenheit value into its context, the corresponding Celsius conversion becomes consistent with this value despite both being wrong.

The example that follows further illustrates this limitation:

Sentence: *Which mountain range is Speichersdorf located near?*
`Speicersdorf is located in the Black Forest mountain region of Germany.`
Ground Truth: Black Forest
Our detection: Black

In this case, our method identifies only the first word of the hallucinated mountain region (*"Black"*) but misses *"Forest"*. Once the context includes the word *"Black"*, the word *"Forest"* becomes a natural and expected continuation, even though both words are factually incorrect.

This limitation shows the difficulty of detecting linked hallucinations when relying only on the model's confidence in a single word, especially if the context is already hallucinated.

6 Conclusion

This work addresses the Mu-SHROOM shared task at SemEval 2025, focusing on detecting word-level hallucinations in LLM outputs. We introduce a novel approach that uses a larger model validation without the need for external knowledge sources.

Our method achieves strong results compared to the proposed baselines, proving to be an excellent starting point for evaluating hallucinations when a ground truth or external sources are unavailable. One key limitation is handling multiple connected hallucinations. The model generates each word based on past text. If a hallucination appears, it becomes part of the context. The model may then continue building on this false information, making the hallucination harder to detect. This can lead to a chain of believable but incorrect statements. To address this, future work could use a broader context or develop mechanisms to review and correct past text when a hallucination is found.

Abstract

In recent years, the tendency of large language models to produce hallucinations has become an object of academic interest. Hallucinated or overgenerated outputs created by LLMs contain factual inaccuracies which can potentially invalidate textual coherence. The Mu-SHROOM shared task sets the goal of developing strategies for detecting hallucinated parts of LLM outputs in a multilingual context. We present an approach applicable across multiple languages, which incorporates the alignment of tokens and hard labels, as well as training a multi-lingual XLM-RoBERTa (Conneau, 2019) model. With this approach we managed to achieve 2nd in Chinese and top-10 positions in 7 other language tracks of the competition.

1 Introduction

In recent years, due to the development of transformer-based architectures (Vaswani, 2017), Natural Language Generation models saw immense advancements. However, the field is currently struggling with the tendency of neural systems to produce fluent, yet factually inaccurate outputs, aggravated by lack of adequate accuracy metrics. All of the above causes the models to "hallucinate".

The overgeneration of inaccurate facts puts in jeopardy the practical applications based on NLG (Mickus et al., 2024), which in turn prompts more interest in tackling the problem of detecting hallucinations in the outputs of NLG models.

The problems mentioned above were the motivation for the Mu-SHROOM shared task, aimed at identifying hallucinations and related overgeneration mistakes (Vázquez et al., 2025). The task builds upon ints previous iteration, but with focus on more languages and LLM outputs.

In this paper we present our approach to detecting hallucinated output using the multilingual XLM-RoBERTa model (Conneau et al., 2019). We use the model inputs and outputs from the provided dataset, which are concatenated and aligned with hard labels and then passed through the model. Apart from that, we also provide the description of the shared task and the datasets, as well as the discussion of results.

2 Related Work

In this section, we offer a short overview of methods used in previous work on detecting hallucinations in LLMs' outputs. We will examine model-agnostic and model-aware approaches, as well as black-box detection methods and prompting-based techniques.

Model-agnostic methods, such as prompt engineering and few-shot learning, focus on improving hallucination detection without relying on model internals. These techniques leverage strategies like meta-regression frameworks and automatic label generation, which allow them to be applied across different LLMs and tasks, offering a flexible solution to hallucination detection (Mehta et al., 2024; Chen et al., 2024; Allen et al., 2024; Arzt et al., 2024; Rykov et al., 2024).

On the other hand, model-aware approaches take advantage of internal signals from LLMs, such as layer activations and attention values, to detect hallucinations more precisely. By directly analyzing the model's internal workings, these methods can provide deeper insights into how LLMs generate outputs. Techniques like Retrieval-Augmented Generation (RAG) and chain-of-verification strategies have been explored to validate generated content against external knowledge sources, ensuring higher accuracy in detecting hallucinations (Liu et al., 2024; Varshney et al., 2023). However, these methods are generally less effective than model-agnostic approaches including (Mehta et al., 2024) and (Obiso et al., 2024) at SHROOM shared task. They are limited by their dependence on open ac-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1325–1331

cess to the model's internal architecture, which may not be possible for closed-source models like ChatGPT (Azaria and Mitchell, 2023).

Prompting-based metrics are also used in hallucination detection, leveraging the instruction following capabilities of LLMs. These methods involve providing LLMs with evaluation guidelines and both the generated and source content (Luo et al., 2023). Various strategies have been explored, including direct and chain-of-thought prompting, and in-context learning (Jain et al., 2023).

3 Task Description and Datasets

3.1 Task Description

The task presented by the organizers concerns the detection of hallucinated spans within a text. In contrast to the binary nature of SemEval-2024 Task 6, where whole texts were labeled as either containing or not containing hallucinations, this year's task concerns the dimension of detecting the position of hallucinations within the text.

This detection relies on two different types of labels, namely soft and hard labels, which are derived from a manual annotation process. Soft labels include all hypothesized spans along with their predicted probability of being an hallucination, whereas hard labels include only the spans that are decisively categorized as hallucination, as visualized in Table 1. In this example, only the last span in the soft labels is included in the hard labels due to achieving a probability higher than 0.5.

Participating teams are ranked based on their intersection-over-union (IoU) scores for hard labels while ties are broken using the Spearman correlation between predicted and true soft labels.

Model input	When was the Swedish Navy founded?

Soft labels	[{"start":1,"prob":0.0909090909,"end":18}, {"start":18,"prob":0.1818181818,"end":33}, {"start":33,"prob":1.0,"end":37}]
Hard labels	[[33,37]]

Table 1: An example of soft and hard labels.

3.2 Datasets

Task organizers supply participants with training, validation, and test datasets in multiple languages. Table 2 illustrates the number of samples for each language across the different dataset splits. Notably, the training set contains samples in English, French, Spanish, and Chinese while the validation set covers 6 additional languages. Basque, Catalan, Czech, and Farsi are test-only languages.

Language	Train	Validation	Test
Arabic	-	50	150
Basque	-	-	99
Catalan	-	-	100
Chinese	200	50	150
Czech	-	-	100
English	809	50	154
Farsi	-	-	100
Finnish	-	50	150
French	1850	50	150
German	-	50	150
Hindi	-	50	150
Italian	-	50	150
Spanish	492	50	152
Swedish	-	49	147

Table 2: Distribution of the training, validation, and test set samples for each language.

Without labeled data in the training set, teams are prompted to devise systems that do not rely on the availability of labeled hallucination data. Each data point in the training set includes the input prompt, the corresponding output text, the HuggingFace identifier of the model which has generated the output, the tokenized version of the output, and the logit values for the tokens.

The validation and test sets follow the same structure as the training data with the addition of providing hard and soft labels for the generated output. Hallucination labels are given at the character level, meaning that each output text may contain one or more hallucination spans. The spans were determined by human annotators with at least 3 people annotating each data point. Soft labels are based on probabilistic scores reflecting the level of consensus among annotators regarding hallucinated spans. These scores are calculated using the proportion of annotators who marked a given span as hallucinated and the resulting labels contain the start and end characters of sequences sharing the same score. Hard labels indicate spans which the majority of the annotators identified as hallucinated.

4 Methodology

Our system utilizes the validation dataset provided by the task organizers, which comprises ten languages. To ensure balanced representation across languages, we first split each language-specific dataset into training and validation subsets using a 90/10 ratio and then merged them to form combined training and validation sets. To address data scarcity, we implemented a cross-lingual label transfer mechanism based on neural machine translation and semantic span alignment. We employed Helsinki-NLP's Opus-MT bilingual models (Tiedemann and Thottingal, 2020) to translate labeled text from a source language into target languages.

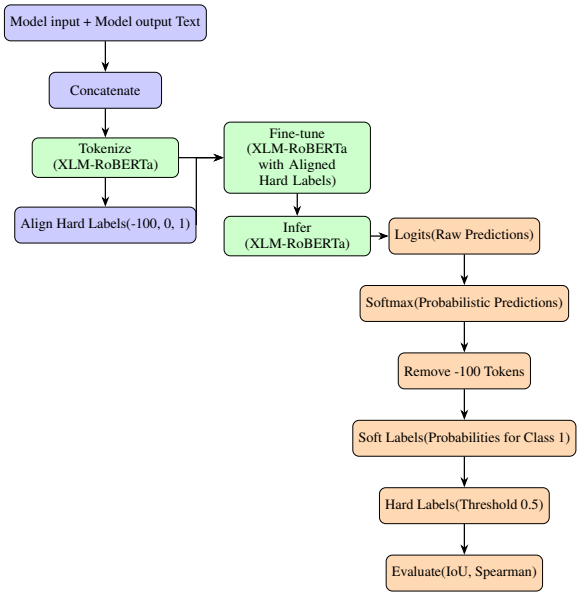

Figure 1: Hallucination detection flowchart.

For accurate projection of labeled spans (hard labels) onto the translated text, we adopted a semantic similarity-based alignment approach. We used the `paraphrase-multilingual-MiniLM-L12-v2` model from Sentence Transformers (Reimers and Gurevych, 2020) to generate embeddings for each labeled span in the source text, as well as for candidate spans in the translated output. To accommodate natural variations in translation length, we introduced a variational span matching strategy: for a source span of length l, we evaluated candidate spans in the translated text with lengths in the range $[l-\delta, , l+\delta]$, where δ is a tunable parameter (set to 5 in our experiments). Cosine similarity between embeddings was used to identify the most semantically aligned span, which was then adjusted to remove any leading or trailing whitespace, ensuring precise label transfer. The resulting multilingual dataset includes model input text, model output text, hard labels, and relevant metadata. We focus on three key components: the model input text, which provides contextual grounding; the model output text, which is analyzed for hallucinations and overgenerations; and the hard labels, which annotate hallucinated or overgenerated spans for use in evaluation and supervision. The overall architecture of our system is depicted in Figure 1.

The flowchart outlines the entire process, starting from concatenating model input and output text, followed by tokenization using XLM-RoBERTa (Conneau, 2019). The next steps involve hard label token alignment, model training, and inference. Post-inference, the logits are processed to calculate soft labels, followed by thresholding to obtain hard labels. Finally, we evaluate performance using the Intersection over Union (IoU) and Spearman correlation metrics as provided by the task organizers.

4.1 Preprocessing Pipeline

The first step of preprocessing is concatenating the model input text with the model output text to form a unified sequence. This ensures that the model retains the necessary context from the input while focusing on evaluating the generated output. The concatenated sequence is then tokenized into tokens or subword units using the model's tokenizer. After tokenization, token-hard-label alignment is performed to map the hard labels onto the tokenized sequence.

Hard labels are provided as nested lists, with each list specifying the start and end indices of hallucinated or overgenerated spans within the model output text. To align these spans with the tokenized sequence, offset mappings are generated for each token, indicating their start and end positions within the concatenated text. Initially, all tokens are assigned a label of -100, marking those that do not belong to the model output text, such as tokens from the model input context and special tokens (e.g., [CLS], [SEP], and [PAD]). The model input text is tokenized separately to determine where the tokens from the model output begin in the concatenated sequence. The start of the model output tokens is identified as the position immediately following the last token of the model input (excluding the special separator token).

To align the hard labels with the tokenized sequence, the model input text length is added to both the start and end indices of the hard-labeled spans. Tokens overlapping these adjusted spans are

labeled as 1 (hallucination), while those outside are labeled 0. Tokens labeled -100 are excluded from the loss calculation, ensuring the model focuses on the relevant output tokens during training. However, tokens labeled -100 still contribute to the context and are used by the model to make predictions for other tokens. This label indicates that these tokens do not affect the loss calculation, without diminishing their role in the model's contextual understanding. For testing, where hard labels are unavailable, all model output tokens are initialized only as 0 or -100. This setup helps distinguish model output tokens from others during prediction.

4.2 Model Training and Inference

We fine-tuned the XLM-RoBERTa model using the aligned hard labels in a supervised learning framework. During training, the model learns to identify hallucinated or overgenerated spans based on the provided hard labels for the model output text, while also using the contextual information from the model input text. This approach helps the model distinguish between hallucinated and non-hallucinated spans at the token level.

During inference, the model's logits are passed through a softmax activation function to generate probabilistic predictions, indicating the likelihood of each token being classified as Class 1 (hallucinated or overgenerated) or Class 0 (neither). Tokens labeled -100 are excluded to focus on model output tokens. Class 1 probabilities are aggregated for soft label evaluation, and a 0.5 threshold is applied to derive binary hard labels. Finally, predictions are evaluated using the mean Intersection over Union (IoU) and Spearman correlation values for each language's test set.

5 Experiments and Results

5.1 Experiments

To provide a more comprehensive evaluation of our model's performance, we present post-submission test results alongside the best IoU scores from the official leaderboard for comparison. While these results were not obtained during the submission window, they reflect improvements that were achieved during our subsequent experiments. The post-submission setting only uses the original validation data, as opposed to transferring labels from the data available in other languages.

Model configuration details for both the submission and post-submission phases are provided in Appendix A. Our official submission used the base variant of XLM-RoBERTa, while post-submission experiments used the larger version for further testing and validation. Training and validation batch sizes were adjusted accordingly to optimize the training process. Notably, the training batch size was increased from 18 to 26 and the validation batch size was increased from 8 to 16 during the post-submission phase.

5.2 Results

Our results (Table 3 and Table 4) show the effectiveness of label alignment in hallucinated span detection across various languages. Leveraging the context provided by the prompt in the fine-tuning stage seems to effectively guide our inference model in the detection of hallucinated spans. With comparable results throughout both of the measured metrics, we do not identify a preference in our system's capability of predicting soft or hard labels.

Language	IoU	ρ	Ranking
Arabic	0.5335	0.5537	11/29

Swedish	0.4183	0.3700	17/27

Table 3: Our best submission results for each language using IoU and Spearman correlation metrics along with our team ranking on the official leaderboard.

For the official submission, we applied label transfer to the target language and utilized validation data from other languages in addition to the original validation set. Post-submission results were obtained using the original validation data alone. As a result, the IoU scores increased for most languages compared to the official submission. The largest improvements were observed in Finnish (0.4221 - 0.6127), Swedish (0.4183 - 0.5728), and Catalan (0.4924 - 0.5532). Notably, Spanish and French exhibited significant drops in

Table 4: Results obtained after the end of the submission period alongside the highest IoU scores from the official leaderboard for reference.

performance. These findings suggest that training without label transfer generally improves performance across languages and that label transfer does not provide a clear advantage in most cases.

5.3 Discussion

Our observations indicate that our system has a tendency to predict a large number of short spans while the reference annotations contain a relatively small number of longer spans. This pattern is consistent across multiple languages. For example, Chinese test data contains an average of 10.58 spans with a mean span length of 34.21, while our Chinese model predicts 137.69 spans with an average length of 1.57.

Table 5 compares model predictions with gold annotations, revealing several behavioral patterns. In the first example, our model produces three different hallucination spans for the same entity, while missing some characters in the middle and at the end. Different tokenizers could lead to different outcomes and we think that experimenting with tokenization configurations could be beneficial. In the second example, our model labels an unrelated subword as hallucination. The following example in Italian demonstrates our model assigning two labels to the same span and failing to identify a full word as hallucination, only labeling the subword. The following German example illustrates how the model falsely produces multiple labels and partially misses a city name. In the last English example, our model labels each year individually rather than coming up with a single label for the range. It also fails to identify a whole another hallucinated span. These findings reveal that our model is still prone to both under- and over-prediction.

6 Conclusion

In this paper, we present a system for the detection of hallucinated spans in text. Our approach successfully applies the small amount of labeled data provided by the task organizers to fine-tune a multilingual XLM-RoBERTa model to this end. By aligning the tokens in a concatenated sequence including both the prompt and its resulting model output to the provided hard labels representing the start and end of a hallucinated span, we are able to leverage the context that the prompt provides at the same time that we make use of the available labeled data.

This system however has some limitations, such as its reliance on larger models for improved performance and its tendency to predict a larger number of spans which are shorter in length than desirable.

Abstract

In today's digital era, individuals convey their feelings, viewpoints, and perspectives across various platforms in nuanced and intricate ways. At times, these expressions can be challenging to articulate and interpret. Emotion recognition aims to identify the most relevant emotions in a text that accurately represent the author's psychological state. Despite its substantial impact on natural language processing (NLP), this task has primarily been researched only in high-resource languages. To bridge this gap, SemEval-2025 Task 11 introduces a multilingual emotion recognition challenge encompassing 32 languages, promoting broader linguistic inclusivity in emotion recognition. This paper presents our participation in this task, where we introduce a language-specific fine-tuned transformer-based system for emotion recognition and emotion intensity prediction. To enhance generalization, we incorporate a multi-sample dropout strategy. Our approach is evaluated across 11 languages, and experimental results demonstrate its competitive performance, achieving top-tier results in certain languages.

1 Introduction

Understanding emotions expressed in a text has gained significant attention in natural language processing (NLP) due to its wide-ranging applications in sentiment analysis, mental health monitoring, and human-computer interaction (Tao and Fang, 2020; Saffar et al., 2023). While sentiment analysis primarily focuses on classifying text into positive, negative, or neutral categories, emotion classification provides a more granular understanding by identifying specific emotions such as joy, sadness, anger, and fear (Mohammad et al., 2018; Ameer et al., 2023).

However, though there are several research on emotion detection in mid- to high-resource languages such as English, Arabic, and Spanish (Mohammad et al., 2018; Saravia et al., 2018; Kumar et al., 2022), very few emotion recognition jobs are done in low-resource languages such as Afrikaans, Hausa, and Romanian (Muhammad et al., 2025a). To bridge this major research gap in emotion recognition, (Muhammad et al., 2025b) introduces a task in SemEval-2025. The task consists of three different tracks. Track A is classifying emotion in a sentence which is structured as a multi-label classification task. Except for English and Afrikaans, sentences in all other languages are required to be classified into six different emotions such as "anger", "fear", "joy", "sadness", "surprise", and "disgust". The "disgust" and "surprise" emotion classes are absent for the English and Afrikaans languages respectively. When a sentence doesn't fall into any of the emotion classes it is categorized as the no emotion instance. Track B is to predict the degree of intensity of each recognized emotion. Track C is to predict the perceived emotion labels of a new text instance in a different target language given a labeled training set in one of the support languages. Among the three tracks, we have participated in the first two. To demonstrate a clear view of the task definition, we articulate an example in Table 1 for the English language.

Sentence	Track A	Track B
I can't believe it! I won the scholarship! This is amazing!	[0 0 1 0 1]	[0 0 3 0 3]

Table 1: Example of Track A and Track B for SemEval-2025 Task 11. In Track A, the values 0 and 1 represent the absence and presence of a specific emotion, respectively. In Track B, the intensity of an emotion is indicated on a scale from 0 to 3, with higher values signifying greater emotional intensity. The classes are presented in the same order as mentioned in the above description.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1332–1341

To address the challenges of multilingual and multi-label emotion recognition, as well as emotion intensity prediction, we propose a system in this paper. Our system leverages language-specific transformers to extract contextualized features for a sentence. We utilize a multi-sample dropout strategy for better generalization in our system.

The remaining parts of this paper are organized as follows: Section 2 introduces our proposed system for emotion recognition and emotion intensity prediction. Section 3 details our experimental settings and evaluation. Section 4 offers insightful discussion. Finally, we conclude our paper and suggest potential avenues for future research in Section 5.

2 System Overview

This section provides an overview of our proposed system for SemEval-2025 Task 11: Bridging the Gap in Text-based Emotion Detection. The competition consists of three separate tracks, and we have participated in the first two. Track A focuses on detecting emotions in textual data across multiple languages, while Track B involves predicting emotion intensity. We have participated across 11 languages for both tracks, as summarized in Table 2. Figure 1 presents a high-level illustration of our proposed system.

Given an input sentence, our system first encodes it with a language-tuned transformer (Vaswani et al., 2017). In addition to the contextual embedding from the transformer, we later use a multi-sample dropout (Inoue, 2019; Aziz et al., 2023) procedure to improve the generalization ability of the system. To obtain final logits (unnormalized scores), we fuse the logits from different dropout samples. Finally, we normalize the logits with sigmoid function (Han and Moraga, 1995) and predict with global thresholding.

2.1 Transformer Models

Unlike conventional sequence-based architectures such as LSTM (Schuster and Paliwal, 1997) and CNN (Goodfellow et al., 2016), transformer models effectively capture long-range dependencies within a sequence. Leveraging multi-head attention and positional embeddings enhances token interactions and contextual understanding. We fine-tune multiple transformer models across various languages to extract contextualized text representations, as illustrated in Table 2.

Ukrainian (ukr)	youscan/ukr-roberta-base

Table 2: Language-specific transformers used in our proposed system. The URLs of the Hugging Face models are provided in Table 7 in Appendix A.

2.2 Multi-sample Dropout

In deep neural networks, dropout is an efficient regularization strategy for better generalization (Srivastava et al., 2014). It randomly drops a portion of neurons from the network to prevent dependency among them and hence reduce over-fitting on the training data. As a result, the trained model shows better performance on unseen data. To further enhance the generalization and fast training, (Inoue, 2019) proposed the multi-sample dropout technique. In contrast to the original dropout, features are fed into multiple samples of different dropout masks. Then the output goes to fully connected layers of shared weights. The resulting logits are then used for loss calculation. The final loss is estimated

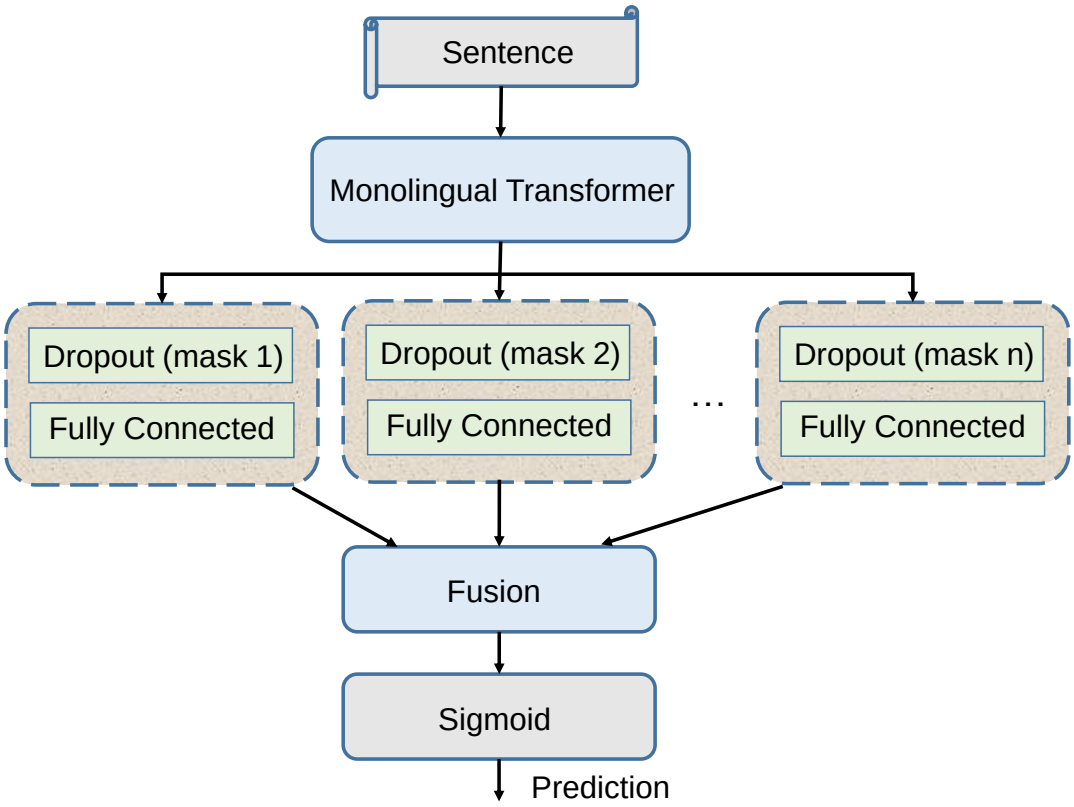

Figure 1: Overview diagram of our proposed system for SemEval-2025 Task 11: Bridging the Gap in Text-based Emotion Detection.

by averaging the observed losses across different samples to achieve a single representation of an input. We utilize a three-sample dropout technique in our proposed system.

2.3 Emotion Classification

During inference, let us get $Logit_1$, $Logit_2$, ... $Logit_n$ from n dropout samples. Then we arithmetic average the logits and pass the output into the sigmoid function (Han and Moraga, 1995) as follows:

$$y = \text{Sigmoid}\left(\frac{\sum_{i=1}^{n} Logit_i}{n}\right) \quad (1)$$

Finally, we predict using thresholding: emotion probabilities y less than the threshold are classified as 'no emotion', while those greater than or equal to the threshold are classified as 'yes'.

2.4 Emotion Intensity Prediction

Track B involves estimating the intensity of emotions for each target class. The intensity levels are classified into four distinct groups: No emotion (0), Low intensity (1), Moderate intensity (2), and High intensity (3). Let p be the probability under which probabilities are predicted to be No emotion (0 intensity) of a class. The remaining probability, $(1-p)$, is evenly distributed into three segments. Each segment has a length of $\frac{1-p}{3}$, denoted as l. The predicted intensity levels, I, are then determined as follows:

$$I = \begin{cases} \text{No}, & \text{if } y < p, \\ \text{Low}, & \text{else if } p \leq y < p + l, \\ \text{Medium}, & \text{else if } p + l \leq y < p + 2 \times l, \\ \text{High}, & \text{otherwise.} \end{cases} \quad (2)$$

3 Experiments and Evaluation

3.1 Dataset Overview

To demonstrate the effectiveness of participants' proposed system for emotion classification, the organizers of SemEval-2025 Task 11 have released two benchmark datasets. The BRIGHTER dataset (Muhammad et al., 2025a) covers 28 languages, while EthioEmo (Belay et al., 2025) includes 4 Ethiopian languages, aiming to bridge the gap in text-based emotion recognition. For

our participation, we have worked with 10 languages from BRIGHTER and one from EthioEmo (Amharic), covering a total of 11 languages. Figure 2 in Appendix B illustrates the dataset statistics across the train, development, and test sets for these languages. Notably, the development set contains significantly fewer samples compared to the train and test sets for all languages. Both datasets support six emotion classes: "anger", "fear", "joy", "sadness", "surprise", and "disgust". However, the "disgust" class is absent in English, and the "surprise" class is absent in Afrikaans. Additionally, the datasets exhibit a long-tail distribution problem across emotion classes (Muhammad et al., 2025a). During the evaluation stage, we combine the training and development sets to enhance model training and assess its performance on the unseen test set provided in the Codabench competition[1].

3.2 Evaluation Measures

The organizers of SemEval-2025 Task 11 employed various evaluation metrics. The primary metric for Track A and Track C is the macro-average F_1 score. For Track B, which focuses on emotion intensity prediction, the Pearson correlation coefficient is used.

3.3 Parameter Settings

In this section, we outline the configuration details of our proposed system, developed for SemEval-2025 Task 11. We fine-tune multiple transformer models available in Hugging Face (Wolf et al., 2019) for various languages. To ensure reproducibility, we conduct experiments using a T4 GPU on Google Colab (Bisong, 2019), setting the manual seed to 66. We set the classifier learning rate to 0.0001 to facilitate faster convergence. For optimization, we employ the AdamW algorithm (Loshchilov and Hutter, 2017). Additionally, we implement a multi-sample dropout strategy with probabilities ranging from 0.1 to 0.3. The hyperparameter settings and their optimal values are summarized in Table 3. All other parameters remain at their default values.

3.4 Results and Analysis

Performance comparison of our proposed system with the baseline (Muhammad et al., 2025b) for Track A and Track B are summarized in Table 4 and 5 respectively. Here, "# Systems" indicates the number of systems reported in the official ranking for a particular language. Following the benchmark of SemEval-2025 task 11, the evaluation is conducted using the primary evaluation metric, macro-average F_1 and Pearson correlation (R) score for track A and track B respectively.

The performance table shows that our system achieves the highest result in the `rus` language and the lowest result in the `ukr` language for Track A. For Track B, the highest Pearson correlation is observed for the `amh` language, while the lowest is for the `arq` language. Our system performs competitively on the leaderboard in certain languages, achieving the highest Pearson correlation for the `amh` language among participants. For a detailed comparison of results across participants, we refer to (Muhammad et al., 2025b).

Hyper-parameters	Optimal Value

4 Discussion

In this section, we estimate the impact of the multi-sample dropout (MSD) strategy in our CSECU-Learners system. Additionally, we compare our system's results with some state-of-the-art (SOTA) multilingual transformers and large language models (LLMs).

Table 6 presents the impact of the MSD technique on emotion classification and intensity prediction. The results are obtained using tuned thresholds across languages on the test set during the post-evaluation phase. The thresholds are provided in Table 8 in Appendix C. For emotion classification, we observe that the CSECU-Learners system with MSD outperforms its counterpart without MSD in 7 of the 11 languages we participated in. Similarly, the MSD-enabled system achieves better results in 7 languages for intensity prediction. Overall, the MSD strategy contributes an improvement of 0.30% in macro-F_1 and 0.31% in Pearson correlation for Track A and Track B, respectively.

Since SemEval-2025 Task 11 focuses on multilingual emotion classification, we compare the performance of our system with several multilingual transformer models. Table 9 in Appendix C presents a comparison between our system and three multilingual transformer-based models: RemBERT (Chung et al., 2020), XLM-R (Conneau et al., 2020), and LaBSE (Feng et al., 2022). This evaluation is conducted using our system's performance during the official evaluation phase. The performance scores for multilingual transformers are taken from BRIGHTER (Muhammad et al., 2025a). The comparison indicates that our system outperforms multilingual transformer-based models in most languages across both tracks.

Large Language Models (LLMs) have recently demonstrated remarkable learning and reasoning capabilities across various downstream tasks. In Table 10 in Appendix C, we present a comparative analysis of several LLMs, including Llama-3.3-70B (Touvron et al., 2023), Qwen2.5-72B (Qwen et al., 2025), and DeepSeek-R1-70B (DeepSeek-AI et al., 2025), alongside our system. The results indicate that our system achieves superior performance over these LLM-based approaches for the majority of languages. This demonstrates the effectiveness of our proposed system in the emotion classification task.

5 Conclusion and Future Direction

This paper presents our proposed system for emotion recognition and intensity prediction. Identifying emotions in a sentence requires more than just superficial analysis; understanding contextual meaning is essential. To address this challenge, we fine-tuned various transformer models across different languages, leveraging their ability to capture contextual embeddings. Additionally, we incorporated a multi-sample dropout strategy to enhance generalization. Experimental results validate the effectiveness of our proposed approach, demonstrating competitive performance in comparison to several existing methods.

In future work, we plan to explore other state-of-the-art transformer architectures and investigate the fusion of multiple transformer models. Since the dataset is imbalanced, we aim to incorporate weighted loss functions to improve learning across all classes.

Limitations

Our proposed system utilizes language-specific transformers, requiring fine-tuning for each language, which can be computationally expensive and time-consuming. Additionally, the performance of the model is influenced by threshold tuning, which may vary across different datasets and may not always generalize well to real-world applications. Furthermore, the system does not address the class imbalance problem in this task, which

Table 7 shows the URLs of the Hugging Face Transformers used for each language in our system.

B Dataset Statistics

Figure 2 presents the distribution of the train, development, and test sets for the SemEval-2025 Task 11 dataset. The illustration includes only the languages in which we participated.

C Performance Evaluation

C.1 Optimal Thresholds

The optimal thresholds used in our system for Track A and Track B across different languages on the test set are presented in Table 8. We report the thresholds both with and without the multi-sample dropout (MSD) strategy.

C.2 Performance Comparison

Table 9 presents a comparative analysis between our proposed system and several multilingual transformers. From the various multilingual transformers discussed in BRIGHTER (Muhammad et al., 2025a), we report the top three performing models. Similarly, Table 10 provides a performance analysis of several large language models on this task. All results for multilingual transformers and large language models are taken from BRIGHTER.

Abstract

Table Question Answering (TQA) is a challenging task that requires reasoning over structured data to extract accurate answers. This paper presents QleverAnswering-PUCRS, our submission to SemEval-2025 Task 8: DataBench, Question-Answering over Tabular Data. QleverAnswering-PUCRS is a modular multi-agent system that employs a structured approach to TQA. The approach revolves around breaking down the task into specialized agents, each dedicated to handling a specific aspect of the problem. Our system was evaluated on benchmark datasets and achieved competitive results, ranking mid-to-top positions in the SemEval-2025 competition. Despite these promising results, we identify areas for improvement, particularly in handling complex queries and nested data structures.

1 Introduction

The rapid growth of structured data across various domains has increased the demand for automated systems capable of extracting and interpreting information from tabular data. TQA is a crucial Natural Language Processing (NLP) task that focuses on generating accurate answers to factual questions using structured information (Jin et al., 2022). Unlike traditional QA systems that rely on free-text corpora, TQA systems must directly retrieve relevant information from relational tables, spreadsheets, or structured databases. Additionally, the limited context window of Large Language Models (LLMs) constrains the amount of tabular data that can be processed in a single prompt, making metadata extraction a key component for precise query resolution.

Task 8 in SemEval 2025 – DataBench, Question-Answering over Tabular Data (Osés Grijalba et al., 2025), introduces a new benchmark for evaluating TQA systems. This benchmark enables the assessment of different question types spanning multiple information domains. The challenge lies in developing systems that can accurately answer queries over standardized datasets, where responses may take various forms, including boolean, categorical, numerical, or lists. Evaluation is based on the system's ability to provide precise answers given a (dataset, question) pair.

In this paper, we introduce QleverAnswering-PUCRS[1], a modular approach to Table Question Answering. Our system decomposes the TQA task into specialized agents, each responsible for a distinct function: metadata extraction, expression generation, error handling, and code execution. By structuring the workflow into interconnected components, QleverAnswering-PUCRS aims to improve observability, reduce execution failures, and enhance accuracy.

We evaluate QleverAnswering-PUCRS on benchmark datasets, demonstrating its effectiveness in handling complex queries over structured data. Our average results ranked us between 9^{th} and 19^{th} out of 49 participating systems across the four different rankings considered in the task. Nonetheless, we identify areas for further improvement and refinement in our approach.

2 Background and Related Work

TQA aims to answer questions referring to data stored in tables (Jin et al., 2022). Early methods had trouble generalizing across many data formats and depended on semantic parsing to translate natural language queries into structured languages like SQL. Modern approaches process tabular data using LLMs, avoiding the need for explicit query translation. Proprietary models tend to perform better, but all models have limits when performing sophisticated queries (Osés Grijalba et al., 2024).

[1]Our code is available at https://github.com/LucasAzeved/SemEval_2025_Task_8_QleverAnsweringPUCRS.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1342–1350

Current research has investigated retrieval-augmented generation (RAG), structured query generation, and simple neural network-based techniques to enhance query resolution. These approaches enable models to overcome context window restrictions by extracting pertinent metadata before query execution (Zhou et al., 2025). Program-based prompting is a further method in which models produce executable code to interpret tabular data rather than immediately responding to queries. This method is used for hybrid question answering by the HPROPRO framework (Shi et al., 2024), which shows good performance without the need for explicit data retrieval or transformation.

The MACT framework (Zhou et al., 2025) introduces a multi-agent approach, where distinct agents handle planning, query formulation, execution, and validation. This division of tasks enhances robustness, allowing for iterative refinement and error handling, leading to performance gains over fine-tuned LLMs in complex table-based reasoning tasks. Error correction mechanisms improve accuracy by identifying logical inconsistencies and refining queries dynamically (Shi et al., 2024).

Program-Aided Language Models (PAL) (Gao et al., 2023) propose generating intermediate Python code to be executed by an interpreter, which improves arithmetic and symbolic reasoning. This delegation enhances accuracy, especially for problems requiring precise calculation or logic that exceeds LLMs' intrinsic capabilities.

The Plan-of-SQLs (POS) framework (Nguyen et al., 2025) emphasizes the need for interpretability in Table QA. By decomposing complex queries into atomic SQL operations, POS enables transparent, step-by-step reasoning that can be verified by humans and LLMs alike. This work is particularly relevant in high-stakes domains, demonstrating that explainability can coexist with competitive performance.

While PAL and POS focus on symbolic execution and explainability, our approach targets the integration of structured program reasoning with lightweight retrieval to improve efficiency and adaptability in practical settings.

3 QleverAnswering-PUCRS

3.1 Task Description

The Question Answering over Tabular Data task generates accurate and contextually relevant responses to factoid questions based on structured data stored in tabular formats. Given a pair (d, q), where d is a dataset, and q is a question, we aim to produce an answer a corresponding to the response of q over d. The system needs to extract, interpret, and synthesize information directly from tables/datasets.

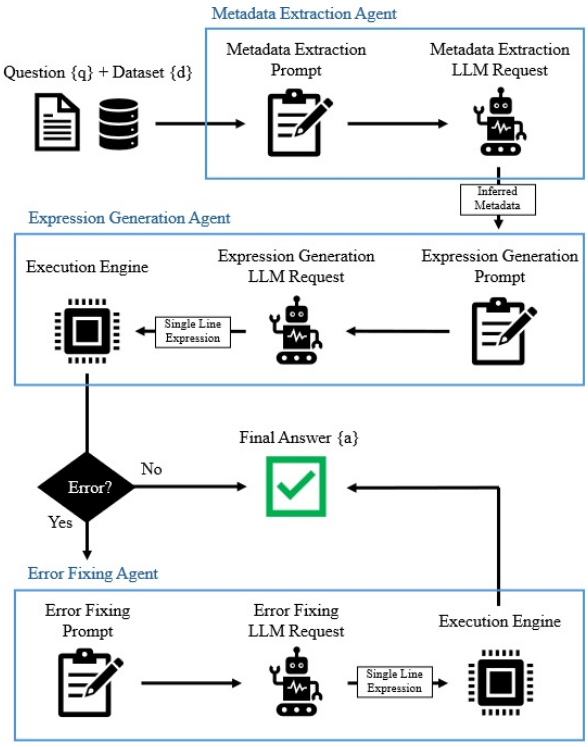

Figure 1: Overview of QleverAnswering-PUCRS

3.2 Solution Overview

QleverAnswering-PUCRS employs a modular agentic approach, where specialized agents handle specific subtasks such as metadata extraction, query interpretation, code generation, and validation. This pipeline aims to improve accuracy, facilitate debugging, and ensure adaptability to complex queries. The system enhances robustness by structuring the workflow into independent yet interconnected agents, allowing for targeted optimizations at each stage. An overview of QleverAnswering-PUCRS can be seen in Figure 1.

3.2.1 Metadata Extraction Agent

Extracting relevant information from large structured datasets is non-trivial, as that they may contain many columns. This fact, added to the limited context window of LLMs, makes it impractical to input an entire dataset in a prompt. Besides, we want to provide a concise prompt that only contains the information related to the question.

The first step of our approach is an *metadata extraction agent*, which pre-processes and structures metadata to guide later steps by filtering, cleaning, and organizing raw data into a prompt. We design the prompt presented in Appendix A.1.

The three components that are inserted into this prompt are (i) the dataframe preview, replacing the field `{df_str}` in the prompt, providing a snapshot of the dataset that captures a limited set of initial rows. This preview aims to allow the LLM to infer potential value distributions, column relationships, and general patterns in the data, ensuring that subsequent steps leverage meaningful insights; (ii) the columns information, on the field `{columns_info_str}`, containing structural details about the dataset, which includes the column names and data types. By incorporating this information, the LLM should be able to determine if the dataset contains categorical or numerical attributes, recognize potential restrictions, and validate whether a query can be executed without encountering errors due to type mismatches; the final and most critical input is (iii) the user query, in the field `{query}`, which represents the natural language question that the system must interpret and translate into a structured response. It is crucial that the query's intent can be readily determined and ambiguity avoided; otherwise, all future generated information can be misleading.

The output of this step consists of four components. The first is a list of relevant columns required to answer the query, and the second is the data type of each relevant column (*e.g.,* integer, string, boolean). The third component is the expected response type for that question, which is one of the following set {`boolean`, `number`, `category`, `list[category]`, `list[number]`}, and the last one is a sample answer, which is a plausible response generated based on the query and dataset preview.

3.2.2 Expression Generation Agent

Once relevant metadata has been identified on the input dataset, the next step is to convert the query into a valid expression that can extract the answer to the question over the provided dataframe. This step of the pipeline receives as input the newly refined information from the *metadata extraction agent*. Based on this data, the agent translates the natural language query into a single-line executable expression. This stage takes the refined data from the *metadata extraction agent* and converts the natural language query into a single-line expression, which disallows loops, variable assignments, or multi-line code. We designed the prompt in Appendix A.2 to achieve this goal.

The prompt template for this agent receives as input (i) the dataframe preview, in the field `{df_str}`, which consists of a small preview of the dataset, (ii) the structured set of metadata inferred from the *metadata extraction agent*, represented as `{generated_information}`, crucial for guiding the generation of the correct expression. This field is responsible for encapsulating key aspects such as the relevant columns, their data types, and the expected response format, ensuring that the generated expression aligns with the given query; (iii) the query itself, in the field `{query}`, which is provided to define the specific operation that must be translated into a valid executable expression.

Given that an incorrect expression may lead to execution failures, this step is critical to the pipeline's success, and its output is directly connected with the *execution engine module*, which acts as the pipeline's execution layer. This module receives a valid expression, executes it over the dataset in a code interpreter, and returns the result, which is the answer to a factoid question.

3.2.3 Error Fixing Agent

Despite careful query construction, execution errors may still arise due to column mismatches, such as referencing a non-existent column or data type conflicts, where numerical operations are applied to categorical data. Logical inconsistencies can also occur if incorrect assumptions are made during metadata extraction, leading to unexpected failures when executing expressions.

To address these issues, the *error fixing agent* automatically detects execution failures and reattempts expression generation with an improved context. Our approach detects errors as they occur. The failing expression and error message are captured in those cases to enhance the correction prompt. Using this updated context, a corrected expression is generated and re-executed by the *execution engine module*.

We designed the prompt in Appendix A.3 to achieve this goal. The inserted information also includes (i) a preview of the DataFrame, replacing the field `{df_str}` in the prompt, which provides a small snapshot of the dataset to offer context for the correction process; (ii) the previously generated expression, in the field

{previous_expression}, which serves as a reference for the attempted solution that encountered an error; (iii) the corresponding error message, represented as {error_encountered}, providing crucial insights into the nature of the failure, facilitating the identification of necessary corrections; and (iv) the query, in the field {query}, which defines the intended operation that must be correctly translated into an executable expression.

This iterative approach strengthens system reliability by reducing manual work and ensuring that erroneous queries can be resolved dynamically.

4 Experimental Setup

4.1 Dataset Description

We worked with two datasets: one during the development phase and another during the competition phase. For development, we used the 65 datasets from DataBench[2] (Osés Grijalba et al., 2024), a benchmark designed to provide a realistic and diverse testing ground for question-answering models over tabular data. DataBench consists of structured CSV-style files with varying numbers of rows and columns, representing real-world datasets across multiple domains.

During the competition phase, we used the 15 datasets provided by the task organizers for system evaluation. These datasets cover a diverse range of domains and vary in the number of rows and columns, allowing the models to be tested in an unseen environment with a wide range of structural complexities. Table 1 presents some statistics of these datasets, including the number of questions, columns, and rows of each test dataset. A Lite version of the datasets, containing the same questions and columns but limited to the first 20 rows of each dataset, was provided by the task organizers.

Dataset	#Ques	#Cols	#Rows
066_IBM_HR	39	35	1,470
067_TripAdvisor	29	10	20,000
068_WorldBank_Awards	34	20	239,461
069_Taxonomy	35	8	703
070_OpenFoodFacts	29	11	9,483
071_COL	36	8	121
072_Admissions	39	9	500
073_Med_Cost	32	7	1,338
074_Lift	35	5	3,000
075_Mortality	29	7	400
076_NBA	36	30	8,835
077_Gestational	31	7	1,012
078_Fires	39	15	517
079_Coffee	38	15	149,116
080_Books	41	13	40

Table 1: Statistics of Competition Datasets

4.2 Agents Description

Metadata Extraction LLM: We used Meta Llama 3 8B (Dubey et al., 2024) to extract key metadata from the dataset and the question. The model processes a structured prompt with a data set preview and a query. We first format the dataset to construct this prompt, ensuring that the column names are cleaned and represent the actual data. Given token limitations, only a subset of rows is included, focusing on covering different value types within the dataset.

Once the formatted prompt is sent to the model, it identifies the relevant columns required to answer the query and determines their data types. The model then classifies the expected response type, selecting from predefined categories to ensure consistency in subsequent processing steps. Additionally, it generates a sample answer based on the provided dataset fragment, serving as a reference. All LLM calls share the same request parameters: temperature = 0.0; max_tokens = 256. A low temperature tends to produce more deterministic responses. Due to API token constraints, where input tokens consume most of the available quota, we set max_tokens to avoid exceeding this limit.

Expression Generation LLM: For expression generation, we used Qwen2.5 Coder 32B Instruct (Hui et al., 2024). The model receives a prompt containing the dataset preview, user query, and the metadata extracted from the previous step. The prompt is designed to include all needed context while staying concise to fit token limits. The model is then instructed to generate a single-line Pandas[3] expression that directly answers the query without defining additional variables or performing unnecessary operations. Multi-line code, loops, and function definitions are explicitly disallowed to maintain compatibility with our execution framework. If the generated expression does not conform to the expected format or contains syntax errors, it is flagged for correction in the error-handling stage.

Ranking General	45/49	44/49
Ranking Open	31/35	31/35

Table 2: Comparison between our system's performance and the task baseline. Bold values indicate the accuracy (%) scores, with the official scores on DataBench after human review shown in parentheses.

Without Error Fixing				
	Acc	Q^+	Q^-	# Errors
DataBench	75,86	396	126	30
DataBench Lite	78,73	411	111	27
With Error Fixing				
	Acc	Q^+	Q^-	# Errors
DataBench	76,82	401	121	25
DataBench Lite	79,50	415	107	23

Table 3: Evaluation results for the DataBench and DataBench Lite on both setups, reporting % accuracy scores (Acc), correct predictions (Q^+), incorrect predictions (Q^-), and total number of errors.

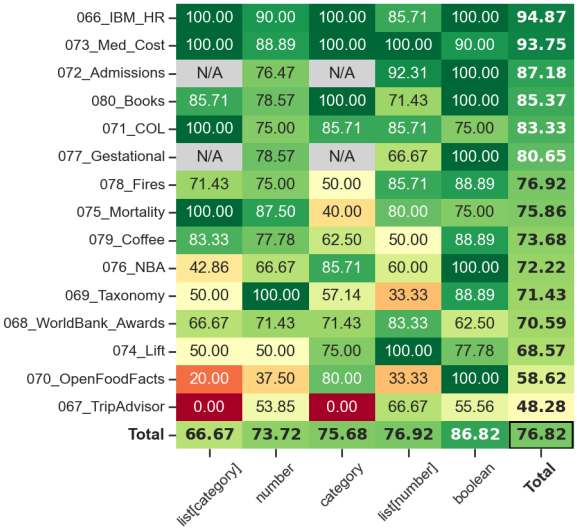

Figure 2: Accuracy heatmap on DataBench Dataset

Error Fixing LLM: We also utilized the Qwen2.5 Coder 32B Instruct (Hui et al., 2024) for error correction. The dataset preview, the previously created expression, the discovered error message, and the original query are all included in the structured prompt sent to the model. This prompt is thoughtfully structured to give all the required debugging context while being brief enough to adhere to token restrictions. The model is specifically told to examine the error, determine its possible causes, and provide a corrected one-line Pandas expression that fixes the problem. The system analyzes the model's response and runs the corrected expression generated against the dataframe. Regardless of the outcome, the execution response is saved as the final solution.

Execution Engine Module: To execute the generated expression, we utilized the `PandasInstructionParser` from LlamaIndex[4], which acts as an execution engine for Pandas-based operations over tabular data. The execution is orchestrated within a controlled pipeline using the `QueryPipeline` (QP) module, ensuring structured processing and response parsing. The pipeline consists of an input component that receives the expression and forwards it to the `PandasInstructionParser`, which interprets and executes the operation over the dataset in a Python 3.10 environment.

5 Results

Table 2 presents the official results of our system. In the open-source model ranking, our scores were 76.82 on Databench and 79.50 on Databench Lite, positioning us 13^{th} and 9^{th}, respectively, of 35 participants. In the general ranking, our scores remained the same, but we ranked 19^{th} and 15^{th} out of 49 participants. These results show strong mid-to-top performance, with our system achieving scores nearly three times higher than the task baseline.

Table 3 presents an ablation study evaluating the impact of the *error fixing agent* on the performance of the system. The results show an accuracy improvement of 0.96% for DataBench and 0.77% for DataBench Lite when the error fixing mechanism is applied. This is an improvement of 16.67% and 14.81% on the number of errors resolved in DataBench and DatabenchLite, respectively.

Figures 2 and 3 present the accuracy scores per semantic `category` (data type) and dataset. One notable observation is the consistency of our results across Databench and Databench Lite, suggesting that our model generalizes well even when restricted to only 20 rows per dataset.

Regarding different semantic types, our system

[4] https://docs.llamaindex.ai/en/stable/

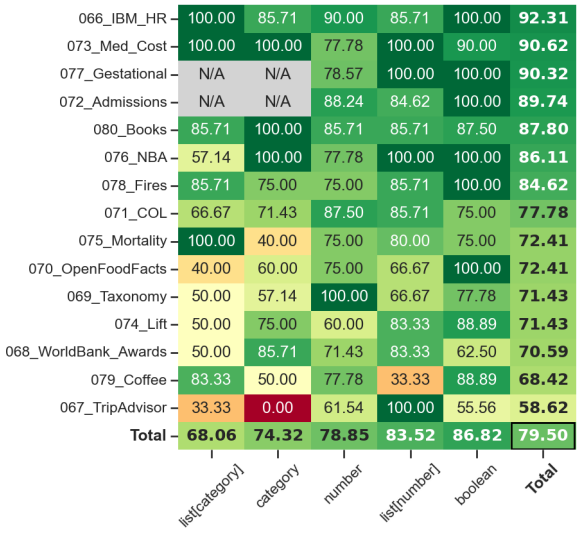

Figure 3: Accuracy heatmap on DataBench Lite Dataset

achieved its highest accuracy in the `boolean` type, which aligns with the expectation that the restricted domain in boolean values is easier to infer. In contrast, the lowest accuracy was observed in the `list[category]` type, which requires handling multiple categorical elements in a single response. The difficulty in correctly parsing and structuring multiple values is likely a contributing factor to this result, highlighting an area where additional refinement in the expression generation process might be beneficial.

One of the most significant drops in accuracy occurred in the `067_TripAdvisor` dataset, where our system obtained the lowest performance among all datasets. A deeper inspection reveals that this dataset contains JSON-formatted strings within queried columns, introducing additional complexity in extracting relevant values. Since our system relies on Pandas expressions to directly parse and filter data, handling embedded JSON structures within textual fields requires additional pre-processing, which was not included in our current pipeline. Similarly, the dataset `070_OpenFoodFacts` exhibited similar problems, but in this case, due to list-formatted strings rather than JSON, requiring specific parsing strategies that were not accounted for. This issue impacted both `list[category]` and `category` type questions, where correct identification and parsing of values were hindered, as well as `number` type questions, particularly those involving "How many..." questions, where quantities needed to be extracted from structured text fields.

Further analyzing the per-dataset performance, we identified patterns that explain specific drops in accuracy.

In the `075_Mortality` dataset, focused on `category` questions, all incorrect predictions occurred in queries requiring the identification of the entity with the highest or lowest average rate. The system consistently inverted the aggregation logic, incorrectly assuming that higher "Rate" values indicated better outcomes, whereas lower rates were preferable. This reveals a limitation in inferring the semantic orientation (*i.e.,* whether minimizing or maximizing is desirable) based solely on dataset structure.

In the `068_WorldBank_Awards` dataset, primarily involving `boolean` questions, errors arose from dataset ambiguities. Even manual inspection revealed that answering required domain knowledge beyond the available data preview, as column names and sample rows were insufficient to disambiguate the intended meaning without additional context.

6 Conclusion

In this work, we presented QleverAnswering-PUCRS, a modular system for Table Question Answering that relies on code generation over structured data. Our approach generates single-line Pandas expressions to extract answers, demonstrating strong performance across multiple semantic categories and significantly surpassing the task baseline in both Databench and Databench Lite evaluations.

Despite these promising results, our analysis revealed specific limitations. The system struggled to correctly infer the semantic orientation of metrics, particularly in tasks requiring judgment on whether lower or higher values are preferable, and showed difficulties when answering questions that demanded external domain knowledge beyond the provided data structure.

For future work, we plan to explore multi-step query execution strategies to improve reasoning over complex tabular data. We also intend to investigate the impact of model size on performance, assess the system's sensitivity to different prompt components, and evaluate iterative error correction methods to determine if multiple repair attempts can further improve accuracy. Additionally, incorporating external dataset descriptions or semantic enrichment mechanisms could mitigate context-related ambiguities.

A Prompt Templates

A.1 Metadata Extraction Prompt

```
<|begin_of_text|><|start_header_id|>system<|end_header_id|>You are an expert in Python and Pandas
    (version 2.2.2). Analyze a DataFrame and a query to infer key metadata required to process the
    query.

Task:
Based on the information provided:
1. Columns Used: Identify the relevant column(s) for answering the query.
2. Column Types: Provide the data types of the relevant columns.
3. Response Type: Choose one of: `boolean`, `number`, `category`, `list[category]`, or
    `list[number]`. No other formats are allowed.
4. Sample Answer: Generate a plausible sample answer based on the query and DataFrame preview,
    aligned with the Response Type.

Requirements:
- Pay close attention to what the query is asking for, it can be tricky.
- Only include columns explicitly needed for the query.
- Base the sample answer on plausible values from the provided DataFrame preview.
- Ensure the response is concise and well-structured.
- Do not provide any extra explanation or context beyond the requested metadata.

Output Format:
Columns Used: (columns_used)
Column Types: (column_types)
Response Type: (response_type)
Sample Answer: (sample_answer)
<|eot_id|>
<|start_header_id|>user<|end_header_id|>
DataFrame Preview:
`{df_str}`

Columns Information:
`{columns_info_str}`

Query:`{query}`
<|eot_id|>
<|start_header_id|>assistant<|end_header_id|> Response:
```

A.2 Expression Generation Prompt

```
<|begin_of_text|><|start_header_id|>system<|end_header_id|>You are working with a pandas DataFrame
    in Python (version 2.2.2), named `df`.
Result of `print(df.head(2))`:
`{df_str}`

The following information was inferred from the DataFrame and query, you MUST use it to generate the
    expression:
`{generated_information}`

Instructions:
1. You are tasked to convert the query into **a SINGLE expression** using Pandas (version 2.2.2).
2. The result of the expression MUST be one of the following types: `boolean`, `number`,
    `category`, `list[category]`, or `list[number]`.
3. You MUST NOT return a DataFrame or any type not listed above.
4. **STRICTLY FORBIDDEN**: Writing multi-line code, defining variables, or using statements like
    `import`, `print`, or assignments (e.g., `x = ...`).
5. The Python expression MUST have only ONE line of code that can be executed directly using the
    `eval()` function.
6. **DO NOT USE NEWLINES** in the expression. Only return the single expression directly.
7. **DO NOT QUOTE THE EXPRESSION**. The output must ONLY be the raw code of the single expression.

*** Pay CLOSE attention to what the query is asking for, it can be tricky. ***
<|eot_id|>
<|start_header_id|>user<|end_header_id|>
Query: `{query}`
<|eot_id|>
<|start_header_id|>assistant<|end_header_id|>Expression:
```

A.3 Error Fixing Prompt

```
<|begin_of_text|><|start_header_id|>system<|end_header_id|>You are working with a Pandas DataFrame
    in Python (version 2.2.2) named `df`. Your task is to fix a failed Pandas expression by
    generating a new one that avoids the same error.
Below is a preview of the DataFrame (result of `print(df.head())`):
`{df_str}`

Task:
1. Analyze the provided DataFrame, query, expected expression reponse information, previous
    expression, and encountered error.
2. Generate a new expression that solves the query and prevents the error.

Previous Attempt:
Expression: `{previous_expression}`
Error: `{error_encountered}`

Expected Expression Reponse Information:
`{generated_information}`

Instructions:
1. The new expression MUST resolve the query and fix the error encountered previously.
2. The result of the expression MUST be one of the following types: `boolean`, `number`,
    `category`, `list[category]`, or `list[number]`. No other types are allowed.
3. You MUST NOT return a DataFrame, dictionary, or any type not explicitly listed above.
4. The Python expression MUST consist of ONLY ONE line of code and MUST be directly executable using
    the `eval()` function.
5. **STRICTLY FORBIDDEN**: Writing multi-line code, defining variables, or using statements like
    `import`, `print`, or assignments (e.g., `x = ...`).
6. **DO NOT INCLUDE NEWLINES** in the expression. Only provide a SINGLE LINE of code.
7. **PRINT ONLY THE RAW EXPRESSION**: Do not include explanations, comments, or quote the
    expression. The output must be directly evaluable.
8. Ensure the new expression fixes the error while strictly adhering to these rules. Failure to
    comply will result in failure of execution.

*** Pay CLOSE attention to what the query is asking for, it can be tricky. ***
<|eot_id|>
<|start_header_id|>user<|end_header_id|>
Query: `{query}`
<|eot_id|>
<|start_header_id|>assistant<|end_header_id|>Expression:

1 Abstract

Food safety incidents cause serious threats to public health, requiring efficient detection systems. This study contributes to SemEval 2025 Task 9: Food Hazard Detection by leveraging insights from existing literature and using multiple BERT-based models for multi-label classification of food hazards and product categories. Using a dataset of food recall notifications, we applied preprocessing techniques to prepare data and address challenges like class imbalance. Experimental results show strong hazard classification performance on ensembled models such as **DistilBERT**, **SciBERT**, and **DeBERTa** but highlight product classification variability. Building on Tyagi et al. (Tyagi et al., 2023) and Madry et al.'s (Rebuffi et al., 2021) work, we explored strategies like ensemble modeling and data augmentation to improve accuracy and explainability, paving the way for scalable food safety solutions.

2 Introduction

The task at hand which lies in the domain of **Food Hazard Detection**(Randl et al., 2025), focuses on developing explainable machine learning systems to classify food hazard-related reports. This task is crucial as food safety incidents pose significant threats to public health and the global economy, leading to foodborne illnesses and product recalls. The challenge involves two key sub-tasks:

- **Sub-task 1 (ST1)**: Classifying food products and hazards categories from textual data.
- **Sub-task 2 (ST2)**: Detecting precise vector representations for product and hazard.

These tasks emphasize both accurate prediction and explainability to enhance trust and usability in real-world applications. The task overview paper provides detailed insights into the structure and objectives of this challenge. Our main strategy involves leveraging multiple BERT-based models for multi-label classification of food hazards and product categories. We employed an ensemble approach, combining models like `DistilBERT`, `DeBERTa`, and `SciBERT` to improve predictive performance and robustness. Additionally, we utilized preprocessing techniques to clean and normalize the dataset, and applied data augmentation to address class imbalance, ensuring a more diverse and representative training set. By participating in this task, we discovered that ensemble learning significantly enhances model performance, achieving a **macro F1 score of 0.7844 on our internal validation set** for Subtask 1 (and **0.4482** on the official test set). For Subtask 2, the ensembled approach yielded **0.442** in the conception-phase internal validation and **0.0315** in the evaluation test phase. According to the official leaderboard, our system ranked **26th for Subtask 1** and **24th for Subtask 2**.

3 Background

Recent advancements in NLP have enabled automated food hazard detection in consumer reviews. Transformer-based models like BERT classify reviews as "safe," "potentially unsafe," or "unsafe," addressing challenges such as class imbalance and limited data. Maharana et al. fine-tuned BERT on expert-validated e-commerce data, achieving a precision of 0.77, recall of 0.71, and F1-score of 0.74 (Maharana et al., 2019). However, small dataset size and linguistic variability hindered generalization.

In foodborne illness detection, encoder-based transformers (RoBERTa, XLM-RoBERTa) and traditional models (SVM, logistic regression) were compared for classifying 7,546 food recall announcements. A novel GPT-CICLe approach combined Conformal Prediction with GPT-3.5-turbo for few-shot learning, reducing large language

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1351–1356

model usage by 60–98% while maintaining accuracy (Randl et al., 2024). TF-IDF-SVM achieved the highest macro F1 scores (0.58 for hazard-category, 0.59 for product-category), outperforming RoBERTa in low-resource settings.

For automating food safety news impact classification, a stacking ensemble integrated classifiers like Naive Bayes, SVM, XGBoost, CNN, LSTM, and BERT. Combining TF-IDF and Word2Vec embeddings enhanced text representation, achieving an F1-score of 0.8052 (Song et al., 2020). Despite its success, computational complexity and dataset constraints limited real-time applications, prompting future efforts to optimize configurations and explore multilingual datasets. In relation to prior work, our method extends Maharana et al.'s fine-tuning of BERT on e-commerce data (Maharana et al., 2019) by tackling **multi-label classification** of both hazards and products simultaneously, rather than single-label safety judgments. Unlike Randl et al.'s GPT-CICLe few-shot prompts (Randl et al., 2024), we employ **deterministic local augmentation** for reproducibility and scale. Compared to Song et al.'s stacking of heterogeneous classifiers (Song et al., 2020), we focus exclusively on **transformer ensembles** to leverage deep contextual embeddings across domain-specific and general models.

4 Data

The dataset used for evaluation consists of food hazard recall notifications collected from various sources, focusing on food safety. It contains a total of 5,966 rows and 10 columns out of which the 6 required columns for our task are shown in Table 1. The dataset was preprocessed to ensure uniformity and relevance for model training. Numerical identifiers, phone numbers, addresses, dates, and unnecessary fields (e.g., Domestic Est. Number, Recall Class) were removed using regex patterns to prevent bias and maintain privacy. Special characters and excessive spaces were eliminated for consistent formatting, and all text was normalized to a uniform format. These steps optimized the dataset for improved machine learning model performance in classification tasks.

5 Experimental Setup

5.1 BERT Baseline

BERT is based on the Transformer architecture introduced in the paper "Attention is All You Need" (Vaswani et al., 2017). BERT was chosen due to its strong contextual understanding and pre-trained knowledge, making it highly effective for text classification tasks with limited training data. Pre-trained models like BERT allow efficient fine-tuning, improving generalization without requiring large datasets.

Table 1: Overview of the dataset fields

Field Name	Description
title	A brief title of the recall notification.
text	Detailed information about the recall.
hazard-category	The category of the hazard (e.g., biological, allergens).
product-category	The category of the product affected (e.g., meat, dairy).
hazard	The specific hazard identified (e.g., listeria monocytogenes).
product	The specific product involved in the recall.

Table 2: Training Parameters for BERT Baseline Model

Parameters	Values
Epochs	3
Batch Size	8
Logging Steps	10
Warmup Steps	500
Weight Decay	0.01

To optimize performance while maintaining efficiency, specific hyperparameters were selected in Table 2. A batch size of 8 was used to balance memory constraints and training stability. Weight decay (0.01) helped prevent overfitting by penalizing large weights. Three training epochs were chosen as BERT fine-tunes effectively with minimal epochs, ensuring stable training, and allowing frequent weight updates without excessive computational costs.

5.2 Ensemble Methods

To improve the efficiency of our tasks, ensembling approach was used that combined multiple individual models to improve overall predictive performance and robustness. The models chosen were:

1. **DistilBERT:** Faster and smaller than standard BERT model so it is efficient in NLP tasks.

2. **DeBERTa:** Good for High-accuracy NLP tasks.

3. **SciBERT:** Scientific domain specific so good in hazards detection for our task.

Model Selection Rationale We chose **SciBERT** for its pre-training on scientific text, which closely matches the technical language of food recall reports; **DeBERTa** for its disentangled attention mechanism that yields richer contextual representations; and **DistilBERT** to balance throughput and accuracy in inference.

The reason for not choosing only the **BERT-Large-uncased** model directly was that large models are well suited for tasks with a significantly larger dataset and more resource-consuming hyperparameters. Based on the findings by Tyagi et al. (Tyagi et al., 2023) ensembled models perform better than large models, as proven by our results. The reason for this is that ensembling combines the predictions of multiple models to produce a more robust and accurate outcome than any individual model, leveraging the strengths and compensating for the weaknesses of different models.

Table 3: Hyperparameter Settings for Ensemble Technique

Hyperparameter	DeBERTa	SciBERT	DistilBERT
Train Epochs	8	8	8
Batch Size	8	16	16
Logging Steps	10	10	10
Warmup Steps	500	500	500
Weight Decay	0.01	0.01	0.01
Parameters	150 M	110 M	67 M

The hyperparameters as shown in Table 3 were chosen to balance training stability and resource constraints. A train and evaluation batch size of 8 was used for DeBERTa due to limited computational resources, while SciBERT and DistilBERT used a batch size of 16 to maximize GPU utilization and training efficiency. The number of training epochs was set to 8 to allow sufficient fine-tuning without risking overfitting. The weight decay value of 0.01 was applied uniformly to regularize the models and prevent overfitting.

Table 4: Model Parameter Comparison

Model	Parameters (Million)
Ensembled Models	327
BERT Large Uncased	336

Table 4 shows that despite BERT having more parameters than the ensemble models combined parameters, the latter performs better. This is because BERT is well suited for tasks with significantly larger datasets, hence ensembling was the suitable approach to our task given our dataset size.

5.3 Data Augmentation

We initially utilized external APIs with structured prompts to generate class-specific, contextually relevant text to address class imbalance and limited sample diversity. While effective for targeted augmentation, this approach was constrained by API rate limits, key exhaustion, and inconsistent latency. To overcome these limitations, we implemented a deterministic local augmentation pipeline using `nlpaug` and BERT-based contextual embeddings.

This method employed substitution-based augmentation (top_k = 50) using "ContextualWordEmbsAug" with the "bert-base-uncased" model. Semantic similarity was validated through spaCy's "en_core_web_md" model, using an initial acceptance threshold of 0.85, adaptively reduced to a minimum of 0.70 when necessary. Each sample underwent up to 200 augmentation attempts, generating a maximum of 10 high-similarity, semantically coherent variants.

Each class—Hazard and Product—was augmented independently to preserve class-specific semantics and avoid drift. Augmentation was confined within individual class groups to maintain label integrity. Overrepresented classes were randomly undersampled using a fixed seed to meet a target count, while underrepresented classes were synthetically expanded. This explains the reduction in dominant class frequencies, as illustrated in Fig. 1 (Hazard) and Fig. 2 (Product), which show class distributions before and after augmentation.

Two augmentation passes were applied per class, and metadata fields (*augmentation_pass*, *try_number*, *is_augmented*) were retained for traceability. This method, implemented using `nlpaug`, yielded a measurable macro F1 score increase from 0.10 (baseline) to 0.32 after augmentation, reflecting a consistent improvement across all classes. The method is scalable, reproducible, and independent of external services, offering a robust solution for large-scale augmentation. Additional results are discussed in the later sections.

Figure 2: Comparison of Product Class Distribution Before and After Augmentation

6 Results and Discussion

6.1 Subtask 1: Hazard and Product Category Identification

Initially, we fine-tuned the **BERT-base-uncased** model to establish a baseline for performanFce. During training, we recorded key metrics such as training loss, validation loss, accuracy, and F1 score for each epoch, using an 80-20 training-validation split. The macro F1 score, reported in Table 5, represents the result on the test dataset, as obtained by submitting the model predictions to **CodaBench**. This baseline model achieved a macro F1 score of **0.41**.

Subsequently, we adopted an ensemble learning approach, combining multiple models to improve performance. The models included in the ensemble were **DistilBERT-base-uncased**, **DeBERTa-base-uncased**, and **SciBERT-base**, the latter being fine-tuned specifically on scientific data. By averaging the logits from these models to generate final predictions, we significantly improved the macro F1 score, achieving **0.78**.

This improvement aligns with the findings of Tyagi et al. (Tyagi et al., 2023), which suggest that ensemble approaches, leveraging multiple foundational models, can outperform larger individual models, despite the latter having more parameters. To validate this hypothesis, we trained the **BERT-large-uncased** model on the same dataset; however, it achieved only a macro F1 score of **0.52**, demonstrating that the ensemble method outperforms larger single-model configurations.

Additionally, we implemented a Conformal In-Context Learning (CICLe) approach, as proposed by Randl et al. (Randl et al., 2024), which utilizes logistic regression as a base classifier and prompts **Llama-3.1 B** for hazard and product category classification. This approach resulted in a macro F1 score of **0.51**, further contributing to the evaluation of different strategies for model improvement.

Table 5: Performance of various fine-tuned models employed for identifying Hazard and Product categories for conception phase ST 1.

Model(s)	Accuracy	Loss	Macro F1 Score
BERT-base-uncased (baseline)	0.56	9.27	0.41
Ensembled (DistilBERT, DeBERTa, SciBERT)	0.39	1.45	**0.78**
BERT-large-uncased	0.43	5.67	0.52
Conformal In-Context Learning (CICL)	-	-	0.51

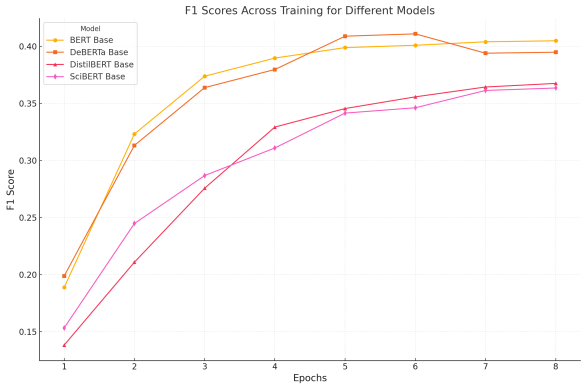

Figure 3: Visual representation of F1 scores across models. The ensembled models show better scores in Macro F1 score as indicated in Table 5.

6.2 Subtask 2: Hazard and Product Identification

For Subtask 2, we directly employed an ensemble of models, including **DistilBERT-base-uncased**, **DeBERTa-base-uncased**, and **SciBERT-base**. Despite the improved model architecture, the extreme class imbalance in this subtask resulted in poor performance, with the models struggling to effectively capture the underlying patterns. Fine-tuning the ensemble on the imbalanced dataset led to a slight improvement, achieving a macro F1 score of **0.12** as indicated in Table 6, which, though better, was still suboptimal for a classification task of this nature.

Table 6: Performance of various fine-tuned models/techniques employed for identifying Hazards and Products for Conception Phase ST2.

Model(s)	Accuracy	Loss	Macro F1 Score
BERT-base-uncased (baseline)	0.32	9.6	0.08
Ensembled (DistilBERT, DeBERTa, SciBERT)	0.53	5.54	0.12
Augmented Ensembled	0.68	4.32	**0.32**

6.3 Quantitative Findings and Analysis

The ensembled models achieved the highest macro F1 score of **0.4482** for Subtask 1 and **0.0315** for Subtask 2 in the evaluation phase. This significantly outperformed the baseline models, demonstrating the effectiveness of model ensembling in handling complex classification tasks.

Ablation studies further confirmed that the ensemble approach consistently outperformed individual models, highlighting the benefits of combining multiple architectures. Additionally, data augmentation played a crucial role in addressing class imbalance, leading to improved model performance.

Phase	Sub-task 1 Score	Sub-task 2 Score
Conception Phase ST1	0.784	0.000
Conception Phase ST2	0.000	0.442
Evaluation Phase	**0.4482**	**0.0315**

Table 7: Scores for Conception and Evaluation Phases

The Conception Phase ST2 score of 0.442 refers to performance on our held-out 20% validation split prior to evaluation-phase tuning. The official evaluation macro F1 (0.0315) was obtained by submitting to the SemEval CodaLab test set, with labels withheld to simulate unseen conditions, which equally weights performance across all label categories irrespective of class distribution. In Task 9, this includes both hazard type and product category labels, requiring robust handling of multi-label imbalance and partial annotations as described in the task formulation (Randl et al., 2025).

7 Conclusion and Future Work

In this paper, we presented our participation in **SemEval 2025 Task 9: Food Hazard Detection**, where we applied advanced BERT-based models to tackle the multi-label classification problem of food hazards and product categories. Although built on established components, our integration of controlled data augmentation with ensemble diversity contributes a reproducible and competitive baseline for food hazard detection under imbalanced conditions. Through extensive experimentation with models such as DistilBERT, SciBERT, and DeBERTa, we achieved strong performance in hazard classification. Our ensemble approach demonstrated promising results, though product classification still exhibited variability, highlighting areas for further improvement. Currently, we are ranked **26** and **24** internationally based on our scores in Subtasks 1 and 2 in the **Submitted** leader-

board.

In the future, the emphasis will be placed on optimizing data augmentations toward mitigating class imbalance issues and building model robustness. Here, extending augmentations over a longer window will diversify and make training data much more representative when considering minority classes. This could include enhancing the diversity of the data with further techniques like domain-specific paraphrasing or leveraging generative approach models for GPT-based synthetic data. Hyperparameters such as learning rate, batch size, and weight decay will also be tuned toward maximizing the model's stability and efficiency. Finally, a study will be performed to discover methods for easing resource consumption while maintaining the performance of the previously underlined concepts to allow for a better level of generalization and scalability in handling a more complex food hazard detection task. The future work will further focus on incorporating multilingual datasets to enhance generalizability, integrating explainability modules such as SHAP or LIME for model transparency, and exploring active learning strategies to iteratively refine the model with user feedback in real-world deployment settings.

8 Limitation

The ensemble approach, combining DistilBERT, DeBERTa, and SciBERT, demonstrated a good performance in hazard classification but faced notable limitations. Despite data augmentation efforts that improved class distributions and boosted overall scores, the models struggled with product classification due to the inherent complexity of diverse product categories and extreme class imbalance. Even after augmentation, synthetic data failed to capture nuanced domain-specific patterns fully. The ensemble's computational complexity also limited real-time deployment, while hyperparameter tuning introduced trade-offs between resource efficiency and training stability. These limitations highlight the need for more advanced augmentation techniques, cost-sensitive learning, or hierarchical classification strategies to address underrepresented classes and improve scalability.

9 Code and Reproducibility

To encourage reproducibility and facilitate future work on food hazard detection, we have made our source code, preprocessing scripts, and configuration files publicly available at:

`https://github.com/HammadxSaj/Sem-Eval-Task09-Dataset`

This repository includes the implementation for all models described in this paper, including BERT fine-tuning, ensemble logic, and data augmentation routines.

Abstract

As the Large Language Model (LLM) gains widespread adoption, increasing attention has been given to the challenge of making LLM forget non-compliant data memorized during its pre-training. Machine Unlearning focuses on efficiently erasing sensitive information from LLM under limited computational resources. To advance research in this area, SemEval 2025 Task 4: "Unlearning Sensitive Content from Large Language Models" introduces three unlearning datasets and establishes a benchmark by evaluating both forgetting effectiveness and the preservation of standard capabilities. In this work, we propose a more controllable forgetting loss, Effective Unlearning Loss, and explore its integration with various techniques to achieve more efficient and controlled unlearning. Our system ultimately ranked 5th on the competition leaderboard.

1 Introduction

Large Language Models (LLMs) have achieved remarkable success across various natural language tasks. However, LLMs tend to memorize sensitive information from their training data, posing potential risks such as privacy breaches and copyright violations (Wang et al., 2024). Malicious attacker can exploit this vulnerability to extract confidential content, leading to unintended exposure. Machine Unlearning has emerged as a research field to address this issue, focusing on the following core challenges(Qu et al., 2023; Li et al., 2025):(1) Preserving essential information and capabilities while ensuring the removal of targeted data. (2) Adapting to different data types. (3) Balancing computational cost and efficiency.

SemEval-2025 Task 4 introduce the challenge "Unlearning Sensitive Content from Large Language Models," aiming to establish a robust benchmark for evaluating the effectiveness of unlearning strategies in LLMs (Ramakrishna et al., 2025a,b). The task encompasses three data categories: long-form synthetic creative documents with different genres, short form synthetic biographies containing personal information, and real documents sampled from the target model's training dataset. Each dataset includes predefined "Forget" and "Retain" sets, and encompasses two evaluation tasks: sentence completion and question-answering. The evaluation not only assesses the success of unlearning but also measures the impact on general capabilities using the MMLU Benchmark. To encourage a balance between computational efficiency and performance, the organizers also impose runtime constraints on submitted solutions.

In this competition, we propose Effective Unlearning Loss (EUL). This aims to erase knowledge related to the data to be forgotten by perturbing the model's gradients during training. We integrate this technique with the standard Supervised Fine-Tuning (SFT) process into a multi-task learning paradigm to ensure controllable unlearning. Additionally, various data processing and augmentation strategies (Choi et al., 2024; Shi et al., 2024) are explored to see their impact on the final performance.

Our contributions are as follows:

- **Introduction of EUL**: This loss is the multiplicative inverse of the original SFT loss. Its inverse property makes it effective in making LLM forget the target knowledge. We integrate it into a multi-task learning paradigm, allowing the model to perform SFT on data that should be retained and EUL on data that should be erased concurrently.
- **Comprehensive Exploration**: We thoroughly investigate the performance of our method under different configurations and data processing/augmentation settings, providing a reliable reference for future research.
- **Competitive Performance**: Our approach

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1357–1369

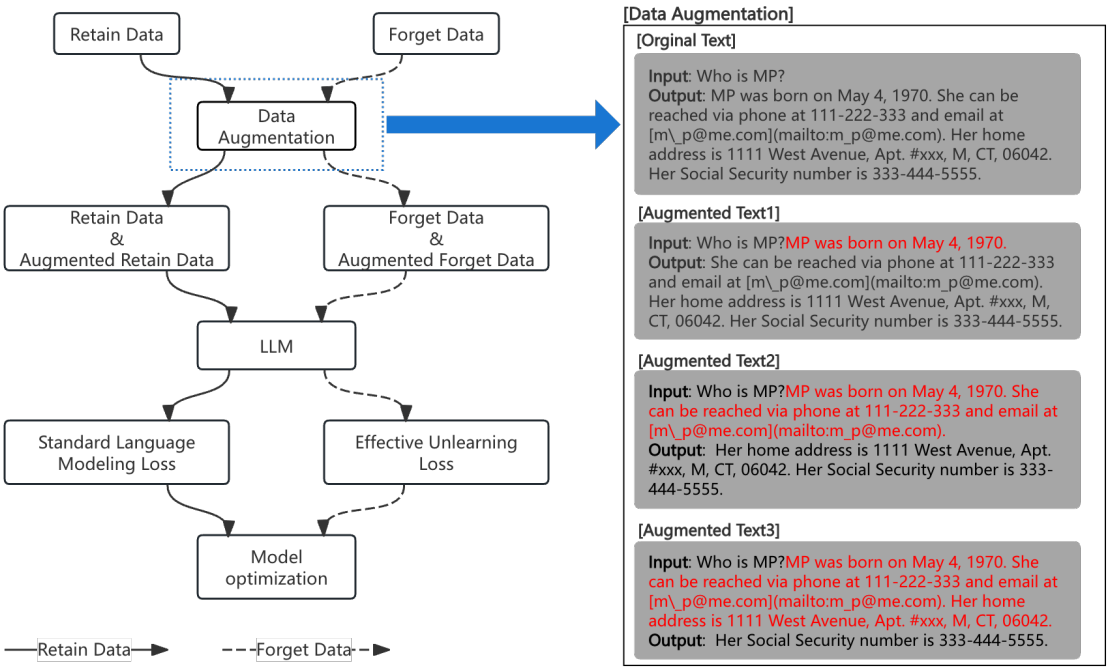

Figure 1: The Overview of Our System.

secures 5th place on the final leaderboard, demonstrating its effectiveness.

2 Background

Research on knowledge unlearning in large language models (LLMs) is an emerging field, with fine-tuning-based unlearning being one of the most common method. This involves retraining the model on datasets containing specific target knowledge to weaken its memory of the unwanted information.

One intuitive unlearning method involves gradient ascent on the forget data, which increases the loss on that data to force the model to forget specified knowledge. However, this often leads to optimization instability and poor performance. To solve this, Veldanda et al. (2024) propose a comprehensive training approach that involves gradient ascent, standard gradient descent on the forget dataset, and minimizing KL divergence to maintain the model's performance on retained knowledge. Similarly, Jang et al. (2022) introduces a gradual gradient ascent approach, which stabilizes the unlearning process and avoids instability.

Another unlearning method involves replacing the forgotten knowledge, such as Choi et al. (2024) and Shi et al. (2024) who replace forgotten answers with negative responses like "I don't know," while Eldan and Russinovich (2023) uses reinforcement learning to identify and replace key phrases. However, Mekala et al. (2024) warns that relying solely on negative feedback for unlearning may result in non-sensical outputs and introduce privacy risks, reducing the model's effectiveness.

In response, we propose a more pragmatic approach to unlearning in LLMs that combines multi-task learning, data augmentation, and EUL to facilitate faster and more efficient knowledge forgetting under constrained resources.

3 System Overview

In this competition, we propose the Effective Unlearning Loss (EUL), which, combined with traditional Supervised Fine-Tuning (SFT), forms a multi-task learning framework. Meanwhile, we observe a significant performance discrepancy between long and short outputs. To mitigate this issue, we incorporate data augmentation. The overall workflow is illustrated in Figure 1.

Section 3.1 provides a detailed introduction of EUL, while section 3.2 demonstrates its integration with the original SFT process to enable multi-task training. Finally, section 3.3 discusses our data augmentation strategies.

3.1 Effective Unlearning Loss

Unlike traditional gradient ascent, we redesign a novel loss function, EUL, which enables the model to achieve the forgetting effect even during gradient descent. The formulation is as follows:

$$L_{EUL} = \alpha \times \frac{1}{L_{ntp}(x_{input}, y_{forget})} \quad (1)$$

Here, $L_{ntp}(x_{input}, y_{forget})$ represents the next-token prediction loss used in conventional SFT, and α is a scaling factor. When the model's output closely aligns with the distribution of the information to be forgotten, the loss increases significantly; conversely, it remains low when the output deviates from that information. Compared to gradient ascent, which can easily lead to model instability, EUL offers a more stable and effective choice, ensuring that the induced forgetting remains within a controlled and safe range.

3.2 Multi-Task Learning

To enable the model to forget specified content while retaining the information we want to keep, we design two tasks: the Forget-Set Task and the Retain-Set Task.

- The Forget-Set Task focuses on the unlearning objective, using data that needs to be forgotten and optimizing the model with L_{EUL}.
- The Retain-Set Task ensures information retention, leveraging non-forgotten data and employing the conventional next-token prediction loss L_{ntp}.

To prevent interference between the two tasks, each batch contains data from only one task at a time. By alternating training between these tasks, the model achieves controlled forgetting in a stable manner.

3.3 Data Augmentation

We observe a long-tail distribution phenomenon in output length within the competition dataset. Further experiments reveal that this imbalance adversely affects model performance. For instance, if the original output is a short text, the unlearning process effectively removes the associated knowledge. However, when the original output is a long text, the unlearning procedure may fail.

To address this issue, we propose a data augmentation strategy based on re-segmentation to balance the distribution of short and long output. Specifically, we segment long output into individual sentences and incrementally move portions of the output into the input, generating shorter outputs as training samples. This process, illustrated in figure 1 right, enhances the model's adaptability to varying output lengths.

In addition, we also try the negative response replace scheme mentioned in (Maini et al., 2024). It achieves the goal of forgetting by replacing sensitive information with the safety terms (for example, "I don't know") and tuning models on it.

4 Experiment

In this competition, the organizers require unlearning to be performed on two models: OLMo-7B and OLMo-1B (Groeneveld et al., 2024). The original tasks include sentence completion and question-answering. To evaluate the effectiveness of unlearning, the organizers propose the following four evaluation metrics:

- **Task Aggregate Score (TAS)**: This metric measures the model's performance across various tasks.
- **Membership Inference Attack Score (MIA)**: This evaluates the extent to which the relevant knowledge is retained or effectively forgotten.
- **MMLU Score**: This measures whether the model's overall linguistic capabilities degrade after the unlearning process.
- **Final Score**: The average of the previous three scores.

We thoroughly explore the impact of different technical combinations on the final unlearning outcome and conduct ablation studies on the modules and hyperparameters. Due to space limitations, all experimental results and analyses presented in the main body of this paper are based on OLMo-1B, with the results for OLMo-7B detailed in Appendix A. All results presented are based on data publicly released by the organizers during the competition period. The results are presented in section 5 and section 6.

All training is performed using LoRA (Hu et al., 2022) for model fine-tuning, with Rank, alpha, and dropout set to 8, 32, and 0.05, respectively. For EUL, α is set as 1. For the training hyperparameters, we use the following settings:$epoch = 5$,

Model Component				Score			
RD	NR	DA	EUL	MIA	TAS	MMLU	Final
×	O	×	×	0.000	0.092	0.281	0.124
×	O	O	×	0.000	0.092	0.278	0.124

5 Result

Table 1 illustrates the impact of different method combinations on performance. Here, EUL denotes Effective Unlearning Loss, NR indicates that the original outputs for the forgotten data are replaced with safety terms. DA is the inclusion of data augmentation during training, RD refers to supervised fine-tuning the data in the retain set, "×" denotes the absence of the corresponding technique, while "O" indicates its application.

The best performance is achieved when using EUL to process forgotten data while incorporating data augmentation and fine-tuning retained data. This success can be attributed to the multi-task training framework, which effectively balances forgetting and retention. Note that although the approaches employing only EUL and the combination of EUL and DA achieve relatively high scores, this performance comes at the significant compromise on the MMLU metric. Such a substantial degradation contradicts the evaluation criteria from the organizers, so we discard them. We derive the following key findings:

- Fine-tuning on retained data is essential, regardless of the chosen technique combination. Experiments omitting RD resulted in a significant drop in MMLU scores, indicating severe degradation in the model's linguistic capabilities.
- Although adding NR improves MMLU, it negatively impacts the unlearning effectiveness. This is due to the small dataset size, making it highly prone to overfitting. In contrast, EUL achieves a better balance between MMLU and unlearning performance.
- Incorporating DA enhances the MIA metric, albeit with a slight trade-off in MMLU. However, since the final score is the average of the three metrics, DA provides an overall positive impact.

Epoch	Step	LR	RD	NR	DA	EUL	MIA	TAS	MMLU	Final
3	484	1.00E-04	O	×	O	O	0.135	0.245	0.272	0.217
6.86	484	1.00E-04	O	×	×	O	0.020	0.103	0.289	0.137
4	646	1.00E-04	O	×	O	O	0.215	0.278	0.270	0.254
9.16	646	1.00E-04	O	×	×	O	0.075	0.265	0.287	0.209
5	807	1.00E-04	O	×	O	O	0.593	0.395	0.275	0.421
11.45	807	1.00E-04	O	×	×	O	0.175	0.306	0.286	0.255

Table 3: Data Augmentation and Training Steps

Due to computational constraints, the most balanced result we obtained before the competition deadline was (RD&NR&EUL). Therefore, our result on the leaderboard is (RD&NR&EUL) result, not our best result. Our best result was (RD&DA&EUL), which showed consistent performance across both OLMo-1B and OLMo-7B. The detailed results can be found in Appendix A.

6 Ablation Study

We also explore the impact of different hyperparamter settings, including learning rate, epoch, magnitude scaling of EUL, and the effectiveness of data augmentation. We present the results in the following sections, which are based on OLMo-1B. The trends for OLMo-7B are consistent with those of OLMo-1B, and all results for both OLMo-1B and OLMo-7B can be found in the Appendix A.

6.1 Hyper-parameters ablation

Table 2 demonstrates the performance variations under different hyperparameters. Due to computational resource limitations, we are only able to test results up to a maximum of 5 epochs. However, it is evident that as the epoch number and learning rate increase, the performance increases

6.2 Data Augmentation and Training Steps

To examine whether the performance improvements from data augmentation are solely due to the increased number of training steps, we conducted a series of controlled experiments, as shown in Table 3. Specifically, we compared models trained with data augmentation for 3, 4, and 5 epochs to models trained for the same number of steps without data augmentation. Although both increasing the number of training steps and applying data augmentation improve prediction performance, the benefit of data augmentation outweighs that of simply increasing training steps.

	MIA	TAS	MMLU	Final
EUL	0.59	0.39	0.28	0.42
EUL^2	0.39	0.22	0.28	0.29

Table 4: Further exploration of EUL capabilities.

6.3 Amplify EUL

To further examine the impact of our EUL approach, we square the EUL to produce more extreme upper and lower bounds for the loss variation. However, as demonstrated in table 4, this magnitude scaling does not yield any noticeable performance improvement.

7 Conclusion

The organizers of SemEval-2025 Task 4 introduce three Machine Unlearning datasets, design to assess unlearning capabilities from multiple perspectives and across various data types. This dataset effectively highlights the key challenges currently faced in Machine Unlearning.

In this competition, we propose a more controllable forgetting loss, EUL, which we integrate with standard Supervised Fine-Tuning (SFT) into a multi-task learning framework. This approach ensures precise unlearning while maximizing the retention of general capabilities. Additionally, we incorporate various data processing and augmentation strategies to further enhance controllable unlearning.

Our experiments demonstrate the effectiveness of EUL and underscored the critical role of standard SFT in training on retained data. Striking the right balance between forgetting and retention is essential for successful unlearning. Furthermore, we introduce an effective data augmentation solution to address the long-tail distribution in text length. Ultimately, our system ranks 5th on the official leaderboard.

Abstract

This paper describes our system for SemEval 2025 Task 7: Previously Fact-Checked Claim Retrieval. The task requires retrieving relevant fact-checks for a given input claim from the extensive, multilingual MultiClaim dataset, which comprises social media posts and fact-checks in several languages. To address this challenge, we first evaluated zero-shot performance using state-of-the-art English and multilingual retrieval models and then fine-tuned the most promising systems, leveraging machine translation to enhance crosslingual retrieval. Our best model achieved an accuracy of 85% on crosslingual data and 92% on monolingual data. [1]

1 Introduction

The spread of misinformation on social media poses a considerable challenge for fact-checkers, who must verify claims quickly and accurately, often across different languages. In our participation in SemEval 2025 Task 7 (Peng et al., 2025), we develop systems that retrieve the most relevant fact-checked claims for a given social media post, irrespective of linguistic differences.

The task is divided into two subtasks:

- **Monolingual Retrieval:** In this subtask, both the social media posts and the fact-checks are in the same language. This setting allows us to focus on language-specific nuances and idiomatic expressions, thereby assessing the system's ability to match claims within a single language.
- **Crosslingual Retrieval:** In this subtask, the social media post and the corresponding fact-checks are in different languages. This scenario reflects real-world situations where misinformation crosses language boundaries, necessitating the alignment of semantic representations across languages.

The task uses a dataset derived from the original MultiClaim dataset (Pikuliak et al., 2023), which includes over 150,000 fact-checks in 8 languages (English, Spanish, German, French, Arabic, Portuguese, Thai, and Malay) and social media posts in 14 languages.

Our approach begins with a preprocessing stage in which raw data is cleaned and summarized to reduce noise and standardize the content. Next, we employ transformer-based models—including LaBSE (Feng et al., 2022), GTR-T5-Base (Ni et al., 2021), and mE5 (Wang et al., 2024)—within a zero-shot evaluation framework to assess their ability to retrieve semantically similar claims across languages. Following the initial evaluation, the most effective models are fine-tuned using the task dataset to improve both precision and recall. An ensemble strategy based on majority voting is then applied to combine the outputs of these models, thereby mitigating the impact of individual model biases. This systematic approach offers a robust methodology for retrieving fact-checked claims in a multilingual context and addresses the challenges associated with misinformation detection.

Our experiments revealed that our ensemble approach consistently enhanced retrieval performance as measured by success-at-10 (S@10), showing an improvement of approximately 3–5 percentage points over the best single-model baseline. At the same time, a closer examination of the results indicates that the system tends to struggle with informal language, ambiguous expressions, and idiomatic usage, particularly in low-resource languages. These observations suggest that further refinement in preprocessing and model adaptation may help address the inherent variability and noise

in social media content.

2 Related Work

Previously Fact-Checked Claim Retrieval (PFCR) is the task of retrieving the most relevant fact-checked claims from a dataset regarding a given social media post. Each claim in the dataset has been reviewed by experts and labeled as either misinformation or not. By ranking and retrieving the most relevant claims, we can infer a label for the post based on its similarity to existing claims.

For each social media post, the system is expected to retrieve 10 most related claims. The evaluation metric is Success@K which is defined as the proportion of cases where a relevant item appears within the top K results returned by a system. A model is considered successful if it includes the correct label within its top 10 ranked responses.

The benchmark includes early contributions from Kazemi et al., 2021, which supported a limited number of languages and primarily focused on specific topics, such as COVID-19. Their dataset originated from WhatsApp, containing 650 post-claim pairs. Despite its limitations, it established a growing research area, inspiring later datasets to expand and refine its scope.

For our study we used MultiClaim, the most comprehensive dataset in the benchmark. MultiClaim is multilingual, covering 39 languages and a wide range of topics while incorporating diverse cultural and social perspectives. It is collected from Facebook, Twitter, Instagram, and Google Fact Check Tools, ensuring broad coverage and diversity. With over 31,000 post-claim pairs, MultiClaim serves as an excellent resource for training models and enhancing fact-checking systems.

The SemEval task consists of two tracks: monolingual and crosslingual. In the monolingual setting, both the post and the claim are in the same language. In contrast, the crosslingual setting involves a post and a claim in different languages, introducing additional challenges for the system. The differences between these tracks and how their respective models operate are illustrated in Figure 1.

3 System Overview

3.1 Preprocessing

In the preprocessing stage, we first cleaned the raw social media data by removing irrelevant elements such as hashtags, emojis, and URLs, which often introduce noise and disrupt semantic analysis. Subsequently, for each post, we concatenated the OCR outputs with the original textual content to create a comprehensive representation. This combined content was then used in both the original language and its English translation, ensuring that subsequent multilingual retrieval tasks could effectively leverage the full scope of available information.

3.2 Summarization

To address the length and noisy nature of social media posts, we applied a summarization step to refine the content, remove irrelevant information, and improve its structure. To generate an effective summarization prompt, we used ReConcile Round Table (Chen et al., 2024) involving three large language models—GPT-4o (OpenAI, 2024), Claude 3.5 Sonnet (Anthropic, 2024), and LLaMA-3.3-70B-Instruct (Meta, 2024). Over three rounds, these models proposed different prompts, and a voting mechanism was used to select the most effective one. The final selected prompt was then provided to summarization models to generate concise and structured summaries, preserving key information while reducing noise.

3.3 Zero-shot experiments

To identify the most effective models for retrieving fact-checked claims, we conducted zero-shot evaluations using several state-of-the-art English and multilingual models. (The models are presented in Tables 3 and 4. These models were selected based on their performance on established benchmarks such as MTEB (Muennighoff et al., 2023) and MMTEB (Enevoldsen et al., 2025). By testing them on the training data, we aimed to assess their ability to capture semantic similarity between social media posts and fact-checks without task-specific fine-tuning. The results of these experiments provided insight into which models were best suited for multilingual claim retrieval and informed our selection of models for further fine-tuning.

3.4 Fine-tuning

Following the zero-shot experiments, we fine-tuned the most effective models using the training data (The models are presented in Tables 5 and 6). To construct the training inputs, each model was given a social media post paired with its corresponding fact-checked claim as a positive sample. The model

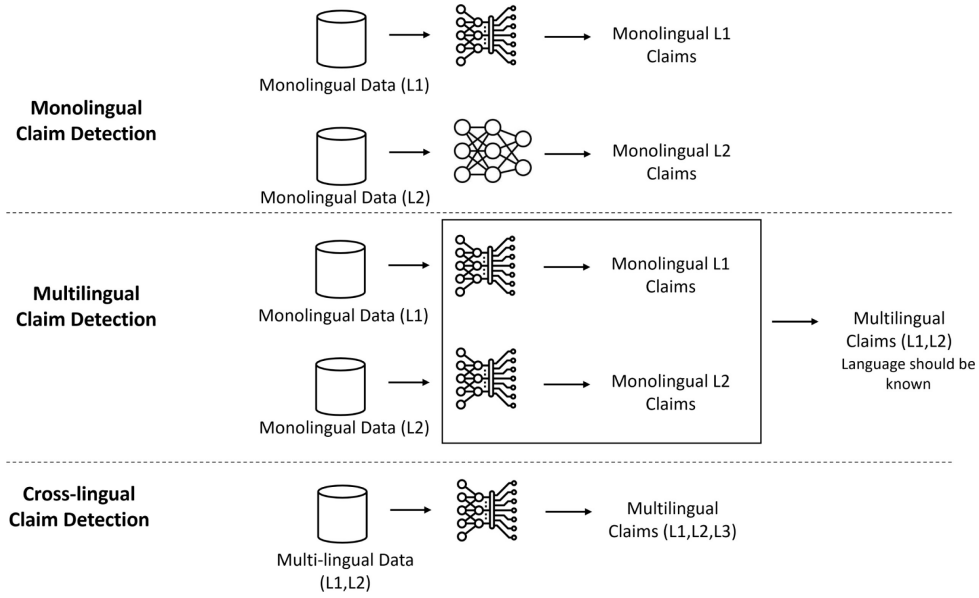

Figure 1: Types of information retrieval including monolingual, multilingual, and crosslingual retrieval illustrated by Panchendrarajan and Zubiaga, 2024

was then trained using the Multiple Negatives Ranking Loss (MNRL), which optimizes the similarity between positive pairs while pushing negative samples further apart. This approach improves the model's ability to distinguish relevant fact-checks from unrelated claims. The loss function is defined as follows:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\log\frac{e^{\text{sim}(q,p_i)}}{\sum_{j=1}^{N}e^{\text{sim}(q,n_j)}} \quad (1)$$

where q represents the query (post), p_i is the positive sample, n_j are the negative samples, and sim denotes a similarity function such as cosine similarity.

3.5 Training Configuration

The following table outlines the hyperparameters used during the fine-tuning process:

Parameter	Value
Batch Size	2 - 16
Learning Rate	1e5 - 3e5
Epochs	1 - 3
Warmup Steps	100
Hardware	(1 - 2) * T4 GPU
Loss Function	MultipleNegativesRankingLoss

Table 1: Training configuration for fine-tuning

This fine-tuning process allowed the models to better capture the semantic relationships between social media posts and fact-checked claims, improving retrieval accuracy.

3.6 Majority Voting

To leverage the strengths of the best-performing models, we applied a majority voting strategy to determine the most relevant fact-checks for each post. For every retrieved fact-check, we assigned a score based on two factors: the confidence of the model in selecting that fact-check, which is the consine similarity of the post and the claim, and the model's accuracy in the corresponding language. The final ranking was determined by summing the scores across all models, and the top 10 fact-checks with the highest scores were selected as the final output for each post. This approach aimed to balance the strengths of different models and improve retrieval robustness across languages.

4 Results

In the summarization phase, we employed several LLMs to reduce text length and eliminate noise. The models used included mT5-multilingual-XLSum (Hasan et al., 2021), BART-large-CNN (Lewis et al., 2019), Falcon3-7B-Instruct (Team, 2024b), Qwen2.5-1.5B-Instruct, and Qwen2.5-7B-Instruct (Team, 2024a), with the latter demonstrating the best performance. We used the last two models to summarize the input text, and the results are presented in Table 2. However, summarization significantly reduced model accuracy. This de-

cline is due to the nature of the fact-checks dataset, which contains many similar instances without direct post-claim mappings in the pairs dataset. As a result, summarization increases the similarity between claims, making it harder for the model to generate distinct embeddings, thereby affecting similarity rankings. For these reasons, we opted to maintain the raw format of the inputs instead of employing summarization.

A wide range of bi-encoder models can be used for information retrieval, each designed to extract embeddings from the input text. By computing the cosine similarity between embedding pairs, we can determine how similar they are. To identify the most effective models, we conducted zero-shot experiments with several candidates, testing multilingual models on the original dataset as well as its English translation. Interestingly, using the English translation typically lowers monolingual accuracy. This is because multilingual models are designed to generalize across multiple languages rather than being optimized for English specifically. However, translating the input text improves crosslingual accuracy. In crosslingual scenarios, where the post and claim are in different languages, multilingual models struggle to generate similar embeddings for semantically equivalent content across languages, leading to better differentiation after translation. We also tested English-specific models, which outperformed multilingual models. Since these models are trained exclusively on English data, they yield the best results when applied to the translated dataset. Overall, multilingual models offer better generalization across languages, while English models excel in single-language tasks. The results of our experiments are presented in Tables 3 and 4.

After conducting multiple zero-shot experiments, we selected the best-performing models and fine-tuned them on the training dataset. The multilingual models were trained on the various languages present in the dataset, while the monolingual models were trained on its English translation. The results are shown in Tables 5 and 6. Fine-tuning significantly improved model performance, highlighting its role in adapting to dataset-specific patterns. Figure 2 illustrates this effect in both monolingual and crosslingual settings, demonstrating substantial improvements across models—except for the UAE-Large-V1 model, which overfit rapidly and failed to generalize to test data.

Notably, fine-tuning benefited the crosslingual setting more than the monolingual one. This is

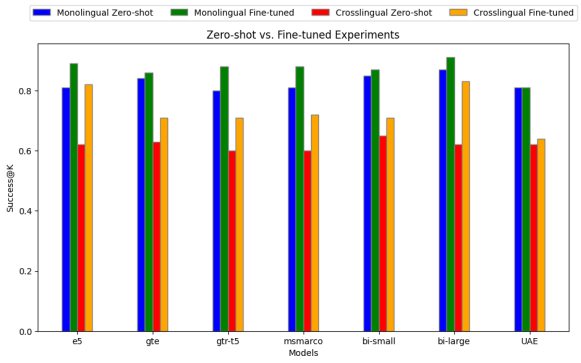

Figure 2: Zero-shot vs Fine-Tuning Performance (S@10)

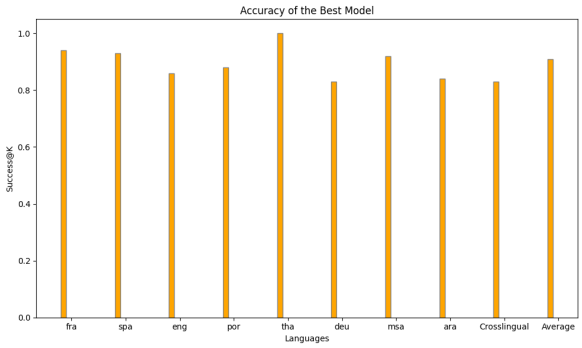

Figure 3: The best model's performance (S@10) on different languages

because multilingual models, not being explicitly optimized for information retrieval tasks, rely on fine-tuning to better learn cross-language mappings. Figure 3 further reveals accuracy discrepancies across languages. English, having the largest fact-checking portion in the dataset, presents greater difficulty in retrieving exact matches, leading to lower accuracy. In contrast, languages with smaller fact-checking portions, such as Thai, achieve higher accuracy due to the availability of more distinct examples. Additionally, some languages like Arabic, suffer from lower accuracy due to limited training data and reduced model familiarity.

While a single model may achieve the highest overall performance, it does not necessarily produce the best results across all languages and scenarios. To address this, a voting mechanism can be employed to leverage the strengths of multiple models, leading to more robust and accurate predictions. The results of this approach are presented in Table 7.

5 Conclusion

In this study, we developed a system for retrieving fact-checked claims from a multilingual dataset. The system uses several stages, including data preprocessing, summarization, zero-shot evaluation, fine-tuning, and an ensemble majority voting approach to match social media posts with relevant fact-checks. Our experiments show that fine-tuning improves performance, especially in crosslingual settings when combined with machine translation. The ensemble strategy also helps to overcome the limitations of individual models, leading to high accuracy in both crosslingual and monolingual tasks.

However, the results reveal some challenges, such as managing informal language and ambiguous expressions, particularly in low-resource languages. Future work should focus on enhancing preprocessing methods, exploring alternative summarization techniques, and incorporating more language resources to improve overall system robustness. Overall, this study provides a clear and effective framework for fact-checked claim retrieval, which is essential for addressing the spread of misinformation.

Abstract

This paper describes our approach to the SemEval-2025 Task 7: Multilingual and Cross-lingual Fact-Checked Claim Retrieval on cross-lingual data. In this study, we developed a system to tackle the verified claim retrieval task, where the objective is to identify relevant, previously fact-checked claims from multilingual data based on a given input claim. We leveraged LLaMA, utilizing its ability to evaluate the relevance of retrieved claims within a retrieval-based fact-checking framework. This approach aimed to explore the impact of large language models (LLMs) on retrieval tasks and assess their effectiveness in enhancing fact-checking accuracy. Additionally, we integrated various embeddings, including e5-large, Jina embeddings, and the MPNet multilingual sentence transformer, to filter and rank a set of 500 candidate claims. These refined claims were then used as input for LLaMA, ensuring that only the most contextually relevant ones were assessed. Our team in the cross-lingual track scored s@10 0.57.

1 Introduction

The rapid proliferation of misinformation in recent years has raised significant concerns across governments, organizations, and individuals. False information spreads rapidly through online platforms, influencing public opinion and decision-making(Vosoughi et al., 2018). To combat this, numerous fact-checking organizations, such as FactCheck.org and Snopes, have emerged to manually verify claims. However, manual fact-checking is labor-intensive and struggles to keep pace with the high volume of misinformation circulating online (Thorne and Vlachos, 2018).

Misinformation is a global issue, requiring fact-checking solutions that extend beyond monolingual settings. To address this challenge, researchers have developed automated fact-checking systems, including verified claim retrieval, where the goal is to find previously fact-checked claims relevant to an input claim (Mansour et al., 2023). This task is particularly crucial as many false claims resurface in different forms across time and languages. While prior work has largely focused on monolingual claim retrieval, real-world misinformation often transcends language barriers, making multilingual claim retrieval a pressing issue.

As illustrated in Figure 1, we tackle multilingual verified claim retrieval by leveraging LLaMA (Touvron et al., 2023), a large language model (LLM) capable of understanding and retrieving fact-checked claims across different languages. To enhance retrieval precision, we incorporate Jina embeddings v2 (Günther et al., 2023)and the MPNet multilingual sentence transformer (Song et al., 2020), filtering and ranking candidate claims before passing them to LLaMA. By extending verified claim retrieval to a multilingual setting, we contribute to developing cross-lingual fact-checking systems that help mitigate misinformation more effectively.

2 Related Work

Multilingual Claim Retrieval. Pikuliak et al. (2023) introduced MultiClaim, the largest dataset for multilingual claim retrieval, featuring 28k posts (27 languages) and 206k fact-checks (39 languages). Their study shows that supervised fine-tuning improves retrieval performance over unsupervised methods.

Monolingual Claim Matching. Previous work has explored retrieval-based ranking for claim matching, using BERT and BM25 to rank check-worthy claims (Shaar et al., 2020). However, their dataset focused only on political claims in monolingual settings.

Cross-Lingual Claim Matching. Efforts to match social media claims with fact-checks across languages have utilized XLM-RoBERTa, BM25, and

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1377–1382

LaBSE (Kazemi et al., 2022). While effective monolingually, cross-lingual performance remains a challenge.

Multimodal Fact-Checking. *RAGAR: Your Falsehood Radar* explores Retrieval-Augmented Generation (RAG) for political claims, integrating textual and image inputs. While CoRAG and ToRAG reasoning techniques improve verification, reliance on GPT-4V (closed-source) limits adaptability (Khaliq et al., 2024).

End-to-End Multimodal Verification. An SBERT-BART framework combines evidence retrieval, claim verification, and explanation generation (Yao et al., 2023). However, SBERT struggles with cross-modal reasoning, affecting its ability to integrate text and visual data effectively.

3 Task Definition and Dataset

3.1 Task

The task at hand is for us to develop an effective system that is capable of retrieving previously fact-checked claims across multiple languages using a large language model (LLM), specifically leveraging LLaMA-3 8 B-Instruct (Large Language Model Meta AI). We selected LLaMA-3 8B-Instruct (Touvron et al., 2023) for our post-filtering step due to its strong performance in instruction-following tasks, especially in natural language inference (NLI) and zero-shot classification, which aligns closely with determining whether a fact-check is relevant to a given social media post. Our purpose is to increase the effectiveness in the identification and validation of claims associated with posts in different languages, using a model trained to differentiate between correct and incorrect claims based on historical data.

Our trained system will process a set of claims and determine whether each claim is relevant to the post. Our objective of this research is to develop an automated fact-checking system that can process multilingual claims and retrieve the most relevant facts for verification. The metric we used, "success@k," is a family of metrics that focuses on the performance of the top-k retrieved results We use this as it is crucial because, in many real-world scenarios, users primarily interact with the first few results. To be concise, Success@k metrics provide a way to evaluate the effectiveness of retrieval systems by focusing on the quality of the top-k results.

3.2 Dataset

This study utilizes the MultiClaim dataset, a large-scale multilingual dataset specifically designed for previously fact-checked claim retrieval (Peng et al., 2025). The dataset was built on top of the dataset by Pikuliak et al. (2023), which consists of 28,092 social media posts in 27 languages, 205,751 professionally fact-checked claims across 39 languages, and 31,305 verified post-claim connections, making it the most extensive and linguistically diverse dataset of its kind. The task organizers further introduced new data, including Turkish and Polish as new languages.

The dataset includes machine-translated versions of each post and claim, along with relevant metadata, enabling cross-lingual retrieval. The social media posts, primarily sourced from platforms such as Twitter and Facebook, frequently reference key political figures (e.g., Donald Trump) and organizations like the World Health Organization (WHO). The maximum post length in the dataset is 1,250 words, while fact-checked claims, particularly those related to political discourse, have a maximum length of approximately 600 words.

For evaluation purposes, we utilize the predefined post-claim pairings curated by the Task organizers, ensuring high-quality ground-truth data for retrieval-based fact-checking (Pikuliak et al., 2023).

4 System Overview

4.1 Pre-processing

Our preprocessing pipeline Figure 1 begins by cleaning and organizing raw posts and fact-checking claims, separating the original text, translations, and scores, while replacing missing "text" with OCR-extracted content. Next, we enrich the dataset by incorporating claim titles and summaries, merging all information based on predefined post-claim pairs, and splitting it into training, validation, and test sets.

Simultaneously, we extract names from URLs as extra metadata, clean the text, and generate summaries using LSA (latent semantic analysis) of the combined fields in our dataset using basic text analysis techniques. The final dataset undergoes language-specific cleaning (via spaCy, Stanza, and regex), alongside Unicode normalization, emoji

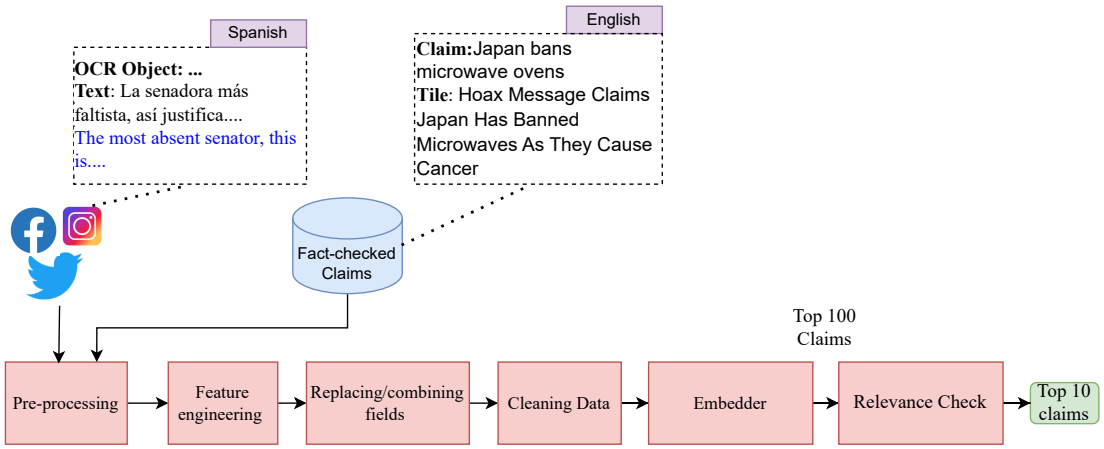

Figure 1: A complete overview of the system. We apply pre-processing steps for cleaning pairs of posts and fact-checked claims, vectorize them with Jina embeddings and finally rerank them with Llama.

conversion, and translation (if needed) to ensure standardized, low-noise text. These steps enhance the quality of embedding generation and summarization for downstream tasks.

4.2 Prompting Methodology

The related works showed that LLMs performed better when the prompt had details (Peskine et al., 2023). Our approach Figure 2 uses a structured, instruction-based prompt (zero-shot) with a task description to classify text into "relevant" or "not relevant" on similarity. We use zero-shot without description to assess the abilities of our prompt if no definition is provided as well. With these prompts, we can understand how adding details to the prompt increases the accuracy of our result. We further ask the model to give us a score according to the relevancy, and according to that we sort our claims for our top 10 result.

4.3 Evaluation

The system will take a given social media post, generate its semantic representation using state-of-the-art embedding models, and compare it against a database of verified claims. The system is designed to work in multiple stages, beginning with data preprocessing, where both posts and claims are normalized and tokenized to ensure consistency.

4.3.1 Models

Next, multilingual embeddings are generated separately for posts and claims to capture semantic similarities across different languages. We use embeddings for research such as jina embeddings, multilingual-e5-large-instruct and mpnet-multilingual: Jina embeddings v2 by Günther et al. (2023), which relies on English translations and filters out 500 claims for our LLaMA model; and second, paraphrase-multilingual-mpnet-base-v2, which processes posts and claims in their original languages and filters out 500 claims. MPNet introduces a novel pre-training approach that combines the strengths of BERT and XLNet while ad-

Instruction:

Your task is to classify the following claim based on the provided list of evidence. You must also produce a confidence score for your classification.

Definition:

- **Claim**: A statement that asserts something to be true, factual, or believable. It may be a fact, an opinion, or a prediction that can be verified or debated. - **Post**: A piece of text, often from social media, that is user-generated and may or may not be verified. Posts can include opinions, observations, rumors, or misinformation.

Task:

Determine whether the claim is relevant to the post. Answer with - **Relevant**: if claim is relevant to post. - **Not-Relevant**: The claim is not relevant to the post. 4. Assign a confidence score between 0 and 1 based on how strongly the post supports the claim.

Guidelines:

- Carefully evaluate the relationship between the claim and the evidence. - Avoid making assumptions beyond the provided evidence. - Focus on the specific information presented in the evidence list. - The JSON response should strictly adhere to the following format: "'json "label": "Relevant", "score": 0.7

Post: Some studies suggest that drinking coffee may improve focus, but the evidence is not conclusive.
Claim: Drinking coffee improves focus.

Response: Relevant 0.5

Figure 2: Prompt that we used for relevance check

dressing their respective limitations, which is better for our embedding generation (Song et al., 2020). Lastly multilingual-e5-large-instruct (Wang et al., 2024), which is a state of the art multilingual text embedding model based on xlm-roberta-large. It is instruction-tuned, enhancing the quality of the embeddings.

4.3.2 Claim Ranking and Retrieval:

As mentioned before, we have utilized Llama as our model for selecting the top 10 claims for each post. For this purpose, we use our Llama model in a zero-shot setting (with and without task description). To refine the retrieved claims, an additional verification step using our LLaMA model determines whether the claim is relevant or not, along with a score ranging from 1 to 0, where 1 indicates it is highly relevant and 0 indicates it is not relevant at all. The final output is a ranked list of fact-checks, providing users with the most relevant and reliable information to verify the claim. The ranking is done by utilising the score provided by Llama. The system is designed to be efficient, scalable, and applicable across multiple languages, addressing the growing challenge of misinformation in the digital space.

4.3.3 Experimental Setup

We use Llama as we want to explore the possibility of how well can LLM perform as a fact retriever on different prompt settings. As mentioned above, we use MPNet multilingual and multilingual e5-large [1] for a purely cross-lingual setting that captures nuanced language variations, making it highly effective in cross-lingual claim retrieval. It helps in providing a balance between semantic understanding and efficiency, improving relevance ranking. Its context-aware embeddings ensure better alignment across different languages. We use Jina embeddings [2] for retrieving the top 500 claims using English translations and then map them to the original language, which is then given to Llama. For retrieval, cosine similarity is computed between a given post and the fact-check claims, and the top 500 claims with the highest similarity scores are selected for further evaluation.

[2] https://huggingface.co/jinaai/jina-embeddings-v2-base-en

5 Results

We are using success@10 as our metric for explaining how well our model performed. This measures the probability or percentage of times that at least one relevant item is found within the top 'k' results of a ranked list. If our retrieved result contains the correct claim from the top 10 claims, we add to our score 1 else, it is 0. LLaMA excels in multilingual claim retrieval due to its strong contextual and semantic understanding. Its attention-based architecture helps detect reworded claims across languages. We find that adding details to the prompt further improves accuracy by aligning it with fact-checking datasets.

Metric Success@10	Value
Llama zero-shot	11%
Jina	55.2%
e5-large	54.3%
MPnet	22%
Llama + Jina (task description)	57.7%
Llama + e5-large(task description)	54.3%
Llama + MPNet (task description)	38.6%

Table 1: Summary of Results. The fine-tuning

We evaluated zero-shot learning, MpNet, e5-large and Jina embedding for claim verification. According to our results table 1, simple **Zero-shot** learning performed poorly as the model failed to understand the task without details, but **zero-shot with task description** was better in results. We also see that the choice of embedders plays an important part in our accuracy, as E5-large performs better than MpNet, and Jina embeddings are much better than E5-large. Jina embedding outperformed both, excelling in semantic similarity and factual consistency, making it more effective for nuanced claim verification. However, it still faced challenges with implicit entailment, requiring external world knowledge.

Our results showed that LLaMA provided a success value of 57.7% using Jina embeddings based on the metric success@10. Although a few competitors achieved higher rankings, our system performed well overall.

6 Conclusion

In conclusion, our approach to retrieving previously fact-checked claims using the LLaMA model across multiple languages has shown promising

results, achieving a success@10 value of 55.7 percent. This demonstrates that LLaMA can effectively assist in automating fact-checking tasks, making the process more efficient and scalable. LLaMA performs well in multilingual claim retrieval because it has a strong understanding of context and semantics across different languages. As a large language model (LLM), it is trained on diverse multilingual data, allowing it to recognize paraphrased or reworded claims. Its attention-based architecture helps it detect long-range dependencies, making it effective in finding related fact-checked claims even when the wording differs. Additionally, using LLaMA with task description prompt on claim verification tasks improves its accuracy by aligning its understanding with real-world fact-checking datasets. While the current success rate is encouraging, further refinements and optimizations are needed to improve the accuracy and reliability of claim retrieval across diverse languages.

Despite its strengths, LLaMA has some limitations. It sometimes overgeneralizes, meaning it might incorrectly match a claim with a similar but factually incorrect statement. Additionally, since LLaMA is not a dedicated fact-checking model, it may hallucinate relationships between claims that do not exist.

Abstract

The *Unlearning Sensitive Content from Large Language Models* task aims to remove targeted datapoints from trained models while minimally affecting their general knowledge. In our work, we leverage parameter-efficient, gradient-based unlearning using low-rank (LoRA) adaptation and layer-focused fine-tuning. To further enhance unlearning effectiveness, we employ data chunking by splitting forget data into disjoint partitions and merging them with cyclically sampled retain samples at a pre-defined ratio. Our task-agnostic method achieves an outstanding forget-retain balance, ranking first on leaderboards and significantly outperforming baselines and competing systems.

1 Introduction

Large Language Models (LLMs) have revolutionized natural language understanding and generation, spanning a large range of tasks such as question-answering (Kamalloo et al., 2023), reasoning (Giadikiaroglou et al., 2024), summarization (Zhang et al., 2024a) and others, showcasing unprecedented scalability and adaptability to novel tasks. However, this remarkable progress is accompanied with several challenges, one of them being their tendency to memorize data (Carlini et al., 2021), leading to the inadvertent leakage of private and copyrighted information, an issue tied to several practical implications (Seh et al., 2020; Herrera Montano et al., 2022; Yan et al., 2024).

In response to the ethical and legal reverberations, the area of *machine unlearning* has gained prominence, focusing on the deletion of targeted information from trained models. Initial unlearning endeavors bridge the gap between data protection (Bost et al., 2015; Bonawitz et al., 2017) and differential privacy (Dwork and Roth, 2014; Papernot et al., 2016), focusing on removing individual data points from classifiers (Ginart et al., 2019). Such seminal works pose the main challenge of unlearning, which targets deleting individual data points *without* re-training the whole network from scratch. Still, challenges such as the catastrophic forgetting (Nguyen et al., 2020), as well as the stochasticity (Bourtoule et al., 2020) and incremental nature (Koh and Liang, 2017) of training, showcase the emerging particularities of unlearning algorithms.

The convergence of unlearning and LLMs arises as a nascent research field accompanied by several challenges, due to their vast and opaque pre-training, large-scale data inter-dependencies, and unbounded label spaces, making it difficult to identify and isolate specific data representations within the model, not to mention efficiently removing them (Yao et al., 2024b). In our work, we explore unlearning strategies on trained LLMs, primarily focusing on fine-tuning, successfully deleting targeted data points without deteriorating the LLM's general knowledge. Specifically, we investigate parameter-efficient gradient-based methods (Jang et al., 2022; Yao et al., 2024a) leveraging data chunking to improve unlearning effectiveness. To achieve this, we employ low-rank adaptation (LoRA) methods (Hu et al., 2021) or selectively fine-tune only the last layers of the model. This approach not only enhances training speed and efficiency, but also introduces a regularization effect mitigating catastrophic collapse by preserving a portion of the base model's weights. As a result, our approach ranked first, surpassing the second best by a large margin. In summary, our method:

1. Leverages parameter-efficient fine-tuning.
2. Achieves near-perfect forget-retain quality.
3. Preserves the model's reasoning abilities avoiding catastrophic collapse.
4. Generalizes well on various data distributions making it robust and widely applicable.

The code for our system is available on GitHub[1].

2 Background

Task description Adhering to the established unlearning frameworks, this task introduces a novel dataset which comprises a *retain* set D_r and a *forget* set D_f (Ramakrishna et al., 2025a,b). The goal is to unlearn information contained in the *forget* set without affecting information present in the *retain* set or degrading the performance of the model on general tasks. Data are divided into three subtasks spanning various language styles: long-form synthetic creative stories, short-form synthetic biographies containing personally identifiable information (PII) and real Wikipedia documents. Moreover, each subtask comes in two types: whole sentences for sentence completion (SC) and question-answer (QA) pairs. Examples are presented in Table 1, while more analysis follows in App. A.

Related work Machine unlearning has gained widespread attention (Xu et al., 2023), driven by emerging data privacy concerns and the pursuit of model robustness. Unlearning was first explored under partitioning data into disjoint sets to impose re-training only on the shards on which forgetting has been requested (Bourtoule et al., 2020). To relieve the burden of full retraining for the affected shard, Neel et al. (2020) propose a method that achieves statistical equivalence between the post-deletion state and the state that would have existed without deletion. Forget-and-relearn (Zhou et al., 2022) removes undesirable features and then enforces learning 'good' ones. Deviating from retraining, Jang et al. (2022) utilize gradient ascent (GA) instead of gradient descent to achieve targeted unlearning with only a few parameter updates. GA serves as a practical unlearning strategy in LLMs (Yao et al., 2024a,b), efficiently intervening with token probabilities, making undesirable generations improbable. Incorporating well-suited loss functions and data-adaptive LoRA initializations helps to resolve GA instabilities when combined with LoRA tuning for unlearning (Cha et al., 2024).

Limitations of Gradient Ascent In practice, GA is performed by negating the prediction loss and applying gradient descent as usual. However, pure GA application poses significant challenges, primarily due to the nature of commonly used loss functions which are bounded from below but not above. When negated, they become unbounded from below, removing meaningful minima and often leading to catastrophic collapse. Due to this instability, GA is typically applied for only a few steps before divergence occurs. Furthermore, most of the research so far focuses on unlearning relatively small amounts of data compared to retain data size (Maini et al., 2024). When GA is extended to larger unlearning datasets, as is the case in this task, instability worsens, causing rapid divergence.

To mitigate these issues, *gradient difference*, which combines GA on unlearning data with gradient descent on retain data, aims to guide the model more stably through the parameter space and prevent its collapse. Another promising avenue leverages *Negative Preference Optimization (NPO)* (Zhang et al., 2024b), where the loss function, inspired by preference optimization with negative examples only, remains lower-bounded and stable. While we do not explore NPO in our work, the limitations of GA underscore the necessity of stabilization mechanisms, shaping the motivation for our proposed approach.

3 System Overview

We propose a novel training scheme for unlearning by introducing modifications and extensions to the

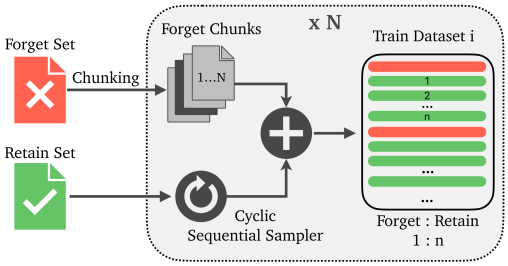

Figure 1: Dataset construction for *Sequential Unlearning*. The forget set is partitioned into N chunks of fixed size, processed sequentially. Retain samples are drawn cyclically to maintain the forget-to-retain ratio $(1 : n)$. This process repeats for N iterations.

gradient difference framework. A key aspect of our approach is partitioning the forget set into distinct chunks and processing them sequentially. This design is inspired by Jang et al. (2022), who suggest that sequential unlearning enhances stability.

3.1 Sequential Unlearning with Gradient Difference

At its core, our approach integrates gradient ascent and descent by jointly optimizing retain and forget data samples in a suitable predefined ratio.

As Figure 1 illustrates, our system employs multiple independent trainers, each sequentially processing a distinct data chunk. The forget set $\mathcal{D}_f$ is partitioned into N disjoint, sequentially processed chunks, $\mathcal{D}_f^1, \mathcal{D}_f^2, \ldots, \mathcal{D}_f^N$. Each chunk $\mathcal{D}_f^i$ is combined with a subset of retain data $\mathcal{D}_r^i$, sampled cyclically and sequentially from the full retain set $\mathcal{D}_r$. Sequential sampling guarantees that samples in $\mathcal{D}_r^i$ are drawn in the same order as they appear in $\mathcal{D}_r$, preserving their relative positions. Cyclic sampling ensures that once the end of $\mathcal{D}_r$ is reached, sampling resumes from the beginning. Also, retain and forget samples are interleaved in a fixed pattern: each forget sample is immediately followed by exactly n retain samples, ensuring a strict ordering throughout training (Figure 1).

The positive integer n determines the proportion of retain to forget samples per chunk, such that: $|\mathcal{D}_r^i| = n|\mathcal{D}_f^i|$ for all $i \in \{1, \ldots, N\}$. This setup ensures continuous exposure to retain data while facilitating effective unlearning. A higher n plays a key role in stabilizing gradient updates, as a value equal or close to 1 can lead to catastrophic collapse.

During training, the loss for forget data is negated, effectively flipping the gradient direction to perform gradient ascent, while standard gradient descent is applied to retain data. Cross-entropy loss

Algorithm 1 Sequential Unlearning with GradDiff

Require: Forget set $\mathcal{D}_f$, Retain set $\mathcal{D}_r$, Chunk size chunk_size, Retain-to-Forget ratio n, Learning rate η, Model parameters θ

Partition $\mathcal{D}_f$ into $N = \lceil |\mathcal{D}_f| / \text{chunk\_size} \rceil$ chunks:

$$\mathcal{D}_f = \{\mathcal{D}_f^1, \ldots, \mathcal{D}_f^N\}$$

for $i = 1$ to N **do**
  Construct $\mathcal{D}_r^i$ by cyclically sampling from $\mathcal{D}_r$ such that $|\mathcal{D}_r^i| = n|\mathcal{D}_f^i|$
  for each optimization step **do**
    Perform forward pass on $\mathcal{D}_f^i \cup \mathcal{D}_r^i$
    Compute average loss for each set:

$$L_{\text{f}} = \frac{1}{|\mathcal{D}_f^i|} \sum_{\mathcal{D}_f^i} \text{CE}(y, \hat{y}), \quad L_{\text{r}} = \frac{1}{|\mathcal{D}_r^i|} \sum_{\mathcal{D}_r^i} \text{CE}(y, \hat{y})$$

    Compute total loss: $L_{\text{total}} = -L_{\text{f}} + L_{\text{r}}$
    Update model parameters: $\theta \leftarrow \theta - \eta \nabla_\theta L_{\text{total}}$
  end for
end for

is used for both retain and forget samples, with the final loss before backpropagation computed as:

$$L = -L_{\text{forget}} + L_{\text{retain}} \tag{1}$$

This process, formally defined in Algorithm 1, effectively applies the gradient difference framework to update model parameters. For each chunk, a new trainer is initialized from scratch on the same hyperparameters, including the initial learning rate, number of epochs and scheduler. Training dynamics remain fully independent across trainers and each iteration follows the standard training procedure, with the only variation being the dataset update as new chunks are processed. An alternative method based on separate and alternating forgetting and retention phases was also explored, and we provide details of this approach in Appendix E.

We underline that our approach is *task-agnostic*, treating all data uniformly without task-specific adjustments. This not only simplifies the method but also enhances generalization and robustness across varying data distributions. To update the model efficiently, we focus on parameter-efficient fine-tuning, either leveraging LoRA adapters, applied both to query-key-value matrices and fully connected layers, or selective fine-tuning only on the last k layers, while keeping the rest of the model frozen. We experiment extensively with both techniques and report results for both of them in Appendix C.2. The final submitted solution utilizes the LoRA method which appears to achieve superior and more consistent overall performance on both train and validation splits.

4 Experimental setup

Dataset The retain and forget data ratio is ∼1:1 across all splits and subtasks. The *train* and *validation* splits were released before evaluation to facilitate experiments and hyperparameter tuning. The final evaluation is conducted on a private, held-out *test* set, closely matching the train set in both size and retain-forget ratio. Table 2 provides a breakdown of sample counts per split and subset (more details in App. A).

Split	Retain	Forget
Train	1136	1112
Val	278	254
Test	xx	xx[2]
Total	2188	2206

Table 2: Size of retain and forget subsets per split.

Unlearning model The organizers released two models of different sizes for system evaluation: one 7B parameter based on *OLMo-7B-0724-Instruct-hf*, and another 1B parameter based on *OLMo-1B-0724-hf*. Both models were fine-tuned to memorize documents from all three subtasks.

Hyperparameters Extensive -yet non-exhaustive- experimentation is conducted on the 7B model to determine our optimal hyperparameters. Key hyperparameters include chunk size, forget-retain ratio, learning rate, number of unlearning epochs per chunk and (effective) batch size. Furthermore, we tune the LoRA parameters r and $alpha$, as well as the number of the last k layers for the Last-k fine-tuning method. We begin with a random search over a coarse range of values for the above variables using the relatively small validation split. We then proceed with more targeted experiments using the larger train split until we converge to the final configuration presented in Appendix B where we discuss specific choices and trade-offs.

Evaluation is based on the following metrics: (1) **Task-Specific Regurgitation**: measured by ROUGE-L and Exact Match (EM) rate, both within [0-1], where higher values indicate better alignment with reference outputs. ROUGE-L captures the longest common subsequence (LCS) for SC prompts, while EM assesses exact matches for QA pairs. High scores are desirable for the retain set (preserving knowledge), whereas for the forget set, lower scores denote better unlearning (they are transformed as $1 - value$ to align with "higher is better"). (2) **Membership Inference Attack (MIA)** assesses unlearning effectiveness using the AUC-ROC of loss distributions between member and non-member data. A score around 0.5 indicates ideal unlearning (random inference). AUC-ROC scores close to 1 suggest *under-unlearning* (retaining forget data), while those close to 0 signal *over-unlearning* (altering behavior beyond intended forgetting). The final score is adjusted as $1 - 2 \times |AUC - 0.5|$, ensuring a [0-1] scale where higher values reflect better unlearning. (3) **MMLU Benchmark** evaluates knowledge-based reasoning averaged across 57 STEM subjects. Submissions with MMLU accuracy dropping below 0.371 (75% of the pre-unlearning checkpoint) are discarded.

The submissions are ranked according to the arithmetic mean of the i) harmonic mean over 12 subtask scores (2 sets {retain-forget} × 3 subtasks × 2 evaluation types), hereinafter referred to as Task Aggregate (TA) ii) MIA score and iii) MMLU average. The final score is computed as follows:

$$\frac{1}{3}\left(H\left(S_{t,e}^{\text{retain}}, 1 - S_{t,e}^{\text{forget}}\right) + S_{\text{MIA}} + S_{\text{MMLU}}\right), \quad t \in \{1,2,3\}, \quad e \in \{\text{ROUGE-L}, \text{EM}\} \quad (2)$$

where H(·) stands for *harmonic mean*, t denotes the subtask and e the evaluation type.

5 Results

Our method achieves leading performance based on the final evaluation score. Table 3 shows the results compared to baselines and the 2^{nd} best submission.

Method	Final Score ↑	Task Aggregate ↑	MIA Score ↑	MMLU Avg. ↑
GA	0.394	0	0.912	0.269
GDiff.	0.243	0	0.382	0.348
KL	0.395	0	**0.916**	0.269
NPO	0.188	0.021	0.080	0.463
2nd best	0.487	**0.944**	0.048	**0.471**
Ours	**0.706**	0.827	0.847	0.443

Table 3: Benchmark of unlearning algorithms on the private test set for the 7B model.

Experimentation shows that there is a trade-off between TA and MIA, clearly reflected in other teams' submissions. Some of them manage to achieve near-perfect TA with minor degradation on MMLU, yet MIA remains extremely low (e.g.

[2]The exact number of samples used for evaluation by the organizers is unknown.

Table 4: Examples of the unlearned model's outputs, a strong and a weak one for each set (forget, retain) from the train split. We include QA pairs only because of limited space, but results regarding SC are illustrated in App. D.

2^{nd} best in Table 3). On the other hand, there are teams that achieve high TA and MIA scores accompanied by severe performance drop on MMLU. These submissions are discarded as they constitute trivial solutions, not useful in a general setting. Our approach differentiates from all others in that it manages to balance all three evaluation criteria, achieving high TA and MIA scores with just slight degradation of the model's reasoning abilities. Moreover, it performs similarly well on the 1B parameter model (ranked first with final score of 0.688) verifying the robustness of our method across different model sizes. App. C contains extensive results, including plots and detailed tables.

Chunk Size Investigation As mentioned above, we leverage chunking to circumvent limitations of gradient-based unlearning methods. Figure 2 depicts that unlearning few samples at a time in a sequential manner clearly boosts performance and prevents catastrophic collapse compared to training on all data at once. For the current train split, a chunk size of 32 yields optimal results. However, this choice is not universal, as experiments on the validation split indicate that smaller datasets tend to benefit from smaller chunk sizes, and determining the optimal value requires some trial and error.

MIA score sensitivity An interesting observation is that the MIA score is highly sensitive to the number of epochs per chunk. Training for 4 epochs results in an AUC-ROC of 0.94, suggesting under-unlearning. However, increasing the epochs to 7 causes the AUC-ROC to drop to 0.29, indicating over-unlearning. This sharp variation highlights the importance of carefully selecting the number of training epochs to achieve effective but at the same time meaningful unlearning.

Qualitative results In Table 4, we present examples of the unlearned model's outputs alongside the reference completions. For each set—forget and retain—from the train split, we include both a strong and a weak example. We observe that the model may lose fluency and generate nonsensical outputs for certain forget inputs, while producing overly verbose responses for some retain inputs. This suggests that, despite favorable metrics, potential shortcomings should still be carefully considered (more examples follow in App. D).

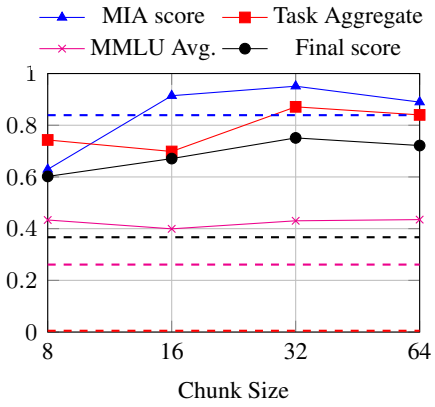

Figure 2: Metrics (MIA, TA, MMLU Avg. and Final score) for the train split with varying chunk size. Dashed lines correspond to the no chunking performance.

6 Conclusion

In this work, we demonstrate the merits of combining parameter-efficient model tuning with strategic data chunking to effectively unlearn targeted content from pre-trained models while minimizing catastrophic forgetting. Our task-agnostic system schedules retain and forget chunks appropriately, attaining superior balance between erasing sensitive information and preserving general knowledge.

A Exploratory data analysis

The SemEval-2025 Task dataset (Ramakrishna et al., 2025b) is structured to support three distinct sub-tasks, each focusing on different types of textual content:

1. **Task 1 (T1)** consists of long-form synthetic creative documents spanning multiple genres, including fictional narratives and descriptive storytelling. These samples often contain rich, elaborate passages with character-driven plots and immersive settings.

2. **Task 2 (T2)** includes short-form synthetic biographies of imaginary individuals that incorporate personally identifiable information (PII), including birth dates, phone numbers, Social Security numbers (SSN), email addresses, and home addresses. These biographies resemble real-world identity descriptions but are entirely artificial.

3. **Task 3 (T3)** is composed of real Wikipedia biographies sourced from the target model's training dataset.

Each of these subtasks is evaluated through two distinct modes: *sentence completion (SC)* and *question-answering (QA)*. In sentence completion, a passage is provided with a trailing portion that the model must generate accurately. In question-answering, the dataset presents questions derived from the documents, requiring concise and contextually accurate responses. The structure of the dataset is as follows: for every single short story from Task 1 and every short biography from Task 3 there is exactly one QA pair relevant to their content. For every synthetic biography from Task 2 there are exactly 5 QA pairs about the person's birth date, SSN, phone number, email address and home address respectively, e.g. *"What is [fake name]'s phone number?"*, *"What is the birth date of [fake name]?"* etc.

This structured approach allows for a comprehensive assessment of language models across varying content complexities and evaluation paradigms. Figure 3 provides a visual representation of the sample distribution across different subtasks and dataset splits, while Table 5 presents a detailed breakdown of the dataset composition. Additionally, table 6 illustrates the overall structure of the dataset, showcasing two representative examples from each subtask—one for SC and its corresponding QA pair.

Both retain and forget subsets contain examples of the exact same structure as described above. Moreover, they are entirely disjoint in terms of the information they contain, meaning that all samples -either SC prompts or QA pairs- that refer to a specific story, person or biography belong to the same subset. In other words, all information that refers to a certain individual or story should either be retained or forgotten.

	Retain			Forget

picture of the dataset's inner structure and size.

To evaluate the model's memorization robustness under different input variations, we introduce controlled perturbations to a specific sample. Each modified input maintains the same underlying structure, allowing us to observe how different distortions affect model predictions. The variations include: misspelling, token insertion, token deletion and adjacent character swap.

Table 7 presents the model's completions to the perturbed inputs. We observe that small variations of the input do not affect the output severely, and the model manages to converge to the reference output and provide correct information even after

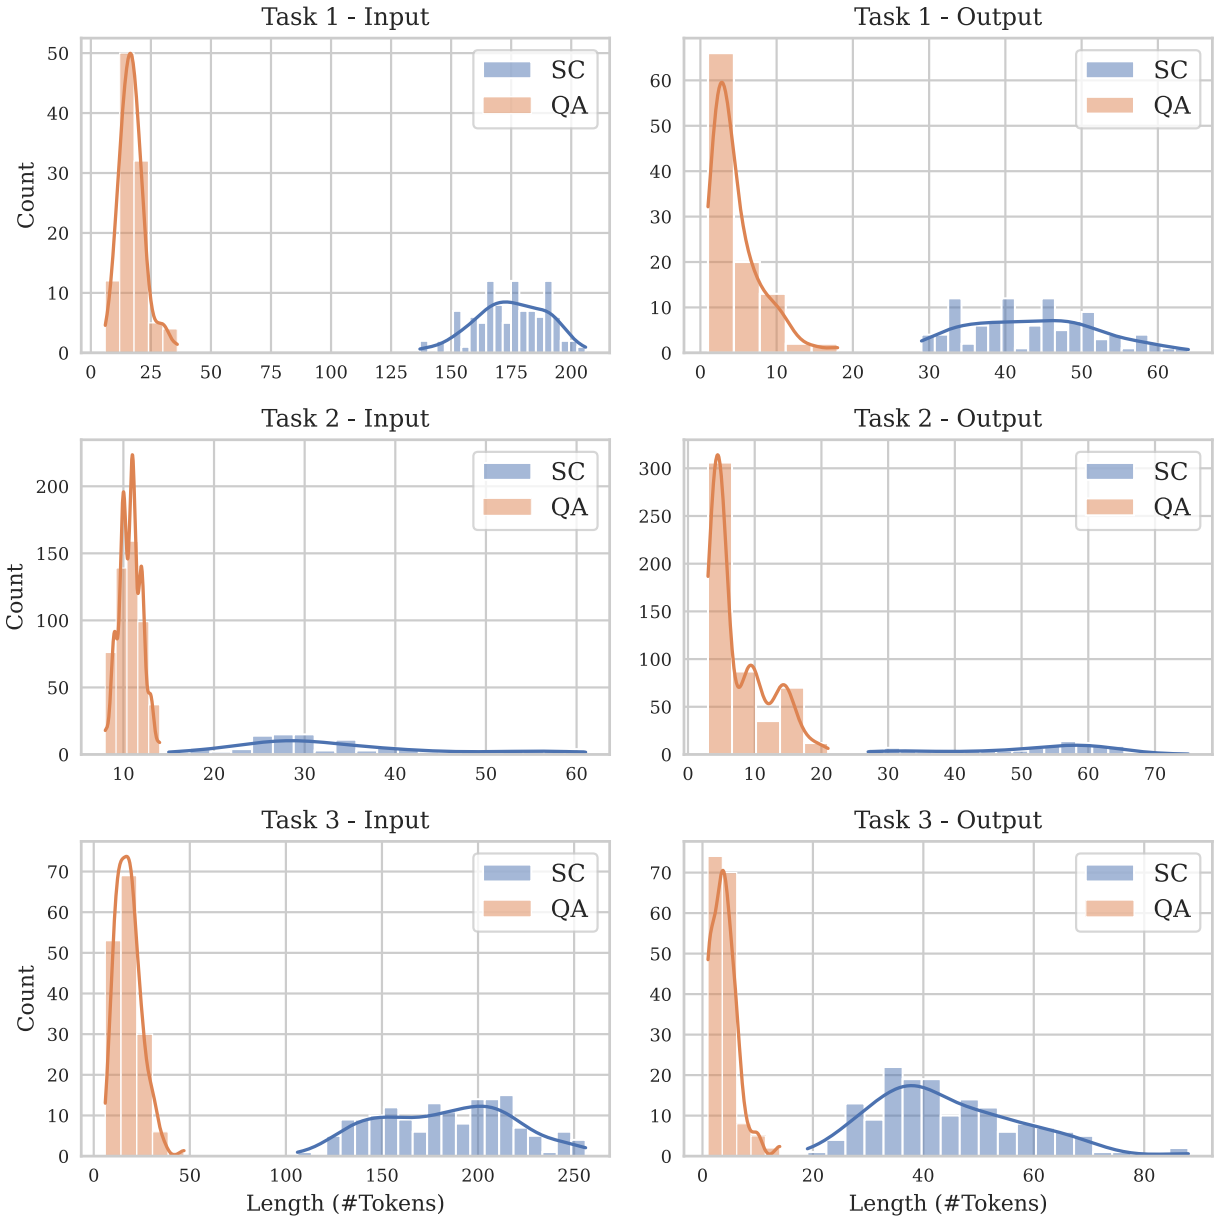

Figure 4: Length distribution of the tokenized input and output sequences for the three subtasks. We distinguish between sentence completion (SC) and question-answer (QA) examples.

minor mistakes at the beginning of the completion (see three last rows of Table 7). However, when the name at the beginning of the input sequence is misspelled, the model fails to provide an accurate response and diverges completely. Interestingly, it consistently preserves the email address format, replicating the misspelled name from the input (see second row of Table 7).

In a similar fashion, we investigate the extent to which the model has memorized the provided documents, approximating qualitatively its memorization accuracy. First, we take a QA pair and gradually shorten the input given to the model. Up to a certain point, the model can correctly infer the original sequence, but when the input becomes too generic (e.g. "Who is the first woman") it ends up generating another QA pair -possibly from its training dataset as well- as shown in the upper section of Table 8.

Proceeding with our next experiment, we substitute the name of a person involved in the story with a different one in addition to shortening the input sequence. Interestingly, in the first case (penultimate row of Table 8) the model produces the original story, keeping track of the new name and using this in place of the initial one, without changing any other element. However, when a slightly longer input is provided it ends up generating an entirely

different, yet coherent, story (last row of Table 8).

In summary, these preliminary experiments provide a qualitative snapshot of the model's behavior under controlled input variations. They highlight the model's capacity to handle minor perturbations while revealing certain vulnerabilities. Although indicative, the findings offer valuable insights that pave the way for more comprehensive evaluations of its memorization robustness.

B Hyperparameter selection

The appropriate selection of hyperparameters is crucial for obtaining the best possible performance out of a system. In our system we distinguish between *system-wide hyperparameters*, which determine the high-level configuration of the system, and *training arguments*, which specify the training dynamics at a lower level. The former include the chunk size, the forget-to-retain ratio, the rank and alpha of the LoRA adapter or k, the number of layers to train if Last-k fine-tuning is performed. Training arguments include the initial learning rate, the effective batch size and the number of epochs. We use the *transformers* library's default configuration for the learning rate scheduler and the optimizer.

Hyperparameter	LoRA	Last-k
System-wide		
Chunk Size	32	32
Forget-Retain Ratio	1:7	1:7
LoRA Rank	16	-
LoRA Alpha	64	-
Last-k k	-	8
Training arguments		
Learning Rate	1e-5	1e-5
Eff. Batch Size	8	8
Number of Epochs	5	6

Table 9: Sequential Unlearning with Gradient Difference best hyperparameters.

The selection of chunk size, LoRA rank (r), scaling factor (a), parameter k, learning rate, and number of epochs was guided by empirical experimentation. These hyperparameters were tuned iteratively based on observed training dynamics, convergence behavior, and the trade-off between computational cost and unlearning efficacy.

The forget-to-retain ratio and the effective batch size were determined through a combination of empirical intuition gained from experimentation and constraints imposed by the available hardware configuration. Notably, a unit batch size (fully stochastic gradient updates) yielded unexpectedly strong results. We hypothesize that the effectiveness of a unit batch size stems from the specificity and precision of gradient updates when performing gradient ascent, as it ensures targeted weight updates, aligning with the nature of unlearning, which targets specific samples and does not involve generalization. However, this approach is computationally inefficient and does not fully utilize the available GPUs - 8 in our case.

To preserve these targeted updates while leveraging all available hardware —i.e., N GPUs— we adopt a per-device batch size of 1 and construct each effective batch to contain a single forget sample along with N-1 (7 in our case) retain samples. Consequently, every optimization step consists of one specific gradient ascent update embedded within N-1 gradient descent updates.

In a distributed setup with 8 GPUs, where the minimum effective batch size is constrained to 8 (one sample per GPU) this is achieved by mixing one forget sample with 7 retain samples (forget-to-retain ratio = 1:7), ensuring that each GPU processes a different sample when performing distributed training using the Distributed Data Parallel (DDP) technique. This rationale underpins our choice of the forget-to-retain ratio and motivates the use of a sequential, rather than random, data sampler, as outlined in the main paper.

C Quantitative Results

In this section we present detailed experiment results including run summary tables and plots of the model performance after every epoch during training. Computing the generative evaluation metrics (RougeL and EM rate) is rather slow and costly as one needs to auto-regressively generate every output and then compare it with the reference. In order to speed up the evaluation process, we use a random sample of the data to compute these metrics after every epoch (usually 32 samples from each set -retain and forget). To make things clear, the forget data sample is drawn from all the chunks that have been processed by the model up to the specific epoch and not from the current chunk only, whereas the retain data sample is drawn from the whole retain set every time. These samples are different every time which may induce some noise in the metrics plots but allows for a more robust view of the model's performance.

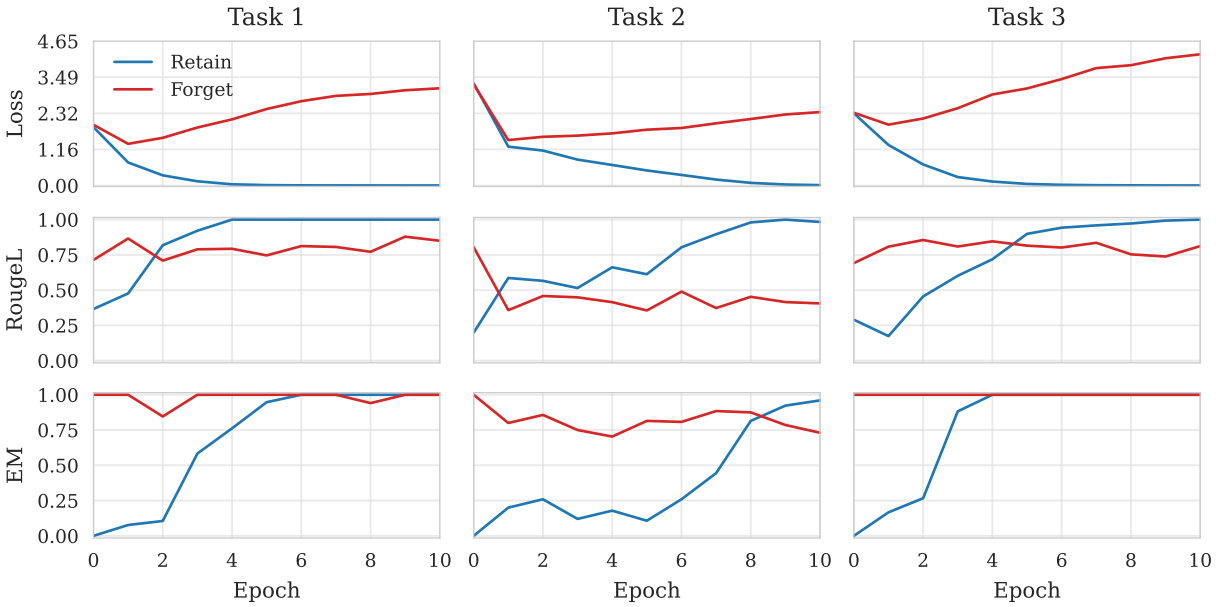

Figure 5: Gold standard: Retraining the base model on the retain data only for 10 epochs, approximating exact unlearning. The diagram shows the evolution of the evaluation metrics (Loss, RougeL and Exact Match) for each subtask across training epochs.

Evaluation Diagram Structure The evaluation metrics are displayed in a diagram structured as a 3×3 grid of subplots, where each column corresponds to a different subtask (Task 1, Task 2, and Task 3), and each row represents a specific evaluation metric. The first row displays the loss values over training epochs, the second row represents the RougeL score for the SC prompts, and the third row illustrates the Exact Match (EM) rate for the QA pairs. Each subplot illustrates the epoch number on the x-axis and the respective metric value on the y-axis. Within each plot, two curves are present: a blue curve, which represents the performance on retain data, and a red curve, which tracks the performance on forget data. The forget metrics, excluding the loss, are plotted as $1 - value$ to ensure that all metrics follow a "higher is better" trend.

Set & Task	RougeL	Exact Match
Forget Avg. (↓)	**0.3161**	**0.0776**
Task 1	0.1617	0.0120

Table 10: Summary of final evaluation metrics for the gold standard model (retraining from scratch on retain data). HMTA stands for the Harmonic Mean Task Aggregate of the 12 task-specific scores presented above, after transforming forget values to $1 - value$).

C.1 *Gold Standard*: Retraining from scratch

As a first step and before exploring methods for efficient unlearning, we tried to approximate exact unlearning by retraining the base model (Olmo-7B-Instruct-hf) from scratch on the retain data only, thus obtaining a *gold standard* model. Although this was not required for this task, it provides a better understanding of the goal of our unlearning algorithm and what the final scores should look like in the ideal scenario.

In order to obtain the gold standard, we train the base model on the retain data only applying supervised fine-tuning with a causal language modeling objective. A LoRA adapter of rank $r = 32$ and scaling factor $a = 64$ is used to avoid excessive training costs and time required for full fine-tuning. We train with an initial learning rate of $1e - 4$ and default scheduler and optimizer for 10 epochs as this is the minimum required to achieve near-perfect memorization of the retain data, as indicated by the evaluation metrics.

Figure 5 shows the evolution of the evaluation metrics (Prediction Loss, RougeL score for the SC prompts and Exact Match rate for the QA pairs) for each task separately both for the retain and forget

Table 11: Examples of the gold standard model's outputs for each set (forget, retain) from the train split. The first column shows the set and the task each example belongs to (e.g. F1: forget set , Task 1 etc.).

set. As expected, in the beginning of the training the loss is high both for retain and forget data, while the RougeL and EM scores are 0 (forget scores are plotted as $1 - value$ so they appear to be 1 in the plot), meaning that the model has no relevant knowledge. As training progresses, the retain loss drops as retain samples are being memorized. For completeness, we present the detailed evaluation report with the final metrics per subset and task in Table 10.

We can derive several useful insights from this analysis. First, the forget loss increases as expected, but it remains stable and does not escalate uncontrollably. Forget metrics, particularly RougeL scores—which measures the longest common subsequence between two sentences—do not converge to zero, as would be expected under perfect unlearning (see Table 10). This is because the forget and retain datasets share the same underlying distribution. While specific details such as names and locations change, the broader sentence structure and phrasing remain similar, leading to a higher overlap in sequence similarity as captured by RougeL.

This effect is especially evident in Task 2, where the RougeL score for the forget set remains close to 0.6. This outcome is expected, given that the documents in this task follow an identical structure, with only personal details varying (e.g., "[Name] was born on [birth date]. His/Her Social Security number is [SSN], and his/her phone number is ...").

For QA pairs, forget scores are generally close to zero, indicating that the model cannot infer the required details without prior exposure. However, Task 2 is an exception, with a forget score near 0.2 (or roughly 1 out of 5). This is expected since the model correctly answers questions about email addresses, as their format remains consistent across all samples (e.g., [name]@me.com).

Table 11 presents some examples of the gold standard model's completions for both sets. Regarding the former, we can see that it has success-

fully memorized almost all data and its completions are identical to the reference. Regarding the latter, the model generates coherent and relevant text that mimics the style of the reference documents but provides inaccurate or repeated information.

C.2 Sequential Unlearning with Gradient Difference

In this section, we present extensive results of our main method Sequential Unlearning with Gradient Difference (SUGD), evaluating unlearning performance across different hyperparameter settings. As a first step, we conduct a fine-grained hyperparameter exploration, monitoring the evolution of task-specific evaluation metrics across training epochs to identify trends and determine optimal configurations, even though we don't report MIA and MMLU scores in this first stage of experimentation. Furthermore, in this first analysis we only train using a LoRA adapter and not Last-k fine-tuning.

The results, summarized in Table 12 provide insight into the effectiveness of different hyperparameter choices in balancing unlearning and retention across the three tasks. For better understanding of the training dynamics and the various trade-offs during training we provide the evaluation diagrams of some indicative runs as well in Figures 6 to 10. As expected, in the beginning of the training the loss is 0 both for retain and forget data, while the RougeL and EM scores are 1 (forget scores are plotted as $1 - value$ so they appear to be 0 in the plot). This essentially means that the model has perfectly memorized both retain and forget data.

Task 2 appears to be the easiest to unlearn, while Tasks 1 and 3 are more challenging, as indicated by the evolution of forget metrics for each task. We posit that due to its structured nature, Task 2 (synthetic PII biographies) is erased quickly, leading to lower forget scores. In contrast, Task 1 (creative writing) and Task 3 (Wikipedia biographies) are harder to unlearn due to their interconnected and contextually rich content.

In addition, the number of epochs per chunk (EPC) has a strong impact on unlearning effectiveness. Too few epochs result in ineffective unlearning, leading to high forget scores, while too many cause excessive knowledge loss, lowering retain scores (see Run 2 Table 12). A sweet spot that balances strong unlearning with high retention needs to be determined through experimentation as it may depend on the size of the dataset and the selected chunk size. Another alternative is to apply early stopping once the metrics have reached a predetermined threshold, which would remove the burden of tuning the number of epochs on top of all the other hyperparameters. However, in the context of this task, where the maximum execution time of our algorithm was limited to 1 hour, this was merely possible due to the time-consuming computation of the generative metrics.

This first analysis indicates the importance of a Retain-to-Forget Ratio (RTF) greater than 1 for effective unlearning. Runs with RTF = 1, such as Run 3, fail to unlearn effectively as indicated by high forget scores. A higher RTF improves unlearning while preserving necessary knowledge and we finally converge to the value of 7 for reasons discussed in the previous section.

With a clear understanding of the role and impact of each hyperparameter, we now focus on more targeted experiments using the larger train split. This section presents comprehensive results, including MIA and MMLU scores and averaged across multiple runs, to provide a robust evaluation of both fine-tuning strategies. Table 13 summarizes the performance of the two efficient fine-tuning methods under investigation: LoRA and Last-k.

LoRA consistently outperforms Last-k across most evaluation metrics, demonstrating not only superior overall results but also greater stability, as indicated by its lower variance across different random seeds. The most effective LoRA configuration is the one applied to all key-query-value matrices and linear projection layers , which significantly enhances performance, particularly in terms of unlearning effectiveness.

While LoRA excels in ensuring effective unlearning while maintaining strong task-specific retention, Last-k fine-tuning better preserves the model's reasoning abilities, as reflected in its superior MMLU scores. This suggests that directly modifying only the last layers allows the model to retain broader knowledge more effectively, albeit at the cost of less effective unlearning.

Finally, Table 14 presents the leaderboard for the 1B parameter model, as provided officially by the task organizers. Our method again achieves high performance similar to the 7B model indicating its robustness across model sizes.

D Qualitative Results

We conclude our analysis by presenting qualitative results that provide deeper insights into our

Table 12: Detailed table of multiple SUGD runs using the 7B model and the validation split. For every run we report the hyperparameters along with the final task-specific evaluation metrics, stacked vertically with the first row corresponding to Task 1 etc. Regarding the table's notation CS: Chunk Size, RTF: Retain-to-Forget ratio, LoRA: (r, α), LR: Learning rate, BS: Effective Batch Size, EPC: Epochs per Chunk, RL: RougeL score, EM: Exact Match rate, HMTA: Harmonic Mean Task Aggregate

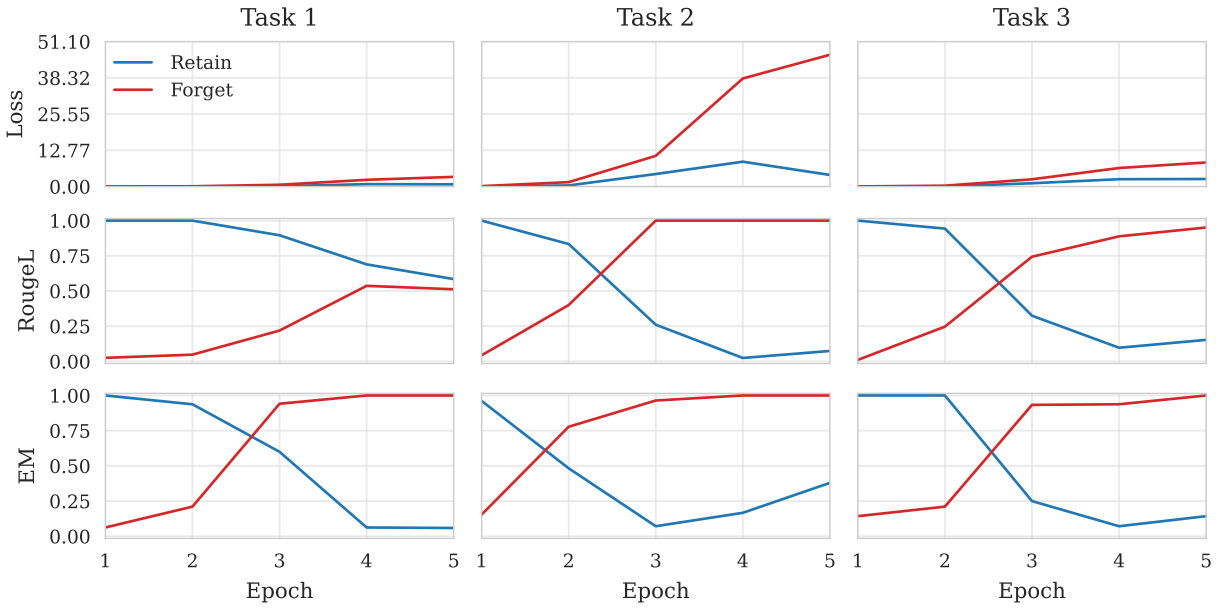

Figure 6: Run 1 SUGD evaluation diagram. Here no chunking is applied. The hyperparameters used are *Retain-to-Forget ratio*=1, (r, α) = (16, 32), *learning rate*=6e-05, *eff. batch size*=16, *epochs*=5.

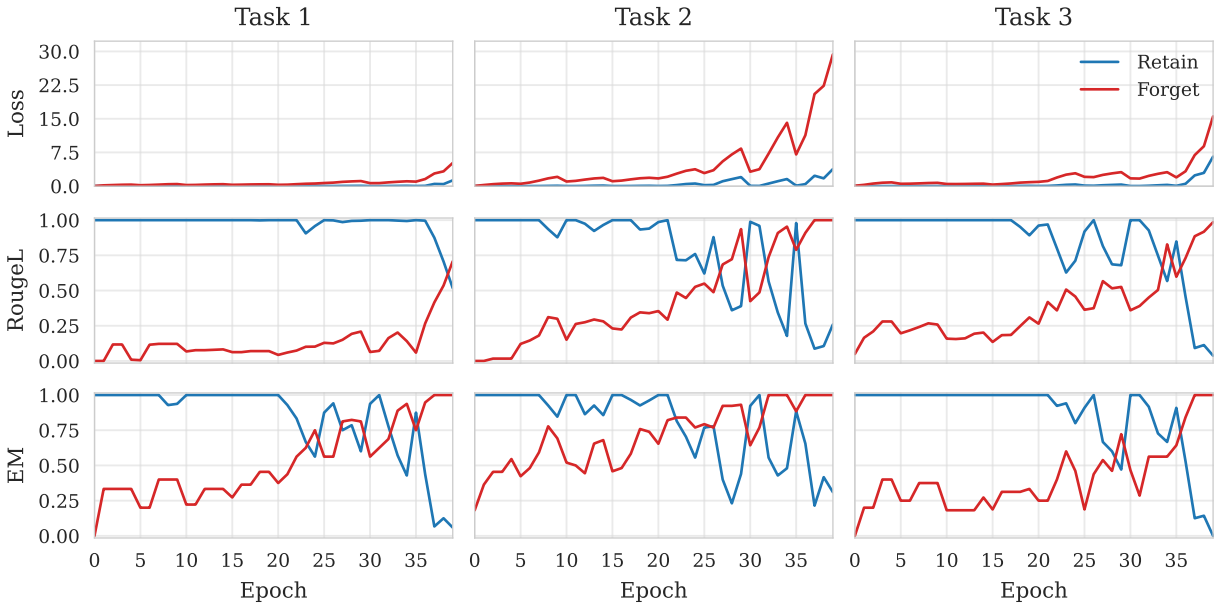

Figure 7: Run 2 SUGD evaluation diagram. The hyperparameters used are *chunk size*=32, *Retain-to-Forget ratio*=3, (r, α) = (16, 32), *learning rate*=5e-05, *eff. batch size*=16, *epochs per chunk*=5.

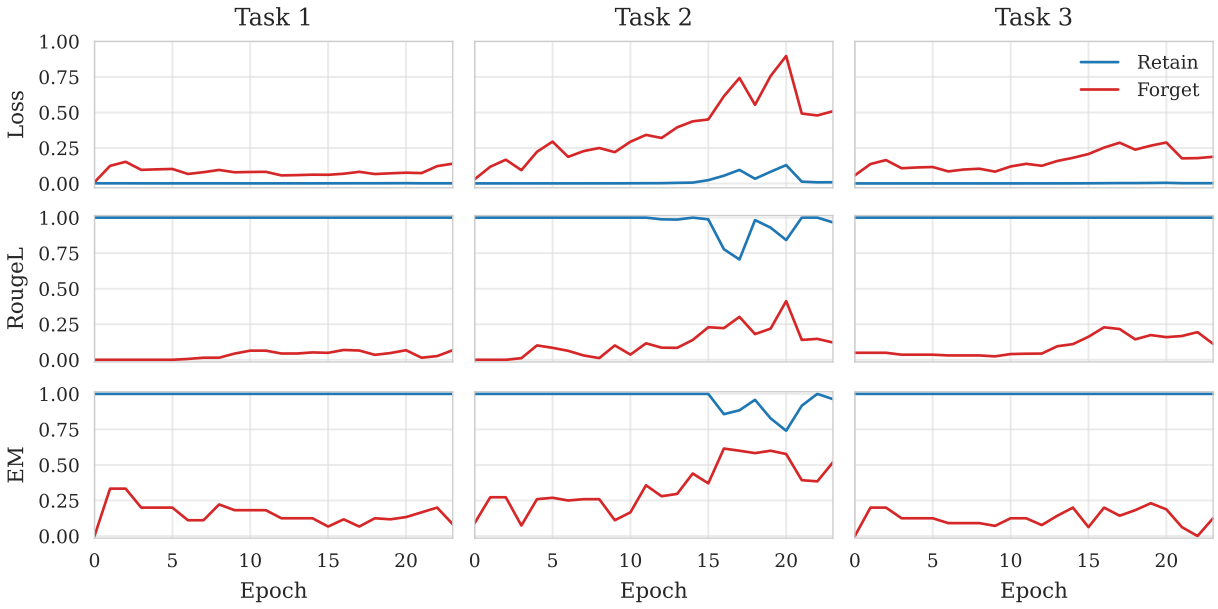

Figure 8: Run 3 SUGD evaluation diagram. The hyperparameters used are *chunk size*=32, *Retain-to-Forget ratio*=1, (r, α) = (16, 32), *learning rate*=5e-05, *eff. batch size*=16, *epochs per chunk*=3.

method's performance and its limitations. Despite achieving strong quantitative metrics, our best-performing method struggles with fluency. While the MMLU scores indicate that the model does not suffer from catastrophic collapse, it frequently generates incoherent responses—particularly for forget samples and, more critically, for general queries. Table 15 presents sentence completion prompts that complement the QA pairs shown in the main paper. These examples confirm a significant loss of fluency when responding to forget inputs. Even if we disregard this aspect given that information that needs to be forgotten is actually hidden, the model also exhibits fluency issues in general queries, most of the times generating repetitive outputs (strangely enough it converges to a specific number, e.g. 10).

This issue is further reflected in task-specific metrics, where forget scores drop to nearly zero across all tasks and evaluation types. This suggests that the model produces nonsensical outputs, as Rouge-L scores would otherwise be higher (e.g., 0.2–0.3, as observed with the gold standard model,

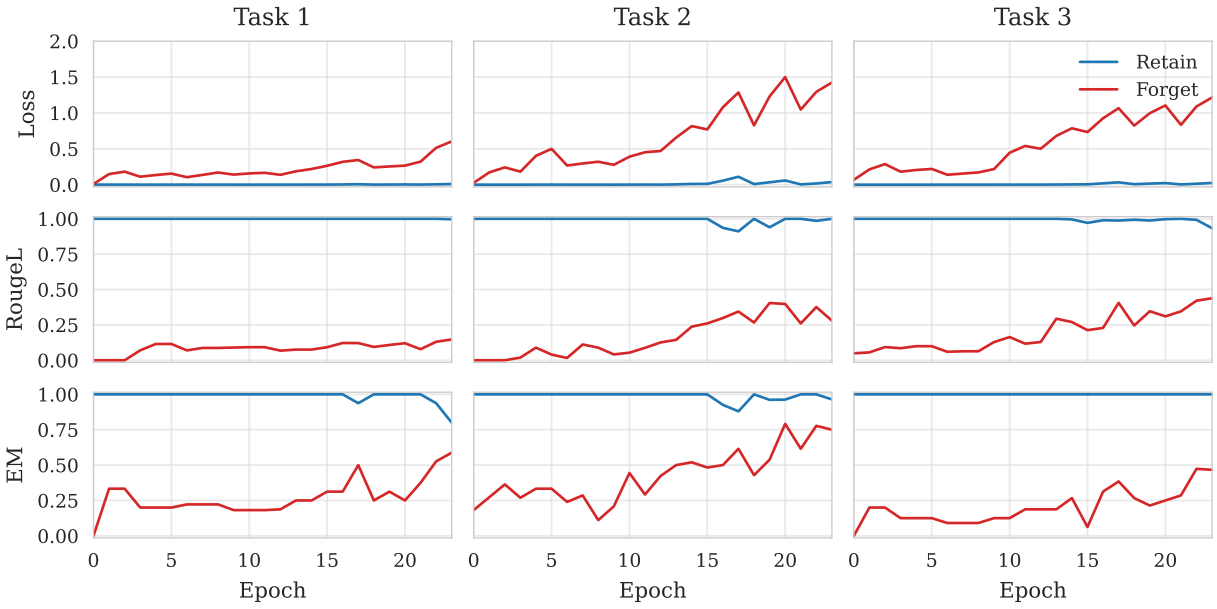

Figure 9: Run 5 SUGD evaluation diagram. The hyperparameters used are *chunk size*=32, *Retain-to-Forget ratio*=3, (r, α) = (16, 32), *learning rate*=5e-05, *eff. batch size*=16, *epochs per chunk*=3.

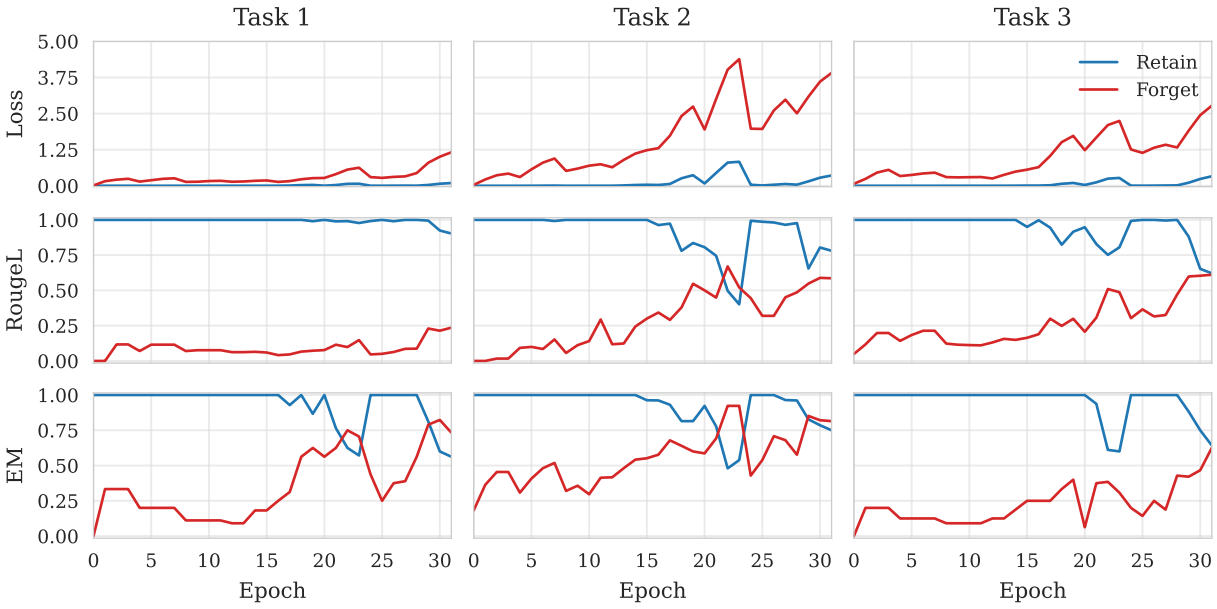

Figure 10: Run 6 SUGD evaluation diagram. The hyperparameters used are *chunk size*=32, *Retain-to-Forget ratio*=3, (r, α) = (16, 32), *learning rate*=5e-05, *eff. batch size*=16, *epochs per chunk*=4.

Table 10). This behavior may improve unlearning metrics but it does not necessarily translate to effective quality unlearning.

In order to circumvent these limitations, we explored the effect of using a unit batch size, as discussed above, by running experiments on a single GPU with fully stochastic gradient updates (batch size = 1). Due to the significantly increased execution time, this configuration was not considered for submission, yet we believe that it is crucial to be presented here as it provides a comprehensive conclusion to our method and analysis. The hyperparameters used in this case are: *chunk size*=32, *Retain-to-Forget ratio*=3, (r, α) = (16, 64), *learning rate*=5e-05, *eff. batch size*=1 and *epochs per chunk*=3.

In Figure 11, we observe that the forget metrics (Rouge-L and EM) start near-perfect from the beginning of training. This is because, after every epoch, evaluation is performed only on forget samples that have already been processed by the model. The high forget scores indicate that these

Table 14: Final leaderboard for the 1B model. Our method consistently outperforms other teams' submissions across model sizes.

processed samples have been successfully removed from memory, demonstrating the effectiveness of the forgetting mechanism.

Examining the loss curves, we note that the forget loss remains relatively stable for Task 1 and Task 3, with only minor fluctuations. This suggests that the forgetting mechanism is mostly stable across training. However, in Task 2, forget loss shows a noticeable increase as training progresses, implying potential instability or difficulty in forgetting certain samples. The retain loss remains close to zero throughout training for all tasks, indicating that the model effectively retains relevant information without significant degradation.

Table 15: Qualitative examples for sentence completion prompts (drawn from the train split) complementing the QA pairs presented in the main paper. For each subtask we intentionally pick a sample our best model (the submitted configuration) struggles with (*Best Model's output* column). Next to its completion we provide the response of a model trained in a fully stochastic way, i.e. using a unit batch size (*Fully Stochastic* column). The latter evidently smooths out many of the other model's pain points, failing to provide a coherent response only for Task 2.

From a qualitative perspective, as shown in Table 15, this training approach significantly improves coherence, correcting nearly all cases where the submitted model fails. Additionally, the MMLU average, which reflects the model's reasoning ability has increased from 0.494 at the pre-unlearning

Set & Task	RougeL	Exact Match
Forget Avg. (↓)	**0.2892**	**0.0117**

MIA Score	0.6738	
MMLU	* 0.5191 *	

Table 16: Summary of final evaluation metrics for the model trained with a batch size of 1. The values closely match those of the gold standard indicating quite successful unlearning. Note that the MMLU average improves compared to the model's performance prior unlearning (0.4946).

checkpoint to 0.519 (see Table 16 for detailed metrics of the fully stochastic run).

E Alternating Gradient Ascent - Descent

E.1 Method

Part of our experimentation focuses on an alternative approach designed to maintain training stability while ensuring effective unlearning by alternating between gradient ascent and descent. The forget set $\mathcal{D}_f$ is partitioned into N chunks of a predefined size:

$$\mathcal{D}_f = \{\mathcal{D}_f^1, \ldots, \mathcal{D}_f^N\}$$

Each chunk $\mathcal{D}_f^i$ undergoes gradient ascent (GA) steps to maximize loss on forget data, inducing unlearning (*forgetting phase*). To counteract potential instability from repeated forgetting, a subset of the retain set $\mathcal{D}_r^i$ is sampled and used for gradient descent (GD), reinforcing retained knowledge (*annealing phase*).

The size of the subset $\mathcal{D}_r^i$ is controlled by the *annealing fraction* $\alpha \in (0, 1]$, which determines what proportion of the retain set is used for stabilization. The goal of the annealing phase is not to retrain the model on all retained samples—since they have already been memorized—but rather to smooth out potential instabilities introduced by the forgetting process. Using a smaller subset ($\alpha < 1$) speeds up training while potentially still providing sufficient stabilization.

Annealing phases are interleaved at a frequency dictated by the *interleaving factor* $\lambda \in [0, 1]$, which regulates how often stabilization is applied during the unlearning process. For example, when $\lambda = 0$, no intermediate annealing is performed, and the model undergoes all forgetting phases without stabilization. When $\lambda = 0.2$, annealing occurs after every 5 forgetting phases, when $\lambda = 0.5$ every 2 etc. Finally, when $\lambda = 1$, every forgetting phase is immediately followed by an annealing phase, ensuring continuous stabilization.

After completing all forgetting phases, an optional final annealing step is applied, where the model is trained on the full retain set $\mathcal{D}_r$ to further mitigate unintended degradation of retained knowledge. The steps of this approach are outlined in Algorithm 2.

Additionally, the forgetting and annealing phases can be configured with different training arguments, such as learning rate, number of epochs, or op-

Algorithm 2 Alternating GA-GD

Require: Forget set $\mathcal{D}_f$, Retain set $\mathcal{D}_r$, Chunk size chunk_size, Interleaving Factor λ, Annealing Fraction α, Learning rate η, Model parameters θ

1	0.937	0.958	0.820	0.835	0.707	0.971	1.000	1.000	1.000	1.000	1.000	1.000	0.126
2	0.985	1.000	0.970	0.983	0.928	1.000	1.000	1.000	1.000	1.000	1.000	1.000	0
3	0.944	1.000	0.968	0.965	0.926	1.000	1.000	1.000	1.000	1.000	1.000	1.000	0

Table 17: Final evaluation metrics for some *Alternating GA-GD* runs on the 7B model using the validation split. Every run is accompanied by the detailed evaluation diagram in Figures 13, 14 and 15 respectively, where the hyperparameters of each run are also mentioned. RL stands for RougeL score computed for the sentence completion pairs, EM stands for Exact Match rate computed for the question-answer pairs and HMTA stands for Harmonic Mean Task Aggregate of the 12 task-specific metrics.

timization settings. This flexibility allows each phase to be handled in a way that best suits its objective. For instance, the forgetting phase often requires more controlled updates to prevent excessive or unstable modifications to the model, which can be achieved by using a smaller learning rate or fewer epochs. In contrast, the annealing phase primarily acts as a stabilizer, meaning it can often tolerate larger learning rates or more epochs to efficiently smooth out instabilities introduced by forgetting. By tuning these hyperparameters independently, the method ensures a balanced trade-off between effective unlearning and model stability.

E.2 Results

In order to get some insights of the method's effectiveness, we conduct experiments using the validation split and evaluate the model after every epoch during training. In Table 17 we present the detailed evaluation metrics for three indicative runs. For every run reported here we also provide the corresponding evaluation diagram for completeness in Figures 13, 14 and 15 respectively. All these experiments are conducted using the 7B model and the validation split. A small-scale experimentation with this method reveals moderate performance, therefore we did not proceed with extensive experiments. However, these results offer useful insights and disclose limitations which our main method aims to resolve.

Regarding some key findings of the presented alternating gradient ascent-descent method, we observe that frequent annealing is almost mandatory to prevent loss explosion and catastrophic collapse. Forgetting, especially when processing later chunks, causes retain loss to increase as well, even though it is not applied on retain data at all. This means that the gradient ascent steps lead to partial catastrophic collapse deteriorating the model's general performance instead of just acting selectively on the forget data samples. In a similar fashion, annealing interestingly lowers forget loss along with its intended function to stabilize retain loss. This hints that annealing forces the model to return somewhere close to its initial state -speaking in terms of the model's parameter space-, on the one hand reversing a potential divergence, but at the same time failing to actually forget the data that need to be forgotten.

F Submission details

Participants are tasked to submit a PyTorch function that performs unlearning on the trained model utilizing the private *test* split. The unlearned model is then evaluated as described above. This code is executed on an AWS EC2 p4d.24xlarge node (8 A100 40GB GPUs), allowing maximum execution time of 1 hour. Throughout our experimentation, we develop our algorithms in the same computational environment, as offered by Amazon Web Services (AWS).

Abstract

Recently, social media has become a platform for different human emotions. Although most existing works treat the user's opinions into a single emotion, the reality is that one user can have more than one emotion at a time, representing multiple emotions at the same time. Multi-label emotion detection is a more advanced and realistic approach, as it acknowledges the complexity of human emotions and their overlapping nature. This paper presents multi-label emotion detection in Amharic and English data. The work is part of SemEval2025 shared task 11, where tasks and datasets are offered by task organizers. To accomplish the aim of the given task, we fine-tune transformers base BERT model, passing through all different workflow pipelines. On unseen test data, the model evaluation achieved 0.6300 and 0.7025 an average macro F1-score for Amharic and English, respectively.

Keywords: Social media, Emotion, Multi-label, BERT

1 Introduction

In the current digital era, people can openly share their thoughts, sentiments, disagreements, opinions, and attitudes on websites, microblogs, and social media platforms. For a number of reasons, including decision-making, product analysis, customer feedback analysis, political promotions, marketing research, and social media monitoring, there is more interest in obtaining these user's attitudes and emotions all around (Belay et al., 2025). However, all those feedbacks come from different feelings and thoughts, thus becoming complicated and needs those emotions to be organized in certain sort of correlations (Bade et al., 2024b).

Emotion detection is a critical area of research in natural language processing (NLP) that focuses on identifying and understanding the emotional states expressed in text. Emotions play a vital role in human communication, influencing how messages are interpreted and how individuals respond to one another. Automatically detecting emotions from text has significant applications in various fields, such as mental health analysis, customer feedback evaluation, social media monitoring, and human-computer interaction. By understanding emotions, systems can provide more personalized and empathetic responses, enhancing user experience and decision-making processes.

In emotion detection, a single emotion refers to the identification of one dominant emotion in a given text. For example, a sentence like "I am so happy today!" would be classified as expressing the emotion "joy." This approach assumes that each text conveys only one primary emotion, which simplifies the task but may not fully capture the complexity of human expression. In reality, people often express multiple emotions simultaneously, as emotions are rarely isolated and can coexist in nuanced ways.

This is where multi-label emotion detection comes into play. Unlike single-emotion classification, multi-label emotion detection recognizes that a single text can express multiple emotions at once. For instance, a sentence like "I feel excited but also a bit nervous about the upcoming event" could be labeled with both "joy" and "fear." Multi-label emotion detection is a more advanced and realistic approach, as it acknowledges the complexity of human emotions and their overlapping nature. It allows for a richer and more accurate representation of the emotional content in text, making it particularly valuable for applications requiring a deeper understanding of human sentiment.

This paper presents our contribution to SemEval 2025 Shared Task 11 (Muhammad et al., 2025b), where the tasks and gold standard dataset were provided by the organizers. The shared task consists of three tracks; however, our team participated exclusively in Track_A, which focuses on detect-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1406–1410

ing multiple emotions from textual inputs across various languages (Belay et al., 2025; Muhammad et al., 2025a). Through this participation, we aim to advance the development of more inclusive and accurate emotion detection systems for Amharic and English data in detailed contexts.

2 Related Works

Recent researches on emotion detection have leveraged various approaches. Serrano-Guerrero et al. (2022) proposed a deep learning architecture based on a bidirectional gated recurrent unit with a multichannel convolutional neural network layer to tackle the issue of identifying numerous emotions from patient reports, collecting a sizable patient viewpoints from a website, and identified several emotions from these evaluations, achieving average accuracy of 95.82%. Deng and Ren (2020) addresses the multiple emotions detection in online social networks from a user-level view, finding emotion labels correlations, social correlations, and temporal correlations from an annotated Twitter data set. They Use a factor graph-based emotion recognition model to detect these multiple emotions, and finally it outperformed the baselines. For multi-label emotion classification, Ameer et al. (2023) examined the application of LSTMs as well as the refinement of Transformer Networks using Transfer Learning in conjunction with a single-attention network and a multiple-attention network. According to the experimental results, their innovative transfer learning models that used pre-trained transformers with and without multiple attention mechanisms were able to achieve an accuracy of 62.4%, surpassing the state-of-the-art on RoBERTa-MA (RoBERTa-Multi-attention).

Rathnayaka et al. (2019) offer a unique Pyramid Attention Network (PAN) based approach for microblog emotion identification, emphasizing the approach's benefit in capturing many emotions present in a single text by evaluating words from several angles, with an accuracy of 58.9%.

To help with context-based multi-label multi-task emotion detection, Bendjoudi et al. (2021) suggests a new deep learning architecture that emphasizes three key modules: body features extraction, scene features extraction, and fusion-decision. Furthermore, a new loss function called multi-label focal loss (MFL) was chosen to handle imbalanced data after comparing three continuous and three categorical loss functions to highlight the significance of synergy between loss functions in multi-task learning. It outperformed the state of the art on the less frequent labels and produced better results than any other combination. Likewise, Zhang et al. (2020) show the methods that have three parts: the general representation module, the emotion representation module, and the adversarial classifier. After incorporating the link between various emotions using emotion descriptors, the model employs adversarial training to avoid over-injecting emotion-relevant data into the shared layer, achieving a macro-average F1 scores of 50.21%, 41.33%, and 40.24% on the Chinese, English, and Indonesian datasets, respectively.

Belay et al. (2025) presented EthioEmo, a multi-label emotion classification dataset for four Ethiopian languages—Amharic (amh), Afan Oromo (orm), Somali (som), and Tigrinya (tir)—alongside the English dataset acquired from SemEval 2018 Task 1 to assess encoder-only, encoder-decoder, and decoder-only language models using zero and few-shot approaches of LLMs to fine-tune smaller language models, concluding that accurate multi-label emotion classification is still insufficient, even for high-resource languages like English, and that there is a significant performance gap between high-resource and low-resource languages.

Muhammad et al. (2025a) introduce BRIGHTER– a set of datasets with multilabeled emotion annotations in 28 languages. With instances from a variety of domains annotated by fluent speakers, BRIGHTER primarily covers low-resource languages from Africa, Asia, Eastern Europe, and Latin America. It also describes the processes involved in data collection and annotation, as well as the difficulties in creating these datasets. It reports various experimental results for intensity-level emotion recognition and monolingual and crosslingual multi-label emotion identification, and it concludes that the results of the investigation, both with and without the use of LLMs, showed significant variability in performance across languages and text domains.

3 Task and Dataset Descriptions

We used datasets that were especially intended for this job in order to detect multi-label emotions in both Amharic and English (Muhammad et al., 2025a; Belay et al., 2025). The class label conains multilple labels including anger, fear, joy, sadness,

and surprise except 'disgust' label belongs to only Amharic data. The task aims to categorize the given input text into either of these class labels, the input text may fall in more than one labels.

Text	Anger	Fear	Joy	Sadness	Surprise
You know what happens when I get one of these stupid ideas in my head	1	1	0	0	0
They don't fear death, and it seems they believe in reincarnation	0	1	0	0	1
My stomach even started giving me fits	0	1	0	1	0
Victim-less, non-violent crimes shouldn't be handled so harshly	1	0	0	0	0

Table 1: Four sample instances of input texts with their correspondence multi-labeled classes, while 1 denotes existance of emotion in that particular label and 0 not.

While Table 1 shows the overview of tasks, Table 2 shows the data sets statistics include training, validation, and test data with comprehensive distributions.

4 Methodology

In this section a comprehensive set of methods and methodologies is described. Our approach optimizes and fine-tunes transformer-based models of BERT-base to improve emotion detection performance. Figure 1 shows the methodology workflow.

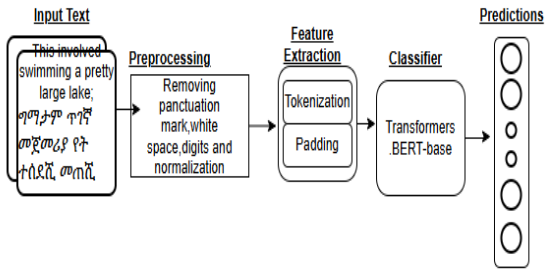

Figure 1: Abstract process of multi-label emotion detection in Amharic and English data.

4.1 Preprocessing and Feature Extraction

In order to standardize the input data and establish necessary circumstances for successful model training, we employed a number of preprocessing approaches. To maintain uniformity (Bade and Seid, 2018), the processing stage entailed converting all textual data to lowercase and eliminating tags, punctuation, and numbers (Bade et al., 2024d). In addition, the tokenization of the texts and the padding of the tokenized pieces in equal length (max-length = 128) are considered in the preprocessing.

Datasets		Languages
Train classes	**English**	**Amharic**
#Anger	333	1,188
#Disgust	–	1,268
#Fear	1,611	109
#Joy	674	549
#Sadness	878	771
#Surprise	838	151
#ideal total*	4,334	4,036
#Actual total^{+}	2,768	3,549
Dev classes		
#Anger	16	207
#Disgust	–	209
#Fear	63	22
#Joy	31	93
#Sadness	35	127
#Surprise	31	27
#Ideal total*	176	685
#Actual total^{+}	116	592
Test classes		
#Anger	322	582
#Disgust	–	628
#Fear	1,544	54
#Joy	670	276
#Sadness	881	355
#Surprise	799	82
#Ideal total	4,216	1,977
#Actual total^{+}	2,767	1,774
#Total^{+}	**5,651**	**5,915**

Table 2: Class-wise dataset statistics of training, development, and testing where '*' denotes the emotions that are overlapped one another and '+' denotes the actual record (row-wise) dataset. '–' indicates that the English data doesn't contain a 'disgust' label.

4.2 Tramsformers Base-Model

The use of a transformer-based model, known for its effectiveness and resilience in managing a variety of NLP tasks, to identify multilabel emotions in two languages was the main point of our methodology (Bade et al., 2024c, 2025). We used the transformers library to tokenize the text data, integrated early stopping, and made dynamic learning rate adjustments to prevent overfitting and speed up convergence to an ideal model state to fine-tune the transformer-based BERT-base model in the data set. Using Hugging Face's Trainer API, training was carefully carried out, utilizing techniques including validation-based tuning and batch size optimization to guarantee the model's efficacy (Mersha et al.,

2024). With regular assessments to modify training parameters based on real-time performance data, the models were trained for a maximum of five epochs. To guarantee improved generalization and dependability on unknown data, the model was verified using a separate validation data set (Bade et al., 2024a).

4.3 Result and Discussion

We observed the ability of the model that was fine-tuned based on the BERT to detect the multilabel emotion in both Amharic and English. The measurement of the performance included the average macro of accuracy (Acc), recall (Rec), precision (Pre), and F1-score.

Accuracy: Measures the proportion of correctly predicted labels over all labels.

Recall:Measures the proportion of correctly predicted positive labels out of all actual positive labels.

Precision:Measures the proportion of correctly predicted positive labels out of all predicted positive labels.

F1-score:The harmonic mean of precision and recall, providing a balance between the two.

However, as a convention and for ranking purpose, the average macro F1-score was used to measure the model performance. The macro-average calculates metrics for each label and then takes the unweighted mean. Thus, our developed BERT-base model achieved the average-macro F1-score of 0.6300 for amharic and 0.7025 for English, respectively. The Table3 gives the details of the results.

Language	Acc	Mac Rec	Mac Pre	Mac F1
Amharic	0.4696	0.6781	0.5910	**0.6300**
English	0.4405	0.7272	0.6822	**0.7025**

Table 3: Performance of the classifier on the test dataset.

From Table 3, it is evident that the selected model exhibits a stronger performance on English data compared to Amharic. While the model achieves an accuracy of 0.4405 and a macro F1 score of 0.7025 for English, it also demonstrates reasonably good results for Amharic, with an accuracy of 0.4696 and a macro F1 score of 0.6300. This suggests that the model is more biased toward English, likely due to factors such as the availability of more training data, better language representation, or inherent linguistic complexities in Amharic. Nevertheless, the model's performance on Amharic is still commendable, indicating its potential for multilingual applications with further optimization and fine-tuning.

5 Error Analysis and Limitation

The investigation demonstrates that the task of classifying emotions is difficult and even complex for human competence. This demonstrates the importance of this task in assessing the current models and noting that, even for high-resource languages like English, multi-label emotion categorization requires further research. The inability to pinpoint the writers' precise emotions—which requires context—and the overlap between some emotion classes, like anger and disgust (for instance, anger and disgust may appear together, and joy and surprise may also exhibit similarities) are some of the challenges. Despite many constraints, our model has demonstrated a comparable performance in detecting multilabel emotions. Table 4 compares the performance of our model against the SemEval base model which used RemBERT, using macro F1 score.

Models	Languages	
	Amharic	English
BERT-base (ours)	0.6300	0.7025
RemBERT (Muhammad et al., 2025a)	0.6383	0.7083
Differences	0.0083	0.0058

Table 4: Comarsion of the performance of our model against SemEval baseline model, reflecting the existance of non significant differences, indicating that almost BERT performed equal to baseline model.

6 Conclusion and Future Work

This study investigated the use of a transformer-based model for multilabel emotion recognition in both Amharic and English. According to the study, the transformer-based BERT model produced the top F1-scores for both the English and Amharic datasets, indicating an effective outcome. The study's findings support the notion that transformer models are highly capable of classifying text in multilabel emotions. To improve the accuracy rate, the next stage should focus on utilizing large datasets, improved fine-tuning techniques, and contextual factors.

Abstract

This paper presents NarrativeNexus' participation in SemEval-2025 Task 10, which focuses on fine-grained entity framing and narrative extraction. Our approach leverages BART, a transformer-based encoder-decoder model, fine-tuned for sequence classification and text generation. We participated in Subtask 1 (Entity Framing) and Subtask 3 (Narrative Extraction) on the English dataset.

For Subtask 1, we employed a BART-based classifier to identify and categorize named entities within news articles, mapping them to predefined roles such as protagonists, antagonists, and innocents. For Subtask 3, we used a generative BART model to produce justifications for dominant narratives.

Our framework incorporated data augmentation through paraphrasing, confidence thresholding for post-processing, and a hallucination filtering module. While the system demonstrated strong narrative coherence, distinguishing between similar roles (e.g., protagonist vs. innocent) proved challenging. NarrativeNexus secured 17th place in Subtask 1 and 5th place in Subtask 3. We highlight effective modeling strategies and discuss concrete directions for future improvements.

1 Introduction

Entity framing and narrative extraction are essential tasks in natural language processing (NLP), enabling applications in media bias detection, sentiment tracking, and sociopolitical discourse analysis.

SemEval-2025 Task 10 comprises three subtasks, of which we addressed two: (1) Entity Framing and (3) Narrative Extraction. Subtask 1 required classification of named entities into predefined roles, while Subtask 3 focused on generating textual justifications for dominant narratives in news articles.

We used BART, a pre-trained transformer model, fine-tuned separately for sequence classification and text generation. Despite BART's strong baseline capabilities, additional techniques such as data augmentation, hallucination filtering, and post-processing were necessary to address domain-specific challenges.

2 Related Work

We reviewed and analyzed previous research on entity framing and narrative extraction, categorizing studies based on their methodologies and objectives.

Sinelnik and Hovy (Sinelnik and Hovy, 2024) explored multilingual disinformation framing using XLM-RoBERTa, effectively detecting thematic frames across multiple languages. Their work highlights the challenges of multilingual preprocessing and the importance of aligning embeddings with linguistic differences.

Xu et al. (Xu et al., 2024) introduced NARCO, a graph-based Transformer-XL model designed for narrative coherence. Their approach improved causal and temporal dependencies in long-form texts, significantly enhancing narrative consistency in text generation tasks.

Papalampidi et al. (Papalampidi et al., 2022) proposed a dynamic entity memory mechanism within a Transformer-XL framework. By tracking entity attributes throughout a narrative, their model ensured coherence and consistency in generated texts, making it valuable for long-form content generation.

Schäfer et al. (Schäfer et al., 2024) applied BERTopic for fake news analysis, demonstrating its superiority over traditional topic modeling methods like LDA and NMF. Their study uncovered nuanced themes within misinformation campaigns, improving content classification and thematic anal-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1411–1414

ysis.

Sinelnik and Hovy (Sinelnik and Hovy, 2024) also examined lexicon-based approaches for frame detection. While these methods offer interpretability and lightweight computation, they struggle to capture rare or evolving thematic frames, limiting their effectiveness for complex analyses.

These studies collectively contribute to advancing NLP methodologies for entity framing, misinformation analysis, and narrative generation. Our work builds upon these insights, leveraging transformer-based models for structured content analysis in SemEval-2025 Task 10.

3 Background

SemEval-2025 Task 10 consists of three subtasks. We participated in:

- **Entity Framing (Subtask 1):** Classify named entities into protagonist, antagonist, or innocent roles using surrounding context.
- **Narrative Extraction (Subtask 3):** Generate justifications for dominant/subnarrative pairs given full article text.

The English dataset was provided by the task organizers, along with gold-standard annotations. Detailed task descriptions are available in the official task paper (Piskorski et al., 2025).

4 Dataset and Preprocessing

The English dataset included approximately:

- Subtask 1: 1242 training instances with entities and context passages (with augmentation).
- Subtask 3: 88 article entries containing dominant/subnarratives (no augmentation was done).

For Subtask 1, we used pre-extracted context passages accompanying each entity in the dataset. These were paired with the corresponding entity and formatted as 'Entity: entity. Context: context' for BART input.

For Subtask 3, documents were truncated to 1,024 tokens using the Hugging Face tokenizer's built-in truncation mechanism, with narrative and subnarrative prepended to the article.

5 System Overview

5.1 Subtask 1: Entity Framing

We developed a BART-based sequence classifier to categorize named entities into *protagonists, antagonists, and innocents*. The dataset contained news articles with named entity mentions, contextual passages, and gold-standard labels. Each training instance was formatted as follows:

```
"Entity: {named entity}. Context:
{text snippet}. Classification:
{label}"
```

We fine-tuned `BART-large` using the BART tokenizer with a maximum sequence length of 512 tokens. The training hyperparameters, including batch size, epochs, and learning rate, are presented in Table 1. During training, we used cross-entropy loss and the AdamW optimizer with a linear decay learning rate scheduler.

To enhance generalization, we applied data augmentation techniques, particularly paraphrasing. We used a mix of GPT-based and Gemini-based paraphrasing APIs to rewrite approximately 15% of context passages in the training set. These paraphrased examples retained the original entity-role labels and were added back into the dataset, effectively doubling the training size.

Post-processing involved confidence thresholding to improve classification reliability. A softmax threshold of 0.5 was used for filtering uncertain predictions. Entities with <50% max confidence were labeled as "Uncertain" and excluded during test-time prediction. Error analysis revealed that distinguishing between *protagonists and innocents* was particularly challenging due to contextual ambiguities in news articles. The model was evaluated on the basis of Accuracy and F1 score. Table 3 presents the evaluation metrics and the scores.

5.2 Subtask 3: Narrative Extraction

For narrative extraction, we fine-tuned BART-large-cnn using a text-to-text generative approach. The dataset contained dominant narratives, subnarratives, and full article texts, structured as follows:

```
"Narrative: {dominant narrative}.
Subnarrative: {subnarrative}.
Article: {full text}"
```

The model was trained with a batch size of 4 for eight epochs, optimizing with cross-entropy loss

and the AdamW optimizer. The hyperparameter settings for Subtask 3 are detailed in Table 2.

A key challenge was ensuring factual consistency between generated justifications and the original article. To mitigate hallucination, we introduced an additional filtering step where justifications with low confidence scores were discarded. The evaluation relied on BLEU and ROUGE scores to measure output fluency and relevance. The model's performance results are presented in Tables 3 and 4.

6 Experimental Setup

6.1 Hyperparameters

The experimental configuration for each subtask is detailed in Tables 1 and 2.

Table 1: Experimental setup for Subtask 1

Configuration	Value
Pre-Trained Model	facebook/bart-large
Epochs	5
Batch Size	8
Learning Rate	5e-5
Data Splits	80% Train, 20% Validation

Table 2: Experimental setup for Subtask 3

Configuration	Value
Pre-Trained Model	BART-large-cnn
Epochs	8
Batch Size	4
Learning Rate	2e-5
Data Splits	80% Train, 20% Validation

7 Results

The performance of our system on the official test sets is presented in Table 4.

Table 3: Training Performance metrics for Subtask 1 and Subtask 3

Metric	Subtask 1	Subtask 3
Accuracy	0.835498	–
F1-score	0.737705	–
BLEU-4	–	0.104933
ROUGE-L	–	0.4138472

Table 4: Test Performance metrics for Subtask 1 and Subtask 3

Metric	Subtask 1	Subtask 3
Exact Match Ratio	0.18300	–
Micro Precision	0.20850	–
Micro Recall	0.18490	–
Micro F1-score	0.19600	–
Accuracy	0.71910	–
Precision	–	0.71991
Recall	–	0.74267
F1 Macro	–	0.73085

For Subtask 1, our system achieved an Exact Match Ratio of 0.18300, with micro precision, recall, and F1-scores of 0.20850, 0.18490, and 0.19600 respectively. The accuracy for identifying the main role of entities was 0.71910. These results indicate the difficulty in capturing fine-grained entity role distinctions, suggesting potential improvements through better feature engineering and model enhancements.

For Subtask 3, our system ranked 10th, achieving a Precision of 0.71991, Recall of 0.74267, and an F1 Macro score of 0.73085. The model demonstrated strong coherence in narrative justification generation, though further refinements in dataset curation and text conditioning techniques could boost performance further.

These results emphasize the effectiveness of transformer-based architectures in entity framing and narrative generation while highlighting areas where improvements in feature extraction and model fine-tuning could lead to higher accuracy.

8 Conclusion

We presented NarrativeNexus' approach to SemEval-2025 Task 10, focusing on entity framing and narrative extraction using BART. Our findings highlight the potential of pre-trained transformer models for structured content analysis, particularly in maintaining narrative coherence. However, challenges such as fine-grained role differentiation and ensuring factual consistency in justification generation remain areas for future improvement. We aim to explore alternative model architectures, data augmentation strategies, and more refined evaluation techniques in future work to enhance entity framing and narrative extraction capabilities. The insights gained from this work contribute to advancing au-

tomated media analysis and NLP applications in discourse understanding.

Abstract

We present a submission to the SemEval 2025 shared task on unlearning sensitive content from LLMs. Our approach employs negative preference optimization using low-rank adaptation. We show that we can utilize this combination to efficiently compute additional regularization terms, which help with unlearning stabilization. The results of our approach significantly exceed the shared task baselines.

1 Introduction

Transformer-based Large Language Models (LLM) trained on large data corpora have shown remarkable performance in many natural language processing tasks. However, their ability to remember portions of the training data (Carlini et al., 2021) might raise legal, ethical, and other issues. These consist of LLMs regurgitating copyright-protected creative content learned from the Web or private personal information such as social security numbers, addresses, and others. For the latter, regulations such as the EU's General Data Protection Regulation (GDPR) or the California Consumer Privacy Act (CCPA) mandate the right for the removal of such information from the training data as per the "Right to be forgotten".

Unfortunately, these issues are often discovered only after model training. Although discarding such sensitive items from the training data sets and subsequent retraining is possible, it is generally prohibitively expensive. The field of machine unlearning tackles this exact issue by treating the removal of information as model fine-tuning. Although several state-of-the-art approaches and benchmarks exist for LLM unlearning (Zhang et al., 2024a; Maini et al., 2024), the field is still relatively unexplored.

To facilitate further progress in the field, Ramakrishna et al. (2025b) developed a comprehensive evaluation challenge for unlearning sensitive datasets in LLM as a part of the International Workshop on Semantic Evaluation.[1] This paper presents our submission to the shared task.

To solve the task, we utilized the state-of-the-art unlearning method negative preference optimization (NPO; Zhang et al., 2024a). We combined this method with low-rank adaptation (LoRA; Hu et al., 2021) because we consider the computational effectiveness of unlearning to be of high importance. Although several approaches use parameter-efficient methods for unlearning in transformers (Gao et al., 2025; LiM et al., 2024; Ding et al., 2025), the combination of NPO and LoRA is novel.

We show that with LoRA, we can cheaply compute additional regularization terms that use the original model's output distribution without any memory overhead. We further show that including the KL divergence minimization regularization stabilizes the unlearning for a higher number of epochs. Furthermore, our solution significantly outperforms the shared task baselines. We release the source code of our submission on GitHub.[2]

2 Task Background

The goal of the shared task (Ramakrishna et al., 2025b) is to build a method for unlearning information from a given target large language model. For a given model, a forget set $\mathcal{D}_{\text{FG}}$, and a retain set $\mathcal{D}_{\text{RT}}$, the method should be able to remove the information present in the forget set from the model while preserving the data from the retain set and not deteriorating the model's performance on unrelated tasks.

As the target model, the task organizers utilized OLMo (a pre-trained LLM), specifically its 7B and 1B versions (Groeneveld et al., 2024). Since OLMo is trained on an open dataset Dolma (Soldaini et al., 2024), it makes for a good choice for this task.

These target models were further fine-tuned to

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1415–1422

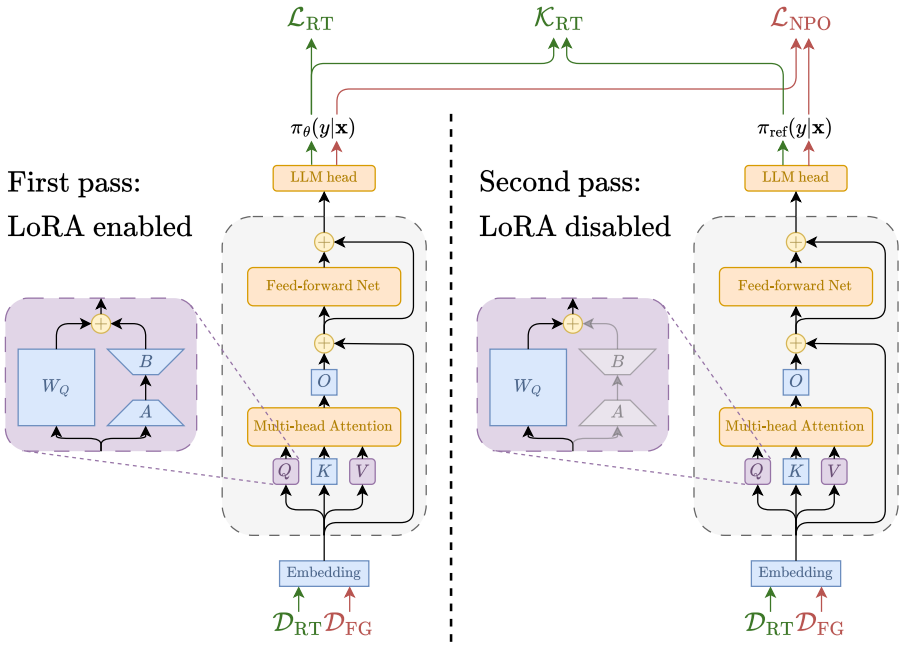

Figure 1: Overview of our unlearning method. We augment the model with LoRA and train only the LoRA parameters. For each batch, we compute our training loss shown in Equation 5 in two passes. During the first pass, we leave the LoRA layers enabled and compute the $\mathcal{L}_{\text{RT}}$ term of our loss. During the second pass, we compute the $\mathcal{K}_{\text{RT}}$ and $\mathcal{L}_{\text{NPO}}$ terms by disabling the LoRA layers and only utilizing the backbone. This way, we do not need to maintain a separate copy of the backbone.

remember a dataset consisting of three document types: long-form synthetic creative documents, short-form synthetic biographies containing personally identifiable information such as fake names, phone numbers, or home addresses, and real documents sampled from the Dolma dataset. Each entry in the dataset consists of input-output pairs that cover either sentence completion or question answering.

The organizers split this dataset into separate retain and forget sets, released the training and validation versions of each for the task, and provided an unlearning evaluation framework LUME (Ramakrishna et al., 2025a). The data is in English only.

3 Method Overview

Our approach for this task combines negative preference optimization (NPO; Zhang et al., 2024a) and low-rank adaptation (LoRA; Hu et al., 2021) for parameter-efficient fine-tuning.

3.1 Negative Preference Optimization

Most currently used unlearning approaches are based on gradient ascent (GA). Consider a language model π_θ with parameters θ, which models the next token y distribution based on context x. The basic premise is to ascend the classic next-token prediction cross-entropy loss on the forget data $\mathcal{D}_{\text{FG}}$ instead of descending it:

$$\mathcal{L}_{\text{GA}}(\theta) = \mathbb{E}_{\mathcal{D}_{\text{FG}}}\left[\log \pi_\theta(y|x)\right] \tag{1}$$

Zhang et al. (2024a) showed that the basic gradient ascent quickly deteriorates the utility of the model and proposed NPO as an alternative unlearning strategy. For the original model π_{ref}, and a positive hyper-parameter β, the NPO loss is as follows:

$$\mathcal{L}_{\text{NPO}}(\theta;\beta) = \\ = \mathbb{E}_{\mathcal{D}_{\text{FG}}}\left[\frac{2}{\beta}\log\left(1+\left(\frac{\pi_\theta(y|x)}{\pi_{\text{ref}}(y|x)}\right)^\beta\right)\right] \tag{2}$$

The authors further show that $\nabla_\theta \mathcal{L}_{\text{NPO}}(\theta;\beta)$ converges to $\nabla_\theta \mathcal{L}_{\text{GA}}(\theta)$ as β approaches zero. For positive values of β, the NPO loss effectively dampens the contribution of already unlearned samples.

We further extend $\mathcal{L}_{\text{NPO}}$ with two regularization terms. Zhang et al. (2024a) regularize the NPO loss with a "retain loss" $\mathcal{L}_{\text{RT}}(\theta)$ to improve their unlearning results.

$$\mathcal{L}_{\text{RT}}(\theta) = -\mathbb{E}_{\mathcal{D}_{\text{RT}}}\left[\log \pi_\theta(y|x)\right] \tag{3}$$

As a complement to the unlearning regularization by $\mathcal{L}_{\text{RT}}$, we also utilized the Kullback-Leibler divergence $\mathcal{K}_{\text{RT}}$ between π_θ and π_{ref} on the retained set. This regularization was also used by Maini et al. (2024).

$$\mathcal{K}_{\text{RT}}(\theta) = \mathbb{E}_{\mathcal{D}_{\text{RT}}}\left[KL\left(\pi_\theta(\cdot|x)||\pi_{\text{ref}}(\cdot|x)\right)\right] \quad (4)$$

The final loss $\mathcal{L}(\theta)$ we used for the task is as follows:

$$\mathcal{L}(\theta;\beta,\gamma,\delta) = \\ = \mathcal{L}_{\text{NPO}}(\theta;\beta) + \gamma\mathcal{L}_{\text{RT}}(\theta) + \delta\mathcal{K}_{\text{RT}}(\theta) \quad (5)$$

A significant issue with this approach is that $\mathcal{L}_{\text{NPO}}$ and $\mathcal{K}_{\text{RT}}$ both require us to maintain the output log-probs of the original π_{ref}. In the case of $\mathcal{L}_{\text{NPO}}$, we only need the log-prob of the specific token in the training set, which we can pre-compute before unlearning. Unfortunately, we need the entire output token distribution for $\mathcal{K}_{\text{RT}}$, which is unfeasible to precompute and save for each token in a sufficiently large training set. Therefore, we must compute it on demand, for which we would typically need to keep a copy of the original model in memory.

Our contribution comes from the insight that with LoRA, we can circumvent the need to keep a copy of the original model because the original model weights are still present within the augmented model. When we need to compute $\pi_{\text{ref}}(\cdot|x)$ for $\mathcal{K}_{\text{RT}}$, we ignore the LoRA transformations. We show the overall workflow of our method in Figure 1. In addition to that, LoRA substantially reduces the memory requirements for fine-tuning using AdamW (Loshchilov and Hutter, 2019).

3.2 Low-Rank Adaptation

The individual attention layers of OLMo each contain four linear transformations W_q, W_k, W_v, $W_o \in \mathbb{R}^{d\times d}$. The width and height d of the matrices are 2048 for OLMo-1B and 4096 for OLMo-7B. The AdamW optimizer stores the gradient moment estimations of these matrices, which poses a significant memory cost for model fine-tuning.

The idea of LoRA is to enhance some of the linear transformations $y := Wx$ within the attention layers of an LLM with a decomposed low-rank linear transformation. For matrices $A \in \mathbb{R}^{r\times d}, B \in \mathbb{R}^{d\times r}$ the augmented transformation becomes $y := Wx + \frac{\alpha}{r}BAx$. The value r is the rank of the transformation, and α is a hyper-parameter constant in r. The factor $\frac{\alpha}{r}$ is often introduced to counteract the effect that increasing r has on the effective learning rate. The original weights W are then frozen during fine-tuning and only the matrices A, B are updated. This drastically decreases the number of trained parameters as r can generally be set to a fairly low value, such as 2 or 5. The memory requirements of AdamW are thus significantly reduced as well.

LoRA has a further benefit over other parameter-efficient fine-tuning methods, such as adapters (Houlsby et al., 2019) and Quantized Side Tuning (Zhang et al., 2024b) in that the we can merge the low-rank matrices into the original weight matrix $W' := W + \frac{\alpha}{r}BA$ after we finish fine-tuning. This allows us to update the model without affecting its architecture.

4 Experiments

For our experiments, we focused on the fine-tuned OLMo-7B model, which we unlearned using the training retain and forget sets, all provided by the task organizers. We chose a fixed value $\beta = 0.5$ of the NPO loss hyper-parameter and $r = \alpha = 5$ for LoRA, as these values gave us reasonably good results. We experimented with various values for the hyper-parameters γ and δ. The learning rate was set to 10^{-4} with a batch size of 4. We perform a broader hyper-parameter search on the OLMo-1B model in Appendix A.

We used four combinations of values for γ, δ. In three of them, we set $\delta = 1$ and experimented with values $0, 0.5$, and 1 for γ to determine the effect of $\mathcal{K}_{\text{RT}}$ on the deterioration of the model. In the last run, we only kept $\mathcal{K}_{\text{RT}}$ with $\delta = 1$ and set $\gamma = 0$. We ran five independent runs with unique seeds for each of the combinations.

Following the shared evaluation scheme, we measure four scores to evaluate the quality of our solution. First, we calculate the ROUGE-L score (Lin, 2004) for each sample in the validation sets. By computing the score separately for sentence-completion and question-answering pairs of each document type in the forget and retain sets, we obtain 12 values. We invert the values for the forget sets and produce the Task score by merging the 12 resulting values using the harmonic mean.

We perform a loss-based Membership Inference Attack (MIA; Duan et al., 2024) and scale the resulting MIA score S_{MIA} to penalize both under-

Run	Epoch	Task score ↑		MIA score ↑		MMLU ↑		Final score ↑	
		μ	σ	μ	σ	μ	σ	μ	σ
$\gamma = 1, \delta = 0.0$	10	.431	.020	.657	.269	.461	.010	**.516**	.089
	20	.449	.029	.389	.117	.449	.008	.429	.043

Baseline GD	–	0	–	.382	–	.348	–	.243	–
Original model	*0*	*0*	–	*0*	–	*.510*	–	*.170*	–

Table 1: Unlearning results on fine-tuned OLMo-7B-0724-Instruct-hf for various hyper-parameters. The first four entries correspond to our experimental runs with different hyper-parameter choices. Each run was repeated five times with different seeds. We report the means and standard deviations of the scores after the 10th and 20th epochs, estimated from those five runs. We compare our results to the baselines reported by task organizers. "GD" stands for Gradient Difference (Liu et al., 2022).

and over-training: $S'_{\text{MIA}} := 1 - 2 \cdot |S_{\text{MIA}} - 0.5|$. To measure the degradation of the model after unlearning, we use the MMLU benchmark (Hendrycks et al., 2021). Finally, we compute the Final score as the arithmetic mean of the previous three scores.

5 Results

In Table 1, we report the mean values and standard deviations of the different scores estimated over the five unlearning runs. We evaluated the scores using the provided validation sets. We show the results after 10 and 20 unlearning epochs. We compare our results with the baselines provided by the shared task organizers.[3] In Figure 2, we show the development of the different scores throughout the epochs.

In general, our runs considerably outperform the provided baseline solutions. The runs that used $\mathcal{L}_{\text{RT}}$ overall did not degrade the MMLU score as much as those where only $\mathcal{K}_{\text{RT}}$ was involved. Including $\mathcal{K}_{\text{RT}}$ with positive δ in the loss slowed the training. However, since achieving a high MIA score required hitting a sweet spot between under- and over-training, including $\mathcal{K}_{\text{RT}}$ helped stability in the long run.

We placed lower than expected on the 7B model in the task leaderboard. This was caused by a logical error in our submission script, which effectively caused our solution to perform only three unlearning epochs instead of 20. We fixed our script for the 1B model evaluation, on which we ranked as expected.

6 Conclusion

The combination of NPO and LoRA proved to be an effective strategy for LLM unlearning. In addition to significant memory usage improvements, LoRA allows us to cheaply compute an additional regularization term, stabilizing the unlearning for a higher number of epochs. In our future work, we wish to further investigate the effect of LoRA and its rank on the resilience of the model to quality deterioration.

A Additional experiments

To choose the parameters for our task submission, we performed two hyper-parameter searches on the provided OLMo-1B model. For the first search, we initially set $r = \alpha = 5$ for the LoRA parameters and searched for optimal values of parameters γ, δ from our training loss shown in Equation 5. We experimented with utilizing only one of the regularization terms by setting one of the γ, δ parameters to zero, as well as combining the two terms with various factors. We kept the NPO regularization parameter constant with the value $\beta = 0.5$. We used the Adam optimizer with a learning rate of 10^{-4} and a batch size of 4 sequences. The fine-tuning ran for 20 epochs. We repeated each run five times with different seeds and averaged the resulting scores. We show the results in Table 2.

Overall, increasing γ and δ led to an increase in the task score. However, too high values of γ or δ led to a drop in the MIA score. On average, the combination of $\gamma = 1, \delta = 0.5$ gave us the best final score. We used this combination for our task submission and for further experiments on the OLMo-7B model, which we discussed in Section 4.

With the parameters $\gamma = 1, \delta = 0.5$, we also performed a second hyper-parameter search for the optimal value of the LoRA rank r. For this search, we kept the value of $\alpha = 5$ constant, as suggested by Hu et al. (2021). We kept β, the learning rate, batch size, and the number of epochs the same as in the previous search. Once again, we ran five experiments for each value of r, and averaged the resulting scores. The results can be seen in Table 3. In Figure 3, we show the development of the scores throughout the epochs. Although some of the runs exhibit better average performance in the various scores, we find the variance in our results too high to draw conclusions. Ultimately, we settled with the rank $r = 5$ for our submission, as we did not see any benefits in increasing the number of parameters with higher ranks.

Abstract

In this paper, we present our submission to SemEval-2025 Task 8: Question Answering over Tabular Data. This task, evaluated on the DataBench dataset, assesses Large Language Models' (LLMs) ability to answer natural language questions over structured data while addressing topic diversity and table size limitations in previous benchmarks. We propose a system that employs effective LLM prompting to translate natural language queries into executable code, enabling accurate responses, error correction, and interpretability. Our approach ranks first in both subtasks of the competition in the proprietary model category, significantly outperforming the organizer's baseline.

1 Introduction

The integration of Large Language Models (LLMs) into question-answering (QA) systems over tabular data has garnered significant attention in recent research, due to their capability to translate natural language into structured queries (Fang et al., 2024). First attempts in language-to-query conversion rely on fine-tuning pre-trained language models, so that they acquire tabular understanding (Liu et al., 2022). The vast contextual knowledge of LLMs, as well as their exposure on multiple modalities, including tabular comprehension, enables them to implicitly translate natural language in structured queries. As tabular QA arises as an emergent LLM ability (Chen, 2023), more and more prompting-based methods showcase improvements (Hegselmann et al., 2022; Nam et al., 2024).

Evaluating LLMs as tabular reasoners was explored with the DataBench dataset (Osés Grijalba et al., 2024), comprising 65 datasets from various domains, accompanied by manually crafted questions in natural language. Answers fall into different categories, such as boolean, categorical, numerical or list. Experiments utilizing in-context learning and code-based prompting reveal that while LLMs show promise, there is significant room for improvement, particularly in smaller scales.

In this paper, we explore a wide range of prompting strategies for Large LLMs to identify optimal methods for converting natural language queries into code and effectively interacting with tabular data. Specifically, we propose a system for generating executable Python functions from natural language queries through LLM prompting. Our approach achieves accuracy scores of 85.63% and 87.93% in the DataBench and DataBench Lite tasks respectively, ranking first in both tasks in the proprietary models category (Osés-Grijalba et al., 2025). After human evaluation, the accuracy increases to 89.85% and 88.89% in DataBench and DataBench Lite respectively. In our system, LLMs are explicitly instructed to articulate their reasoning process, improving the reliability of their outputs and facilitating interpretability.

Our code is available on GitHub[1].

2 Background

2.1 Task description

The data used for this task are sourced from DataBench (Osés Grijalba et al., 2024). The task consists of queries in the form of (T, Q) where T is a structured table containing a set of c columns $\{\text{col}_1, \ldots, \text{col}_c\}$ and a set of r rows $\{\text{row}_1, \ldots, \text{row}_r\}$. Each row consists of c values $\{\text{row}_{i,1}, \ldots, \text{row}_{i,c}\}$, which correspond to the entries in the table for the respective columns. These values can be of various data types commonly found in real-world datasets in English, such as numbers, categorical values, dates, and text. Additionally, some values may be missing. The expected answer to the query is a value a of type `boolean`, `category`, `number`, `list[category]` or, `list[number]`. Answers are computed based on a small subset of the columns

[1] https://github.com/andrewevag/tabularqa

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1423–1435

and may either be values directly present in T or include statistics computed on these values.

Two subtasks are proposed with regards to the size of the table T of the input query:

Subtask I: DataBench QA – A table of any size is provided along with a question in natural language.

Subtask II: DataBench Lite QA – The same task is performed using a sampled version of the tables, where a maximum of 20 rows is retained.

2.2 Related work

LLMs excel in various tasks but struggle with tabular data, especially when key information is dispersed across large tables and complex queries (Ye et al., 2023). This necessitates shifting from direct LLM reasoning to generating intermediate representations in SQL or Python (Zhang et al., 2023b). For instance, Zhang et al. (2023a) serialize table schemas, enabling GPT-3 to iteratively refine SQL queries by correcting syntax and compilation errors. Similarly, Plan-of-SQLs (POS) (Giang et al., 2024) decomposes complex queries, reducing reliance on advanced Text-to-SQL models. PAL (Gao et al., 2023) generates intermediate programmatic steps, outsourcing execution to a Python interpreter. Lei et al. (2023) integrate multiple LLMs into a toolkit, leveraging Chain of Thought (CoT) (Wei et al., 2023) and Program of Thoughts (PoT) (Chen et al., 2022) prompting to enhance SQL-based reasoning. TabLLM (Zha et al., 2023) further extends comprehension by jointly training LLMs on tables and text. Building on this, Ye et al. (2023) improve table-based reasoning by segmenting large tables into relevant sub-tables and decomposing complex queries. Unlike intermediate representation-based methods, Wu and Hou (2025) use in-context learning with retrieval-augmented generation (RAG) for direct tabular query answering. Agarwal et al. (2025) enhance in-context learning by integrating tabular data and queries into a unified hybrid graph. Zhu et al. (2024) employ a step-wise pipeline to distill knowledge, enabling smaller models for discrete reasoning over tabular data.

3 System Overview

Our system mainly performs text-to-Python code conversions to queries via prompting. This allows for a lightweight and task-agnostic implementation that employs LLMs without further training. Specifically, the system consists of two modules: the Main Module and the Error-Fixing Module. An overview of the architecture provided in Figure 1.

3.1 Main Module

This module is responsible for translating the query (T, Q) into executable Python code. First, a prompt is generated by applying a predefined template to the input (T, Q). This prompt is then provided to an LLM, which completes a Python function P that takes the table T as a `DataFrame` input and, when executed, answers the question Q. The generated code is executed by a Python interpreter, which calls the function with the table T and outputs the predicted answer $\hat{a}$. If execution completes without errors, $\hat{a}$ is considered the system's final prediction. Otherwise, the Error-Fixing Module is invoked.

Prompt The prompt template f is used to structure the input of the LLM based on a (T, Q) pair, incorporating the following fields:

1. Task Description (TD): A comment describing the objective of completing a Python function to answer Q, followed by the function header.

2. Column Description (CD): A multiline comment listing the column indices, names, data types, and example values in CSV format.

3. Sample Rows (SR): A comment containing the first n rows of the table. Columns with values exceeding n_c characters are truncated, and values are right-aligned with spaces (Rajkumar et al., 2022).

4. Columns Used and Answer Type (CUAT): Comments specifying the columns required to answer Q, their data types, and the expected answer type.

Since CUAT is unknown for a new (T, Q) pair, generating P involves two steps. First, the LLM is prompted with (T, Q) using an incomplete version of f, denoted as f_{inc}, which contains TD, CD, and SR, to infer CUAT. Then, the inferred CUAT is incorporated into f, forming a complete prompt with all four fields.

In both steps, we leverage in-context learning by incorporating k manually crafted examples $\{(T_i, Q_i, P_i)\}_{i=1}^{k}$, where each (T_i, Q_i) pair represents a table and its corresponding query, and P_i is a program that processes T_i to answer Q_i. Each example is structured using the same template f, (CUAT is extracted by the P_i), and is appended with the corresponding P_i. The complete prompt for the first step is:

$$p_1 = (f(T_1, Q_1)||P_1)||\ldots||(f(T_k, Q_k)||P_k)$$

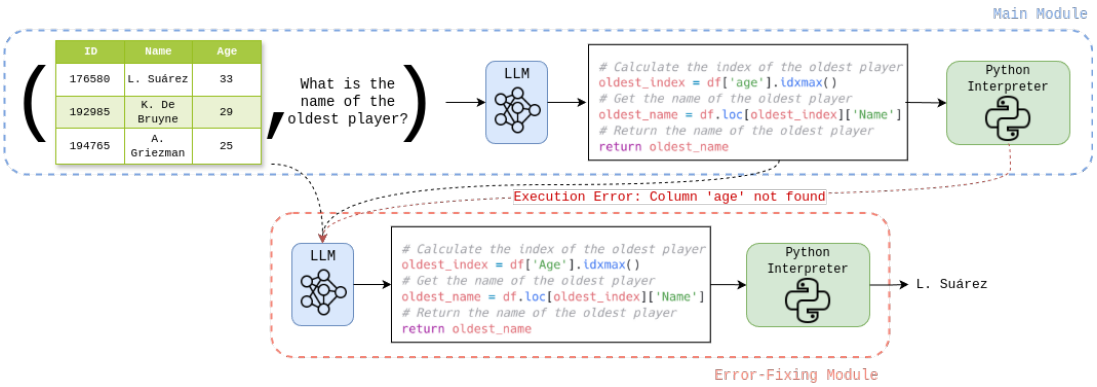

Figure 1: Overview of the architecture of our system.

$||f_{\text{inc}}(T, Q)$ while for the second: $p_2 = (f(T_1, Q_1)||P_1)|| \ldots ||(f(T_k, Q_k)||P_k)||f(T, Q)$, where p_1, p_2 are the prompts used for Steps 1 and 2, respectively, and the CUAT field in $f(T, Q)$ of p_2 is computed by $g(p_1)$, where g is the output of LLM given a prompt. Further details on prompt construction are provided in the Appendix A.

Example Programs Furthermore, to enhance program generation, we incorporate a CoT strategy. This involves inserting comments describing intermediate reasoning steps, interleaved with the Python statements implementing these steps. Our approach aligns with methods used in PAL (Gao et al., 2023) and PoT (Chen et al., 2022), aiming to leverage LLMs' reasoning capabilities while mitigating computational inaccuracies by offloading calculations to the Python interpreter. Meaningful variable names are also included in example programs, as they can further facilitate reasoning by clarifying intent.

Upon observing the example programs, the LLM generates a completion of the Python function P to answer Q, incorporating its reasoning in comments. The generated program is then executed by the Python interpreter, which outputs the predicted answer $\hat{a}$. If execution timeouts or fails, both the generated code and a description of the error are passed to the Error-Fixing Module.

3.2 Error-Fixing Module

This module utilizes an LLM prompted to correct execution errors in the function P. The prompt includes the following components:

1. Task Description: A description of the objective, instructing the model to fix the error.

2. Faulty Program: The erroneous code presented in the format $f(T, Q)||P$.

3. Code Error: A description message of the execution error.

4. Function Header: The corrected function signature that the model will complete.

Once the LLM generates the corrected function, it is executed in the Python interpreter to produce the answer $\hat{a}$. If execution completes successfully without timing out or failing, the system's final prediction is $\hat{a}$. Otherwise, it retries until the maximum attempts and outputs `Error` if all fail.

4 Experimental Setup

Dataset The dataset used for model development is publicly available on Hugging Face[2]. It contains 1,308 questions across 65 tables. We derive our exemplars from the predefined `train` split, comprising 988 questions from 49 tables. The columns required to answer each question, their data types, and the answer's data type are precomputed by the task organizers and included in the dataset. Our annotations focus solely on the expected code and reasoning steps generated by the LLM. Model evaluation is conducted on the `dev` split, which includes 320 questions from 16 tables, as well as on the `test` set, which consists of 522 questions from 15 tables and serves as the basis for the final ranking.

Evaluation Metric Model performance is assessed using a relaxed accuracy measure, which accounts for predictions with equivalent semantic meaning, e.g. the prediction `"Yes"` is considered correct if the gold answer is `True`. Numerical answers are truncated to two decimal places before being compared against the gold answer. The evaluation metric is provided by the task organizers through the `databench_eval`[3] Python package.

[2] https://huggingface.co/datasets/cardiffnlp/databench

[3] https://github.com/jorses/databench_eval

Baseline The baseline system employs a model to convert the input query into a Python function that takes the table as a `Pandas DataFrame` and returns the answer to the question. The generated function is then executed by the Python interpreter. The prompt includes detailed task instructions along with a simple example of a completed function. Additionally, it provides the names of the columns in the input `DataFrame` as a list. The model utilized is stable-code-3b-GGUF[4].

Models and Hyperparameters We evaluate the performance of multiple LLMs as components of our system. In all experiments, the same LLM is used for both the Main and Error-Fixing Modules. The models include open-source variants of Llama (8B, 70B, and 405B), proprietary models like Claude 3.5 Sonnet, and code-generation models such as Qwen 2.5-Coder 7B. Details on model versions are in Appendix D.

For code generation, we select a temperature of `temp=0` and `top_p=0.9` in all experiments, except for the Error-Fixing Module for smaller models ($\leq$ 70B parameters), where we set `temp=1` and allow up to three invocation attempts. The Main Module processes five rows from the table, while the Error-Fixing Module processes ten rows for both DataBench and DataBench Lite. The prompt includes nine exemplar cases, ensuring coverage of all possible answer data types in DataBench.

Resources Experiments involving Claude 3.5 Sonnet and Llama 3.1 Instruct 405B are conducted using Amazon Bedrock, while experiments with the remaining models are performed using Ollama on 4 NVIDIA A10G GPUs.

5 Results

Rankings Table 1 presents accuracy scores on `dev` and `test` set for our system, considering LLMs of different sizes. We rank 1^{st} in both subtasks in the proprietary models track when employing Claude 3.5 Sonnet, which demonstrates substantial improvements over the baseline, surpassing it by $\sim$60% in both subtasks. Moreover, our system ranks 3^{rd} in DataBench in the open-source category using Llama 3.1 Instruct 405B. Our system significantly outperforms the baseline even when employing smaller models ($\leq$ 8B parameters). The accuracy scores of both smaller models rank just below the 2^{nd} and 3^{rd} positions in DataBench and DataBench Lite respectively, in the smaller model ranking. However, due to submission limitations in the official competition, smaller models' predictions were not submitted and are therefore not reflected in the final competition rankings.

Large vs. Small Models Our findings indicate that our system's performance is heavily influenced by the overall capabilities of the LLM used. Larger models achieve up to 20% higher accuracy in both subtasks, which is expected given their superior code generation capabilities. This is evident even when compared with a smaller model that is specifically trained for code generation tasks.

Information in the Prompt We conduct an *ablation study* on the different fields included in the prompt used in the Main Module to assess their impact on performance. Specifically, we evaluate the accuracy of the Main Module using Llama 3.1 Instruct 405B as the underlying LLM, incrementally increasing the amount of information provided in the prompt until it matches the final system configuration. The results are reported in Table 2, including the following configurations:

1. **Simple Example + TD + CD + SR**: The prompt includes the fields TD, CD, and SR, along with a simple example of a completed function that calculates the number of rows in a `DataFrame`, as used in the baseline.
2. **Few-Shot (FS)**: The prompt includes examples of completed functions using single-line `Pandas` statements. The LLM is instructed to generate function completions in a similar format.
3. **FS CoT**: The prompt includes examples of completed functions with the reasoning steps in comments. The LLM is instructed to generate responses following the same approach.
4. **FS TD + CD + SR**: The prompt includes TD, CD, and SR, along with examples of completed functions using single-line `Pandas` statements. The LLM is instructed to generate single-line function completions.
5. **FS CoT + TD + CD + SR**: The prompt includes all fields of the Main Module, excluding CUAT. The exemplars contain reasoning steps as comments, and the LLM is prompted to generate responses following the same approach.

We observe that the sole inclusion of column and row descriptions provides minimal improvement in model accuracy on the `test` set, while performance decreases on the `dev` set. However,

Table 3: Accuracy scores (%) for the `test` set of Main Module and Full System, and number of errors fixed by the Error-Fixing Module for all models. **Bold** highlights best accuracy results across models.

their significance becomes apparent when multiple exemplars illustrating the task are included in the prompt. In the FS setting, model performance significantly improves across all datasets and subtasks; Notably, the mere incorporation of a single task demonstration increases accuracy by more than 10% across all datasets and subtasks. Finally, allowing the LLM to explicitly express its reasoning—detailing the information extracted from the table, the expected outcome, and the intermediate steps to derive the answer—leads to a consistent improvement in performance across all tasks.

Significance of the Error-Fixing Module We present the `test` set accuracy scores with and without the involvement of the Error-Fixing Module, along with the number of correctly fixed errors—resulting in the gold label— in Table 3. The Error-Fixing Module provides an average accuracy increase of 2.4% across all models and subtasks.

Larger models, such as Claude 3.5 Sonnet and Llama 3.1 Instruct 405B, produce fewer execution errors and successfully correct more than 40% of them across all tasks. In contrast, smaller models generate a higher number of errors and demonstrate limited error-correction capabilities, successfully resolving only 30% of their execution errors at most. While further improvements to the Error-Fixing Module could substantially enhance the accuracy of smaller models, their impact on larger models would likely be minimal, as these models are inherently less prone to generating code that results in execution errors.

6 Conclusion

In this work, we present our system for SemEval-2025 Task 8: Question-Answering Over Tabular Data, which translates natural language questions into executable Python functions using only LLM prompting. Our approach decomposes the task into smaller steps, explicitly demonstrating its reasoning process, and incorporates a self-correction mechanism to handle execution errors. As a result, our system ranks first in both subtasks within the proprietary model category.

A Prompts

A.1 Main Module

We display the prompt used in the system's Main Module. A single annotated exemplar, i.e., $f(T_1, Q_1)||P_1$, is presented in Figure 2. Multiple exemplars are included before the definition of the function to be completed. The final segment of the prompt, $f_{\text{inc}}(T, Q)$, corresponding to an example query, is shown in Figure 3.

The column description notably includes (1) the number of non-null values present in each column, (2) the type of the column as parsed by `Pandas`, (3) a list of all Python types present in the column, and (4) example values of categorical columns enclosed in quotes to highlight cases requiring special handling. For instance, all categorical values in the column `'Name'` in Figure 2 begin with a space character. In all our examples, we include up to five values. If all values in a categorical column are fewer than five, we explicitly note their values.

The LLM is instructed, within the same prompt, to first predict the columns used to answer the question, their types, and the type of the answer. It then generates reasoning comments along with the code to derive the answer. The response of Llama 3.1 Instruct 405B for the prompt ending in Figure 3 is presented in Figure 4. The model correctly identifies the relevant columns and the answer type. Subsequently, it generates the code in multiple steps, clearly outlining its reasoning through comments above the corresponding statements.

A.2 Error-Fixing Module

An example prompt for the Error-Fixing Module concerning an execution error is displayed in Figure 5. The actual representation of roles in the implementation varies depending on the LLM used. The task description is followed by the function signature and the erroneous code generated by the LLM, $f(T, Q)||P$. The generation from the Main Module is then followed by the error message. The model is subsequently tasked with rewriting the function to both fix the execution error and correctly answer the question. The completion of Llama 3.1 Instruct 405B for the prompt in Figure 5 is shown in Figure 6.

The error message conveys critical information that the model could not infer from the initial prompt. For example, although the response of the Main Module in Figure 4 follows the essential steps to answer the question, the model is unaware that the column `'Weight Class'` contains the value `'Open'`. Given the potentially large size of tables in the dataset, crucial information necessary to answer the question may not be included in the prompt but can instead be inferred from the error message.

A.3 Prompt Size

M.M Avg. #Tokens		E.F.M Avg. #Tokens	
DB	DB Lite	DB	DB Lite
Llama Family (128K)			
19,160.9	6,518.2	2.738.4	3268.2
Claude 3.5 Sonnet (200K)			
22,764.7	7,391.7	6,573.4	4,037.8
Qwen2.5-Coder 7B (128K)			
21,816.1	7,058.2	2,700.2	3,117.7

Table 4: Average Token Count for the prompt generated in the Main Module (M.M) and Error-Fixing Module (E.F.M) for both subtasks of the `test` set for the different model families. The size of the context window for the different families is presented in parenthesis.

We present the average number of tokens in the prompts for both the Main and Error-Fixing Modules across the different model families in Table 4. On average, the Main Module utilizes approximately 20K for all models. Meanwhile, the Error-Fixing Module includes the header and the erroneous code produced in the prompt without additional exemplars demonstrating the task. As a result, the Error-Fixing Module requires fewer tokens, remaining below 4K tokens in most cases.

B Exploratory data analysis

Tables The DataBench dataset consists of a total of 80 tables (65 in the `train` and `dev` sets, and 15 in the `test` set) of varying sizes and diverse content. The distribution of table row counts across all sets in the DataBench task is shown in Figure 7. Table sizes range from fewer than 100 rows to several hundred thousand rows. In contrast, all tables in

Figure 6: Example response from Llama 3.1 Instruct 405B as component of the Error-Fixing Module.

DataBench Lite contain only 20 rows, sampled from the larger dataset.

Figure 8 presents the distribution of column counts across all dataset splits. The number of columns in DataBench ranges from 3 to 123 in the dev set and up to 35 in the test set.

Questions DataBench and DataBench Lite contain the same set of questions, with the only difference being that DataBench Lite uses sampled subsets of the original tables. Example questions, along with their corresponding answers, answer data types, and the columns used in their derivation, are presented in Table 5. All questions are answered exclusively using information present in the table.

In the annotated train and dev sets, the derivation of answers involves one, two, or three columns. Figure 9 presents an overview of the column data types utilized across the dataset. The most commonly used column data types in these sets are number and category.

The dataset defines five possible answer data types:

1. boolean: The only type with a predefined set of values (True or False).
2. number: Includes both integers and real numbers.
3. category: A single categorical value represented as a string.
4. list[category]: A list containing a fixed number of categorical values.
5. list[number]: A list containing a fixed number of numerical values.

Both datasets contain an equal number of questions corresponding to each possible answer data type.

Use of Textual Columns We analyzed the role of textual columns in cases where they contribute to the answer in the annotated train and dev sets, identifying 30 such instances. These cases include questions where the text data type appears among the utilized column data types included in the annotations. Textual columns are used in one of the following ways:

1. **Uniqueness Tests**: The answer depends on whether the column contains unique values.
2. **Length Conditions**: The length of the text in each cell contributes to the answer.
3. **Existence and Occurrence of Substrings**: The answer is derived based on whether a cell contains a specific substring or the number of times the substring appears within the cell.
4. **Word Count**: The number of words in each cell contributes to the answer.
5. **Index-Based Lookup**: The answer consists of one or more cells from the column, selected based on a Boolean mask.

We observe that all of these tasks can be addressed solely through programmatic statements and do not require more advanced natural language processing capabilities, such as sentiment analysis of each cell of a textual column. Consequently, we focus exclusively on program generation and do not explore more sophisticated techniques for extracting information from textual columns, such as those proposed in (Cheng et al., 2023; Gemmell and Dalton, 2023).

C Example Generations of the Main Module

Responses generated by the Main Module for the questions in Table 5 are presented in Table 6. The responses were produced using Claude 3.5 Sonnet. The model first predicts the columns it will use to answer the question, along with the expected data type of the answer. It then generates the function completion, demonstrating a strong ability to follow exemplars and decompose its reasoning into smaller steps. This structured thought process allows for efficient verification and provides some confidence in assessing the correctness of the generated response.

Larger models, such as Claude 3.5 Sonnet and Llama 3.1 Instruct 405B, exhibit a strong grasp of the underlying programming language, making them less prone to syntactic errors (Wang et al., 2025). However, they are still susceptible to semantic errors such as reasoning mistakes. For instance, in the first entry of Table 6, the model incorrectly predicts the relevant column to use, despite the column name being partially mentioned in the question. Additionally, LLMs can make more subtle reasoning errors. In the final entry, for example, the Main Module incorrectly retrieves the four highest

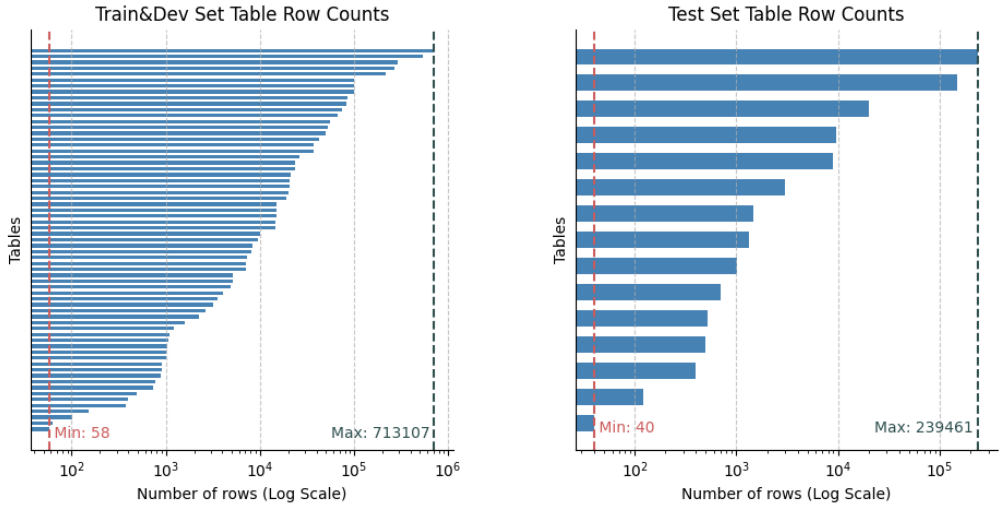

Figure 7: Number of rows of all tables in `train` & `dev` set and in the `test` set.

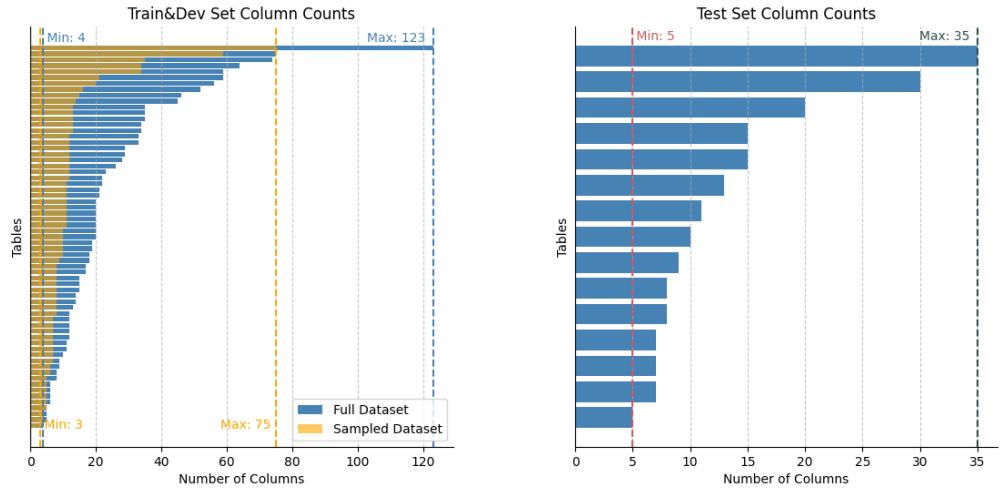

Figure 8: Number of columns of all tables in `train` & `dev` set and in the `test` set. Sampled versions of the tables used in the `test` set for DataBench Lite include all columns of the original tables.

Question	Answer	Answer Type	Columns used
How many unique types of animals are there?	`4`	`number`	`['class_type']`
Is the maximum level of Extraversion greater than the maximum level of Agreeableness?	`True`	`boolean`	`['Extraversion', 'Agreeableness']`
What are the top 3 reviewer locations with the most reviews?	`['United States', 'Australia', 'Malta']`	`list[category]`	`['Reviewer_Location']`
What is the most frequent age group among the respondents?	`25-34`	`category`	`['How old are you?']`
What are the top 4 numbers of claims in the patents?	`[12, 18, 7, 13]`	`list[number]`	`['num_claims']`

Table 5: Sample questions with the corresponding answers, data types of answer and the names of the columns used to answer the question sampled from DataBench Lite `train` and `dev` sets.

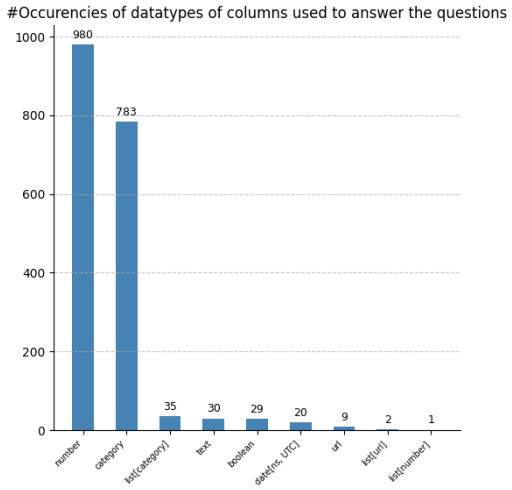

Figure 9: Number of times a column of each data type is used in a query. This categorization includes the samples in the `train` and `dev` set, which are annotated by the task organizers.

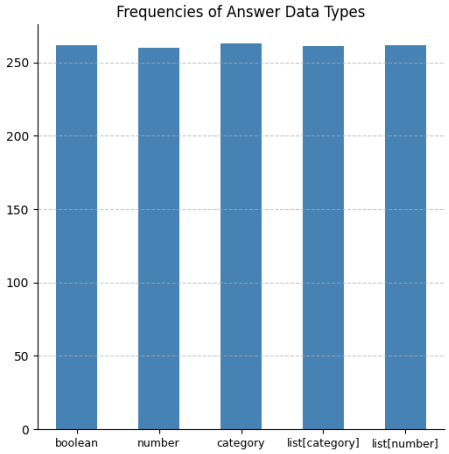

Figure 10: The frequencies of every answer data type in DataBench `train` and `dev` set.

values of the numerical column `num_claims` instead of identifying the four most common values, as required.

Even in cases where errors occur, the structured format of the generated responses allows for quick validation of the LLM's output. The categorization of errors in code generation has been an area of recent research (Wang et al., 2025). Adapting these error taxonomies to the tabular setting and further refining error classification is a promising research direction. Such efforts could enhance our understanding of errors LLMs make when translating natural language queries to code in Table Question Answering (TQA) and aid in developing methods to mitigate them.

D Model Versions

The models used in this study are the latest available versions at the time of experimentation. Specifically, they include a combination of proprietary and open-source models, along with models trained specifically for code generation. The proprietary models include Claude 3.5 Sonnet[5], developed by Anthropic. Additionally, we incorporate open-source models such as Llama 3.3 70B[6], Llama 3.1 8B[7], and Llama 3.1 Instruct 405B[8], which offer varying parameter sizes to assess performance scaling effects. Lastly, we include Qwen 2.5-Coder 7B[9], a model specifically optimized for code generation, to evaluate its effectiveness in program synthesis tasks.

HalluSearch at SemEval-2025 Task 3: A Search-Enhanced RAG Pipeline for Hallucination Detection

Mohamed A. Abdallah, Samhaa R. El-Beltagy
School of Information Technology, Newgiza University
mohamedabdallah9850@gmail.com, samhaa@computer.org

Abstract

In this paper, we present **HalluSearch**, a multilingual pipeline designed to detect fabricated text spans in Large Language Model (LLM) outputs. Developed as part of Mu-SHROOM, the Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes, HalluSearch couples retrieval-augmented verification with fine-grained factual splitting to identify and localize hallucinations in 14 different languages. Empirical evaluations show that HalluSearch performs competitively, placing fourth in both English (within the top 10%) and Czech. While the system's retrieval-based strategy generally proves robust, it faces challenges in languages with limited online coverage, underscoring the need for further research to ensure consistent hallucination detection across diverse linguistic contexts.

1 Introduction

Ever since the introduction of the transformer architecture (Vaswani et al., 2017) and more specifically with the rise of decoder-only large language models (LLMs), significant advances in the field of natural language processing have been made LLMs excel at text generation and are widely used for tasks such as translation, summarization, and question answering.

Despite their impressive capabilities, being statistical language models, LLMs can sometimes produce factually incorrect or inaccurate statements, often presented in a very convincing manner. This phenomenon is commonly referred to as hallucination. Hallucination is a significant drawback of LLMs which vary in scale from a few billion to hundreds of billions of parameters (Brown et al., 2020). It has been observed that relatively smaller models tend to hallucinate more frequently due to limitations in their training data and model complexity (Li et al., 2024).

Hallucinations in LLMs can have grave consequences. For example, in critical domains like healthcare, relying on an LLM that hallucinates, for diagnosis, can lead to deaths or disabilities. Similarly, in the business and technology sectors, hallucinations may result in poor decision-making, leading to significant financial losses and misallocated investments. Therefore, detecting and localizing hallucinated segments in LLM responses is crucial for developing trustworthy LLM-driven applications.

Mu-SHROOM, is a Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes (Vázquez et al., 2025) and is and extension to an earlier task, SHROOM (Mickus et al., 2024) and is part of SemEval-2025. The task aims to identify spans of text corresponding to hallucinations within a multilingual context, covering 14 languages: Arabic (Modern standard), Basque, Catalan, Chinese (Mandarin), Czech, English, Farsi, Finnish, French, German, Hindi, Italian, Spanish, and Swedish.

In this shared task, each datapoint consists of an output string generated by one of the publicly available LLMs in response to a user query. The goal is to calculate, on a character-level, the probability that a character is part of a hallucination span.

In this work, we propose a novel system, HalluSearch**,** designed to detect hallucinated spans in multilingual LLM responses. Our approach utilizes retrieval-augmented generation (RAG) as introduced by (Lewis et al., 2020) where external, trusted sources are used to factcheck a model's response which in turn helps determine which parts of a model's response are fabricated, or factual. Our experiments show that HalluSearch achieves competitive performance in several languages such as, English and Czech.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1436–1441

We believe that this is largely due to the availability of online resources related to topics covered in the task. However, challenges persist in consistently detecting hallucinations across other languages, highlighting the need for further refinement and adaptation of the presented approach.

All code and experiment details are publicly available in our GitHub repository, to ensure transparency and reproducibility.

2 Related work

As stated earlier, the term 'Hallucination' has been recently used to describe a challenging phenomenon in the context of LLMs. This phenomenon involves generated content that is nonsensical or unfaithful to the input or context provided. The work of (Berberette et al., 2024) re-examines the notion of hallucinations in LLMs through the lens of human psychology. The authors argue that traditional use of this term may be misleading when applied to AI-generated content and emphasize the value of a psychologically informed approach depending on cognitive dissonance, suggestibility, and confabulation as the basis for their approach to mitigate hallucinations and other issues in LLMs.

(Xu et al., 2025) formally addressed hallucination for LLMs by employing results from learning theory findings and demonstrated that hallucination is inevitable for all computable LLMs. HaluEval proposed by (Li et al., 2023) provided a large-scale benchmark for evaluating an LLM's ability to recognize hallucinations. Tonmoy et al. (Tonmoy et al., 2024) surveyed various strategies for mitigating hallucinations, offering insights into potential solutions for this persistent issue.

SHROOM was launched to address the challenge of detecting hallucinations in output generated by Natural Language Generation (NLG) systems. Solutions such as Halu-NLP (Mehta et al., 2024) and OPDAI (Chen et al., 2024) have been proposed to tackle these challenges. However, pinpointing the exact locations of hallucinations was not addressed by this task. Mu-SHROOM, the current iteration of SHROOM, has thus introduced this goal while narrowing the focus to question answering and corresponding LLMs outputs.

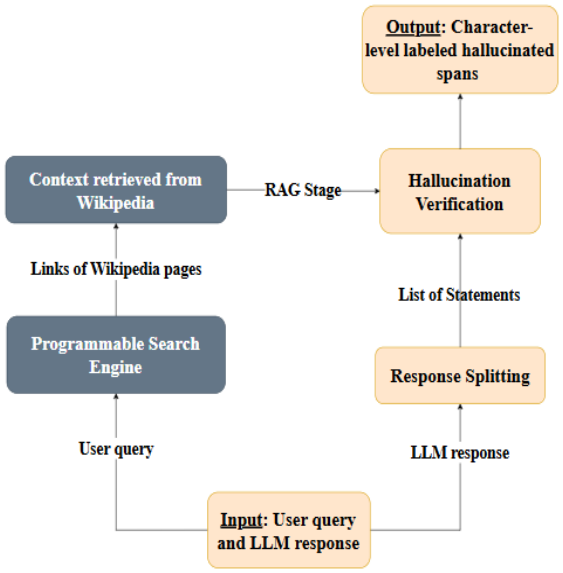

Figure 1: Illustration of HalluSearch building blocks

3 Methodology and Experimental setup

Our HalluSearch pipeline includes three major parts: (1) Factual Splitting, (2) Context Retrieval, and (3) Hallucination Verification. The pipeline begins with an input of user query and an LLM-generated response. It then employs the **Factual Splitting** module to divide the text into discrete factual **statements**. Next, the **Context Retrieval** stage uses search results from Wikipedia to gather relevant background information for each query. Finally, the **Hallucination Verification** step compares each statement to its retrieved context counterpart and annotates any spans that looks unsupported or incorrect at a character-level granularity, resulting in an output of labeled hallucinated segments, as shown in figure 1.

3.1 Factual Splitting

In this work, we have aimed to break down a LLM response to a query, into segments that ideally each contain a single verifiable proposition. By doing this, our system can isolate discrete claims or statements of a larger LLM-generated response and verify them independently. We have named this step fact splitting.

This approach draws inspiration from earlier work on claim extraction in fact-checking tasks, such as the FEVER dataset (Thorne et al., 2018), where individual claims are identified and evaluated against a knowledge base. Similarly, the notion of "atomic content units" introduced in

summarization literature (Narayan et al., 2018; Maynez et al., 2020) has shown that decomposing a complex text into smaller, independent factual assertions can greatly improve downstream verification

By applying a similar splitting method in our system, we reduce the risk of conflating multiple assertions within a single verification step minimizing the likelihood of mistakenly flagging correct statements (false positives) or overlooking genuinely incorrect content leaving it undetected within a more extensive chunk of text (false negatives).

The implemented factual splitting module leverages a prompt-based approach to generate atomic claims. Specifically, we employed, the GPT-4o model was used to generate a structured JSON output containing atomic claims and their exact substrings. To achieve this, we crafted a carefully designed prompt that emphasizes the importance of capturing short words and phrases carrying standalone claims (e.g., "Yes," "No," or their multilingual equivalents), while preserving punctuation, spacing, and capitalization.

If a fragment can stand on its own as a separate claim, it is separated from longer statements to facilitate more precise downstream verification. The prompt also enforces strict JSON formatting, which helps us map each extracted statement back to its location in the original text without losing track of language-specific nuances.

Through this fine-grained segmentation, the subsequent verification steps are better positioned to align each claim with authoritative context and detect potential hallucinations on a more granular level.

3.2 Context Retrieval

Retrieval-Augmented Generation (RAG) is a powerful technique that enriches language model outputs with external evidence, thereby enhancing factual accuracy and reducing hallucinations (Lewis et al., 2020; Izacard et al., 2021). Rather than relying solely on knowledge learned by LLMs during pretraining, a RAG-based system queries an external knowledge source, such as a search index or document database, to ground its inferences.

This approach has proven to be effective for tasks like open-domain question answering, where up-to-date or domain-specific context is essential. In our pipeline, we apply a similar principle by integrating a Google Custom Search[1] component. This component retrieves potentially relevant web content related to the original input query, allowing our verification model to check each factual statement against live, authoritative sources.

We select the highest-ranked retrieved result for a reputable knowledge source such as Wikipedia, as we aim to obtain the most relevant background information possible. Wikipedia was chosen as a primary knowledge source whenever it appears in the results, due to its status as the most diverse, popular, and widely used encyclopedia globally. Fallbacks are utilized to address incomplete or unavailable search results.

Specifically, two fallback strategies were implemented to retrieve some form of context. In the first strategy, keyword extraction on the user query or statement is carried out to reissue a more concise, focused query to the Custom Search API. This step can be critical in languages or domains where standard queries are too broad, or if initial results are sparse.

If this strategy fails to produce a usable context, we resort to a language model fallback, prompting an LLM (GPT 4o in our case) to generate a short textual passage in the same language as the query.

Although this third option is less reliable in terms of factual grounding, since the LLM itself can hallucinate, it ensures that the verification stage has at least some reference text to work with, Table 1 shows an example of fallback scenarios. Hence, our retrieval architecture remains robust across scenarios where conventional search engines might lack indexed pages or face query limitations, thereby maintaining a RAG-inspired approach in all but the most complicated cases.

3.3 Hallucination Verification

The goal of this step is to determine whether each independent claim is a hallucination or not. To carry out this step, each independent claim is paired with a context as detailed in the previous step.

Once each statement is paired with contextual information, the next challenge is fact verification (Thorne et al., 2018; Augenstein et al., 2019). Earlier verification systems relied on specialized classifiers or natural language inference (NLI)

Example: User Query
Comment a été initialement été appelée la vile de Kaspiisk à sa création?
System Log
No items in Google Search results.
Retrying search with extracted keywords: 'vile Kaspiisk création'
No items in Google Search results.
No context found from Google. Calling LLM to answer the query in the same language.

Table 1: Handling fallback scenarios with keyword extraction and LLM call.

models to judge correctness. However, our approach uses a RAG based approach, where an LLM (GPT 4o in our case) is prompted to cross-check each statement against the retrieved context and identify any specific substrings that contradict the context. This is consistent with the approach presented in (Zheng et al., 2024; Wang et al., 2023).

In this way, our system provides minimal conflicting spans instead of binary labels alone. This allows for more human-interpretable rationales and delivers the incorrect portions of statements in a clearer manner.

The prompt that is passed to the LLM (GPT 4o) is carefully structured system prompt that includes both the source context and a JSON array of factual statements. Detailed guidelines for extracting contradictory substrings help the system handles diverse errors, such as uncertainties or logical inconsistencies, while verifying each factual statement against its retrieved context. In postprocessing, flagged substrings are mapped back to their exact positions in the original text, enabling precise error analysis as detailed in the next subsection.

3.4 Postprocessing

After hallucination verification, the flagged substrings must be accurately realigned to the original text. Our postprocessing module achieves this by searching for each extracted substring in the full model output and noting its start and end character indices. We provide two output variants, each aligned with the official Mu-SHROOM metrics. First, a hard-label extractor returns discrete spans for computing intersection-over-union (IoU) against gold annotations.

Second, a soft-label annotator assigns a probability of hallucination. This annotation is consistent with how the data was originally annotated; each span was given a probability of being hallucinated according to the votes it was assigned by the annotators. Soft labels are required to compute the correlation with annotator probabilities. With a single LLM taking the decision, annotation is done by labeling detected hallucinated characters with ones and all others with zeros ensuring compatibility with Mu-SHROOM's rigorous benchmarks.

3.5 Variants and Practical Challenges

In addition to mainly depending on GPT-4o[2] closed source model in our experiments, we conducted experiments with open-source models in a voting-style ensemble approach, allowing multiple models to collaboratively vote on detecting hallucination spans in each response as originally done by the annotators, however, results with this approach were not very impressive. We also tested deepseek-reasoner[3] model exclusively for Arabic queries, which achieved better performance on Arabic content than GPT-4o.

Our goal was to establish a generic system that is robust to multilingual data. However, implementation challenges arose when dealing with 14 languages, each featuring distinct morphological rules and varying levels of web coverage. Certain languages, like Basque or Farsi, have limited online resources which reflected adversely on search engine results. This limitation forced reliance on fallback strategies such as LLM-based context generation risking further hallucination.

Moreover, when extracting keywords from morphologically rich, under-resourced languages nonsensical or misleading outputs hinder effective context retrieval. These factors can undermine retrieval success and make robust coverage more difficult to achieve, degrading the system performance. This highlights the complexity of the multilingual hallucination detection task, pushing for more robust fallback strategies and meticulous pre and post processing steps.

Table 2: Performance metrics over test data across multiple languages

4 Results

In our experiments (Table 2), HalluSearch exhibits strong performance in several languages, notably ranking **4th** on **English** and **Czech** (complete results are found in Mu-SHROOM's original paper, Vázquez et al., 2025). We observe that prompt refinements, such as adding chain-of-thought reasoning instructions, can yield significant gains, with GPT-4o improving English results. Using 'deepseek-reasoner' model boosts Arabic performance.

Conversely, attempts to combine multiple open-source models and voting ensemble did not enhance results, possibly due to inconsistent alignment between the models' annotations. Overall, HalluSearch's approach to fact verification demonstrates competitiveness across diverse languages, but the variation in rank shows the complexities that remain an open challenge in multilingual hallucination span detection.

5 Conclusion

In this work, we have presented HalluSearch, the aim of which was to address the problem of detecting LLM hallucinations. HalluSearch is a search-enhanced RAG pipeline that pinpoints potentially fabricated or incorrect spans in multilingual outputs. By using precise factual splitting, context retrieval from reliable sources, and a prompt-based verification step, our system provides both hard-label and soft-label annotations for hallucination spans. Evaluation results demonstrate that HalluSearch competes well in multilingual settings despite inherent difficulties such as limited content availability in less-resourced languages.

These findings highlight the importance of robust, cross-lingual retrieval strategies and careful prompt engineering. Future research will delve into addressing low-resource languages more effectively, improving fallback mechanisms, and exploring fine-grained alignment techniques for enhanced span detection accuracy.

COGNAC at SemEval-2025 Task 10: Multi-level Narrative Classification with Summarization and Hierarchical Prompting

Azwad Anjum Islam & Mark A. Finlayson
Florida International University
Knight Foundation School of Computing and Information Sciences
11200 SW 8th Street, Miami, FL 33199, USA
{aisla028, markaf}@fiu.edu

Abstract

We present our approach to solving the *Narrative Classification* portion of the *Multilingual Characterization and Extraction of Narratives* SemEval-2025 challenge (Task 10, Subtask 2) for the English language. This task is a multi-label, multi-class document classification task, where the classes were defined via natural language titles, descriptions, short examples, and annotator instructions, with only a few (and sometime no) labeled examples for training. Our approach leverages a text-summarization, binary relevance with zero-shot prompts, and hierarchical prompting using Large Language Models (LLM) to identify the narratives and subnarratives in the provided news articles. Notably, we did not use the labeled examples to train the system. Our approach well outperforms the official baseline and achieves an F_1 score of 0.55 (narratives) and 0.43 (subnarratives), and placed 2nd in the test-set leaderboard at the system submission deadline. We provide an in-depth analysis of the construction and effectiveness of our approach using both open-source (LLaMA 3.1-8B-Instruct) and proprietary (GPT 4o-mini) Large Language Models under different prompting setups.

1 Introduction

Disinformation, misinformation, propaganda, and foreign malign influence (FMI) have become serious problems in the modern information environment. One commonality amongst them is the use of *narrative* to drive their effects. A *narrative* can be defined as a concise, concrete description of a set of events involving a small number of actors, often supporting an evaluative judgment. The ability to automatically identify narratives in textual materials (for example, news or social media) would be of great use to tracking, understanding, and mitigating pernicious influence.

Task 10 at SemEval-2025, *Multilingual Characterization and Extraction of Narratives from Online News* (Piskorski et al., 2025), focuses on automatic identification of different types of narratives and subnarratives, as well as identifying the roles of the relevant entities in news articles. The task is divided into three subtasks—*Entity Framing*, *Narrative Classification*, and *Narrative Extraction*—spanning five languages: Bulgarian, English, Hindi, Portuguese, and Russian. We work on the *Subtask 2: Narrative Classification* for English, where we develop a prompt-based approach to identify narratives and their subtypes in news data.

Subtask 2 defines two domains (*Climate Change* [CC] and *Ukraine-Russia War* [URW]), for which the task creators have defined a set of top-level narratives, each having specific subnarratives. Each news article associated with the domains is labeled with some number of top-level narratives and subnarratives, with no restriction on the number of labels. Each top-level narrative and subnarrative is defined by a title (e.g., *Criticism of Climate Policies*), plus a longer definition, instructions, and zero or more examples. Thus, Subtask 2 is a multi-label, multi-class document classification task.

Our approach has three stages. First, we apply a summarization step that condenses the target document (i.e., a news article) into a uniform length, information-dense representation. Second, we apply class-specific zero-shot prompts using a binary relevance strategy (Zhang et al., 2018) to classify each document as to its top-level narrative category, aggregating results to generate multi-label outputs. Third, we use hierarchical prompting (Liu et al., 2021) to produce subnarrative labels for each narrative found in the articles. We experiment with both open-source (LLaMA 3.1-8B-Instruct) (Meta, 2024) and proprietary models (GPT-4o-mini) (OpenAI, 2024) . Notably, our approach does not use any of the labeled training data for fine-tuning or other model optimizations (barring the experiment comparing zero-shot vs. few-shot setup, where we find that the zero-shot approach performs bet-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1442–1449

ter overall). Our system achieved an F_1 score of 0.55 for narratives and 0.43 for sub-narratives, placing 2nd in the official leaderboard for English (the leading system obtained scores of 0.59 and 0.44, respectively). It is notable that our approach was competitive despite the absence of computationally expensive model training.

The remainder of the paper is structured as follows. We first provide background on the topic of narrative classification and prompt-based solutions in general (§2). We next describe the data and task definition provided by the task organizers (§3). We then elaborate on our methodology and experimental set-up (§4), and report the result from the official submission along with some additional experiments (§5). Finally, we enumerate our contributions and discuss our findings, limitations, and scope for future improvements (§6).

2 Related Work

Multi-label document classification is the task of assigning multiple relevant labels or categories to a text, as opposed to a single label (Tsoumakas and Katakis, 2007). Traditional Machine Learning (ML) and Natural Language Processing (NLP) approaches have developed various methods to tackle this problem. One common approach is *binary relevance*, where the task is decomposed into independent binary classification problems for each label (Zhang et al., 2018). Another is *classifier chains*, which extends binary relevance by linking classifiers in a chain, allowing label predictions to influence one another and capture label dependencies (Read et al., 2011). A third method, *label power-set*, treats each unique combination of labels as a separate class, transforming the problem into a mutually exclusive multi-class classification task (Madjarov et al., 2012).

With the development of large language models (LLMs) (Radford et al., 2019; Brown et al., 2020; Ouyang et al., 2022; Touvron et al., 2023), a new paradigm for text classification has emerged: instead of training a model specifically for a classification task, it is now possible to *prompt* a pretrained LLM to classify text by describing the task in natural language. This approach has gained widespread popularity as LLMs have shown strong performance in new classification tasks through in-context learning (ICL) with just a few prompt examples (Brown et al., 2020). In scenarios where little to no training data is available, this approach is especially attractive.

Peskine et al. (2023) showed how LLMs can use class definition to produce multi-label classification with zero-shot prompting. This label-by-label prompting in an one-vs-rest manner is simple and allows the model to focus on a binary question each time, potentially improving reliability for each label. This approach is more computationally expensive due to requiring multiple queries for each input. An alternative prompting strategy to increase efficiency is to prompt the LLM to produce all desired labels in one pass. However, this approach increases the classification complexity, which can lead to reduced performance. (Trust and Minghim, 2024; Kostina et al., 2025) Additionally, classification involving multiple classes require more sophisticated prompts and reasoning steps to guide the model, which may also increase format deviation in a model's output, compared to binary classification with simple yes/no format (Kostina et al., 2025).

3 SemEval-24 Task 10 Data

SemEval-2025 Task 10 focuses on analyzing news articles in five languages: Bulgarian, English, Hindi, Portuguese, and Russian and comprises three separate subtasks. We work on subtask 2 in English, which is a multi-label, multi-class narrative classification task. Given a news article and the two-level taxonomy of narrative labels for each domain (where each narrative is subdivided into subnarratives), the task is to assign the article all the appropriate narrative and subnarrative labels. The two domains for this task were: the Ukraine-Russia War (URW) and Climate Change (CC). Each narrative and subnarrative is defined by a title, a short definition, zero or more example statements, and sometimes, additional instructions. For example: the narrative ***Criticism of climate policies*** under the CC domain is defined as: *Statements that question the effectiveness, economic impact, or motives behind climate policies. Example: "It is all because of the decision to switch to electric."* while the subnarrative ***Climate policies are ineffective*** under this narrative is defined as: *Statements suggesting that climate policies fail to achieve their intended environmental goals. Example: "There is absolutely no point in banning straws, it can even have the opposite effect."*

The English training data comprised 399 articles, with 176 from the *Climate Change* domain and 223

from the *Ukraine-Russia War* domain. Additionally, a development dataset of 41 labeled articles (24: *CC*, 17: *URW*) and a test dataset of 101 unlabeled articles (48: *CC*, 53: *URW*) were released by the task organizers. Each article in the training and development dataset is annotated with one or more high-level narrative(s) as well as corresponding finer-grained subnarrative(s). In the case where specific narrative or subnarrative label could not be assigned, the "Other" pseudo-label was used.

4 Approach

Our approach for the Narrative Classification subtask has three steps: (1) summarization that makes the articles more uniform in length and style (§4.1); (2) a set of zero-shot, class-specific LLM prompts to produce binary outputs for each top-level narrative class (§4.2); and (3) a hierarchical prompting technique to sequentially identify subnarrative classes only when the corresponding narrative classes are detected (§4.3).

In this task, the number of class and subclass labels was large compared to the available labeled data. Figure 1 shows the distribution of the number of available labeled samples per subnarrative class. Notably, some subnarrative classes never appear in the English training data. This rendered approaches like supervised learning and fine-tuning problematic for those classes. Therefore, we opted for a prompt-based approach using pre-trained LLMs. For our experiments, we chose one open-source model (LLaMA 3.1-8B-Instruct) and one proprietary model (GPT-4o-mini). It is worth mentioning that, in the English training data, the domain of each input article is indicated in the filename, so we assume knowledge of the domain for all experiments. However, we also conducted an auxiliary experiment that showed LLMs could automatically identify[1] the domain of the input texts in 99% of cases (435 out of 440 articles) across the training and validation datasets.

4.1 Article Summarization

Long-form news articles often contain statements that are not directly related to the main themes of the article. We sometimes found the LLMs to be confused by statements that are either not important, or less important, in the overall context of the article, resulting in false positive labels. To counter this issue, we first experimented **prompt tuning**, adjusting the prompt by instructing the model to base its decisions only on statements pertinent to the main themes of the article, while keeping the input unchanged. We also tried **summarization**, in which we prompted the same LLM used for the classification steps (LLaMA 3.1-8B-Instruct or GPT-4o-mini) to summarize the article into a more concise and information dense form (the prompt is shown in Appendix A).

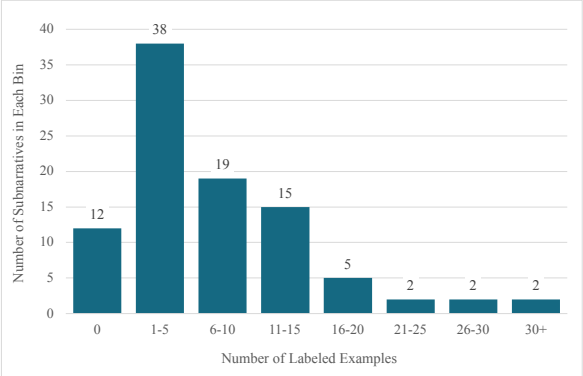

Figure 1: Summary of available English data samples per subnarrative class (including pseudo-labels) in the training data, grouped into bins

Table 1 shows the differences between classification performance on the development data after top-level narrative classification in step 2 (§4.2), depending on whether the texts were unmodified, subjected to prompt tuning, or summarized. We see that summarization results in significant improvement in case of LLaMA, whereas the effect is less pronounced with the more advanced GPT model.

It is worth noting that in the top-level narrative classification, having a high accuracy score is especially important, as misclassifications at this level are guaranteed to produce more errors in subsequent subnarrative classifications. We define accuracy by the percentage of decisions taken by the model that were correct. Correct decisions include assigning correct labels as well as not assigning incorrect labels to articles.

4.2 Binary Relevance with Zero-Shot Prompting

The task is a multi-label multi-class classification problem with more than ten narratives in each domain. Use of a single large prompt to identify all the correct classes in a text risks putting a burden of excessive information on the LLM. It also makes it harder to define the different narratives effec-

[1]We prompted the GPT-4o-mini model with the prompt: "Given the following text text, determine if its content is primarily about *Climate Change* or *Ukraine Russia War*".

tively while keeping the prompt concise and clear. To alleviate this problem, we treated the top-level multi-label classification task as a series of binary classification tasks using the binary relevance technique. For each narrative class, a class-specific prompt was developed using the definition, example statements, and optional annotation instruction provided in the official taxonomy. The prompts were developed following recommended practices of prompt engineering:

Persona: Researchers have found role-play prompting to consistently surpass the standard zero-shot approach across most datasets (Kong et al., 2024; Tseng et al., 2024). We assigned the model in our experiments the role of an "expert narratologist" in the corresponding domain.

Context: We provide relevant context to the model including the definition of narratives in the taxonomy, descriptions of common subnarratives with example statements, and additional instructions when available in the taxonomy.

Clear instructions: We clearly outline the task and provide step-by-step guidelines for the model to follow, which has been shown to improve model response (Wu et al., 2023).

Chain of Thought (CoT): Eliciting a series of intermediate reasoning steps can significantly improve complex reasoning capabilities of LLMs (Wei et al., 2023). In our experiments, we take advantage of zero-shot CoT by prompting the LLM to produce the intermediate reasoning steps.

Output format: We explicitly specify the desired output format in our prompts to avoid output inconsistency and format deviation, which is crucial to ensure accurate parsing of narrative labels generated by the model (Liu et al., 2024).

The template for the narrative classification prompts is given in Appendix B. Table 2 shows the performance improvement achieved with the binary relevance method over using a single prompt.

We also compared zero-shot with few-shot prompting. Few-shot prompting is often favored over zero-shot prompting as the former generally produces more accurate results (Brown et al., 2020). For the narrative-classification task, we experimented with 0-shot, 2-shot, and 4-shot prompting using the two LLMs, while using the summarized articles as input. We randomly selected one (or two) positive example(s) and an equal number of negative example(s) from the training data to produce the 2-shot (or 4-shot) prompts for this experiment. This is the only experiment where we make use of the labeled training data. Table 3 shows the comparative performance across different shot settings. We see that 0-shot prompting achieves better accuracy overall, while the micro F_1 score remains consistent across different shot settings. The difference is again more significant for the LLaMA model compared to the GPT model.

4.3 Hierarchical Prompting for Subnarrative Detection

Once the top-level narratives had been identified, we used hierarchical prompting to classify subnarratives in each text by using class-specific prompts for each of the narratives. If the LLM classifies a narrative as present in an article in the top-level narrative classification step, the model is then subsequently prompted to identify the appropriate subnarrative(s) in the article with a prompt specific to that particular narrative class. This sequential approach simplifies the subnarrative classification process for the LLM model by providing information about the presence of the top-level narrative, as well as reducing the number of possible classes. Notably, we do not use the binary relevance method in this level considering the comparatively small number of possible classes and computational complexity. The subnarrative classification prompts were developed following the same prompt engi-

Method		Acc.	F_1

Prompt-tuning	0.51	0.52

Table 4: Performance in subnarrative classification using full and summarized input articles, paired with different top-level narrative classification strategies.

neering practices described in section 4.2. The template for these prompts is given in Appendix C.

For the subnarrative classification, we experimented with both the full articles and their summaries as inputs to the LLM. These two input strategies were paired with multiple top-level narrative classification strategies described previously (i.e., using prompt-tuning on full articles, using 0-shot prompting on summarized articles etc.) to construct different variants of the pipeline. Table 4 shows the results. Interestingly, summarized inputs produced better results even for fine-grained subnarrative classification. This may be attributed to the normalizing effect the summarization step had on the structure and readability of the input articles.

5 Results

For the final submission, we chose the best performing model based on our experiments on the development set, which was GPT-4o-model with zero-shot prompts using summarized articles as input in both narrative and subnarrative classification step. Table 5 shows results from the official evaluation of our methods on the unlabeled test dataset, together with other top performers. The official evaluation measure for ranking was the averaged

samples F_1 score computed for the subnarrative labels. We achieve high F_1 score in both narrative and subnarrative classification, and rank 2nd despite not using the labeled training dataset, or computationally expensive model fine-tuning.

Our experiments showed that summarization significantly enhanced classification performance. We attribute this to summarization making the input more information-dense and uniformly structured. We also found that breaking down a complex multi-label classification problem into a series of simpler binary classifications led to better performance, which is consistent with the observations of many other researchers that LLMs are better at performing simple tasks with a clear goal compared to complex tasks with more sophisticated instructions. These effects were much more pronounced with the smaller model, which is consistent with the assumption that more advanced LLMs are better at handling complex tasks. It also indicates that using a larger, state-of-the-art model may further improve the performance of our approach.

5.1 Error Analysis:

As the training data was not used for for training or fine-tuning the model, we were able to leverage it for the purpose of error analysis. We found that the system exhibited a conservative prediction strategy, favoring under-prediction. At the top-level narrative classification, only 17% of classification errors were false positives, while 83% were false negatives. However, this behavior was intended, and was achieved through instruction-tuning (e.g. via phrases like "...the provided text *explicitly* includes the narrative...", "...such statements are *prominently* present..." etc.. See Appendix B). Due to the overwhelmingly large number of true negative cases for all narrative classes compared to true positives, a less conservative prompt—while reducing some false negatives—causes substantial rise in false positive errors and negatively affects overall performance. Due to this conservative approach, the

LLMs often did not identify narratives when the narratives were only subtly indicated in the text. For example, the phrase "Russia is at war with pure evil" did not trigger a positive identification for the narrative "Praise of Russia". Also, upon manual inspection of some of the reasoning steps produced by the LLMs, we noticed that both LLMs were able to produce reasonable and coherent chain-of-thoughts behind their answers most of the time, but they often fell short in identifying more nuanced clues necessary for complex narrative types. For example, the LLMs frequently failed to distinguish between "Criticism of international entities" and "Criticism of political organizations and figures" subnarratives under the narrative "Criticism of institutions and authorities".

6 Conclusion

In this paper, we proposed a prompt-based approach to the multi-label multi-class narrative classification problem introduced at SemEval-2025 (Task 10, Subtask 2) for the English language. We leveraged text-summarization, binary relevance with Large Language Models (LLMs), and hierarchical prompting technique to label broad narratives as well as fine-grained subnarratives in news articles. We developed zero-shot prompts for each narrative and subnarrative class solely from the provided taxonomy, avoiding the need for training data and expensive model fine-tuning. This approach achieved competitive performance, placing 2nd in the leaderboard.

Despite promising results, there is much room for improvement. Our approach does not consider the possibility that some labels may be more likely to co-occur together. While we take advantage of class-specific prompts in a binary relevance approach, further refinement of these prompts with help of domain experts could help address specific weaknesses in individual narrative classifications. Additionally, we only applied our approach for the English dataset, which leaves its multilingual capability an open question for future studies.

A Summarization Prompt

```
Summarize the following input text and output the summary in 300 words or less. Retain all the main topics, sentiments, and narratives of the text.
```

B Narrative Classification Prompt Template

We used the following template to generate narrative classification prompts from the official taxonomy.

```
Role: You are an expert narratologist skilled in analyzing and identifying narratives within text, particularly in the domain of <domain>.
Determine whether the provided text explicitly includes the narrative <narrative>

Definition of the Narrative:
The narrative <narrative> is defined by <definition from taxonomy>.
Example of statement that aligns with this narrative: <example from taxonomy>
Common Themes within this Narrative may include: <list of subnarratives, with definition and example from taxonomy>
Or other statements supporting <narrative>.

Follow these guidelines: Read the provided text carefully.
Find if there are any statements the strongly support the narrative <narrative>.
Answer "Yes" if such statements are prominently present.
Answer "No" if statements supporting the narrative <narrative> are not prominently present.
Explain your reasoning for the decision, referencing specific statements from the text.

Output format:
The first line should be a single word, either "Yes" or "No", depending on your decision. The second line should contain your reasoning for your decision, in a single paragraph.

Input:
```

C Subnarrative Classification Prompt Template

We used the following template to generate narrative classification prompts from the official taxonomy.

```
Role: You are an expert narratologist skilled in analyzing and identifying narratives within text, particularly in the domain of <domain>.
Your task is to analyze a given text that contains the narrative <top-level narrative> and identify what specific subtype of the narrative is present in the text.

The narrative <top-level narrative> may have the following subtypes:
<subnarrative 1>, which is defined by <definition from taxonomy>.
Example of statements supporting this subtype: <example from taxonomy>
<subnarrative 2>, which is defined by <definition from taxonomy>.
Example of statements supporting this subtype: <example from taxonomy>
.
.
.
'Other' which is defined by the absence of the previously mentioned specified subtypes.

Task:
Read the input text.
Decide which one of the specified subtypes of <top-level narrative> are present in the text.
Carefully consider the distinctions between their definitions and choose the best one.
If you cannot choose one best answer, it is possible to answer multiple subtypes.
Answer "Other" if you don't find any of the specified subtypes.
Also explain your reasoning.

Output format:
First line of output should only be the name of the subtype. If your answer is more than one subtypes, they should be separated by commas(,).
Second line of output should be the reasoning for your answer in a single paragraph.

Input:
```

SyntaxMind at SemEval-2025 Task 11: BERT Base Multi-label Emotion Detection Using Gated Recurrent Unit

Md. Shihab Uddin Riad and Mohammad Aman Ullah
Dept. Of Computer Science & Engineering
International Islamic University Chittagong
shihab.riadn@gmail.com and aman_cse@iiuc.ac.bd

Abstract

Emotions influence human behavior, speech, and expression, making their detection crucial in Natural Language Processing (NLP). While most prior research has focused on single-label emotion classification, real-world emotions are often multi-faceted. This paper describes our participation in SemEval-2025 Task 11, Track A (Multi-label Emotion Detection) and Track B (Emotion Intensity). We employed BERT as a feature extractor with stacked GRUs, which resulted in better stability and convergence. Our system was evaluated across 19 languages for Track A and 9 languages for Track B.

1 Introduction

Emotions play a significant role in shaping human behavior, speech patterns, and body language. Natural Language Processing (NLP) plays a crucial role in analyzing and extracting valuable information based on emotions. Earlier research on sentiment and emotion analysis has primarily focused on single-label classification, where a piece of text is assigned just one emotion or sentiment category, like “happy" or “sad". However, human emotions are rarely that simple, people often experience and express multiple emotions at once. For example, a movie review might convey both excitement and disappointment, or a social media post might reflect anger and fear simultaneously. Multi-label emotion classification addresses this complexity by allowing a system to identify and tag multiple emotions within the same text, providing a more accurate and nuanced understanding of human emotional expression. To address this challenge, we present our submission for SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection(Muhammad et al., 2025b) which is based on “BRIGHTER: BRIdging the Gap in Human-Annotated Textual Emotion Recognition Datasets for 28 Languages”(Muhammad et al., 2025a) and “Evaluating the Capabilities of Large Language Models for Multi-label Emotion Understanding”(Belay et al., 2025). The task is divided into three tracks and we participated in Track A: Multi-label Emotion Detection, and Track B: Emotion Intensity. While participating in the task, we observed that training the model presented several challenges, particularly with overfitting and data imbalance. Specifically, when using pre-trained embeddings like GloVe(Pennington et al., 2014), the model over-fitted quickly, likely due to its tendency to memorize the training data rather than generalize to unseen examples. To address the unbalanced dataset, we experimented with SMOTE (Synthetic Minority Oversampling Technique) (Chawla et al., 2002), but this approach did not yield favorable results, possibly because it introduced synthetic samples that failed to capture the true emotional context of the data. Additionally, we attempted to augment our dataset with data from the SemEval-2018 Affect in Tweets(Mohammad et al., 2018) task to enrich the training set. However, this also did not improve performance. Finally we used BERT as feature extractor with two stacked layer of Gated Recurrent Units(GRUs) to overcome unstable training and achieve better convergence on overall (per language) dataset. We participated in a total of 19 languages for Track A and 9 languages for Track B.

2 Related Works

In the past most of emotion or sentiment analysis related work heavily relied on machine learning based approaches (Mullen and Collier, 2004);(Jain et al., 2017). Such work critically depended on hand-crafted features.

(Kar et al., 2017), provides two different methodologies to work on sentiment analysis on financial data. They used both machine learning based approach and deep learning technique in their study.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1450–1455

In latter one, they incorporated Convolution Neural Network (CNN) (LeCun et al., 1989) and GRU to predict sentiment of financial data.

(Baziotis et al., 2018), at SemEval-2018 Task 1, proposed a Bidirectional Long short-term memory(Hochreiter and Schmidhuber, 1997) (Bi-LSTM) architecture equipped with a multi-layer self attention mechanism. They used a set of word2vec word embeddings that were enhanced by a set of word emotional attributes and trained on an extensive collection of 550 million Twitter messages.

(Ameer et al., 2023), proposed models, based on Bi-LSTM with multiple attention layers, implemented n independent attention mechanisms for n emotion labels, where each attention mechanism learns information specific to its corresponding emotion label. The study also implemented transformer models with multiple attention (MA) layers, including XLNet-MA, DistilBERT-MA, and RoBERTa-MA. Multiple attention mechanisms were incorporated into the output of these Transformer models, and the models were fine-tuned on the datasets.

3 System Overview

3.1 Logarithmic Weights Calculation

To address class imbalance in the dataset, logarithmic weighting is employed to adjust the contribution of each class. The logarithmic weights are determined using the formula:

$$w_i = \log\left(1 + \frac{\text{total samples}}{\text{class totals}_i}\right) \quad (1)$$

Here, each class weight is derived by taking the natural logarithm of the inverse class frequency, scaled by the total sample count. This approach ensures that underrepresented classes receive higher weights, mitigating the effects of class imbalance during model training.

To maintain a relative scale, the computed weights are normalized by dividing by the minimum weight value:

$$w_i = \frac{w_i}{\min(w)} \quad (2)$$

This ensures that the smallest weight is set to 1 while preserving relative differences among classes.

3.2 BERT Embedding

BERT (Bidirectional Encoder Representations from Transformers), introduced by (Devlin et al., 2019), is a transformer-based model designed for natural language processing tasks. Unlike traditional models that process text uni-directionally, BERT leverages bidirectional context, pre-training on large corpora to capture deep semantic and syntactic relationships. For English, we used bert-base-uncased as the feature extractor, while for Chinese, we employed bert-base-chinese, and for German, we utilized bert-base-german-cased. For all other languages, we relied on multilingual BERT (mBERT) from Hugging Face. We are using these models for the task of multi-label emotion detection and emotion intensity prediction.

3.3 Gated Recurrent Unit (GRU)

Gated Recurrent Units (GRUs), proposed by (Cho et al., 2014), are a type of recurrent neural network (RNN) designed to model sequential data efficiently. GRUs simplify traditional RNNs by using update and reset gates to control information flow, mitigating issues like vanishing gradients while maintaining performance comparable to Long Short-Term Memory (LSTM) units. In a bidirectional GRU (Bi-GRU), the model processes sequences in both forward and backward directions, capturing past and future context simultaneously. This bidirectional approach enhances the model's ability to understand dependencies in text, making it particularly effective for tasks requiring comprehensive sequence comprehension, such as emotion detection. We used 128 hidden states in the Bi-GRU for this task to balance model capacity and computational efficiency.

3.4 Output Layer

The output layer of the model is designed to transform the processed features into predictions for the target emotion labels. It consists of a dense layer that takes an input dimensionality equal to twice the hidden dimension, reflecting the combined forward and backward representations from the bidirectional GRU. This layer maps these features to a set of output scores, where each score corresponds to one of the emotion categories in the multi-label task.

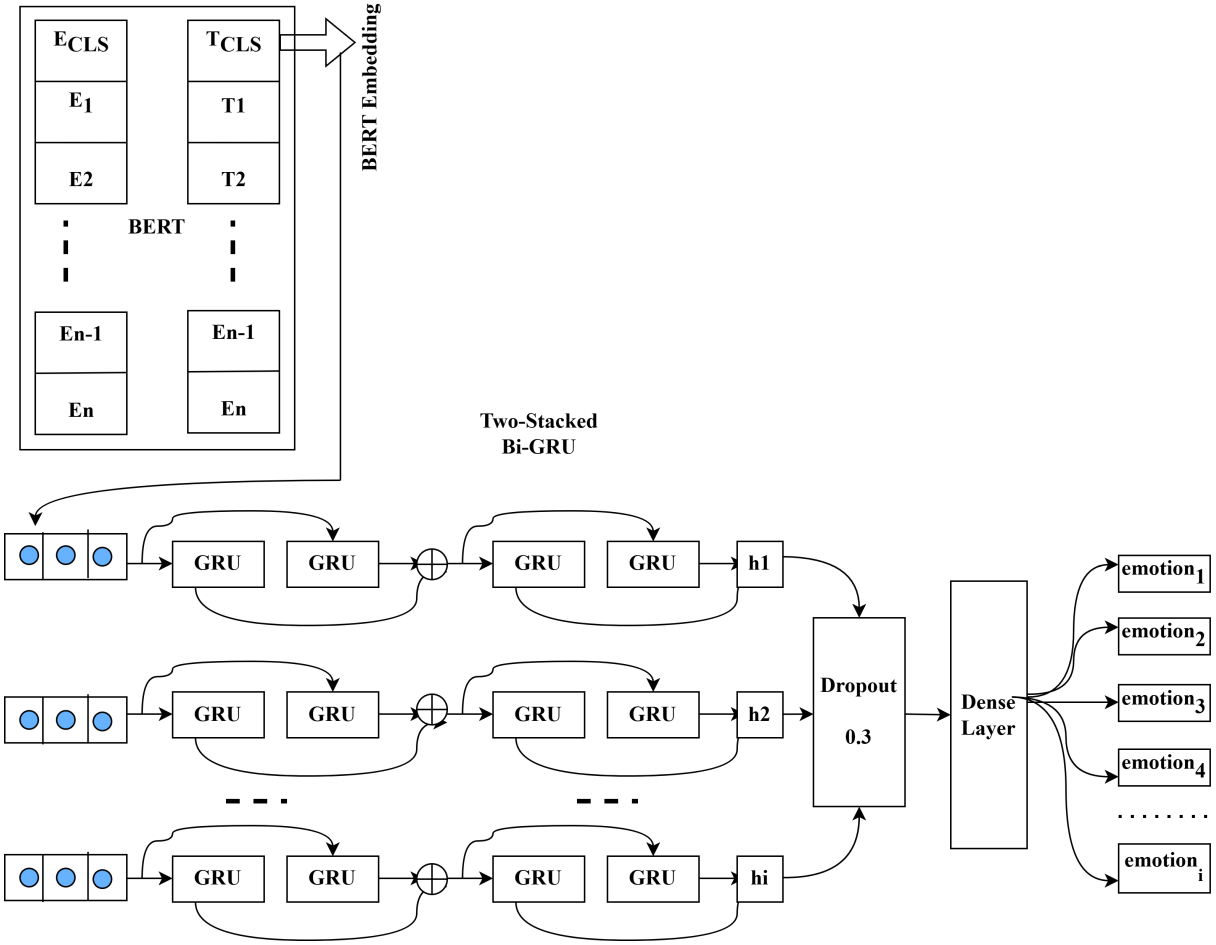

Figure 1: Proposed Model (BERT + Bi-GRU)

4 Experimental Setup

Preprocessing was minimal across the languages studied. For languages other than English, no preprocessing steps were applied. For English, only basic operations were performed, including lowercasing text and expanding contractions, to standardize the input data. To train the model, we utilized BCEWithLogitsLoss as the loss function for multi-label classification, COnsistent RAnk Logits (CORAL) (Cao et al., 2020) as the loss function for emotion intensity, employed the AdamW (Loshchilov and Hutter, 2019) optimizer for efficient parameter updates, and implemented early stopping to prevent overfitting.

Parameters	Track A	Track B
Batch size	2	16
Learning rate	1×10^{-5}	1×10^{-5}
Loss function	BCEWithLogitsLoss	CORAL
Optimizer	AdamW	AdamW
Dropout	0.3	0.3
Hidden Units	128	256

5 Results

5.1 Track A

Table 2 presents the macro F1 scores for different models evaluated on the test dataset for SemEval-2025 Task 11 Track A. Our model, denoted as **Ours (SyntaxMind)**, is compared against PAI, PA-oneteam-1, and the SemEval Baseline across 19 languages.

Among the 19 languages, our model achieved competitive results in several cases but lagged behind the top-performing models. For high-resource languages such as English (eng), Spanish (esp), and Hindi (hin), our model achieved macro F1 scores of 0.6646, 0.5739, and 0.6508, respectively. While these results are reasonable, they remain lower than the best-performing model (PAI), which achieved 0.823, 0.8488, and 0.9197, respectively. Similarly, our model performed moderately well on

Table 3: Comparison of Pearson Correlation scores across 9 languages on the test dataset for SemEval-2025 Task 11 Track B

German (deu) and Russian (rus), obtaining 0.4868 and 0.6596, respectively.

In low-resource languages such as Yoruba (yor), Swahili (swa), and Sundanese (sun), the performance of all models declined significantly. Our model achieved macro F1 scores of 0.2614, 0.2408, and 0.3556, respectively.

For Arabic dialects, including Algerian Arabic (arq) and Moroccan Arabic (ary), our model obtained scores of 0.4567 and 0.3733, whereas PAI achieved 0.6687 and 0.6292, respectively. A similar trend was observed for Portuguese variants, where our model's performance on Brazilian Portuguese (ptbr) and Mozambican Portuguese (ptmz) was 0.3142 and 0.3706, lower than the leading model's 0.6833 and 0.5477, respectively.

Our model demonstrated moderate performance in languages such as Romanian (ron), Ukrainian (ukr), and Tatar (tat), with macro F1 scores of 0.6171, 0.315, and 0.4912, respectively. Despite this, the highest-performing models achieved significantly better scores.

Though we have beaten the SemEval Baseline model results in the arq, chn, swa, and yor languages.

5.2 Track B

Table 3 shows the results of our system indicate that while it performs moderately well in some languages, there is a significant gap compared to the

top-performing systems. The highest Pearson Correlation score out model achieved in 0.4791 for Chinese (chn), while the lowest is 0.1576 for Arabic Algerian (arq). Across all nine languages, our system consistently lags behind PAI and PA-oneteam-1, suggesting limitations in capturing the nuances of emotion intensity. Notably, performance is particularly weak for Arabic Algerian (arq), Ukrainian (ukr), and Brazilian Portuguese (ptbr), indicating potential challenges in handling certain linguistic structures or data limitations. Compared to the SemEval Baseline, our system performs better in most cases but still requires significant improvements.

6 Conclusion

In this paper, we demonstrate our proposed model (BERT + GRU) for tackling the multi-label emotion challenge. Although our performance was not optimal, we intend to improve our model in the coming days. We also aspire to participate in Track 3 (Cross-lingual Emotion Detection) in the future.

Abstract

This study introduces a methodology centred on Llama 3 fine-tuning for the classification of entities mentioned within news articles, based on a predefined role taxonomy. The research is conducted as part of SemEval-2025 Task 10, which focuses on the automatic identification of narratives, their classification, and the determination of the roles of the relevant entities involved. The developed system was specifically used within Subtask 1 on Entity Framing. The approach used is based on parameter-efficient fine-tuning, in order to minimize the computational costs while maintaining reasonably good model performance across all datasets and languages involved. The model achieved promising results on both the development and test sets. Specifically, during the final evaluation phase, it attained an average accuracy of 0.84 on the main role and an average Exact Match Ratio of 0.41 in the prediction of fine-grained roles across all the five languages involved, i.e. Bulgarian, English, Hindi, Portuguese and Russian. The best performance was observed for English (3rd place out of 32 participants), on a par with Hindi and Russian. The paper provides an overview of the system adopted for the task and discusses the results obtained.

1 Introduction

The way entities are presented within a text plays a crucial role in shaping the narrative and influencing public opinion. Entity framing refers to the process by which a text assigns specific roles to the actors involved in an event, based on a predefined set of roles. This phenomenon is far from neutral, as defining a subject as a "victim" rather than a "perpetrator," for example, can significantly influence how an event is perceived by the reader. The study of the dynamics of mis/disinformation and information manipulation has received growing attention, both within the NLP community and beyond (Wardle, 2018), and understanding how language structures reality and public debate has become a key task. Several efforts have been made in this direction, both in developing computational–though theoretically-grounded–frameworks (Minnema et al., 2022; Wang et al., 2024) and in creating linguistic resources and label taxonomies aimed at thoroughly analyzing the phenomenon (Ziems and Yang, 2021; Mahmoud et al., 2025). These resources, in turn, contribute to advancing the state of the art in automatic approaches.

In this paper, we present a computational approach to this challenging issue in the context of our participation in Subtask 1 of SemEval-2025 Task 10 on Multilingual Characterization and Extraction of Narratives from Online News (Piskorski et al., 2025). Subtask 1 on Entity Framing precisely focuses on assigning one or more roles to entities mentioned within an article, based on a predefined taxonomy. This task is proposed as a span classification problem and presents both multi-class and multi-label challenges: multiple roles can be assigned to a single entity, and the number of possible roles is extensive. Our approach relies on parameter-efficient fine-tuning using QLoRA and Llama 3 (8B parameters) as the reference model. During training, we experimented with different prompting strategies in order to assess the impact on results of two key factors:

- The number of fine-grained roles predicted by the model (this aspect in particular is related to the challenges posed by multi-label classification).
- The influence of surrounding context.

The paper provides an overview of the task addressed and the approach followed in developing our system, finally discussing the results obtained on the datasets released for the competition in the different setups.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1456–1464

2 Background

Given a news article and a list of entity mentions (including their span offsets), the task of entity framing consists in assigning one or more roles to each entity based on a predefined taxonomy. The taxonomy provided for this task covers three main roles: *protagonist*, *antagonist* and *innocent*. Protagonists represent entities with a positive role in society, who actively strive for the common good. In contrast, antagonists oppose the good deeds of the protagonists by performing cruel acts against people or things. In between these two opposing factions are the innocents. They represent the outcasts and people who are victims of injustice. A detailed list of fine-grained roles is associated with each one of these main roles.[1]

The dataset made available by the organizers consists of articles dealing with two main topics, Ukraine-Russia war and climate change, and it includes five languages: English, Bulgarian, Hindi, Russian and Portuguese. Each article in the dataset includes a title and its content, while the annotations specify entity classifications. For each entity, the dataset provides its position within the article, the assigned main role along with the associated fine-grained roles.

Concerning the task evaluation criteria, in addition to metrics assessing main role accuracy and measures such as micro-precision, micro-recall, and micro-F score, the primary evaluation metric used to determine the ranking is the Exact Match Ratio (EMR), which is computed as follows:

$$\text{EMR} = \frac{1}{n}\sum_{i=1}^{n} I(y_i = \hat{y}_i)$$

where n is the total number of samples, I is the indicator function, which is equal to 1 if the predicted value matches the true value and 0 otherwise. This is a highly stringent metric, as it prioritizes fully correct results while penalizing partially correct ones.

Next section describes the main characteristics of the system, which takes into account the task's peculiarities just outlined.

[1]Due to space constraints, we do not include in this overview the whole set of fine-grained roles, that can instead be consulted at the following link: https://propaganda.math.unipd.it/semeval2025task10/ENTITY-ROLE-TAXONOMY.pdf.

3 Dataset Overview

The dataset used for the model training phase consists of approximately 5500 annotations, in which in 47% of the cases the annotated entities are classified as antagonists, in 32% of the cases as protagonists, and in 21% of the cases as innocents. An imbalance towards the antagonist class is therefore immediately apparent, and is also visible in the evaluation dataset, which justifies more annotations on this class in order to optimize the classifier. With regard to subclass labels, the distribution is also uneven. In fact, some labels have a significantly low number of annotations. In the case of "Spy" or "Martyr", for instance, the number of annotations is less than 1%. More details on the dataset development and composition are provided in the main task report (Piskorski et al., 2025).

4 System Overview

The pipeline followed for the system development included three main steps of data pre-processing, prompt definition and actual fine-tuning. As further detailed below, the former two steps aimed at properly addressing the challenges posed by multi-label classification and the impact of different context windows, while the fine-tuning process was set so as to reduce the computational cost deriving from the use of large language models.

Data pre-processing This phase begins with the segmentation of the input articles into individual sentences using a pre-trained model tailored to each source language. Afterward, the tokenized text is processed by a module that identifies the relevant portion of the article containing the entity to be classified, alongside its annotation (entity name and character offset). A variable parameter, the context size, is specified, to determine the number of sentences included in the final passage to pass to the prompt. Furthermore, non-English data was translated into English.

At this stage, a comparison was made against a number of Python libraries for the automatic translation of sentences, from which it emerged that GoogleTrans [2] offered a good trade-off between response time and translation quality.

The last operation performed in this phase is the augmentation of the training dataset, in order to extend the distribution of underrepresented sub-roles. As mentioned in Section 3, the training dataset is

[2]https://pypi.org/project/googletrans/

characterized by a strong imbalance in the distribution of sub-class labels. New examples were generated from existing ones, through the use of the Llama 3-8b model and the definition of a simple prompt. The instructions given to the model include the replacement of some terms with synonyms, leaving the name of the entity and the general meaning of the sentence unchanged.During this phase, a series of tests are carried out to ensure good quality in the examples generated via LLM. In particular, from a set of elements generated by Llama via the starting prompt, a manual analysis of the results is performed to identify potential frequent errors from which additional prompts can be generated. One of the most common errors concerns the fact that the model tries to achieve the result by substituting names of persons or things. To try to refine the result, synonyms are specified in the prompt. During the actual data augmentation process, a check is performed on the output produced by the model to ensure the presence of the entity to be classified within the sentence. If this check fails, the generated sentence is discarded in order to avoid the addition of noise within the final dataset.

Prompt definition The model training process relies on a fine-tuning technique that uses prompts to represent annotations. A prompt is structured defining the classification problem and listing the possible sub-classes that can be assigned to an entity. The prompt then includes the entity's name, the relevant article portion, and the correct label for the entity. During evaluation, the model is provided with the same prompt, where it must predict the appropriate sub-classes. A crucial aspect of the approach involves handling annotations associated with multiple sub-roles. To address this, we devised three possible prompting strategies:

- *S1 - Single prompt with all fine-grained roles*: The prompt precisely includes a single example with all the associated roles and sub-roles. The underlying assumption is that training the model with a single prompt per full annotation should be beneficial, as it exposes the model to the full set of expected sub-classes for each entity. This setup is intended to help the model learn the relationships between subclasses, hence maximizing the EMR.

- *S2 - Different prompts for each fine-grained role*: The annotation is split into multiple examples, each featuring only one sub-role. This approach aims at maximizing the model's ability to recognize individual sub-roles independently and at reducing the complexity of each training instance.

- *S3 - Mixed approach*: It combines elements of the previous strategies, with the aim of balancing their advantages.

While experiments were carried out with all three strategies, as also discussed in Section 6.1, S2 was eventually selected as primary prompting strategy.

Fine-tuning The model is fine-tuned using the QLoRA technique (Dettmers et al., 2024), which combines quantization with LoRA. Specifically, QLoRA applies quantization to reduce memory requirements while employing LoRA to adapt the model's parameters via low-rank matrices. The adaptation is controlled using key configuration parameters, including $lora\_alpha$, $lora\_dropout$, and r, which regulate the scaling of the low-rank matrices, dropout probability, and the rank of the adaptation matrices, respectively.

5 Experiment Setup

All the experiments carried out for this task were performed only using the data made available by the organizers. As mentioned in Section 4, during the training phase, we augmented the data, thus passing from an overall amount of around 5500 to 6750 annotated entities across the five languages.

For the data pre-processing step, we used Stanza (Qi et al., 2020) for the sentence splitting (as this library supports all the five languages included in the dataset) and the GoogleTrans library to translate the data in English. As regards the context window, we observed that increasing the number of sentences to include in the input did not necessarily lead to better predictions. As a matter of fact, this often introduced conflicting annotations for the same entity. After several testings, we finally opted for a span of three sentences, as this allowed to provide a reasonable amount of information to get accurate predictions.

The model used is Meta-Llama-3-8B-Instruct[3]. For its fine-tuning, the model was loaded with four-bit quantization, and the LoRA parameters

[3]https://huggingface.co/meta-llama/Meta-Llama-3-8B-Instruct

were configured as follows: lora_aplha = 16, lora_dropout=0 and r=6. AdamW was used as optimizer. The model was trained over five epochs due to the small dataset size. With particular reference to the QLoRA, the training settings used are: gradient_accumulation_steps=8, learning_rate=2e-4, max_grad_norm=0.3, warmup_ratio=0.03, per_device_train_batch_size=1, loss_function = cross-entropy.

All experiments were performed in a Google Colab environment, with a A100 GPU (40 GB VRAM).

6 Results

This section aims to provide an overview not only of the final results obtained during the evaluation phase, but also of the preliminary results obtained in the development phase while experimenting with the different prompting strategies.

6.1 Results on the Development Set

As described in Section 4, different approaches were followed to prepare the data for the fine-tuning process, with the aim of assessing which one would better address the challenges deriving from both the extensive set of available fine-grained roles and the possibility of assigning multiple classes to each relevant entity within the articles. For the classification of the main role, it is assigned automatically based on the predicted subclass membership.

As regards S1 strategy, where the prompt includes a single example with all the associated roles and sub-roles, despite some encouraging results on the Portuguese set, the approach proved unsuccessful overall, as also shown in Table 1. While, in fact, the model was generally able to properly identify the main role (as shown by the average accuracy), correctly predicting all sub-roles in one pass consistently proved more challenging in all languages, especially in Bulgarian and English.

Lang.	EMR	Micro P	Micro R	Micro F1	Accuracy Main Role
EN	0.3846	0.4494	0.40	0.4233	0.9231

avg.	0.4657	0.5247	0.4832	0.5030	0.869

Table 1: Results obtained on the development set with the S1 prompting strategy.

In the alternative approach (i.e., S2), each annotation involving several sub-classes was divided into a number of prompts corresponding to the number of sub-classes assigned. This strategy resulted in significant improvements in terms of main role accuracy and EMR for English and Portuguese; for the remaining languages conflicting behaviors were observed: while the accuracy for the main role decreased, the prediction of sub-roles actually benefited from this kind of approach and resulted in a consistent increase of micro-P/R/F_1 and EMR, as reported in Table 2.

Lang.	EMR	Micro P	Micro R	Micro F1	Accuracy Main Role
EN	0.5385	0.5652	0.52	0.5417	0.956
PT	**0.7069**	0.7672	0.7177	0.7417	0.9655
BG	0.4194	0.5161	0.4706	0.4923	0.7419
HI	0.475	0.5487	0.4935	0.5197	0.7929
RU	0.5349	0.5465	0.5281	0.5281	0.8953
avg.	**0.5349**	**0.5887**	**0.5459**	**0.5647**	**0.8703**

Table 2: Results obtained on the development set with the S2 prompting strategy.

The third strategy tested attempts to combine the two previous approaches, showing the model both multi-class prompts and individual predictions. The full results are reported in Table 3. Similarly to the previous results, the highest scores are obtained on the Portuguese data; however, when comparing such values to the ones obtained with S1 and S2, we observe that this mixed approach did not contribute to the model's improvement, neither in terms of main role prediction (with an accuracy value comparable to S1) nor of sub-roles. While in fact the remaining scores are higher than the ones in S1, they do not outperform S2. We thus remark that, in these settings, predicting multiple sub-roles at once can be more penalizing, especially in terms of EMR, compared to predicting a single label. This motivated our choice to finally use the model fine-tuned with the S2 approach to submit our predictions for the final evaluation phase.

Lingua	EMR	Micro P	Micro R	Micro F1	Accuracy Main Role
EN	0.4505	0.5056	0.4500	0.4762	0.9121
PT	**0.6638**	0.7241	0.6774	0.7000	0.9397
BG	0.3871	0.4839	0.4412	0.4615	0.7742
HI	0.4500	0.5233	0.4740	0.4974	0.7821
RU	0.5000	0.5116	0.4944	0.5029	0.9186
avg.	0.5073	0.5497	0.5074	0.5276	0.8653

Table 3: Results obtained on the development set with the S3 prompting strategy.

As additional experiment in this phase, we further tested the S2 strategy with the aim of assessing the impact of the context dimension on the per-

formance of the model. Table 4 shows the results obtained from the fine-tuned model on a dataset of annotations in which only one context sentence is taken for classification, unlike the previous experiments in which the dataset was developed using a context size of three sentences (as also mentioned in Section 5).

Lingua	EMR	Micro P	Micro R	Micro F1	Accuracy Main Role
EN	0.4505	0.5056	0.4500	0.4762	0.9121
PT	**0.6638**	0.7241	0.6774	0.7000	0.9397
BG	0.3871	0.4839	0.4412	0.4615	0.7742
HI	0.4500	0.5233	0.4740	0.4974	0.7821
RU	0.5000	0.5116	0.4944	0.5029	0.9186
avg.	0.5073	0.5497	0.5074	0.5276	0.8653

Table 4: Results obtained on the development test using a single context sentence.

As expected, reducing the context window resulted in lower performance overall, thus confirming that a larger context size generally allows the model to make more accurate predictions.

6.2 Results on the Test Set

The test set provided by the organizers for Subtask 1 consists of 235 annotated entities for English, 124 for Bulgarian, 316 for Hindi, 297 for Portuguese and 214 for Russian. Table 5 reports the results obtained with S2 prompting strategy for the fine-tuning of Llama 3 on the official test set of the task. These results are also available on the official page of the task.[4]

Lang.	EMR	Micro P	Micro R	Micro F1	Accuracy Main Role
EN	0.3745	0.4487	0.3962	0.4208	0.9191
PT	0.3670	0.4324	0.3963	0.4136	0.8081
BG	0.4597	0.4797	0.4609	0.4701	0.8871
HI	0.4019	0.5253	0.4346	0.4756	0.7563
RU	**0.4673**	0.5142	0.4802	0.4966	0.8131
avg.	0.4140	0.4800	0.4336	0.4550	0.8367

Table 5: System's results on the test set for Subtask 1.

The model's highest EMR is achieved on Russian, followed by Bulgarian and Hindi; quite surprisingly, the lowest EMR score is for Portuguese, which instead was the language with the best results on the development set with all the fine-tuning approaches explored in this work. Even the values of micro-P/R/F_1 generally align with EMR, showing that the model performed best in distinguishing fine-grained roles particularly in Russian and Bulgarian, with the other languges lagging behind. As regards the main role classification, the system achieves reasonably good results across all languages, with an overall average accuracy of 0.84. Contrarily to fine-grained roles, the highest performance is obtained with the English data, while the lowest is with Hindi. This suggests that, despite the observed challenges with sub-role identification, the model remains reliable when tasked with main role categorization.

Table 5 highlights a substantial difference in performance between the development and the test set, particularly for the Portuguese language. A plausible factor contributing to this discrepancy might lie in the distribution of sub-class labels within the datasets. In the development set, the most frequent sub-class is Victim, accounting for 48% of the instances. The performance obtained by the model on this dataset suggests a good understanding of this label by Llama. Notably, Victim is also the most represented sub-class in the training data, with a frequency of 17.45% across all languages. This strong imbalance in the Portuguese development set, which favors a sub-class the model appears to properly identify, may have contributed to the high EMR observed. However, since gold labels are not available for the test set, no definitive conclusions can be drawn regarding class distribution in that partition.

7 Error Analysis

To complete our description, we carried out an exploratory error analysis of the model configuration that obtained the best results during the development phase and was finally employed for the evaluation phase; specifically, the configuration is the one featuring 3 context sentences in the prompt and using S2 as prompting strategy. The analysis was performed on the development data itself, due to the absence of the gold labels for the test set. As a case study, we opted for the Hindi section of the task dataset, since it provides a larger number of annotated entities (280) compared to the other languages, thus allowing for a more reliable basis for observing the model's behavior. The full confusion matrix is shown in Appendix B.

The sub-roles for which the model was completely unable to make correct predictions are 'Guardian', 'Traitor', 'Rebel', 'Scapegoat', 'Bigot' and 'Spy'. Conversely, the three sub-classes with the highest number of correct predictions are 'Sabo-

[4] https://propaganda.math.unipd.it/semeval2025task10/leaderboard.html

teur', 'Exploited' and 'Peacemaker'. Among these three, 'Peacemaker' stands out with an accuracy of around 0.7. Notably, 'Peacemaker' appears only in 6% of the training dataset, suggesting that label frequency alone does not determine classification success. This is further supported by the case of 'Foreign Adversary', which, despite having a frequency of over 10% in the training set, was classified with an accuracy of only 0.38.

A significant source of error involves the 'Virtuous' sub-role. As the matrix shows, the model frequently confuses this sub-class with others. In particular, the number of false positives for this sub-role is 16. A recurrent misclassification is between 'Exploited' and 'Virtuous', with the model incorrectly predicting the latter for the former 10 times. This type of error is particularly critical as it affects not only the sub-role but also the broader classification of the main role (since 'Exploited' is a specification of the 'Innocent' role, while 'Virtuous' falls under the 'Protagonist' category). The 'Exploited' sub-role proved to be quite problematic indeed, as despite achieving 27 correct predictions, it also exhibited a high number of false positives (19) and false negatives (28), indicating substantial confusion in distinguishing it from similar categories.

Certainly the main factor related to the low EMR score concerns the nature of the metric itself, as it does not distinguish partially right answers from wrong answers. This makes the correct prediction of multi-subclass annotations particularly complex. In addition, the choice of the S2 prompting strategy for training the model results in the inability of the model to predict annotations from two or more sub-classes. In spite of this, it is preferred over the other two strategies because of the greater accuracy in annotations from only one sub-class. From a grammatical point of view, the model makes several errors that can be traced back to certain writing techniques commonly used within articles; these are not correctly understood by the model. For example, passive forms often lead the model to treat entities as active subjects, despite the fact that they are the patients, i.e. the entities undergoing the action. In Example 1 below, the model mistakes Ukraine for an active subject by misclassifying it as Conspirator.

(1) *'This is a perfect example of how censorship leads to destruction. Zelensky wants Ukraine to be destroyed. There is nothing to hide'*

In some cases, one can see how the irony used by the writers leads the model to a semantic misreading. In Example 2, the model literally interprets the sentence by classifying the entity as deceiver, whereas the correct classification is Tyrant.

(2) *'Klaus Schwab wants to ban people from washing their trousers more than once a month Klaus Schwab's World Economic Forum (WEF) has issued guidelines on how often the public should be allowed to wash their clothes, including underwear and gym clothes'*

In addition, the size of the context significantly influences the correct prediction of the entities. In fact, although three article sentences are extracted as context for each classification, in some cases the sentences are short and of little meaning, thus making the classification more challenging.

8 Conclusions

The paper described an approach based on Llama 3 fine-tuning to tackle Subtask 1 on Entity Framing. The results we obtained especially within the final evaluation phase indicate that while the model generally classifies entities' main roles quite effectively, it struggles more with exact sub-role matching, as seen in the moderate scores obtained in terms of EMR, which was also the primary metric used for this task and determining its ranking. Another general remark concerns the fact that performance greatly varied by language and especially between the development and test sets, suggesting that factors such as dataset composition, but also translation effects could have had an impact on results. Future improvements could focus on enhancing sub-role differentiation, possibly through better prompting strategies or alternative fine-tuning approaches.

A Prompt Examples

A.1 Example of S1 - Single prompt with all fine-grained roles

Classify the entity using one or more labels choosing from these: 'Instigator', 'Conspirator', 'Tyrant', 'Foreign Adversary',
'Traitor', 'Spy', 'Saboteur', 'Corrupt', 'Incompetent', 'Terrorist', 'Deceiver','Bigot', 'Guardian', 'Martyr','Peacemaker', 'Rebel', 'Underdog', 'Virtuous', 'Forgotten', 'Exploited', 'Victim', 'Scapegoat'.
Entity: Vladimir Putin
Context: Putin called the withdrawal of the Ukrainian Armed Forces from the Donbass and Novorossia a condition for peace 'In order to complete the special military operation (SVO) in Ukraine, Kiev must begin to implement Russia's peace initiatives, which were outlined during the Russian leader's meeting with the leadership of the Ministry of Foreign Affairs'. This statement was made by Russian President Vladimir Putin on 5 July at a press conference after negotiations with Hungarian Prime Minister Viktor Orban.
Label: Guardian, Peacemaker

A.2 Example of S2 - Different prompts for each fine-grained role

A.2.1 1st prompt

Classify the entity using one or more labels choosing from these: 'Instigator', 'Conspirator', 'Tyrant', 'Foreign Adversary',
'Traitor', 'Spy', 'Saboteur', 'Corrupt', 'Incompetent', 'Terrorist', 'Deceiver','Bigot', 'Guardian', 'Martyr','Peacemaker', 'Rebel', 'Underdog', 'Virtuous', 'Forgotten', 'Exploited', 'Victim', 'Scapegoat'.
Entity: Vladimir Putin
Context: Putin called the withdrawal of the Ukrainian Armed Forces from the Donbass and Novorossia a condition for peace 'In order to complete the special military operation (SVO) in Ukraine, Kiev must begin to implement Russia's peace initiatives, which were outlined during the Russian leader's meeting with the leadership of the Ministry of Foreign Affairs'. This statement was made by Russian President Vladimir Putin on 5 July at a press conference after negotiations with Hungarian Prime Minister Viktor Orban.
Label: Guardian

A.2.2 2nd prompt

Classify the entity using one or more labels choosing from these: 'Instigator', 'Conspirator', 'Tyrant', 'Foreign Adversary',
'Traitor', 'Spy', 'Saboteur', 'Corrupt', 'Incompetent', 'Terrorist', 'Deceiver','Bigot', 'Guardian', 'Martyr','Peacemaker', 'Rebel', 'Underdog', 'Virtuous', 'Forgotten', 'Exploited', 'Victim', 'Scapegoat'.
Entity: Vladimir Putin
Context: Putin called the withdrawal of the Ukrainian Armed Forces from the Donbass and Novorossia a condition for peace 'In order to complete the special military operation (SVO) in Ukraine, Kiev must begin to implement Russia's peace initiatives, which were outlined during the Russian leader's meeting with the leadership of the Ministry of Foreign Affairs'. This statement was made by Russian President Vladimir Putin on 5 July at a press conference after negotiations with Hungarian Prime Minister Viktor Orban.
Label: Peacemaker

A.3 Example of S3 - Mixed approach

A.3.1 1st prompt

Classify the entity using one or more labels choosing from these: 'Instigator', 'Conspirator', 'Tyrant', 'Foreign Adversary',
'Traitor', 'Spy', 'Saboteur', 'Corrupt', 'Incompetent', 'Terrorist', 'Deceiver','Bigot', 'Guardian', 'Martyr','Peacemaker', 'Rebel', 'Underdog', 'Virtuous', 'Forgotten', 'Exploited', 'Victim', 'Scapegoat'.
Entity: Vladimir Putin
Context: Putin called the withdrawal of the Ukrainian Armed Forces from the Donbass and Novorossia a condition for peace 'In order to complete the special military operation (SVO) in Ukraine, Kiev must begin to implement Russia's peace initiatives, which were outlined during the Russian leader's meeting with the leadership of the Ministry of Foreign Affairs'. This statement was made by Russian President Vladimir Putin on 5 July at a press conference after negotiations with Hungarian Prime Minister Viktor Orban.
Label: Guardian

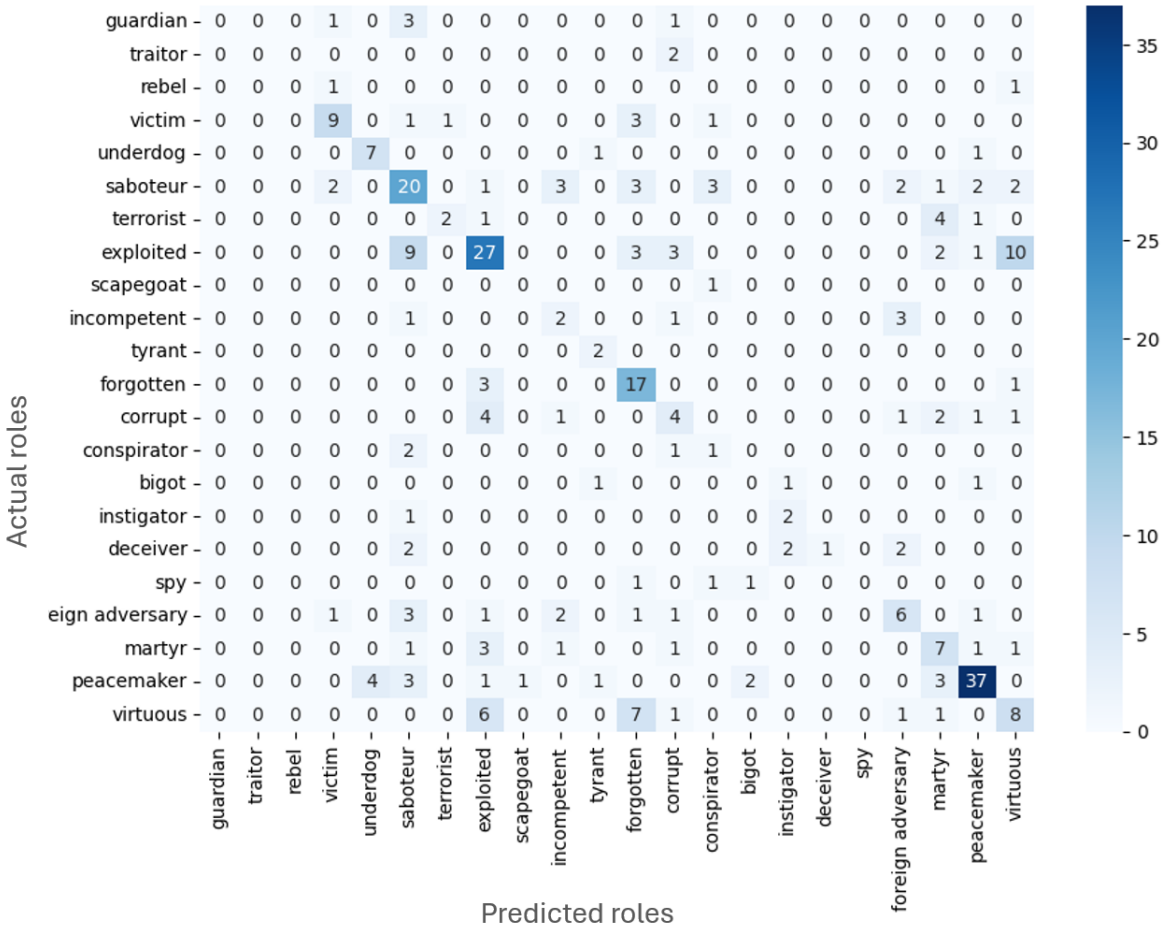
A.3.2 2nd prompt

Classify the entity using one or more labels choosing from these: 'Instigator', 'Conspirator', 'Tyrant', 'Foreign Adversary',
'Traitor', 'Spy', 'Saboteur', 'Corrupt', 'Incompetent', 'Terrorist', 'Deceiver','Bigot', 'Guardian', 'Martyr','Peacemaker', 'Rebel', 'Underdog', 'Virtuous', 'Forgotten', 'Exploited', 'Victim', 'Scapegoat'.
Entity: Vladimir Putin
Context: Putin called the withdrawal of the Ukrainian Armed Forces from the Donbass and Novorossia a condition for peace 'In order to complete the special military operation (SVO) in Ukraine, Kiev must begin to implement Russia's peace initiatives, which were outlined during the Russian leader's meeting with the leadership of the Ministry of Foreign Affairs'. This statement was made by Russian President Vladimir Putin on 5 July at a press conference after negotiations with Hungarian Prime Minister Viktor Orban.
Label: Peacemaker

A.3.3 3rd prompt

Classify the entity using one or more labels choosing from these: 'Instigator', 'Conspirator', 'Tyrant', 'Foreign Adversary',
'Traitor', 'Spy', 'Saboteur', 'Corrupt', 'Incompetent', 'Terrorist', 'Deceiver','Bigot', 'Guardian', 'Martyr','Peacemaker', 'Rebel', 'Underdog', 'Virtuous', 'Forgotten', 'Exploited', 'Victim', 'Scapegoat'.
Entity: Vladimir Putin
Context: Putin called the withdrawal of the Ukrainian Armed Forces from the Donbass and Novorossia a condition for peace 'In order to complete the special military operation (SVO) in Ukraine, Kiev must begin to implement Russia's peace initiatives, which were outlined during the Russian leader's meeting with the leadership of the Ministry of Foreign Affairs'. This statement was made by Russian President Vladimir Putin on 5 July at a press conference after negotiations with Hungarian Prime Minister Viktor Orban.
Label: Guardian, Peacemaker

B Confusion Matrix



ITF-NLP at SemEval-2025 Task 11: An Exploration of English and German Multi-label Emotion Detection using Fine-tuned Transformer Models

Samantha Kent and **Theresa Nindel**
Fraunhofer FKIE
Fraunhoferstraße 20, 53343 Wachtberg, Germany
{samantha.kent,theresa.nindel}@fkie.fraunhofer.de

Abstract

We present our submission to Task 11, Bridging the Gap in Text-Based Emotion Detection, of the 19th International Workshop on Semantic Evaluation (SemEval) 2025. We participated in track A, multi-label emotion detection, in both German and English. Our approach is based on fine-tuning transformer models for each language, and our models achieve a macro F1 of 0.75 and 0.62 for English and German respectively. Furthermore, we analyze the data available for training to gain insight into the model predictions.

1 Introduction

The American Psychological Association defines emotion as "conscious mental reactions (such as anger or fear) subjectively experienced as strong feelings usually directed toward a specific object and typically accompanied by physiological and behavioral changes in the body"[1].

Most research in emotion detection in Natural Language Processing (NLP) is based on two different types of emotion theories. The first group of theories views emotions as universal categories (e.g.(Ekman, 1992) and (Plutchik, 1980)), and the second focuses on defining emotions in two or three dimensions, such as valance, arousal and dominance e.g. (Russell, 1980). Furthermore, current research is exploring the possibility of multiple emotions being present in one sentence or utterance. Task 11, Bridging the Gap in Text-Based Emotion Detection, at the International Workshop on Semantic Evaluation (SemEval), focuses on cross-lingual and multi-label emotion detection (Muhammad et al., 2025b).

We participated in Task A 'Multi-label Emotion Detection' for the languages German and English. The aim of the task was to detect the emotions Anger, Fear, Joy, Sadness, and Surprise for English, and the German data also includes the class Disgust. Notably, a text can contain multiple emotions, thus takes into account the co-existence or even potential overlapping of emotions in one sentence. An example in English can be found below:

```
{text: It could have been my eye
   -- but my glasses probably
   blocked that from happening,
   and diverted the injury higher
    up on my head.,
 gold labels: fear and surprise}
```

Previous shared tasks on emotions demonstrate a range of different approaches. Affect in Tweets at Semeval 2018 includes emotion classification systems based on SVMs and LSTMs (Mohammad et al., 2018). Neural architectures were also the most common approach for an emotion shared task related to context in emotion detection (Chatterjee et al., 2019). For the WASSA 2022 shared task, emotion label prediction was conducted for a series of essays using Ekman's six emotion classes. Most teams used systems with pre-trained Transformer mechanisms such as BERT, RoBERTa and DeBERTa (Barriere et al., 2022). Following this, most participants in the WASSA EXALT Shared Task on explainability for Cross-Lingual Emotions in Tweets use some form of Generative Large Language Model (LLM) (Maladry et al., 2024).

Based on the previous approaches to emotion shared tasks, we decide to focus on fine-tuning a transformers model for each language, English and German, and to use the results as a starting point to analyze the emotion labels in more detail. We chose to draw upon well-established discriminative transformer models instead of generative LLMs as our main focus is on advancing the understanding of decisions made by those commonly used baseline models. In general, we are interested in exploring the emotion classes, linking model performance to the data, and comparing the differences between

[1] https://www.apa.org/topics/emotions.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1465–1472

the two languages.

2 Data

The following chapter describes the data available for training in English and German that was provided by the task organizers. For both languages, the train/development/test instances stem from Reddit and was annotated using language-specific human-annotators. A more detailed overview of the dataset, that contains human-annotated emotion data for 28 different languages, can be found in (Muhammad et al., 2025a).

The **German** data consists of 2803 annotated texts and was labeled for six different emotions: Anger, Disgust, Fear, Joy, Sadness, and Surprise. Each text contains one or more labels, with an average of 1.17 emotion label per text, where 24.76% ($n = 694$) were labeled as not containing any emotions (neutral). 41.42% ($n = 1161$) were labeled with one emotion, 25.76% ($n = 722$) with two, 7.49% ($n = 210$) with three, 0.54% ($n = 15$) with four and 0.04% ($n = 1$) with five different emotions.

The **English** data contains 2884 annotated texts and was labeled for five different emotions: Anger, Fear, Joy, Sadness, and Surprise. 8.74% ($n = 252$) texts were labeled as not containing any emotions (neutral). 41.16% ($n = 1187$) were labeled with one emotion, 37.21% ($n = 1073$) with two, 10.82% ($n = 312$) with three, 2.01% ($n = 58$) with four and 0.07% ($n = 2$) with five different emotions.

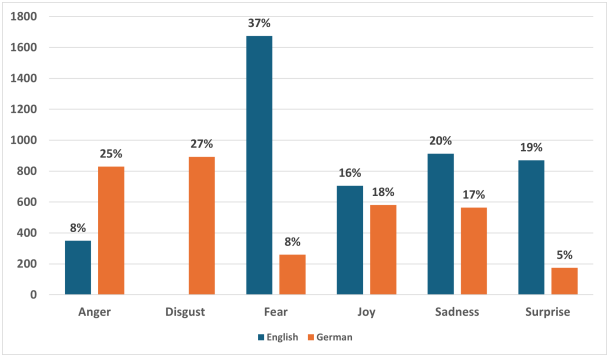


Figure 1: Emotion class distribution for English and German data.

Figure 1 illustrates the class imbalance in both the English and German train datasets. For English, the largest class is Fear (37%), and the smallest is Anger (8%). Contrastingly, in the German data, Fear (8%) is one of the smallest classes and Anger (25%) is the largest.

3 System Description

During the development phase, a number of pretrained models obtained from Hugging Face's model repository[2] were tested with regard to their ability to solve the given task. Model training/evaluation was implemented with the help of the Simple Transformers library (Rajapakse, 2019) and Pytorch (Paszke et al., 2019).

We used a similar approach for both languages and tested various model combinations and train/development/test splits. In submission 1 in both languages, the models were fine-tuned on the training data provided by the organizers. The development data was used to evaluate the models. For the second and third submissions, the training and development data was reshuffled and split into a new a training, development, and held out test set (distribution 70/20/10%). Additionally, weights were calculated for all classes and used during training to lessen the effects of the uneven class distribution for each language individually.

The **English** models submitted during the test phase were based on DeBERTa (He et al., 2020) and RoBERTa (Liu et al., 2019). The DeBERTa model, used for submission 1, was trained using the training data provided by the organizers for 5 epochs with the following hyperparameters: training batch size: 32, learning rate: 2e-5, max length: 125. For submissions 2 and 3, a RoBERTa model was fine-tuned using an 80/20 train and development split. The parameters are similar to the previous model, except training was conducted with a learning rate of 3e-5 and max length was set to 100. The difference between the two models in submission 2 and 3 is based on a different train split, providing the models with different data for fine-tuning.

The best performing model for **German**, which was subsequently used for all submissions, was xlm-roberta-large-finetuned-conll03-german (Conneau et al., 2019). As the name suggests, the model is based on XLM-RoBERTa-large (Conneau et al., 2019) and was fine-tuned on a German dataset. Hyperparameter testing resulted in the following optimal parameter combination: Epochs: 5, Learning rate: 3e-5, Training batch size: 16.

4 Results

Table 1 below shows results of the submissions that were made using the final test data provided by the

[2]https://huggingface.co/models

organizers. They are similar to the monolingual results reported by the organizers (Muhammad et al., 2025a).

For **English**, the best performing model achieved a macro F1 of 0.7501 (submission 3), and is also the submission on the final rank list. Submission 1, the DeBERTa model, did not perform as well as the other two RoBERTa models. This is surprising considering it outperformed the other two models on our own test data. There was a much larger drop in performance between our own test set and the final set for this model compared to the two RoBERTa models. Interestingly, the model for submission 1 was trained without using weighting to balance out the uneven class distribution, as the performance on our own test set was similar with or without weighting. The weights were used for model training in submissions 2 and 3. This suggests that using weighing as a strategy to balance the classes contributed to the robustness of the models.

	1	2	3
English			
Own test data	0.783	0.752	0.774
Final test data	0.6991	0.7485	**0.7501**
German			
Own test data	0.6608	0.6445	0.6414
Final test data	0.6231	0.6131	**0.6222**

Table 1: Results for English and German on final test data. The best performing models from the official ranking are in bold.

For **German**, the macro F1 scores ranged from 0.6131 to 0.6231. A drop in macro F1-scores between the self-compiled test set and the test set provided by the organizers can be observed for all three submissions. The smallest difference is present in the scores achieved by model 3. While model 3 has the lowest macro F1-score on the self-compiled test set, it seems to be the most robust when it comes to the prediction of previously unseen data. Further analysis would be needed to evaluate if the greater difference between macro F1-scores for the first two submissions could be due to over-fitting.

As well as looking at the overall performance, we also inspected the model's performance on the individual classes. The **German** models struggled to correctly predict the classes Fear and Surprise specifically. We showed in the data description that these classes are underrepresented in the German data. The weighting that was implemented during fine-tuning to lessen the effect of the unbalanced data distribution was not sufficient. The best performing classes, Anger and Joy, are also highly represented in the data.

	English	**German**
Anger	0.6621	0.7536
Disgust	-	0.6987
Fear	0.8398	0.4784
Joy	0.7546	0.7389
Sadness	0.7621	0.6443
Surprise	0.7316	0.4192
Macro F1	0.7501	0.6222

Table 2: Fine-grained results on submission 3 for English and German.

For **English**, a similar pattern of emotion class size and the model's ability to accurately predict the class can be observed. Fear outperforms the other classes with an F1 of 0.8398, and Anger is by far the smallest emotion class and also achieves the lowest f-score.

5 Analysis

In this section we analyze the corpus data and link the results to possible performance issues in the models. We further explore specific emotion classes, namely Anger and Disgust in German and Fear and Sadness in English.

5.1 German

To gain more insights into the performance of our best German model (model 3), the data available for training as well as the errors made by the model were analyzed. Out of the 2604 German sentences in the test data, only 1274 (48.92%) are correct, with all possible labels correctly predicted by the model. There is a difference when analyzing the per class or per sentence predictions. Even though the model achieves a macro-F1 of 0.62, when taking into account whether all emotions are predicted correctly, the results are not as accurate. Figure 2 below shows the distribution of the number of labels per sentence for all sentences that were predicted incorrectly. About 80% of errors stem from sentences that should contain one or two labels, with the majority of misclassifications being due to the models predicting multiple emotions where only one is correct. Therefore, in a first analy-

sis step, we want to evaluate the most frequent label combinations in the training data to determine whether overlapping or co-occurring emotions are the source of some of the German model errors.

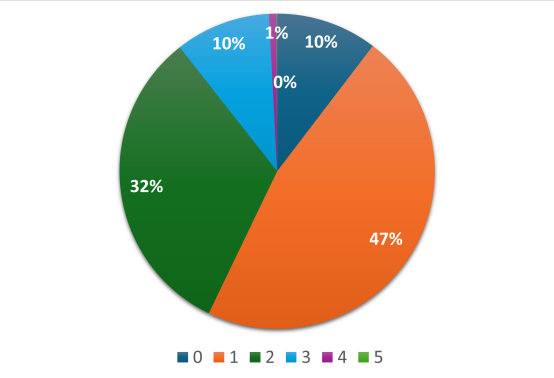

Figure 2: Number of labels per wrong prediction (de)

In total, the ten emotion combinations in figure 3 account for 2417 instances of all available data points (86.23% of the train/development corpus). Notably, the emotions Anger and Disgust appear together in two of these top 10 combinations and make up the biggest two-label combination with 384 (13.70%) entries in the corpus. Therefore, to ascertain how similar the classes are, we decided to analyze the most common words included in the texts associated with the two emotion categories in more detail. Stop words were not considered for this analysis.

Label(s)	**Nr.**
No Emotions/Neutral	694
Joy	435
Anger, Disgust	384
Sadness	220
Disgust	181
Anger	158
Anger, Disgust, Sadness	118
Fear	106
Surprise	61
Disgust, Sadness	60

Table 3: Top 10 Label (Combinations) in the German Dataset

The results in figure 4 in appendix A show a high lexical overlap between the categories Anger and Disgust. Nouns such as 'Israel', 'Krieg' (war), 'Gaza' and 'Hamas' are frequent in both emotions. As the emotions often co-occur in the data, this is not surprising. However, the question arises if this co-occurrence leads to a tendency of the model to learn similar representations based on the content of the classes rather than the associated emotions. To examine this question, we explore sentences that were annotated as only Anger, but have instead been classified as Disgust or a combination of Anger and Disgust, and vice versa.

Gold Labels	**Predictions**	**%**
Anger (140)	Disgust	61 (43.57)
	Fear	6 (4.29)
	Joy	6 (4.29)
	Sadness	1 (0.71)
	Surprise	7 (5)
Disgust (164)	Anger	46 (28.05)
	Fear	6 (3.66)
	Joy	8 (4.88)
	Sadness	17 (10.37)
	Surprise	6 (3.66)

Table 4: Classification Errors for Anger and Disgust.

Table 4 illustrates that our best German model predicted either Disgust or a combination of Anger and Disgust instead of the correct label Anger, in 43.57% of all errors related to Anger (as a single emotion annotation). Contrastingly, Joy, for example, was only predicted in combination with Anger in 4.29% of cases. This is also reflected in our train data: Joy and Anger, as well as Fear and Anger, are only labeled in combination 14 times, whereas Anger and Disgust are present as a label combination in 384 sentences (see table 3).

Even though there may also be other reasons for this type of misclassification, the very similar vocabulary in both the Anger and Disgust classes is likely to cause difficulties. The following example serves to illustrate this mix-up. Here, the relevant words are *Krieg* and *Ukraine*. Both are among the most frequent words in both categories, Anger and Disgust, in the data available for training.

```
{text: Einfache Wahrheiten: Wer "
   gegen Krieg ist", sollte die
   Ukraine bestmöglich bei ihrer
   Verteidigung unterstützen. Wer
    diese Unterstützung ablehnt,
   unterstützt de facto Putin in
   seinem Krieg.
 gold label: anger
 predicted labels: anger and
    disgust}
```

In general, our analysis seems to indicate that

the model may in fact be learning similar representations for the emotions Anger and Disgust. This is understandable considering the distribution of classes in the data, as well as the analysis regarding the most common words. The performance of the model in both classes is good, but nonetheless, the multi-label aspect of the task means it might be difficult to actually distinguish between these two classes.

5.2 English

We adopt the same method of analysis for the English dataset In order to determine whether a similar pattern is present in English. With a total of 2884 sentences in the train data, the top 10 label combinations account for 85.64% of the dataset. Similarly to German, we see one two-label combination that occurs frequently in the training data, namely, Fear and Sadness. There does seem to be such a strong co-occurrence of only two specific labels as in German, because Fear and Surprise also often occur in the same sentence. To ensure comparability between the two languages we again further analyze the sentences containing the top two co-occurring emotions.

To start with, the most common words of these two emotion categories were analyzed. The results can be found in appendix A, figure 5. Nouns such as 'head', 'eyes', 'hand' and 'heart' stand out at a first glance, indicating that there does seem to be a common topic in both emotions. However, there are also many verbs present in the top words and the difference in frequency of occurrence is a bit larger between the two emotions compared to in German. Whilst a similar pattern can be observed for English, there does not seem to be such a strong indication of overlapping topics in English Fear and Sadness compared to the German Anger and Disgust.

A more in-depth analysis of the the test data shows that a total of 1381 English sentences (49.91%), out of the possible 2767 sentences in the English test data, are incorrectly classified by the RoBERTa model. Figure 3 illustrates that more than 50% of errors stem from sentences that contain more than one emotion prediction, but also for English a large percentage of errors is due to misclassifications in sentences containing single emotions.

Based on the frequent label combinations in the training data, we further explore if the class combinations learned during training also influence the predicted labels. Table 6 provides an overview of misclassifications related to the most frequent emotion combination Fear and Sadness. As is true for the German analysis, the figures in the table show the relationship between the misclassifications in those emotion classes, but do not account for all possible combinations. Also as expected based on the German data, classes that frequently appear together in the train data, also seem to be a source of error for the predictions.

Label(s)	**Nr.**
Joy	448
Fear, Sadness	429
Fear	425
Fear, Surprise	337
No Emotions/Neutral	252
Sadness	139
Fear, Sadness, Surprise	127
Surprise	117
Joy, Surprise	114
Anger, Fear, Sadness	82

Table 5: Top 10 Label (Combinations) in the English Dataset

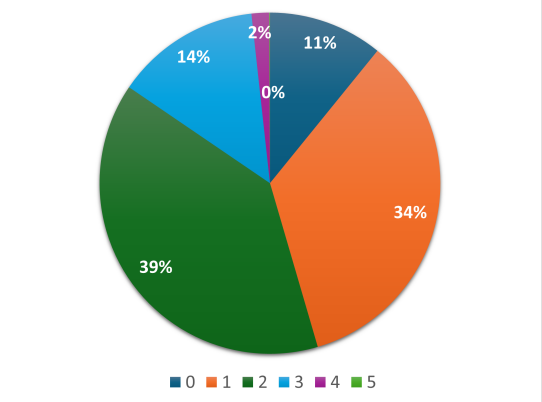

Figure 3: Number of labels per wrong prediction (en)

Gold Labels	**Predictions**	**%**
Fear (172)	Sadness	56 (32.56)
	Anger	7 (4.07)
	Joy	14 (8.14)
	Surprise	45 (26.16)
Sadness (70)	Fear	41 (58.57)
	Anger	4 (5.71)
	Joy	9 (12.86)
	Surprise	3 (4.29)

Table 6: Classification Errors for Fear and Sadness.

In the example sentence below, the label should have been predicted as Fear, but Sadness has also been included as a prediction label. The most frequent words from the classes Fear and Sadness in figure 5 in appendix A, show that *head* is frequent in both classes, but more dominant in Fear.

```
{text: Meanwhile my head began to
    pound and I grew quite
   nauseous.
 gold label: fear
 predicted labels: fear and
    sadness}
```

6 Conclusion

We participated in the Semeval 2025 shared task on text-based emotion detection. We participated in task A in English and German and our results are a macro F1 of 0.75 and 0.62 respectively. These are similar to those achieved by the organizers for their monolingual models (Muhammad et al., 2025a). Our approach was based on fine-tuning well-established transformers models and we optimized the model parameters for each language and experimented with different approaches to optimizing the training data. We found that the most effective strategy to improve both performance and robustness in the models for both languages was to balance the emotion classes in the data.

In general, our analysis of the train and test data suggests, for both German and English, that there is a connection between class size and model performance for that specific class. We also demonstrated with our analysis the difficulty in classifying more closely related emotions, specifically Anger and Disgust in German, and Fear and Sadness in English. This seems to be related to their more frequent co-occurrence as annotated labels in the training data, which then also has an effect on how closely related the topics in each class are. Future work includes expanding the emotion correlation analyses and applying our findings when balancing the dataset in pre-processing.

When comparing the two languages, based on the most frequent words it seems as though a majority of the sentences in German data are related to politics, whereas in the English data the prevailing topic seems to be health. A larger dataset with more diverse topics might be helpful in ensuring robustness in future models. It would be interesting to explore the topics present in the data for the other languages in the shared task, and also see what role the topic clusters may play in cross-lingual emotion detection.

In general, the definition of emotion already suggests that subjectivity plays a large role in correctly perceiving emotion, and multi-label annotations make the task of emotion detection even more challenging. The example below serves to illustrate the need for annotating multiple emotions in one sentence, as there is evidently an expression of both negative and positive emotion. However, due to the subjectivity of perceiving emotion, the need for all five emotion labels is debatable. We therefore acknowledge the difficulty of collecting and annotating emotion data.

```
{text: Yeah...welcome to being 25
   , btw...it is awful thus far
   ...but...SHIT at least I get
   to be 25!
 gold label: anger, fear, joy,
    sadness, surprise}
```

Abstract

This paper describes our submission to the SemEval-2025 Task 3: Mu-SHROOM, a shared task focused on hallucination span detection in the outputs of large language models (LLMs). The goal of the task is to identify spans of text that, despite being grammatically sound, are not supported by external sources. As a baseline, we employed random and zero-probability classifiers to gauge the difficulty of the task. Our main system combines a Retrieval-Augmented Generation (RAG) module with a Natural Language Inference (NLI) model to detect hallucinated spans. The RAG module retrieves information from Wikipedia and generates a premise, which is then compared to the LLM output using a multilingual NLI model in a sliding window approach. Our final system achieved competitive results, demonstrating the effectiveness of integrating RAG with NLI for fine-grained hallucination detection.

1 Introduction

Large language models (LLMs) are specialized in generating human-like text in various styles, which lends them to many practical applications. However, even the most sophisticated models can produce hallucinations, making users question their reliability and putting the adoption of machine learning pipelines in jeopardy (Rykov et al., 2024). Hallucination refers to the generation of texts or responses that exhibit grammatical correctness, fluency, and authenticity, but deviate from the provided source inputs or do not align with factual accuracy (Ji et al., 2023; Ye et al., 2023). This is a phenomenon that established evaluation metrics struggle to detect (Bahad et al., 2024); as a result, it has now become imperative to develop systems that can assess the factual consistency of a claim with respect to context (Zha et al., 2023).

The SemEval shared task Mu-SHROOM (Vázquez et al., 2025) provides an opportunity to develop solutions to the problem of hallucinations in LLMs. The objective of the task is to classify spans, which are continuous segments of text within LLM outputs, as hallucinations. For instance, in the generated sentence "Marie Curie won three Nobel Prizes for her work in physics and chemistry," the span "won three Nobel Prizes" would be labeled as a hallucination, since she actually won two. To this end, we only consider spans hallucinated when the LLM output contradicts the relevant retrievable information. The detection of hallucination spans allows for a more fine-grained understanding of where hallucinations occur in LLMs, as well as giving an indication of the severity of hallucinations in LLMs. This is something that a binary classification is not able to provide, given its simplicity.

In this paper, we present a linear composite system that employs a Retrieval-Augmented Generation (RAG) question-and-answer system to generate an answer to the question in each prompt; combines the question-answer pair into a unified premise with a generative LLM; and compares this premise with the subject model output using an off-the-shelf Natural Language Inference (NLI) model. We compare the performance of this system with several baselines, and discuss its strengths and weaknesses.

2 Background

The Shared-task on Hallucinations and Related Observable Overgeneration Mistakes (SHROOM) has been put forth by Mickus et al. (2024) to address the issue of hallucinations in LLMs. The main objective of SHROOM is the development of systems that detect hallucinations in the generated output of LLMs. In the shared task, participants must detect grammatically sound outputs that nonetheless contain incorrect or unsupported semantic information compared to a source input. This task can be done with or without access to the model that produced

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1473–1478

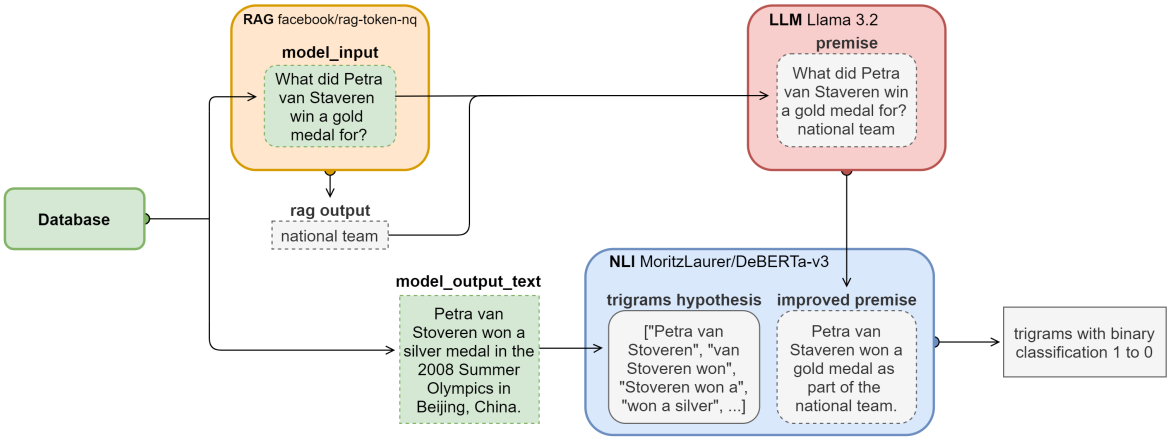

Figure 1: Overview of the improved and final system pipeline.

the output: respectively, these are the model-aware and model-agnostic versions of the task (Bahad et al., 2024; Mickus et al., 2024).

In this previous shared task, NLI-based approaches achieved the best performance. (Maksimov et al., 2024; Obiso et al., 2024). The objective of NLI systems is to determine the truth value of a hypothesis, given a premise. As an example, the premise *"the pedestrian walks on the zebra crossing"* and the hypothesis *"the pedestrian must yield"* produces a contradiction and is judged false; the same premise with the hypothesis *"the pedestrian is wearing a green shirt"* results in a neutral judgment, though this can also be rendered as false.

The remarkable similarity between NLI and the SHROOM task lent itself to several submissions utilizing models that were (pre-)trained on NLI data. The DeepPavlov team of Maksimov et al. (2024) opted to directly train RoBERTa and similar models as well as a Text-to-Text Transfer Transformer on NLI data. On the other hand, the HaRMoNEE team of Obiso et al. (2024) selected a pre-trained RoBERTa model and fine-tuned it using data from SHROOM. The models produced by these teams achieved accuracies of 0.80 and higher, with HaRMoNEE's approach being the best model in the model-aware version of the task.

Systems that operate on a similar objective of NLI, such as those for information retrieval, paraphrasing, fact verification and textual similarity, can be unified under a single model for information alignment (Zha et al., 2023). RAG frameworks have shown promising results in regard to hallucinations. These systems combine generative models with retrieval mechanisms. This hybrid method not only improves the factual accuracy of the generated text, but also helps mitigate the risk of hallucinations by grounding the output in verifiable data (Lewis et al., 2020).

The system used in this paper will use the insights from these works to combine NLI with RAG to create a pipeline for hallucination detection on text spans. In this way, we hope to build upon the best-performing systems from the SHROOM task and test their resilience against a different method of hallucination detection.

3 Data

In the SemEval 2025 Task-3 Mu-SHROOM, the task is to detect hallucination spans in the outputs of instruction-tuned LLMs in a multilingual context. To this end, the data is provided in 24 different languages, with each output being produced by a variety of open-source LLMs. The LLM output is provided in the format of a human question, a generated answer and, in the case of the validation set, labels for hallucinated spans that use string positions. The last of these is divided into soft labels, which indicate the probability of hallucinations, and hard labels, which assert spans as hallucinated if the probability exceeded 50%.

Val	Test	Total
50	154	1013

Table 1: The English data distribution for the shared task.

We chose to focus on the English language for this study, which was split at around 75%, 5% and

15% for training, validation and testing data respectively. The database and dataset distribution as utilized in our study can be seen in Table 1. While we confirm that an unlabeled training set was available, we did not make use of this set in our system.

4 Method

Our approach can be distilled into three distinct steps. The pipeline for this system is shown in Figure 1. First, the RAG model retrieves the relevant information from a Wikipedia vector index based on the prompt question, and generates an appropriate answer to form a premise. Afterwards, our model tokenizes the hallucinated answer using the Treebank tokenizer from the NLTK library (Bird and Loper, 2004). Finally, the hallucinated answer is fed in token trigrams to the NLI model as hypotheses, with the trigrams being fed in a sliding-window fashion.

Besides our main system, we also created a baseline classifier that uses random probabilities and all-zero probabilities. The random-probability baseline classifier is the default and assigns completely random probabilities to each span, making each output unique and not reproducible. The alternative approach assigns a 0.0 value for all probabilities. These baselines are meant to gauge the effectiveness of our systems in the absence of external baseline metrics during development.

4.1 Retrieval-Augmented Generation

We employ the RAG system as designed by Lewis et al. (2020) and use the default wiki_dpr vector (Karpukhin et al., 2020) as its dataset. Due to computational constraints, we did not include a document screening stage to filter irrelevant or low-quality factual documents; this represents realistic limitations in low-resource settings.

The handling of the RAG output can occur in two ways. The more basic implementation concatenates the input question and the RAG answer to form the premise. In our main system, we employ Llama 3.2 (Dubey et al., 2024) running under the Ollama API to rewrite the concatenated premise into a natural-language answer to the question. The prompt used for this component, as well as the manner in which a question and answer pair is formulated in the prompt, can be found in Appendix A. We tested both approaches in this study.

4.2 Natural Language Inference

We employ an off-the-shelf multilingual DeBERTa NLI model that is fine-tuned on three datasets (Laurer et al., 2022; He et al., 2021, 2023), comprising 885 to 242 NLI hypothesis-premise pairs. We use this model as it was provided, without any additional fine-tuning on the provided hallucination detection dataset or other similar datasets.

The NLI model evaluates whether the claims in the generated response logically follow from the RAG premise, given in regression probabilities of entailment, neutrality and contradiction. If the contradiction probability of a trigram is at least 0.1 and it is larger than the entailment probability, then it scores that trigram as 1; otherwise, it is left as 0. The soft label probability for each token is the average classification of every trigram that the token occurs in. While this averaging method provides an intuitive and lightweight way to generate soft labels, we acknowledge that this differs from conventional hallucination detection practices.

4.3 Evaluation

To evaluate the performance of our system, Vázquez et al. (2025) have specified the use of an Intersection over Union (IoU) score and Spearman's correlation coefficient (ρ). The IoU is calculated on the index sets of hallucination spans between the gold reference and the predictions per hypothesis. If the calculated hallucination probability score of a span is greater than 0.5, the evaluation program classifies the span as a hallucination. The span is then converted to a set of indices. For instance, the soft label {"start": 32, "prob": 0.667, "end": 34} is transformed into the set {32, 33, 34}. The indices for all spans classified as hallucinations is combined into a single set. These sets are compared between the gold reference and the predictions of the models. To calculate ρ between the gold reference and the predictions, the evaluator program compares probability vectors for all of the spans.

5 Results

Our main system ranked 32nd on the English-language leaderboard, measured by the IoU score on the test set. We applied our baseline models to the validation set only; the baseline scores reported for the test set are provided by Vázquez et al. (2025). The full results are shown in Table 2.

The all-zero baseline resulted in an IoU score of

Validation	**IoU**	**Cor**
Baseline (all-zero)	0.040	0.000
Baseline (random)	0.187	0.179
System	0.198	0.171
System (+ Llama)	**0.240**	**0.201**
Test	**IoU**	**Cor**
Baseline (neural)	0.031	0.119
Baseline (mark none)	0.033	0.000
System	0.275	0.261
System (+ Llama)	0.315	**0.304**
Baseline (mark all)	**0.349**	0.000

Table 2: The results from our system on the validation and test sets, as compared to the available baseline systems. The scores with systems in italics were gathered from the leaderboard.

0.040 and a correlation score of 0.000, indicating that it fails to provide meaningful hallucination span predictions. The random baseline performed slightly better, achieving an IoU score of 0.187 and a correlation of 0.179, demonstrating that a completely random assignment can capture some degree of variation in hallucination spans, though it remains unreliable.

Our main model on the validation set achieved an IoU score of 0.198 and a correlation score of 0.171, showing a slight improvement over the baseline models. In the test set, our model demonstrated a larger increase in performance, with an IoU score of 0.275 and a correlation of 0.261. This suggests that our concatenation-based system yields an improvement in identifying hallucination spans beyond what is captured by baseline approaches; however, if this were the case, the effect size is negligible.

The improved system with Llama premise rewriting demonstrated the most visible gains in performance. On the validation set, the improved system achieved an IoU of 0.240 and a correlation of 0.201. The results for the improved system on the test set yielded our highest scores overall, with an IoU of 0.315 and a correlation of 0.304. These results indicate that the addition of a premise-rewriting step refines the hallucination detection process and leads to a more robust identification of hallucination spans.

6 Discussion

The results indicate that our proposed system provides a noticeable improvement over our baseline models. Using retrieval-augmented generation, the model ensures that the responses generated are grounded in relevant contextual information. Furthermore, NLI-based evaluation at the trigram level enables a more granular detection of hallucination spans, which is not possible with binary classification approaches.

A key strength of our approach lies in the introduction of a premise rewriting step, which improves alignment between generated text and factual sources before the NLI step. The empirical results show that this method enhances the detection performance of the hallucination range. However, this did not improve the detection of subtle hallucinations or the handling of paraphrased incorrect information.

Our core approach has a few systematic flaws worth addressing. For instance, we used an off-the-shelf NLI model without additional task-specific fine-tuning. While this allowed for rapid experimentation, it may have resulted in worse overall performance. Fine-tuning or adapting the model on the hallucination detection dataset itself could have improved performance by aligning the model more closely with task-specific patterns. A similar problem exists for our RAG component, whereby an unscreened set of documents may have led to lower-quality training data for the RAG model. We expect a custom, curated set of documents to improve the overall efficacy of the model.

In addition, our system is non-standard in ways that could affect performance. Many systems either use external factual documentation to explicitly verify claims or assess internal output consistency across different runs. In contrast, our method does not rely on external factual verification beyond the initial RAG retrieval, nor does it compare outputs across runs. Furthermore, the detection is entirely localized, whereby the contradiction entailment is combined with the span searching. This may also have contributed to a lower leaderboard rank.

We manually checked differences in span hallucination assessment for the validation set between the gold reference and our best model, in order to better understand the performance of our model. In particular, the span annotations in the gold standard are different from the spans that we created using the Treebank tokenizer. For instance, the first identified span in the sentence "The Elysiphale order contains 5 genera." is the word 'the' for our own system, and 'Elysiphale' for the gold reference. The last identified span is '.' and 'genera.'

respectively. In this example, the identified span 'genera' is assigned a probability of 1.0 by our own model, and the span 'genera.', including the period, is assigned 0.2 in the gold standard. If our NLI model classifies a trigram as a hallucination, that classification is extended to all of its constituents. This makes it prone to false positives, especially at string boundaries. We highlight an example of this behavior in Table 3.

Tokens	Predicted prob.	Gold prob.
The	0.0	0.0
Elysiphale	0.0	0.2
order	0.3333	0.0
contains	0.6666	0.0
5	1.0	1.0
genera	1.0	0.2
.	1.0	

Table 3: A comparison of the predicted and gold-standard soft labels for the sentence "The Elysiphale order contains 5 genera." The gold standard counts 'genera.' as a single token.

Finally, in the returned answers for the validation set, there were several questions that the RAG could not parse meaningfully. For instance, a query for the debut of Chance the Rapper returned his birth date, whereas a query for four elements in Zhejiang cuisine returned a single element. As a result, this augments only a part of the total output, instead of representing a fully augmented approach. Given that these answers were in a similar format to correct answers, we conclude that these are limitations of the RAG system itself and not the formulation of the questions. Future research could explore an alternative implementation that returns nearby answers in a JSON format, though the feasibility of this approach for vectors remains to be seen. Future work could also optimize the vector for an improvement in ease of use and deployment.

7 Conclusion

This paper presents a novel approach to hallucination span detection in machine-generated text through RAG and NLI. Our research is conducted within the framework of the Mu-SHROOM shared task, contributing to the broader effort of evaluating and improving hallucination detection techniques. Our results demonstrate that our proposed method outperforms baseline approaches and provides a more fine-grained understanding of hallucinations in LLM outputs. The introduction of a premise-rewriting step within the pipeline further enhances detection accuracy.

We recognize that our system has a variety of shortcomings that contributed to a lower score than most. In particular, future research could explore more selective labeling and a RAG-like system with an array of outputs. Nevertheless, we believe that our study contributes to the Mu-SHROOM shared task by providing information on hallucination span detection. In this way, we hope to advance research on the factual reliability of content generated by LLMs by mitigating the presentation of faulty information.

A Appendix

A.1 Llama prompt example

Your task is to rewrite a question and answer pair into a single, declarative sentence. Include all information from the original question, as well as information included in the answer. Both the question and the answer are provided below. Always assume the provided answer is correct. Do not include anything other than the resulting sentence in your response.

Question: What did Petra van Staveren win a gold medal for?
Answer: national team

JNLP at SemEval-2025 Task 1: Multimodal Idiomaticity Representation with Large Language Models

Abstract

Idioms and figurative language are nuanced linguistic phenomena that transport semanticity and culture via non-compositional multi-word expressions. This type of figurative language remains difficult for small and large language models to handle. For language models to become more valuable as translators and even companions, natural language must be understood and generated. A portion of this is idiomatic and figurative language. Various attempts have been made to identify idiomaticity in text. The approach presented in this paper represents an intuitive attempt to accurately address Task 1: AdMIRe Subtask A to correctly order a series of images and captions by concatenating the image captions as a sequence. The methods employ the reliability of a pre-trained vision and language model for the image-type task and a large language model with instruction fine-tuning for a causal language model approach to handle the caption portion of the task. The models chosen for development in the pipeline were based on their respective reliability in captioning and instruction fine-tuning.

1 Introduction

The idiomaticity of a multi-word expression has been traditionally difficult for many language models, due to the non-compositional nature of this type of figurative language. When interpreting meaning from a sequence that may contain an idiom, a language model must chunk accurately and identify the possible multi-word expression with phrase analysis. For general pre-trained models without training or fine-tuning for this downstream task, the contextual embeddings tend to interfere with this detection. The embeddings must change internally or externally to accommodate for the lack of "sense" the phrase would make if treated as a literal and compositional phrase. Disregarding tokenization, consider a word by word embedding of this sentence, "They became relaxed when they saw that the test was about transformers (Vaswani et al., 2017), thinking that this was their bread and butter." The transformer is not bread nor is it butter, so we can assume that the embeddings for this sentence would skew from the intended meaning of the sentence. Now, we consider mapping "*their bread and butter*" with a word or phrase of similar meaning:
"They became relaxed..., thinking this was *their bread and butter*."
"They..., thinking this was *semantically similar word or phrase*."
"They..., thinking this was *easy*."
Or
"They... this was *going to be easy*."

In order for the language model to make this leap, expressions must be analyzed, the semanticity must be determined, and the phrase must be mapped to an equivalent or similar literal phrase or word in the embedding space.

Extending this to a vision model seems like a logical step. Vision models have become more ubiquitous recently with the introduction of QWEN-VL (Wang et al., 2024), DINOv2 (Oquab et al., 2023), GIT (Wang et al., 2022), Vision Transformers (Dosovitskiy et al., 2021) and adapted distillation models (Chen et al., 2022a) (Chen et al., 2022b) , and the reliable CNNs (LeCun et al., 1998). A vision and language model provides a concise description of an image. The existing models perform this task at a SOTA level for complicated images with complex description requirements with notable results from GIT on the MS COCO dataset (Lin et al., 2014) with CIDEr evaluation score of 138.5 (Vedantam et al., 2015) and QWEN-VL on the Flickr30k dataset (Young et al., 2014)with a BLEU-4 score of 41.2 (Papineni et al., 2002). Despite the impressive evaluation scores, these models still output a caption based on the actual facts of

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1479–1484

the image rather than an inferred meaning about the image.

Combining the vision and figurative language ideas can be considered difficult in isolation, but concatenating the image captions as a sentence, could allow for the multi-word expression treatment as described above. For the task of sequencing images and captions based on their relative position that may contain idiomatic expressions in visual representation or text, we employed the functionality of the BLIP vision and language model for image captioning (Li et al., 2022), while an instruction fine-tuned (Chung et al., 2022) QWEN-2.5 handled the image captions for sequencing (Wang et al., 2024).

2 Related Work

This general approach for idiomaticity has been refined using a variety of novel methods, including contrastive learning in the form of adaptive triplets (He et al., 2024), BERT-based binary classification (Devlin et al., 2019; Wang et al., 2021), single token approaches (Yin and Sch"utze, 2015; Li et al., 2018; Cordeiro et al., 2019; Phelps, 2022), analyses of pre-trained language model performance using standard evaluation techniques (Tayyar Madabushi et al., 2021), such as STS (Agirre et al., 2012) and cosine similarity (Salton and McGill, 1983), and recent studies concerned with recent LLM performance on various datasets (Phelps et al., 2024) . A number of datasets have also been created for evaluation and training in model development, including the Semeval 2022 task B dataset (Agirre et al., 2012), for multilingual idiomaticity detection and sentence embedding evaluation across languages; EPIE (Saxena and Paul, 2020), English possible idiomatic expressions, designed for binary idiomaticity classification tasks; MAGPIE (Haagsma et al., 2020), for idiom interpretation, paraphrasing, and contextual understanding; and Llidioms, multilingual linked idiom dataset. Vision models including the aforementioned QWEN-VL (Wang et al., 2024), text generation and image understanding; DINOv2 (Oquab et al., 2023), self-supervised image representations, GIT (Wang et al., 2022), a generative image-to-text transformer; Vision Transformers, replacing convolutional layers with an attention mechanism; distillation models, transfer learning; and CNNs (LeCun et al., 1998), extracting hierarchical structures from images which have primarily been pre-trained for generalizability for SOTA performance on various tasks or fine-tuned to perform exceedingly well on specific tasks, such as VQA (visual question answering) or image captioning. The performance of these general models is leveraged as the basis on which we attempted to build a fine-tuned and idiom-robust vision and language model.

3 System Overview

The goal of this task was to rank images based on how accurately they reflect the meaning of a nominal compound (potential idiom phrase) as used in a given context sentence. Formally, given a short text nominal compound (x), its corresponding context sentence (S), and a set of five images or image captions ($\mathcal{I}$), a machine learning system must determine the ranking of these five images ($y = [\text{image}_i]_{1 \leq i \leq 5}$).

For ranking the images, this approach was based on the instruction fine-tuning a Vision Language model and prompting technique to develop two approaches: *end-to-end* and *comparing operator* -based methods. In an *end-to-end* system, depicted in Figure 1, all information provided for this task is shown, including (1) instruction message, (2) nominal compound, (3) sentence context, (4) picture information and train a model to generate the ranking of all images together. In the approach based on *comparing operator*, the focus was on training a model to learn the operator of the comparison between two images, which image is closer to the meaning of the potential idiom phrase in sentence context, and then used these results to implement the insertion sort algorithms to achieve the final ranking of all images. Formally, the two approaches can be represented in the following formulas:

$$\textit{end-to-end}: \quad \mathbb{P}(y \mid x, S, \{\mathcal{I}_i\}_{1 \leq i \leq 5}) \tag{1}$$

$$\textit{comparing operator}: \quad \mathbb{P}(\{\text{Y, N}\} \mid x, S, \mathcal{I}_i, \mathcal{I}_{j|i \neq j}) \tag{2}$$

In the first approach (*end-to-end*), the Vision LMs were expected to be able to understand both the meaning of the focal phrase (nominal compound) expressed in the context sentence and the content of the provided images for the ranking process. This approach can utilize the full advantage of VLMs, which require the system to process whole images as input, thereby needing additional computing resources as the number of images increases. To avoid this problem, a second approach was developed, *comparing operator*, which only

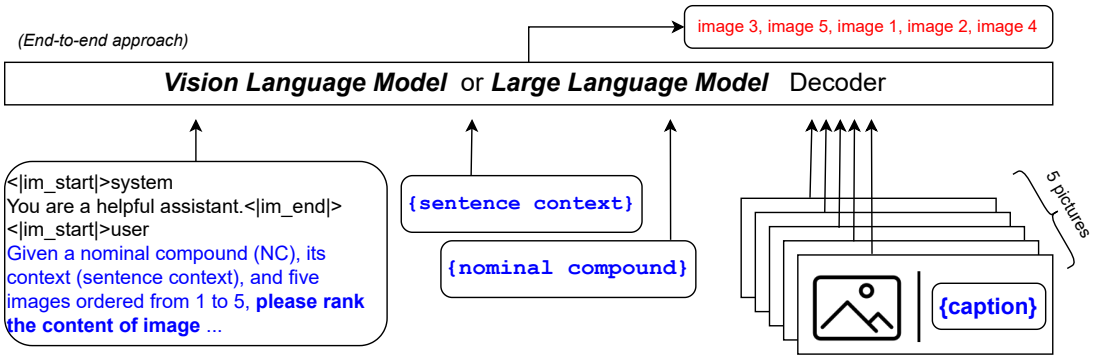

Figure 1: Overview of our approach for Subtask A.

compared a pair of images. The image chosen was closer in meaning to the focal phrase in the context sentence. Although this approach was able to deal with scaling the number of images for ranking, it may have ignored some features regarding the relationships among various images, allowing VLMs to avoid having an overall view of images.

The following methods represent work pertaining to Task1: AdMIRe subtask A, including *images and text* and *text only*. Overall, this method was shared between both these settings. For the images and text settings, the content of images was used to rank the similarity with the context sentence supported by pre-trained VLMs. For the text-only model, captions of images were utilized to represent the content and train LLMs. Moreover, extensive experiments were also conducted with a new caption generated by the BLIP (Li et al., 2022) language model to compare the effectiveness of the image's caption to the overall system.

Building on the strong vision-language understanding abilities of pre-trained models (Wang et al., 2024), instruction prompting was utilized to help the model interpret the task requirements. This approach aligned with instruction fine-tuning as described by Chung et al. (2022), employing a *causal language modeling* objective to train the LLM in generating the ranking of images or determining which image was closer to the context sentence. LoRA (Hu et al., 2022) was used to enhance efficiency, as it functions as a lightweight training method that minimizes the number of trainable parameters. The fine-tuned LLM was trained to model and generate the expected output based on the given input information.

$$s = \text{prompting}(y, x, S, \{\mathcal{I}_i\}_{1 \leq i \leq 5}) \quad (3)$$

$$\mathbb{P}(s) = \Pi_{z=1}^{|s|} \mathbb{P}(s_z | s_0, s_1, \ldots, s_{z-1}) \quad (4)$$

where s and x denote token sequences, and z represents the token index within the prompting input.

4 Experimental Setup

Dataset. For evaluating our methods, the original emotional dataset provided by the SemEval Task 1 (Pickard et al., 2025) organization was used. The dataset is divided into three subsets: training, development, test, and extended test sets, covering two phases of the competition: development and test. The held-out portion of the data is used for hyperparameter tuning, ensuring that the optimized checkpoints are chosen based on this internal development set.

Evaluation Metric. According to the competition guidelines, the evaluation metrics used to assess the quality of our model ranking are Top-1 Accuracy and the DCG score.

Settings. Experiments were conducted under the following settings, with results presented in Table 1:

1. Instruction fine-tuning of an LLM (`Qwen/Qwen2.5-72B-Instruct`) using the *end-to-end* strategy with original caption data for image information.

2. Similar to the first experiment, but using the *comparing operator* strategy.

3. Instruction fine-tuning of a Vision-Language Model (`Qwen/Qwen2.5-VL-72B-Instruct`) using the *end-to-end* strategy on raw image data (without caption text).

4. Similar to the first experiment, but using synthesized captions generated by the BLIP (Li et al., 2022) pre-trained model.

Task	Strategy	Caption Data	Model type	Top1 Acc.	DCG Score	Top1 Acc. (XE)	DCG Score (XE)
(Results obtained during the competition)							
Text only	*end-to-end*	*O*	LLM	**0.67**	3.04	0.51	2.857
Text only	*comparing operator*	*O*	LLM	0.20	2.30	0.44	2.769
Images and Text	*end-to-end*	G	LLM	0.53	**3.14**	0.55	**3.126**
Images and Text	*end-to-end*	*O+G*	LLM	0.53	2.91	0.58	3.037
(Results obtained in the post-evaluation phase)							
Images and Text	*end-to-end*	-	VLM	0.60	3.05	**0.62**	3.053

Table 1: Results on the test set. The values *O* and *G* in the *Caption Data* column represent the provided **o**riginal image caption and the synthesized caption **g**enerated by the BLIP LLM model, respectively.

5. Similar to the first experiment, but using a concatenation of the synthesized captions with the original captions.

5 Results and Analysis

Performance differences were observed across model types, input modalities, and task strategies, based on both competition and post-evaluation results. When instruction fine-tuning was performed on a language-only model (Qwen/Qwen2.5-72B-Instruct) using the end-to-end strategy with original caption data (O), the highest Top-1 accuracy (0.67) and strong Discounted Cumulative Gain (DCG) score (3.04) were obtained among all competition-phase models. Alternatively, when the same model was trained using the comparing operator strategy, performance dropped substantially (0.20 Top-1 accuracy, 2.30 DCG), indicating that comparison-style supervision was less compatible with the model's inference behavior.

Introducing multimodal input—either through synthesized captions (G), concatenated caption sources (O+G), or raw image data—led to important differences. Models fine-tuned with the end-to-end strategy using BLIP-generated captions (G) or concatenated original and generated captions (O+G) achieved moderately strong Top-1 accuracies (0.53 for both), though only slight improvements in DCG scores were observed. These models also demonstrated higher Top-1 accuracy when measured using a cross-entropy variant (0.55 and 0.58, respectively), suggesting better ranking reliability under probabilistic evaluation.

Post-evaluation results for the vision-language model (Qwen/Qwen2.5-VL-72B-Instruct), trained on raw image data using the end-to-end strategy, revealed the most balanced profile. While its Top-1 accuracy (0.60) was marginally lower than the best text-only system, the DCG score (3.05) and cross-entropy-based metrics (Top-1 accuracy of 0.62, DCG of 3.053) surpassed those of all other systems. These findings indicate that deeper integration of vision and language components—rather than only relying on intermediate captions—provides stronger generalization across both metrics.

Across all settings, models trained with the end-to-end strategy consistently outperformed those trained with comparative strategy, reinforcing the conclusion that generative instruction tuning better aligns with the strengths of both LLMs and VLMs. Further, multimodal enrichment via raw images or multiple caption sources proved beneficial, particularly under subjective and rank-sensitive evaluation.

6 Conclusion

This analysis reinforces the impact of task framing, modality integration, and caption strategy on the performance of instruction-tuned models for multimodal reasoning. Generative approaches consistently outperformed comparative ones, and native vision-language models showed strong post-evaluation performance, particularly in the DCG metric. Supplementing or replacing original captions with synthesized alternatives also yielded benefits, especially when used in combination. These findings support the continued development of instruction-tuned, generative pipelines with integrated multimodal architectures, and suggest that future systems should explore richer forms of input representation to maximize both top-1 and ranking-based performance across evaluation phases. Developments of this type will reach their optimal purpose by achieving the natural language understand-

ing and generation of figurative language sought after to help AI systems bridge gaps in communication.

Abstract

Emotions play a fundamental role in the decision-making process, shaping human actions across diverse disciplines. The extensive usage of emotion intensity detection approaches has generated substantial research interest during the last few years. Efficient multi-label emotion intensity detection remains unsatisfactory even for high-resource languages, with a substantial performance gap among well-resourced and under-resourced languages. Team **Tewodros** participated in SemEval-2025 Task 11, Track B, focusing on detecting text-based emotion intensity. Our work involved multi-label emotion intensity detection across three languages: Amharic, English, and Spanish, using the (afro-xlmr-large-76L), (DeBERTa-v3-base), and (BERT-base-Spanish-wwm-uncased) models. The models achieved an average F1 score of 0.6503 for Amharic, 0.5943 for English, and an accuracy score of 0.6228 for Spanish. These results demonstrate the effectiveness of our models in capturing emotion intensity across multiple languages.

1 Introduction

The modern digital era allows users to freely express their feelings, attitudes, and opinions through websites, microblogs, and social media platforms (Wiebe et al., 2005; Mohammad and Kiritchenko, 2018; Mohammad et al., 2018a; Acheampong et al., 2020; Andalibi and Buss, 2020; Rodríguez-Ibánez et al., 2023). This has increased interest in extracting user sentiments and emotions towards events for different purposes, including social media monitoring, product analysis, political promotions, customer feedback analysis, and marketing research (Nandwani and Verma, 2021; Naidoo et al., 2022; Shehu, 2023; Kusal et al., 2023a; Achamaleh et al., 2025). Language is not just a medium of communication but also a way to express emotions, sentiments, and their intensity (Richards, 2022).

The task of emotion classification within NLP stands as a complex challenge that involves assigning emotional labels to texts to reveal the precise mental state of writers/users (Alswaidan and Menai, 2020; Tao and Fang, 2020; Mohammad, 2022; Saffar et al., 2023). The challenge of emotion detection exceeds sentiment analysis (Birjali et al., 2021) because emotions span a wide spectrum and single texts can contain multiple feelings, while cultural and linguistic differences impact interpretation and transferability (Yu, 2022; Kusal et al., 2023b; Wang et al., 2024b).

Multi-label Emotion Classification (MLEC) (Ameer et al., 2020; Deng and Ren, 2020; Liu et al., 2023) involves analyzing complete emotional expressions within written content, thereby demonstrating its value as a complex yet fundamental Natural Language Processing (NLP) task because one text may convey various simultaneous emotions. Multi-label classification differs from single-label by enabling instances to possess different mixture levels of emotions from the complete emotion set (Belay et al., 2024). Different machine learning (ML) algorithms (Azari et al., 2020; Alslaity and Orji, 2024) such as Naive Bayes (NB), k-nearest neighbors, and Support Vector Machines (SVM) have been applied to resolve emotion classification problems, often incorporating linguistic and contextual features for better performance.

The detection method of emotions in coarse-grained systems only identifies emotions and ignores their intensity level. Traditional emotion classification approaches can determine whether a sentence expresses happiness or sadness but do not quantify how intense the emotion is (Setiawan and Chowanda, 2023). Fine-grained emotion intensity detection aims to capture these variations, which is crucial for distinguishing sentences with the same emotion but different intensities. Detecting emotion intensity requires identifying intensity words and other linguistic factors that influence the

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1485–1494

degree of emotion expressed in the text (Mashal and Asnani, 2017; Chutia and Baruah, 2024).

Despite growing research in this domain, most studies focus on data-rich languages due to the unavailability of datasets for data-scarce languages (Mageuresse et al., 2020; Abiola et al., 2025b,a). This gap has led to limited advancements in emotion intensity detection for languages spoken in linguistically diverse regions such as Africa and Asia, which together account for over 4,000 languages (Irwin, 2020; Welmers, 2024).

The workshop organizers launched SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection (Track B) as a response to address the current research gap. The task serves as a research platform that allows scientists and researchers to build and evaluate multi-label emotion intensity detection methods while targeting the gap between languages with varying linguistic resources.

2 Literature Review

The process of emotion classification (EC) analyzes verbal and nonverbal indicators, including text and facial expressions, together with body language and speech, to determine a subject's emotional state (Dadebayev et al., 2022; A.V. et al., 2024). The main goal of EC consists of detecting emotions through categorization across text expressions, including anger, disgust, and fear, together with happiness, sadness, and surprise emotions. Psychologists argue about essential emotions, but different psychological frameworks propose between six and twenty emotions as core (Plutchik, 1980; Frijda, 1988; Parrot, 2001; Russell, 2003).

Several dimensional models of emotion have been developed, yet only a limited number persist as dominant frameworks. The Circumplex model (Russell, 2005) features eight emotional groups established through 28 emotion words, and the Positive-and Negative-Activation (PANA) model demonstrates an emotion ranging from high positive to low positive activation (Watson and Tellegen, 1985). Most researchers in emotional-based research continue to use Ekman's model (Ekman, 1992) to divide emotions into six core categories that include joy, surprise, happiness, anger, sadness, disgust, and also fear (Hoemann et al., 2020).

The research community has created text mining solutions to analyze emotions on social media (Goldenberg and Willer, 2023), especially Twitter, through Naïve Bayes machine learning strategies (Wikarsa and Thahir, 2015; Mohammad and Bravo-Marquez, 2017). The tagging of emotions in online news through multi-source systems is addressed by researchers who introduce a two-layer logistic regression model in their approach (Yu et al., 2015; Bostan and Klinger, 2019). Research in emotion classification underwent several developments by integrating word and character n-grams (Mohammad, 2012) with sentiment and emotion lexicons (Mohammad et al., 2015) as well as neural network models (Felbo et al., 2017; Köper et al., 2017).

There has been an increased emphasis in NLP research (Graterol et al., 2021) that incorporates Large Language Models (LLMs) for emotion identification, mainly within data-rich and data-scarce languages (Belay et al., 2024; Muhammad et al., 2025c; Tonja et al., 2024). EmoBench represents a new assessment method that tests LLMs for detecting emotional origins across English and Chinese languages, as described by (Sabour et al., 2024). (Liu et al., 2024) proposed EmoLLMs, fine-tuning open-source LLMs for affective analysis and emotion prediction. The researchers (Cageggi et al., 2023) applied MT5 model fine-tuning before conducting evaluations of both FLAN and ChatGPT through few-shot prompting for multi-label emotion classification.

Mostly used emotion classification datasets exist, including: (Wang et al., 2024a) SemEval-2024 Task 3, (Muhammad et al., 2025c) SemEval Task 11, (Muhammad et al., 2025b,a) BRIGHTER, (Bianchi et al., 2022) Multilingual Emotion Prediction (XLM-EMO), (Ameer et al., 2023) WASSA 2023 Shared Task 2, (Ciobotaru et al., 2022) Romanian Emotion Dataset (REDv2), (Demszky et al., 2020) GoEmotions, and Balanced Multi-Label Emotional Tweets (BMET) (Huang et al., 2021).

The detection of emotion intensity in text (Zad et al., 2021) has become a core capability of the multi-label emotion classification (MLEC) process to identify emotional levels (Ameer et al., 2020). The SemEval-2018 Task 1 (Mohammad et al., 2018b) together with the Multimodal Multi-label Emotion, Intensity, and Sentiment Dialogue Dataset (MEISD) (Firdaus et al., 2020) and EmoIn-Hindi (Singh et al., 2022) demonstrate examples of emotion classification.

The development of emotion analysis through deep learning techniques signifies an increasing preference for sophisticated emotion detection methods. Distinguishing sentences from the same

emotion category requires examining their emotional strength because intensity plays a vital role in these cases (Htait et al., 2016; Refaee and Rieser, 2016; Lenc et al., 2016). The intensity of individual words stands as an approach to measure sentence-level intensity since words that share related meanings push emotional strength either upward or downward (Alejo et al., 2020).

The detection of emotional intensity in text documents remains a subject that researchers have studied comparatively less than sentiment intensity (Alm et al., 2005; Aman and Szpakowicz, 2007; Bollen et al., 2009; Neviarouskaya et al., 2009; Brooks et al., 2013). This gap in research has been addressed through several notable studies. The semi-supervised approach defines an adjective intensity scale through contextual analysis of high-intensity words (Sharma et al., 2015). Sciences have studied automated approaches for emotional intensity tagging in sentences with WordNet Affect alongside word sense disambiguation (de Albornoz et al., 2010). These research techniques aim to establish quantitative methods that identify emotional intensity levels across a given textual content.

The first major attempt to introduce emotion intensity annotation occurred when (Strapparava and Mihalcea, 2007) participated in SemEval-2007 shared task competitions. The study employed a 0 to 100 continuous scale through which annotators rated emotions present in newspaper headlines. The development of rating emotion intensity at a granular level still encounters specific collection difficulties. The process faces major problems because different annotators tend to rate the same piece of text with substantially varying scores (one person assigned 79 while another only gave 62).

Researchers have made important progress in emotion classification, but their work mostly concentrates on high-resource languages (Strapparava and Mihalcea, 2007; Seyeditabari et al., 2018; Chatterjee et al., 2019; Kumar et al., 2022), whereas the investigation of emotion detection within Ethiopian languages along with other low-resource languages remains scarce (Muhammad et al., 2025b). Benchmark datasets primarily emerge for English together with popular languages, which impede proper generalization of research outcomes across diverse linguistic settings (Yimam et al., 2020; Tela et al., 2020; Muhammad et al., 2023). The current emotion datasets derive from single-source text corpora, which affect their representativeness, while state-of-the-art LLMs for both multi-label and multilingual emotion classification remain underexplored domains (Yimam et al., 2021). Our team extends this research on Track B of SemEval 2025 Task 11 to address the existing gaps in emotion intensity detection. The assessment task requires emotion annotation with perceived levels of intensity, which range from 0 for no emotion to 3 for high intensity according to sadness, fear, and so on. To detect emotion intensity in high- and low-resource languages, this work investigates methods and datasets and demonstrates results. Extending from the extant literature, it is our intention to contribute by culturally informed approaches to improve the efficiency of this task.

3 Methodology

The research methodology included data preprocessing, feature extraction, and text classification procedures on textual data collected from diverse sources in English, Spanish, and Amharic languages. The data was divided into three distinct sets: training, development, and testing. Each sample was labeled with one of six emotional states: surprise, anger, joy, fear, disgust, joy, and sadness. We loaded the data through Pandas to examine its structure while confirming essential attributes exist. We determined emotion frequencies through value_count functions.

The feature engineering process involved CountVectorizer's bigram tokenization technique alongside a selection of the top 90 bigrams per language for improving input representation. The model design included provisions that allowed it to detect important linguistic patterns regardless of the text's language.

The model architecture incorporated Afro-XLMR-Large-76L for Amharic, DeBERTa-v3-Base for English, and BERT-Base-Spanish-WWM-Uncased for Spanish. Different tokenization methods applied to textual data through model-specific tokenizers resulted in Hugging Face datasets for training purposes. The training speed was accelerated by using fp16=True during mixed precision operations. The training process employed 16 samples per batch and set the learning rate at 2e-5. A Trainer class and CrossEntropyLoss module enabled the computation of class weights for balancing class distribution in the training process. The training process lasted for 20 epochs through early stopping to avoid overfitting. Multiple performance metrics, including accuracy, macro F1-score, and

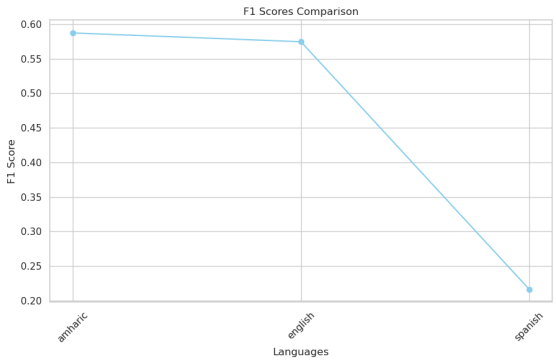

Figure 1: F1 Comparison Scores of English, Spanish and Amharic Languages from the Dev Set

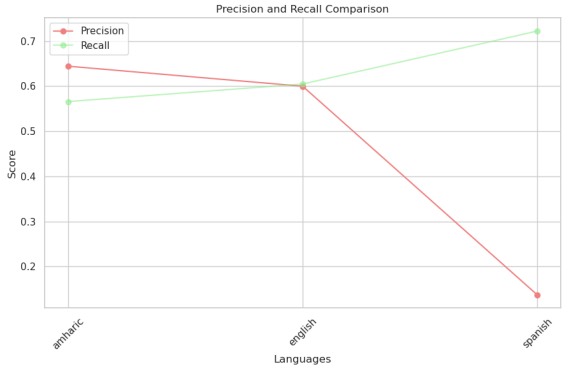

Figure 2: Precision and Recall Scores Comparison of Amharic, English and Spanish Languages from the Dev Set

per-label F1-score, served to assess model performance during evaluation.

4 Dataset Analysis

The SemEval 2025 Task 11 dataset, Track B (Emotion Intensity Detection), originates from the paper (Belay et al., 2024). The dataset provides labeled intensity scores for joy, sadness, fear, anger, surprise, and disgust. Our analysis focuses on examining three languages: English, Spanish, and Amharic, which represent a mix of high-resource and low-resource linguistic contexts. The dataset is compiled from diverse sources, including news portals X (formerly Twitter), YouTube, and Facebook, capturing a mix of formal and informal emotional expressions. Social media data poses distinct challenges, such as the use of abbreviations, informal phrasing, and extreme variations in emotional intensity, while news articles typically present structured and neutral emotional tones. Table 1 demonstrats the emotion distribution across datasets (Train and Dev) for Spanish, English, and Amharic, illustrating the varying intensity of all 6 emotional stats. Through this analysis, we seek to address the gap in emotion intensity detection for both data-rich and data-scarce languages, ensuring that models effectively process diverse grammatical structures and cultural nuances in emotional expression.

5 Experimental Setup

Experimental Setup Our experiment utilized a training-validation split on the dataset to ensure a balanced distribution of emotion intensity labels for the six perceived emotions: joy, sadness, fear, anger, surprise, and disgust. Language-specific preprocessing techniques were applied to address platform-specific variations and the models were trained in a high-performance computing environment for efficient training. For model training, we fine-tuned Afro-XLMR-Large-76L, DeBERTa-v3-Base, and BERT-Base-Spanish-WWM-Uncased, leveraging their capabilities in multilingual and language-specific emotion detection. Each model was initialized with pre-trained weights and fine-tuned on the dataset to capture nuanced emotional patterns across the six emotion categories. To evaluate model performance, we developed a comprehensive evaluation pipeline, using accuracy, F1-score, and Pearson correlation as key metrics to assess the effectiveness of emotion intensity detection. Generalization was tested on unseen test data from different platforms and contexts. Additionally, we also integrated language-agnostic embeddings to enhance robustness across multiple languages. Model hyperparameters were optimized through experimental tuning to balance precision and computational efficiency in detecting joy, sadness, fear, anger, surprise, and disgust across varied textual contexts.

6 Results

Our evaluation focuses on measuring the model's effectiveness in detecting emotion intensity across the three languages: English, Spanish, and Amharic. We used Pearson correlation (r) as a key metric to evaluate the alignment between predicted emotion intensity scores and gold-standard annotations. Table 2 summarizes the model's performance across the six emotions: joy, surprise, fear, anger, disgust, and sadness based on the test set that the workshop organizer's provided. Overall, the model achieved its highest performance in Amharic, followed by Spanish and English, suggesting its abil-

Dataset	Anger	Disgust	Fear	Joy	Sadness	Surprise	Total
Spanish (Train)	939	1343	635	1315	635	840	5707
Spanish (Dev)	68	136	63	115	59	83	524
English (Train)	497	0	2573	963	1376	1126	6535
English (Dev)	27	0	96	43	54	43	263
Amharic (Train)	1429	1878	145	883	1211	165	5711
Amharic (Dev)	234	310	22	147	203	31	947

Table 1: Emotion distribution across datasets (Train and Dev) for Spanish, English, and Amharic.

Language	Anger	Disgust	Fear	Joy	Sadness	Surprise	Avg. Pearson r
Amharic	0.5406	0.6775	0.5656	0.7997	0.7343	0.5843	0.6503
English	0.4761	-	0.6606	0.7276	0.6162	0.4909	0.5943
Spanish	0.5942	0.6180	0.6764	0.6246	0.6114	0.6124	0.6228

Table 2: Emotion Scores across different Languages

Language	Model	F1 Score
Amharic	afro-xlmr-large-76L	0.6503
English	DeBERTa-v3-base	0.5943
Spanish	spanish-wwm-uncased	0.6228

Table 3: Results obtained from the testset for emotion intensity.

ity to capture emotion intensity variations even in a low-resource language. These findings highlight the model's capability to generalize across different languages, despite variations in linguistic resources and data availability. Figures 1 and 2 highlight the F1, precision, and recall scores for all three languages, while Table 3 presents the F1 score for each language.

7 Discussion

The F1 Scores of AfroXLMR-Base reached their highest levels across all languages, especially Amharic and Spanish, which proves its powerful multi-language capabilities. DeBERTa succeeded within English datasets but experienced difficulties working with languages with fewer available resources. The BERT-based Spanish model performed effectively for Spanish tasks but displayed a weak translation ability between languages. The models' performance suffered mostly because of class imbalance when identifying rare emotions, including disgust and surprise. Transformer models demonstrated superior performance than traditional deep learning approaches, as AfroXLMR achieved the best results in precision and recall metrics. The research agenda should encompass emotion-based pre-training and approaches to address imbalanced classes. Table 3 summarizes the model results.

7.1 Error Analysis

Most misclassifications happened in Amharic, indicating difficulties with low-resource languages and class imbalance issues. The best F1 score of AfroXLMR could not prevent it from mistaking emotions with similar intensity levels, particularly between sadness and fear. DeBERTa made frequent mistakes in English by labelling strong emotions as moderate since they were written with subtle indicators. The Spanish predictions displayed misinterpretations between joy and surprise categories due to patterns that were similar in the language. The detection accuracy needs better fine-tuning of models alongside additional emotional features and balanced training datasets to achieve superior outcomes in multilingual emotion inscription detection.

8 Conclusion

This research work used transformer models that were fine-tuned specifically for Amharic, English, and Spanish to understand emotional intensity across the three languages. The research process included text preprocessing along with feature engineering before training Afro-XLMR-Large-76L, DeBERTa-v3-Base, and BERT-Base-Spanish-WWM-Uncased models. The tested models exhibited superior performance for detecting emotion intensity variations in Amharic with an F1 score of 0.6503, followed by Spanish with an F1 score of 0.6228, and English with an F1 score of 0.5943. While our models perform well across multiple

languages, detection of underrepresented emotions and low-resource languages remains a challenge. Future work should focus on exploring data augmentation techniques and developing adaptation frameworks to achieve better results with multilingual fusion approaches. These advancements will further enhance emotion intensity detection, ensuring more robust and accurate predictions across diverse linguistic and cultural contexts.

Acknowledgments

The work was done with partial support from the Mexican Government through the grant A1-S-47854 of CONACYT, Mexico, grants 20241816, 20241819, and 20240951 of the Secretaría de Investigación y Posgrado of the Instituto Politécnico Nacional, Mexico. The authors thank the CONACYT for the computing resources brought to them through the Plataforma de Aprendizaje Profundo para Tecnologías del Lenguaje of the Laboratorio de Supercómputo of the INAOE, Mexico and acknowledge the support of Microsoft through the Microsoft Latin America PhD Award.

Abstract

This paper describes the machine translation system submitted to the SemEval-2025 Entity-Aware Machine Translation Task by the SheffieldGATE Team. We proposed a multi-agent entity-aware machine translation system that operates through three distinct reasoning stages: entity recognition, knowledge enhancement, and translation decision-making. The innovation in our approach lies in leveraging large language models to generate contextually relevant queries during the knowledge enhancement stage, extracting candidate entities and their translations from external knowledge bases. In the final translation decision-making stage, we employ fine-tuned large language models to denoise the retrieved knowledge, selecting the most relevant entity information to ensure accurate translation of the original text. Experimental results demonstrate our system's effectiveness. In SemEval-2025 Task 2, our system ranks first among all systems in Spanish entity translation metrics and third in Italian. For systems that do not use gold standard entity IDs during test set inference, ours achieves the highest overall scores across four language pairs: German, French, Italian, and Spanish.

1 Introduction

Machine translation has made significant progress in recent years, but it still faces substantial challenges when processing texts containing named entities. Existing research focuses mainly on improving overall translation quality using metrics such as BLEU (Papineni et al., 2002), which treat all words equally. However, from a human comprehension perspective, different components within a sentence do not contribute equally to the quality of translation. Named entities often carry information crucial for accurate communication, cultural transmission, and domain-specific translation (Li et al., 2018). Particularly in dynamic contexts such as social media, even state-of-the-art translation models encounter significant difficulties when handling named entities (Rikters and Miwa, 2024).

The challenges in named entity translation primarily stem from several key factors. First, the continuous emergence of new entities makes it difficult for translation systems based on fixed vocabularies to adapt. Second, the correct translation of entities often depends on context. Additionally, in informal settings such as social media, users often employ entities in creative ways, further complicating the translation task. These challenges underscore the necessity of developing specialized entity-aware machine translation approaches.

To effectively address the challenges in named entity translation, this paper makes the following key contributions: First, we design a three-stage reasoning framework based on Large Language Models (LLMs) (Wei et al., 2023), specifically optimised for named entity translation. Second, we propose innovative entity query generation mechanisms that effectively integrate information from external knowledge bases. Experimental results show that our approach achieves significant improvements across multiple language pairs in named entity translation tasks. These findings provide new insights for the future development of entity-aware machine translation systems.

The remainder of this paper is organised as follows. Section 2 reviews related work, Section 3 describes the system design, Section 4 presents experimental results and analysis, and Section 5 concludes the paper and explores directions for future work.

2 Related Work

Named entity translation has emerged as a key challenge in machine translation. SemEval-2025 Task 2 (Conia et al., 2025) marks the first entity-aware machine translation evaluation task, providing a standardised assessment framework for re-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1495–1503

search in this field. The task uses the XC-Translate dataset (Conia et al., 2024), which represents the first large-scale manual annotated dataset focused on cross-cultural entity translation. Based on these developments, we present a review of major research progress in this field.

2.1 Entity-Aware Machine Translation

Entity-aware machine translation focuses on improving the translation of texts containing named entities. Recent research has developed several neural network architectures to enhance entity translation accuracy. These include entity classifiers embedded within encoder-decoder frameworks (Xie et al., 2022) and multi-task learning strategies that combine Named Entity Recognition (NER) with translation tasks (Rikters and Miwa, 2024). However, these methods face challenges in handling dynamic entities and informal text. Social media presents particular difficulties, where users often employ entities creatively, adding complexity to the translation task.

2.2 Knowledge-Enhanced Neural Machine Translation

Researchers are exploring ways to incorporate external knowledge into translation systems to improve the handling of named entities. Zeng et al.(Zeng et al., 2023) explored dictionary-based methods for entity translation, although this approach struggled with ambiguous entities. Conia et al.(Conia et al., 2024) proposed using multilingual knowledge graphs for retrieval-augmented generation(RAG), offering new perspectives for cross-cultural machine translation. These studies demonstrate that the effective use of external knowledge significantly improves the quality of entity translation.

2.3 Large Language Models for Translation

Large language models have transformed translation through their extensive pre-training data and capabilities. These models demonstrate superior entity disambiguation and translation performance compared to traditional neural machine translation models, primarily due to their exposure to vast amounts of multilingual data. The introduction of Chain-of-Thought reasoning (Wei et al., 2023) provides a new paradigm for complex language understanding tasks. However, these models may struggle with new entities or domain-specific knowledge, where their pre-trained knowledge can be outdated or imprecise.

3 System Description

We present **SHEF Machine Translation System** a multi-agent entity-aware machine translation system that employs a multi-stage reasoning mechanism. Through three key steps, entity extraction, knowledge enhancement, and translation decision, our system achieves high-quality entity translation.

The overall architecture of the system is illustrated in Figure 1.

3.1 System Architecture Overview

Our system implements a three-stage reasoning mechanism based on multiagent collaboration, breaking down translation tasks into subtasks. We incorporate a knowledge enhancement module that leverages external knowledge bases to improve the translation accuracy of entities and implement a verification and optimisation mechanism through a second agent to detect reasoning failures and maintain quality control.

3.2 Model Selections

Due to training resource constraints, we choose Llama-3.3-70B-Instruct (Aaron Grattafiori, 2024) as our base model. To optimise the performance of the model while reducing computational overhead, we employ QLoRA(Dettmers et al., 2023) for parameter-efficient fine-tuning. The model is specifically optimised for three tasks: entity recognition, knowledge fusion, and translation decision-making. We also integrate DeepSeek-R1(DeepSeek-AI et al., 2025) as a verification model.

3.3 Multi-stage Reasoning Mechanism

3.3.1 Entity Recognition Stage

In the first stage the LLM (Large Language Model) acts as a named entity recognizer, precisely extracting key entities from the source text. We design specific prompt templates to guide the model in identifying entities that have the most significant semantic impact on the original text. This precise entity identification lays the foundation for subsequent knowledge enhancement and translation.

3.3.2 Knowledge Enhancement Stage

The second stage implements LLM (Large Language Model)-based query enhancement with effi-

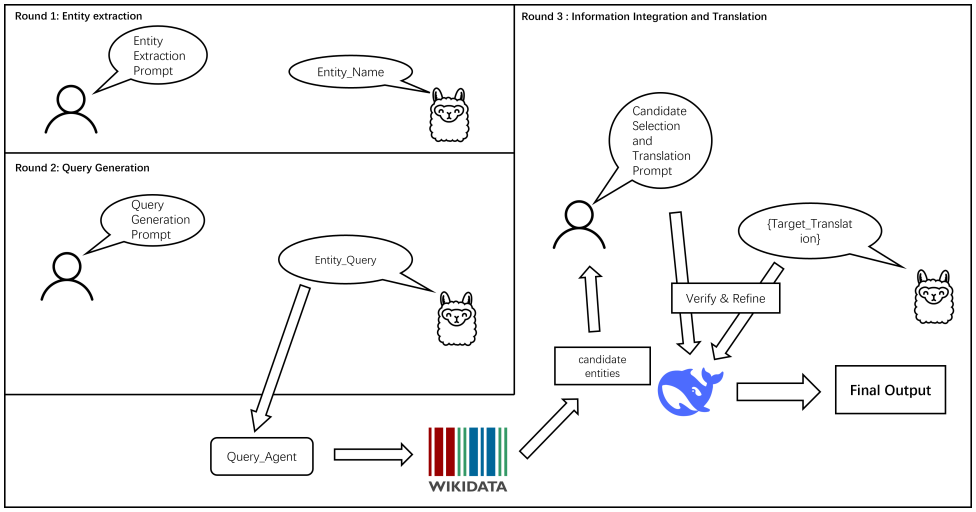

Figure 1: The architecture of our multi-agent cross-lingual entity translation system. The system consists of three main stages: (1) entity recognition, (2) knowledge enhancement with retrieval, and (3) translation decision-making, followed by a verification and optimisation module. The prompt used for this stage is provided in the Section 6 : Appendix

cient entity retrieval. Our approach consists of two main components:

Query Construction: We prompt the entity name (extracted in the first stage) along with the original text to the LLM (Large Language Model). This leverages the information from the original text and the model's pre-trained knowledge to generate enhanced query representations containing two key elements: the standardised entity name and a contextual entity description.

Entity Retrieval: As illustrated in Figure 2, our retrieval agent leverages the Wikidata API to initially retrieve entity names. The agent significantly narrows the search space by pruning retrieved named entities, retaining only the top 10 most relevant candidates. After obtaining these candidate entities, we employ SentenceTransformers (Reimers and Gurevych, 2019) to encode both the LLM (Large Language Model)-generated query representations and the names and descriptions of all candidates. The agent then determines the final similarity ranking using a weighted cosine similarity approach, wherein similarity scores for names and descriptions are computed separately and combined using predefined weights α and β.

This hybrid approach combines LLM (Large Language Model) knowledge enhancement with efficient retrieval techniques, enhancing semantic understanding while maintaining computational efficiency.

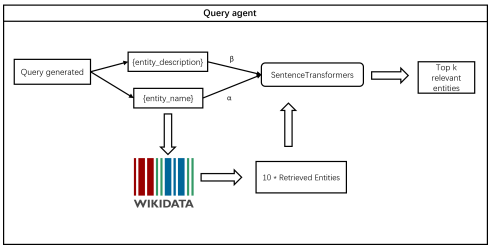

Figure 2: Overview of the entity retrieval process. The query agent retrieves candidate entities from Wikidata using the entity name and prunes them to the top 10 most relevant candidates. A weighted cosine similarity ranking is then applied to determine the top k entities.

3.3.3 Translation Stage

The third stage leverages the LLM (Large Language Model)'s semantic understanding and denoising capabilities for translation decisions. We prompt the large language model with the original text and information from retrieved candidate entities. This includes names and descriptions in the target language. Drawing on semantic understanding capabilities from pre-training, the LLM (Large Language Model) identifies which candidate entity best matches the original context. This effectively filters out candidates that are superficially similar but semantically distinct. Such filtering eliminates interference at the semantic level. During training, we implement negative sample learning. We provide potential entities and randomly replace one candidate with an irrelevant entity to introduce noise. Through this fine-tuning approach, we acti-

vate the LLM (Large Language Model)'s inherent denoising capability. This enables accurate translation decisions in complex contexts.

3.4 Verification and Optimisation Mechanism

The system integrates an independent verification and optimisation module using the DeepSeek-R1(DeepSeek-AI et al., 2025) model for the detection of reasoning failures. Our failure detection rules focus on three aspects: completeness check of entity recognition, relevance verification of generated query, and semantic consistency assessment between translation results and the original text. Based on these rules, the verification model performs comprehensive reviews of the three-stage reasoning process, identifying potential errors and improving the results. The prompt used for this stage is provided in the Appendix.

3.5 Data Augmentation

We built a specialised three-stage dialogue dataset based on the XC-Translate dataset (Conia et al., 2024) to train our main model, focusing specifically on four language pairs: English-German (en-de), English-French (en-fr), English-Spanish (en-es), and English-Italian (en-it). Starting with gold-standard entity IDs provided in the XC-Translate dataset, we retrieved entity names and descriptions from Wikidata. These retrievals formed the basis for our first stage, which focused on entity recognition tasks and our second stage, which was dedicated to query generation. To augment the data, our entity retrieval module was employed to obtain entities most analogous for precise alignment, while semantically unrelated entities were intentionally introduced as negative examples during the third stage. This dual approach prevents the model from overgeneralising and forming incorrect associations, enabling the LLM (Large Language Model) to make accurate translation decisions not only when presented with similar entity information, but also across diverse inputs, rather than relying solely on similarity features. By combining these three stages of dialogue reasoning, the LLM (Large Language Model) better utilises information from the source text. It also leverages both its pre-training capabilities and its ability to interact with the external knowledge base.

3.6 Training Setup

Leveraging the excellent cross-lingual generalisation capabilities of large language models, where training on a language pair improves translation performance across other pairs (Yang et al., 2024), we implement a multilingual joint training strategy rather than developing separate models for each language pair. This approach maximises the model's inherent cross-lingual abilities, while substantially reducing computational resource requirements. All our experiments were conducted on 4 NVIDIA A100 GPUs (80GB each). Detailed information on model training hyperparameters, data preprocessing procedures, and experimental environment configurations is provided in Appendix Table 2.

4 Experiments and Results

4.1 Baseline Setup

We utilise a fine-tuned Llama-3.3-70B-Instruct (Aaron Grattafiori, 2024) as our baseline model, which undergoes the same multilingual joint training strategy on the XC-Translate dataset (Conia et al., 2024) as our system. The baseline was trained using data from four language pairs: English-German, English-French, English-Italian, and English-Spanish, without any data augmentation preprocessing. The detailed statistics of our

dataset are presented in Appendix Table 3. For each language pair, we reserved 10% of the samples as a validation set to monitor the training process. The training parameters remain consistent for both systems. The prompts used for baseline experiments are available in Section 6: Appendix.

4.2 Hyperparameters

In our system, we introduced three key hyperparameters to optimise the retrieval and translation process:

- α: The weight assigned to entity names generated by the LLM (Large Language Model) when retrieving from Wikidata. This parameter controls how much importance is given to the entity's name during the retrieval process.
- β: The weight assigned to entity descriptions generated by the LLM (Large Language Model) when retrieving from Wikidata. This parameter determines how much the system should consider the entity's description during retrieval.
- k: The number of candidate entities provided to the LLM (Large Language Model) in the final stage for translation decision-making. This parameter controls how many potential entity matches the model considers before making its final translation decision.

Together, these hyperparameters allow us to balance the relative importance of entity names versus descriptions (α and β) and control the breadth of candidates considered (k) during the entity translation process. In our submitted system, we assign $\alpha = 0.5$ and $\beta = 0.5$, ensuring equal contribution from both components. To optimise the balance between computational efficiency and retrieval effectiveness, we select (k = 3), which prevents excessive input length while providing sufficient candidate entities for downstream processing.

4.3 Evaluation Metrics

To evaluate our system, we employ two complementary metrics:

- **M-ETA** (Conia et al., 2024): Measures the proportion of correctly translated named entities by comparing predicted entity translations against gold standard references.
- **COMET** (Rei et al., 2020): A neural-based metric that evaluates overall translation quality by comparing machine translations to human references, providing scores for translation fluency and adequacy.

These metrics enable us to assess both entity translation accuracy and general translation quality.

4.4 Ablation Study

To evaluate component contributions in our framework, we conducted a comprehensive ablation study across all language pairs. Given the computational intensity of our full framework and due to significant time and hardware constraints, we performed these ablation experiments on the smaller Llama-3-8B model rather than the larger variants. This smaller-scale experimentation, shown in the lower section of Table 1, still provided valuable insights into component effectiveness. We compared our system against several variants: (1) a baseline system (llama8b_baseline) trained without our three-stage reasoning framework, (2) our standard system with all components (llama8b_full_system), (3) our system with an enhanced verification component (llama8b_deepseek_verify), and (4) a system without Wikidata retrieval (llama_without_wiki) that uses Chain-of-Thought (CoT) to emphasise entities.

4.4.1 Impact of Three-Stage Reasoning Framework

Our results demonstrate the substantial impact of our proposed framework on named entity translation. Comparing the baseline system with our standard implementation reveals an average improvement of 40.77 in M-ETA scores (from 25.39 to 66.16). COMET scores also improved by 4.56 (from 86.28 to 90.84). This significant performance gap underscores the importance of our structured approach. The three-stage framework effectively decomposes the complex task into manageable subproblems.

4.4.2 Importance of the Verification Component

Our error analysis revealed that most translation errors originated from the entity recognition stage. The verification component effectively addresses this issue. The enhanced verification system (llama8b_deepseek_verify) further improves M-ETA scores by 4.84 points (from 66.16 to 71.00)

compared to our standard system. This improvement is consistent across all language pairs, with the largest gains observed in German (5.85 points) and Italian (4.29 points).

While the verification component slightly reduces COMET scores in some languages, particularly Spanish (from 91.88 to 87.77), it maintains or improves scores in others. This suggests a trade-off between entity translation accuracy and overall fluency in certain contexts. Nevertheless, the substantial M-ETA improvements justify the inclusion of this component in mission-critical entity translation scenarios.

4.4.3 Knowledge Retrieval Importance and CoT Limitations

We observe that using CoT to emphasise entities without external knowledge base (Wikidata) retrieval shows minimal improvement. The average M-ETA score increased slightly from the baseline's 25.39 to 28.24. However, this improvement is negligible compared to our knowledge-enhanced systems. The full system outperforms the CoT-only approach by 37.92 M-ETA. COMET scores show a similar pattern, with the full system scoring 4.07 points higher than the CoT-only variant.

These findings indicate that while CoT is effective for complex reasoning tasks in general, its benefits are surprisingly modest for entity-aware translation, which requires broader and more comprehensive knowledge. External knowledge retrieval proves to be the critical component in our framework. The Wikidata integration provides authoritative entity information that may not be fully captured in the model's parametric knowledge. In our complete system, CoT serves not as a standalone solution but as an essential mechanism for integrating and reasoning with knowledge retrieved from external sources, enabling more effective use of this information during the translation process.

4.4.4 Language-Specific Patterns

Our ablation study reveals consistent patterns across languages. The performance gains are most pronounced for Spanish and Italian, with German and French showing relatively lower improvements. This pattern aligns with our main results in Table 1 and supports our observation about linguistic distance affecting entity translation performance. Even the lowest-performing pair (English-German) shows a substantial improvement compared to the baseline.

These ablation results validate our design choices. They emphasise the necessity of both the three-stage reasoning approach and external knowledge integration. The CoT technique provides only marginal benefits by itself. The verification component offers substantial improvements in entity translation accuracy, particularly for challenging cases missed in the initial recognition stage.

When comparing these results with our main results in Table 1, we observe an interesting pattern. The performance gap between our knowledge-enhanced systems and variants without external knowledge appears more pronounced with larger models. This suggests that larger models (such as Llama-3.3-70B used in our main experiments) derive significantly greater benefits from external knowledge resources. The experimental results confirm that these larger models possess enhanced abilities to leverage structured knowledge for complex reasoning tasks, with superior prompt understanding and reasoning capabilities. This finding further emphasises the importance of our knowledge-augmented approach, particularly when applied to larger-scale foundation models.

4.5 Result and Analysis

Experimental results demonstrate that our proposed three-stage reasoning framework significantly enhances LLMs' named entity translation capabilities. As shown in Table 1, our system achieves excellent performance across four language pairs, with average M-ETA scores reaching 89.79 and COMET scores of 93.33. Notably, we observe clear performance variations between different language pairs: Italian (M-ETA: 93.02) and Spanish (M-ETA: 90.5) perform best, while German (M-ETA: 85.57) shows relatively lower scores. We attribute this disparity primarily to the greater linguistic distance between German and the source language (English), as German's compound word formation and complex morphological structures pose additional challenges for entity recognition and translation.

Our comprehensive ablation study provides further insights into these results. The substantial performance gap between knowledge-enhanced and knowledge-free variants confirms that external knowledge retrieval is the critical component in our framework. While Chain-of-Thought reasoning alone provides minimal benefits for entity translation, its integration with external knowledge substantially amplifies performance. This syn-

ergy is particularly pronounced in our Llama-3.3-70B implementation, suggesting that larger models possess enhanced abilities to leverage structured knowledge for entity translation due to their superior prompt understanding and reasoning capabilities.

The verification component in our framework addresses a key source of entity translation errors identified in our analysis, further improving entity translation accuracy. These improvements are consistent across all language pairs, with the language-specific patterns in our ablation study mirroring those in our main experiments - Spanish and Italian showing the largest gains, and German the lowest, albeit still substantial. This consistency across model scales reinforces our observation that linguistic distance significantly impacts entity translation performance, even when employing a multilingual joint training strategy designed to leverage cross-lingual generalisation capabilities.

5 Conclusion

This paper presents a multi-agent entity-aware machine translation system that addresses key challenges in named entity translation. Our main contribution lies in designing a three-stage LLM (Large Language Model) reasoning framework (entity recognition, knowledge enhancement, and translation decision-making) specifically optimised for named entity translation, utilising innovative entity query generation mechanisms that effectively integrate information from external knowledge bases. Experimental results demonstrate the effectiveness of our approach, which ranked first in Spanish entity translation metrics in SemEval-2025 Task 2, and achieved the highest overall scores across four language pairs (German, French, Italian, and Spanish) among systems that do not use gold standard entity IDs during test set inference.

Future work will focus on addressing the unique challenges of named entity translation in social media environments and developing more suitable approaches for informal texts and culture-specific expressions.

Limitations

Despite our system's excellent performance, several limitations remain, including the substantial computational resources required for deploying multiple large language models and the increased latency from sequential processing of our multi-stage reasoning framework. Additionally, our system still struggles with informal entity expressions commonly found on social media platforms.

6 Appendix

6.1 Prompt Details

6.1.1 Prompt : Entity Extraction

The system extracts the main named entity from the given text using the following prompt:

```
Extract the main named entity from the
    following text: {text}
```

6.1.2 Prompt : Query Generation

Once the entity is extracted, the system generates a structured query in JSON format to retrieve relevant knowledge from Wikidata:

```
Generate a query in JSON format (with name,
    description) for {Entity_Name} based on the
    following text: {text}
```

6.1.3 Prompt : Candidate Selection and Translation

The final step involves selecting the most appropriate candidate entity from Wikidata and translating the given text into the target language. The selection and translation process is guided by the following prompt:

```
Select the most appropriate candidate entities
    based on the following text and translate
    the following text to {target_language}
    based on its translation in the target
    language:

Candidate entities:
[
    {
        "Original name": {Entity_Name},
        "Target name":
            {Entity_Name_in_Target_Language},
        "Description":
            {Entity_Description_in_Target_Language}
    },
```

```
    ... {Other Candidate Entities} ...
]

Source Text: {Text}
```

6.1.4 Prompt for Reasoning Failure Detection and Translation Refinement

Below is the full prompt used for reasoning failure detection and translation refinement.

```
You are a verification and optimization module,
    designed to detect reasoning failures and
    refine translation outputs. Process the
    input according to the following steps and
    comply with the output format to output the
    results.

Step 1: Detection of reasoning failure based on
    the following three aspects
1. Entity Recognition Completeness
   - Identify key entities in the source text.
   - Compare with the first round response to
       find omissions, misinterpretations, or
       incorrect additions.

2. Query Relevance
   - Verify if the second-round query
       misdescribes the extracted entities.

3. Semantic Consistency
   - Compare translated text with the original
       meaning.
   - Detect shifts in meaning, tone, or
       cultural nuances.

Step 2: Improving translation based on the
    following aspects
- Correct identified reasoning failures.
- Ensure terminology consistency.
- Improve clarity, fluency, and naturalness
    while preserving intent.
- Provide a step-by-step justification for each
    correction.

Example Output Format:
[REASONING ANALYSIS]
Detailed breakdown of detected failures and
    their reasons.

[IMPROVED TRANSLATION]
<result/>
{final_translation_with_justification}
</result>

Input:
- Original Text: {original_text}
- Dialogue History:
    {three_rounds_dialogue_history}
```

6.1.5 Baseline Prompt

```
You are a helpful translation assistant.
    Translate the following text from English
    to {target_language}. Provide only the
    translation without any additional
    information: {text}
```

6.2 Key Parameters

6.2.1 Training Parameters

Parameter	
Learning rate	1.0×10^{-4}
Training epochs	5.0
Learning rate scheduler	Cosine
Warmup ratio	0.1
Precision	BF16
Random seed	42

Table 2: Key Training Parameters for SemEval 2025 Task A4

6.3 Dataset Distribution

Language Pair	Training Set	Test Set
English-German	4,087	5,876
English-French	5,531	5,465
English-Italian	3,739	5,098
English-Spanish	5,160	5,338

Abstract

This paper presents our system for SemEval-2025 Task 8: DataBench, Question-Answering over Tabular Data. The primary objective of this task is to perform question answering on given tabular datasets from diverse domains under two subtasks: DataBench QA (Subtask I) and DataBench Lite QA (Subtask II). To tackle both subtasks, we developed a zero-shot solution with a particular emphasis on leveraging Large Language Model (LLM)-based code generation. Specifically, we propose a Python code generation framework utilizing state-of-the-art open-source LLMs to generate executable Pandas code via optimized prompting strategies. Our experiments reveal that different LLMs exhibit varying levels of effectiveness in Python code generation. Additionally, results show that Python code generation achieves superior performance in tabular question answering compared to alternative approaches. Although our ranking among zero-shot systems is unknown at the time of this paper's submission, our system achieved eighth place in Subtask I and sixth place in Subtask II among the 30 systems that outperformed the baseline in the open-source models category.

1 Introduction

Question Answering (QA) is a fundamental task in Natural Language Processing (NLP), where the most relevant answers are retrieved from a given document or plain text. Apart from such unstructured data, working with widely used structured data is crucial for real-world applications. Moreover, structured data encompasses a much broader semantic scope. One important form of structured data is tabular data, which consists of rows with a consistent set of features. Unlike unstructured documents, tabular data exhibits complex and heterogeneous relationships that require specialized processing techniques. Information retrieval from tabular data is typically performed using various SQL queries and similar approaches. However, these methods depend on rigid rule-based systems and fail to consider the semantic properties of the data. Consequently, natural-language queries over tabular data face significant limitations. As a result, question-answering systems developed for tabular data have garnered significant interest among researchers.

The process of converting a natural language query into a machine-executable logical form is known as semantic parsing (Wang et al., 2015). Early studies primarily focused on datasets that required adapting specific logical forms for each table structure type. This approach, however, led to suboptimal performance, particularly in tabular structures spanning multiple domains (Pasupat and Liang, 2015). On the other hand, end-to-end trained transformers are widely employed, as they handle both question/query interpretation and reasoning over tabular data (Deng et al., 2020). The recent advancements in LLMs have become a pivotal focus in tabular question answering, as in many other problem domains. However, LLM-based approaches introduce several challenges, including high computational costs and limited context length, making scalable and efficient tabular QA systems an open research problem. To address these challenges and foster the development of effective tabular question-answering methods, SemEval-2025 Task 8 (Osés Grijalba et al., 2025) has been designed to introduce the necessary level of difficulty through two distinct subtasks.

In this paper, we propose a zero-shot system to address these tasks, focusing primarily on LLM-based code generation. Our approach introduces a unified framework leveraging state-of-the-art open-source LLMs, including DeepSeek-R1 (DeepSeek-AI et al., 2025a), DeepSeek-V3 (DeepSeek-AI et al., 2025b), Qwen2.5-Coder-32B-

[*]These authors contributed equally.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1504–1514

Instruct (Hui et al., 2024), and Llama-3.3-70B-Instruct (AI@Meta, 2024). We employ efficient prompting strategies to generate executable Python Pandas[1] library code. To enhance LLM understanding of tabular structures, the generated Python code is executed in a controlled environment. A key feature of our system is its iterative error-handling mechanism. If the initial code execution fails, the error message and faulty code are sent back to the LLM for correction, with a maximum of two iterations. This mechanism significantly improves robustness, reducing failure rates in complex queries.

We observe that one model in our pipeline achieves the highest accuracy on Subtask I (84.67%), while another leads Subtask II (85.05%), both without task-specific fine-tuning. All code is available on our GitHub repository[2].

2 Related Work

This section reviews recent developments in LLMs, focusing on their applications in tabular question answering.

In recent years, the emergence of the Transformer architecture (Vaswani et al., 2017) has led to remarkable advancements in language modeling tasks. This progress has resulted in state-of-the-art performance across various NLP tasks. Consequently, the application of transformer architectures to problems requiring tabular modeling has become inevitable. Early studies primarily focused on different embedding mechanisms (Yin et al., 2020), pre-training strategies (Wang et al., 2021), and architectural modifications (Huang et al., 2020). The core approach introduced by these methods was pre-training Transformer architectures from scratch for tabular data (Herzig et al., 2020). However, this approach faces efficiency and scalability limitations, particularly when models need to generalize across multiple domains. Generally, pre-trained language models struggle to adapt efficiently to task-specific tabular datasets.

More recently, the emergence of LLMs has brought about a significant transformation in the field. Models such as GPT-3 (Brown et al., 2020) and LLaMa (Touvron et al., 2023) have demonstrated strong few-shot and zero-shot capabilities, achieving state-of-the-art performance across various tasks while often requiring little to no task-specific data. These advancements have enabled the use of a single, unified model for solving complex tabular tasks. The transition from training models from scratch or adapting pre-trained language models to leveraging LLMs represents a significant paradigm shift in tabular data processing. However, the application of LLMs to tabular question answering introduces several challenges. One major limitation is the context length constraint inherent to LLMs. When processing large or multiple tables, the limited context size prevents the model from encoding all necessary information. Additionally, handling multiple tables often leads to hallucinations, where models generate inaccurate or misleading responses.

To overcome these limitations, researchers have leveraged the in-context learning capabilities of LLMs. The effectiveness of LLM-based approaches largely depends on how tabular data and question queries are represented and utilized. For tabular data, appropriate table schemas and prompting strategies incorporating relevant examples are designed to enhance model comprehension. Query representation can also significantly impact performance. A common strategy involves decomposing complex queries into step-by-step subqueries, improving model interpretability (Yang et al., 2024). Another approach is transforming queries into intermediate representations such as Python code or SQL queries, enabling structured execution (Cao et al., 2023; Zhang et al., 2024). These advancements have led to models capable of performing task-specific reasoning without requiring additional fine-tuning.

Building on insights from previous studies, we find that effectively addressing SemEval-2025 Task 8 requires a deep understanding of query semantics and table structures, as well as the ability to generate accurate answers across diverse answer formats. Motivated by these challenges, we introduce a novel framework that integrates schema-guided prompting, controlled execution, and an error-handling mechanism. Our extensive evaluations and prompt strategy experiments highlight the effectiveness of our approach in enhancing accuracy and robustness. These findings show the practicality and applicability of the proposed approach in real-world scenarios, where tabular data must be processed dynamically without requiring task-specific fine-tuning.

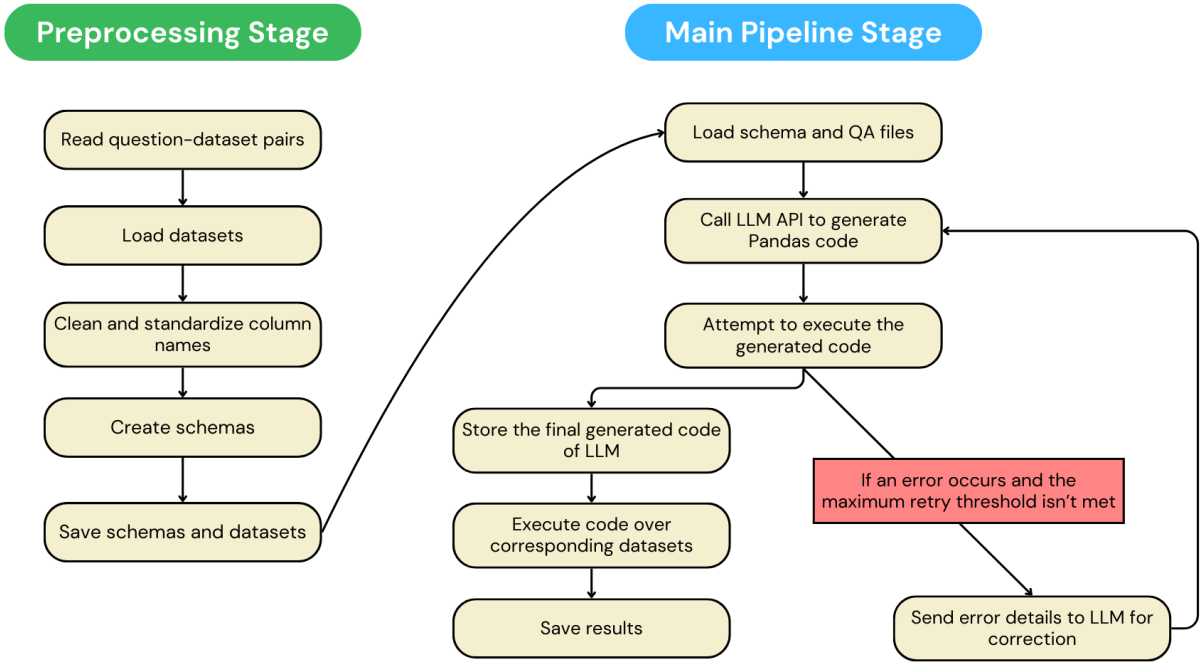

Figure 1: Our proposed framework.

3 Data

The original DataBench dataset (Osés Grijalba et al., 2024) provides 1308 questions from 65 different domains, each containing question-answer pairs written in English. During the competition, this dataset was expanded with the addition of a new test split (Osés Grijalba et al., 2025). The exact dataset statistics are presented in Table 1. The train and development splits contain the following columns:

- **question**: The natural language question.
- **answer**: The response to the question for DataBench QA subtask.
- **type**: The type of the answer, which can be **boolean, number, category, list[category], list[number]**.
- **columns_used**: The columns of the dataset required to answer the question.
- **column_types**: The data types of these columns, which include boolean, number (e.g., UInt8, uint32, uint16).
- **sample_answer**: The response to the question for DataBench Lite QA subtask.
- **dataset**: The name of the dataset from which the question is derived.

The sample_answer column is specifically included for the DataBench QA Lite subtask, which is a simplified version of the DataBench QA task. This subset consists of 20 sampled entries from the original dataset, serving as a small-scale reference for evaluation.

Split	Questions	Datasets
Train	988	49
Dev	320	16
Test	522	15

Table 1: DataBench dataset statistics.

In contrast to these extensively annotated train and development splits, the test split only has question and dataset columns to ensure proper evaluation without data leak for the competition.

Although the dataset provides structured train and development splits with detailed annotations, this study did not utilize these data for training, as we preferred a zero-shot approach that does not involve fine-tuning.

4 System Overview

Our approach involves two main steps in providing an answer to questions over tabular data: preprocessing and then code generation and execution. The complete workflow is illustrated in Figure 1.

4.1 Preprocessing

Our preprocessing steps include obtaining the given questions and datasets from the competition website, followed by a series of normalization and standardization techniques, and finally creating a

schema for each dataset for LLM prompting. Each dataset is transformed with transformation rules. First, all spaces and non-word characters are replaced with underscores except for trailing special characters, which are removed. Second, all column names are converted to lowercase, and duplicate columns are renamed by appending a number to each duplicate. For example, if there are two cols named "col" and "Col@", the second one becomes "col_2".

After normalization and standardization, we construct a schema for each dataset to enhance the LLM's understanding of the table structure. The schemas include each dataset's name, each column, each column's data type, 5 unique values from each column, and the total unique values that a column contains. The example values are limited to a hundred characters total to avoid excessive verbosity and potential token overload. Examples of the constructed schemas can be seen in Appendix A, (e.g., see the schema for the TripAdvisor dataset in Appendix A.1). We use the full dataset for schema creation for both full and sample datasets.

4.2 Code Generation and Execution

The code generation step is done with a prompt that includes the question, detailed instructions and the corresponding dataset schema. A detailed breakdown of the code generation prompt is provided in Appendix B. The generated code is executed in a controlled environment, where dynamic imports are extracted, and the execution output is captured in its original format. In cases where execution fails, an error handling mechanism is triggered. The system captures the error message along with the faulty code and sends it to the LLM for automatic correction. The LLM then generates a revised version of the code. This iterative process is run until the predefined threshold is met. If the provided code is still faulty after the maximum number of attempts, execution is terminated for that query. The execution result from the last successfully executed code is then set as the final answer for the corresponding question.

5 Experimental Setup

Our zero-shot framework was tested on the officially released development and test datasets of SemEval 2025 Task 8, covering its two subtasks (Osés Grijalba et al., 2025). The models used in our system were selected based on their performance in code generation tasks, ensuring their effectiveness in handling structured and semi-structured tabular question answering. Additionally, we opted for a maximum of two iterations based on preliminary experiments, which showed that attempts beyond two iterations rarely produced further improvements. To provide a more comprehensive error analysis, we also conducted additional experiments with three iterations. To evaluate system performance, we used Accuracy, the official evaluation metric of SemEval 2025 Task 8. Furthermore, we analyzed the impact of our iterative error-handling mechanism on execution reliability by measuring error reduction rates across different models. These evaluations provide insights into both models accuracy and execution robustness in tabular question answering.

6 Results

The performance of the models is presented in Table 2. Our results indicate that one of the DeepSeek models (i.e., DeepSeek-R1 and DeepSeek-V3) outperforms all other models across both subtasks. We see that DeepSeek-V3 falls behind all the others on the development sets, but performs better specifically on the test set of Subtask I. DeepSeek-R1, which is a subsequent iteration, building upon V3 with enhanced capabilities via reinforcement learning, outperforms Qwen2.5-Coder-32B-Instruct and Llama-3.3-70B-Instruct models on all tasks and datasets, falling behind DeepSeek-V3 by 0.52 percentage points on the Subtask I test set.

Moreover, in the official evaluation within the open-source models category, our best-performing model ranked eighth in Subtask I and sixth in Subtask II, placing among the 30 systems that outperformed the baseline. These results further highlight the effectiveness of our approach in zero-shot tabular question answering. At the time of this paper's submission, due to a lack of information on other solutions, we were unable to evaluate our performance relative to other zero-shot systems in the competition. Through our manual observations, we identified that the test datasets are significantly more challenging. However, we do not believe that every question-answer pair in these datasets can perfectly represent the real-world performance of the models. Nonetheless, the widening performance gap in the more challenging test sets suggests that DeepSeek-R1 may generalize to the problem more effectively, providing evidence of its

Models	Subtask I (DataBench)		Subtask II (DataBench Lite)	
	Dev	Test	Dev	Test
DeepSeek-R1	**88.43**	84.09	**86.56**	**85.05**
DeepSeek-V3	82.50	**84.67**	78.75	80.84
Qwen2.5-Coder-32B-Instruct	87.18	83.90	85.31	81.99
Llama-3.3-70B-Instruct	86.56	83.14	82.81	81.03

Table 2: Results on the DataBench subtasks across all models.

Models	Dev Set	Test Set
DeepSeek-R1	$9 \rightarrow 6$	$15 \rightarrow 7$
DeepSeek-V3	$35 \rightarrow 11$	$18 \rightarrow 9$
Qwen2.5-Coder-32B-Instruct	$11 \rightarrow 9$	$25 \rightarrow 8$
Llama-3.3-70B-Instruct	$16 \rightarrow 5$	$16 \rightarrow 10$

Table 3: The change in the amount of code execution errors before and after the error fixing loop.

superior adaptability.

In addition, as shown in Table 3, our error handling mechanism decreases the number of execution errors by nearly half on average, demonstrating not only its effectiveness but also its necessity for ensuring reliable execution. It should be noted that the initial error rate and the accuracy over both tasks show a strong correlation, with models that achieve higher accuracy also generating less faulty code to begin with. This suggests that better-performing models inherently produce more reliable code, thereby reducing the need for iterative error correction loops and improving overall execution efficiency.

To analyze error patterns and the impact of our correction mechanism in greater detail, we grouped errors into three main categories: Runtime, Degenerate Loop, and Syntax. Notably, the Runtime category includes diverse errors such as KeyError and ValueError, but for simplicity, we report them under a single label. Our findings also indicate that some errors transform into different types across iterations.

We define Degenerate Loop errors as cases where an LLM repeatedly generates identical or nearly identical output sequences, continuing indefinitely until it reaches its maximum token limit.

Table 4 presents the distribution of error types across models and iterations. Results show that most initial failures are due to Runtime errors, while Syntax and Loop errors are less frequent but may persist across multiple correction attempts. Specifically, Syntax errors are observed exclusively in DeepSeek-R1 and DeepSeek-V3 models, with no such errors detected for Llama-3.3-70B-Instruct or Qwen2.5-Coder-32B-Instruct across any dataset or iteration.

Similarly, Degenerate Loop errors are observed solely in DeepSeek-R1 and DeepSeek-V3, with no occurrences in Llama-3.3-70B-Instruct or Qwen2.5-Coder-32B-Instruct. As shown in Figures 2 and 3, although some Degenerate Loop errors are corrected, a notable portion still results in failures.

Finally, Figure 2 provides an overview of error resolution across iterations, showing that most runtime errors are resolved within the first two attempts. Figure 3 further breaks down specific error types, such as FileNotFoundError, KeyError, and NameError, offering a more fine-grained view.

7 Conclusions

In conclusion, this paper presented the solution developed by the ITUNLP group for SemEval-2025 Task 8. The proposed approach addressed the tabular question answering task in zero-shot scenarios. Our method yields promising results in zero-shot tabular question answering, achieving higher ranks (8^{th} place in Subtask I and 6^{th} in Subtask II) within the 30 participant systems in the open-source category. Since these 30 systems may have employed fine-tuning or few-shot learning techniques, further analysis would be possible upon the publication of the system description papers that achieved better results on the same category of the shared task, which will provide a clearer understanding of our ranking within zero-shot frameworks.

As this study focuses only on open-source LLMs, future work could include evaluating proprietary LLMs within our proposed framework to gain a broader perspective on model performance. Furthermore, the DataBench dataset consists of questions that require using only a single table. As future work, we aim to evaluate our zero-shot model's performance on multi-table reasoning tasks, further expanding its applicability.

B Code Generation Prompts

B.1 Pandas Code Generation without Error Handling

Natural Language to Python Code with Pandas

Generate a python code to answer this question: `{question}` that strictly follows the instructions below:

The code should return a print statement with the answer to the question.
The code should leave the answer be and not print anything other than the variable that holds the answer.
Please write a single Python code block that answers the following question and prints the result in one line at the end.
If the question doesn't specifically ask for it, don't use unique() or drop_duplicates() functions.

If it is a Yes or No question, the answer should be a boolean.
Do not include any explanations, comments, or additional code blocks.
Do not print intermediate steps just the answer.
Do not interact with the user.
Never display any sort of dataframes or tables.
Your output can never take more than a single line after printing and it can never be any sort of objects such as pandas or numpy objects, series etc.
Your output must be one of the following:

Boolean: True/False
Category/String: A value
Number: A numerical value
List[category/string]: ['cat', 'dog']
List[number]: [1, 2, 3]
So the outputs have to be native python

Given the dataset schema {schema}

The following python code made for pandas for the parquet file {dataset_name}.parquet reads the parquet file and running it returns the answer that is enough to answer the question `{question}`

B.2 Pandas Code Generation with Error Handling

The following prompt replaces the part after the schema is given of the previous prompt.

Natural Language to Python Code with Pandas - Error Correction

The following codes generated an error when executed:

```
{code_1}/{error_1},
{code_2}/{error_2},
... %
```

Error: {error_msg} Solve the error and provide the corrected code
The following python code made for pandas for the parquet file {dataset_name}.parquet reads the parquet file and running it returns the answer that is enough to answer the question `{question}` with the error fixed

Fossils at SemEval-2025 Task 9: Tasting Loss Functions for Food Hazard Detection in Text Reports

Aman Sinha[1] **and Federica Gamba**[2]
[1]Institut Elie Cartan de Lorraine, Université de Lorraine, Nancy, France
[2]Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic

Abstract

Food hazard detection is an emerging field where NLP solutions are being explored. Despite the recent accessibility of powerful language models, one of the key challenges that still persists is the high class imbalance within datasets, often referred to in the literature as the *long tail problem*. In this work, we present a study exploring different loss functions borrowed from the field of visual recognition, to tackle long-tailed class imbalance for food hazard detection in text reports. Our submission to SemEval-2025 Task 9 on the Food Hazard Detection Challenge shows how re-weighting mechanisms in loss functions prove beneficial in class imbalance scenarios. In particular, we empirically show that class-balanced and focal loss functions outperform all other loss strategies for Subtask 1 and 2 respectively.

Fossils-FHD

1 Introduction

Ensuring food safety is a critical global challenge, as contaminated food can lead to severe health risks and economic losses. Contaminants such as biological hazards (e.g., Salmonella, Listeria, E. coli), chemical hazards (e.g., pesticide residues, heavy metals, food additives), and physical hazards (e.g., glass, plastic, metal fragments) pose significant risks to consumers. Early detection of such hazards is thus essential for protecting public health. With the growing availability of text-based data sources, such as news articles and social media posts, Natural Language Processing (NLP) techniques can represent an asset to provide scalable solutions for detecting and classifying food hazards from unstructured text.

This observation has motivated our participation in the SemEval-2025 Task 9 (Randl et al., 2025), which focuses on the "Food Hazard Detection Challenge" and aims at developing classification systems for titles of food-incident reports collected from the web. The provided dataset includes manually labeled English food recall titles from official food agency websites (e.g., FDA). The task comprises of two sub-tasks: (a) **Subtask1**: *Text classification for food hazard prediction*, predicting the type of hazard and product; (b) **Subtask2**: *Food hazard and product "vector" detection*, predicting the exact hazard and product.

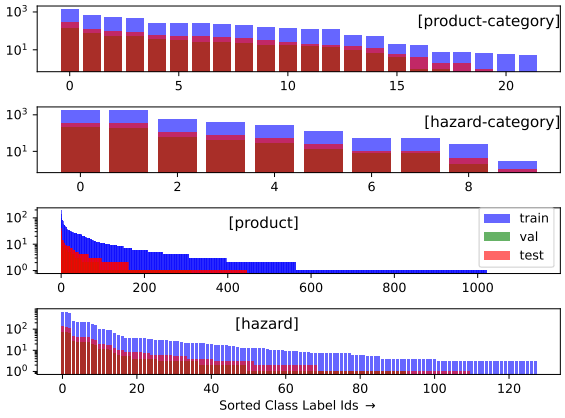

Figure 1: The *long tail* problem in the food hazard detection dataset. The plots shows overlapping bar plots for train-val-test splits with x-axis denoting label ids (descending sorted by frequency for each split) and y-axis as log-scaled class frequency.

Despite the potential of NLP techniques for food safety monitoring, several challenges still remain. In particular, we observe that the dataset (see fig. 1) suffers from a *long tail* problem (Zhang et al., 2023), showing a substantial aggregate frequency for classes that individually have very low frequency. In addition to this, at times, the test set may include previously unseen classes that are absent from the training data[1]. Therefore, this scenario presents two distinct challenges: adapting the model to classes for which it has encountered (i) a very low number of instances, and (ii) no instances

[1]This applies to the *product* set of labels. (See fig. 2)

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1515–1521

at all. Moreover, when the model is trained on the training set, it inherently assumes a similar class distribution in the test set. This reflects the independent and identically distributed (IID) assumption, which presumes that the training and test datasets share the same underlying distribution.

The long-tailed class imbalance represents a common problem in practical visual recognition tasks, often limiting the practicality of deep network based recognition models in real-world applications, since they can be easily biased towards dominant classes and perform poorly on tail classes. Acknowledging a similar issue in the setting of the Food Hazard Detection in text reports, in this paper we present the following contributions: (a) We participate in both subtasks of SemEval-2025 Task 9 on the Food Hazard Detection Challenge. (b) We direct our investigation toward assessing the effectiveness of various loss functions in mitigating the impact of long-tailed class imbalance. (c) Our final submission for each subtask is an ensemble of multiple models trained using different loss functions.

2 Related Work

Food Hazard Detection in Text Reports To date, NLP research on food hazards has primarily been framed as a binary detection task, focusing on detecting the presence or absence of hazards rather than classifying incidents into specific hazard categories. This approach has been used to generate warnings from online texts, for instance, by Maharana et al. (2019), who leveraged Amazon reviews matched with FDA food recall announcements for hazard detection, and by Tao et al. (2023), who combined Twitter data with reports from the U.S. Centers for Disease Control and Prevention. As existing datasets (Hu et al., 2022) follow the same approach and focus on hazard detection, Randl et al. (2024) introduced the first openly accessible resource for text classification of food hazards. The dataset is structured into two levels of granularity and provides the data for SemEval-2025 Task 9 (Randl et al., 2025).

Long Tail Imbalance in NLP Severe class imbalance is one of the most prominent challenges that Randl et al. (2024) identified in the dataset, affecting overall classification performance in particular for low-frequency categories.

In general, various approaches have been explored to address long-tail imbalance. Among those, data augmentation techniques aim to artificially increase the number of samples in low-frequency classes, by generating synthetic examples for underrepresented categories (Wei and Zou, 2019; Anaby-Tavor et al., 2020).

Other approaches include oversampling and undersampling techniques. In Random Under-Sampling (RUS), a subset of head-class samples is randomly selected while the remaining samples are discarded to match the number of tail-class instances. Random Over-Sampling (ROS) randomly reproduces tail-class samples to match the number of head-class samples. To tackle overfitting that often results from ROS, Synthetic Minority Over-Sampling Technique (SMOTE) (Chawla et al., 2002) creates a new artificial sample through interpolation between each existing head-class sample. Furthermore, transfer learning can enhance model performance by leveraging knowledge from head classes to improve tail-class representations (Wang et al., 2017), while decoupled learning (Kang et al., 2020) divides learning into two stages: (a) applying end-to-end learning using conventional methods for representation learning, and (b) fixing the feature extractor while retraining the downstream task model for classification.

Another strategy that has been explored is cost-sensitive learning, an algorithm-level approach that assigns higher weights to underrepresented classes to mitigate bias toward frequent categories and improve model generalization. This strategy is often adopted to tackle the long-tail problem in the visual recognition field (Zhang et al., 2023). Unlike more complex solutions that often require extensive resources, loss function modifications offer a lightweight and interpretable strategy that can enhance model performance even with limited data. As a fundamental aspect of model training, they do not replace but rather complement advanced techniques, making them broadly applicable across different models. In light of this, we chose to investigate loss modification as the primary strategy for the shared task.

3 Theoretical Background

3.1 Problem Formulation

We consider a supervised learning setting with N training samples denoted by pair $<X_i, y_i>$ using which we want to train a classifier $f(\theta)$ for a task T which has C train classes such that,

$$f_T(X_{unseen}|\theta) = \hat{p}_{unseen}$$

Here, p_{unseen} is predicted probability vector of length C, where j_{th} element of the vector corresponds to the predicted probability for X_{unseen} associated with class j.

3.2 Loss Functions

In line with the above setting, we describe below five loss functions that we borrow from the literature, in comparison to the standard cross-entropy ($L_{\texttt{ce}}$) loss function:

Weighted CrossEntropy Loss is denoted by $L_{\texttt{wce}}$ and is given by:

$$L_{\texttt{wce}} = -\frac{1}{N}\sum_{i=1}^{N}\sum_{j=1}^{C} \mathbf{w}_j y_{ij} \texttt{log}(\hat{p}_{ij}) \quad (1)$$

where $\mathbf{w}_j$ is the weight for class j and class weights $\mathbf{w}$ are provided to handle class imbalance.

Focal Loss denoted by $L_{\texttt{fl}}$ is another enhancement of the standard cross-entropy loss designed to address class imbalance (Lin et al., 2017) by focusing on "hard" examples, while reducing the loss for "easy" examples. For a multi-class classification problem, it is defined as:

$$L_{\texttt{fl}} = -\alpha_t(1-\hat{p}_{i,y_i})^{\gamma}\texttt{log}(\hat{p}_{i,y_i}) \quad (2)$$

where γ is the focusing parameter to reduce the contribution of "easy" examples (default set to 2.0).

Class-Balanced Loss is designed to address the issue of class imbalance by reweighting the loss contribution of each class based on its effective number of samples. The Class-Balanced Loss (Cui et al., 2019), denoted by $L_{\texttt{cb}}$, uses the following weight for each class, denoted as follows:

$$\mathbf{w}_c = \frac{1-\beta}{1-\beta^{n_c}} \quad (3)$$

where, n_c is the number of samples in class c; β is a hyperparameter ($0 \leq \beta < 1$) controlling the effect of reweighting. The final loss is scaled as: $\mathbf{w}_c$ x $L_{\texttt{ce}}$ loss.

Equalization Loss is used primarily in object detection tasks to address the class imbalance problem, especially for cases with a heavy foreground-background imbalance or long-tailed distributions (Tan et al., 2020). It modifies the standard cross-entropy loss with a suppression term for negative samples based on their class frequencies. It aims to balance the gradients from positive and negative samples.

	Product-cat.	Hazard-cat.	Product	Hazard
Train	22	10	1022	128
Validation	18	9	312	93
Test	20	10	447	110

Figure 2: Entity distribution and overlap across dataset splits. The Venn diagram shows the overlap of unique entity types among the train, validation, and test sets. Colored counts indicate shared entities across splits. The table summarizes the total count of each entity type per split for the four tasks.

$$L_{\texttt{eq}} = -\sum_{i=1}^{C} y_i log(p_i) - (1-y_i) * w_i * log(1-p_i) \quad (4)$$

where y_i is ground truth one-hot vector; p_i is predicted probability for class i; and w_i is the suppression weight for negative samples, often defined based on class frequencies or other heuristics.

LDAM Loss short for Label-Distribution-Aware Margin Loss ($L_{\texttt{ldam}}$) tackles the issue of long tail class imbalance (Cao et al., 2019) by adjusting the decision boundary for classes based on their frequency by adding a margin, which is inversely proportional to the square root of class frequencies.

$$L_{\texttt{ldam}} = -\frac{1}{N}\sum_{i=1}^{N} \texttt{log}\left(\frac{exp(z_{y_i} - \Delta_{y_i})}{\sum_{j=1}^{C} exp(z_j)}\right) \quad (5)$$

where, z_j is logits for class j, y_i is the ground truth class for sample i, N is the total number of samples. Δ_c is modified margin for class c and is defined as $\Delta_c = \frac{C}{\sqrt{N_c}}$. where C is a hyperparameter controlling the scale of the margin and N_c is the number of samples for class c.

Table 1: Overall results on individual tasks. Each score is the mean of all the configuration with 3 seed runs, while the subscript depicts standard deviation. **Bold** denotes the highest overall score across all the loss functions.

4 Experimental Setup

Dataset Description. The dataset contains timestamp (dd/mm/yyyy) (`timestamp`), title (`title`) and associated text (`text`) along with four labels for every sample. These labels include the product/ hazard category and product/ hazard name. Overall, the dataset comprises of 5082 training samples, 565 validation samples and 997 test samples. The training set in total contains 22 unique labels for *product-category*, 10 for *hazard-category* which together is part of **Subtask1**; further, it contains 1022 unqiue labels for *product* and 128 for *hazard* labels as a part of **Subtask2**. The distribution of unique labels in different data splits is shown in the Venn diagram in fig. 2.

Evaluation Metrics. The two subtasks are evaluated separately by averaging over the macro-F1 ($F1$) over hazard- and product- related tasks.

$$\textbf{Subtask1} = \frac{F1_{\text{product-category}} + F1_{\text{hazard-category}}}{2}$$

$$\textbf{Subtask2} = \frac{F1_{\text{product}} + F1_{\text{hazard}}}{2}$$

PLMs. We use `bert-base-cased` as our pretrained language model (PLM) to perform experiments investigating the impact of different types of loss function.

Hyperparameters. We perform hyperparameter search with different configurations for each loss function. We utilize different learning rates (lr), batch sizes (bs), inputs (I) and run each configuration for 50 epochs with early stopping using 3 different seeds. Details are provided in the Appendix A.

5 Results

In Table 1, we present the overall mean and standard deviation across all configurations we experimented with, using validation data as our test set. The results are reported for different loss functions in comparison to the cross-entropy loss function ($L_{\texttt{ce}}$).

$L_{\texttt{ce}}$	$73.36_{3.8}$	$42.59_{3.2}$	$70.13_{2.3}$	$42.17_{4.03}$

Table 2: Overall results for both the subtasks. **Bold** denotes the highest avg. score across all the loss functions.

We performed initial experiments investigating the use of only-`title`, only-`text`, and `title+text`. We obtained the best results with `title+text` and continued the rest of the experiments using `title+text` as input.

We observe that on the validation set, for *product-category* and *hazard-category* class-balanced ($L_{\texttt{cb}}$) outperforms all the other loss function strategies. Further, for *product* and *hazard*, focal loss ($L_{\texttt{f1}}$) outperforms all other loss functions. This trend is followed on the test set as well except in the case of *hazard-category*, where cross-entropy loss function ($L_{\texttt{ce}}$) outperforms class-balanced loss function ($L_{\texttt{cb}}$).

However, when subjected to the evaluation metrics provided by the SemEval-2025 Task 9 (Randl et al., 2025), we observe a consistent trend where the class-balanced loss function ($L_{\texttt{cb}}$) and the focal loss function ($L_{\texttt{f1}}$) outperform all other loss function strategies for **Subtask 1** and **Subtask 2**, respectively.

Our final submission. We prepare an ensemble of multiple configurations using various loss func-

	Subtask1				Subtask2		
	lr	bs	score		lr	bs	score
$L_{\texttt{cb}}$	5e-05	32	76.44	$L_{\texttt{fl}}$	5e-05	32	48.76
$L_{\texttt{ldam}}$	1e-05	32	76.13	$L_{\texttt{ce}}$	5e-05	32	48.49
$L_{\texttt{ldam}}$	1e-05	16	76.07	$L_{\texttt{fl}}$	5e-05	32	47.79
$L_{\texttt{fl}}$	5e-05	64	75.60	$L_{\texttt{fl}}$	5e-05	64	47.56
$L_{\texttt{ldam}}$	3e-05	16	75.59	$L_{\texttt{eq}}$	5e-05	32	47.10
$L_{\texttt{wce}}$	1e-05	32	75.57	$L_{\texttt{ce}}$	5e-05	64	47.07
$L_{\texttt{cb}}$	1e-05	32	75.55	$L_{\texttt{fl}}$	3e-05	32	47.07
$L_{\texttt{cb}}$	5e-05	64	75.37	$L_{\texttt{fl}}$	3e-05	16	46.51
$L_{\texttt{cb}}$	1e-05	32	75.23	$L_{\texttt{eq}}$	3e-05	32	46.50

Table 3: Best configurations on test set for each subtask. In all configurations, the models were trained on a concatenation of text and title for 50 epochs.

tions, for which we consider the best 9 configurations based on the validation scores (See table 5) for each of the four categories by using the majority voting technique. Using these top 9 configurations, we obtain predictions on the test set. We separately prepare ensembles for **Subtask1** and **Subtask2** by adding one by one configurations based on stopping criteria of validation scores. For **Subtask1**, we submitted the ensemble of top-9 configurations from Table 5. For *product-category*, we used $L_{\texttt{ldam}} + L_{\texttt{cb}} + L_{\texttt{wce}}$; for *hazard-category*, we used $L_{\texttt{cb}} + L_{\texttt{ldam}} + L_{\texttt{wce}} + L_{\texttt{ce}} + L_{\texttt{eq}}$. And, for **Subtask2**, we submitted the ensemble of top-7 configurations from Table 5. For *product*, we used $L_{\texttt{fl}} + L_{\texttt{eq}} + L_{\texttt{ce}}$ and for *hazard*, we used $L_{\texttt{ldam}} + L_{\texttt{eq}} + L_{\texttt{fl}} + L_{\texttt{ce}}$.

For **Subtask1**, in the pool of total 27 submissions for the test set, our final submission scored +5% more than the overall `Mean` submission and also more the `Median` submission. However, the best submission outperformed ours by approximately 4%. Overall, our submission was ranked 11th out of 27 and 9th among the 20 systems that used only `title+text` as input.

For **Subtask2**, our submission outperformed the `Mean` by +11% and the `Median` by approximately 1%. However, our submission fell short of the best system by 6%. Overall, our submission was ranked 6th in the pool of 26 submissions and 5th among the 18 systems that used only `title+text` as input.

During error analysis, we investigate our submission for the *product* task, which exhibits a unique disparity between the training set and the test set, as there are 82 out-of-distribution (OOD) classes present in the test set (see fig. 2). Upon further examination of the effectiveness of the system, we find that the model was unable to identify any of those classes. This is one of the clear limitations of loss function-based strategies for addressing the long-tailed imbalance problem.

	Subtask1	Subtask2
Best	**82.23**	**54.73**
Mean	$73.15_{11.5}$	$37.32_{16.7}$
Median	77.37	47.83
Ours	78.15	48.48
`title+text` Rank	9^{th} /20	5^{th} /18
`Overall` Rank	11^{th} /27	6^{th} /26

Table 4: Overview of the final leaderboard. `Overall` Rank corresponds to final leaderboard ranking provided by the Shared Task Organizers, whereas `title+text` Rank is overall ranking filtered by teams which use only `title` and `text` as inputs.

6 Conclusion

In this paper, we presented our submission to SemEval-2025 Task 9: Food Hazard Detection Challenge, where we focused on addressing the challenge of heavy class imbalance in the provided dataset. Our approach was designed to improve model performance despite the skewed class distribution. By exploring and implementing modifications to the loss function, we showed how techniques commonly used in visual recognition tasks to handle long-tail distributions can also be effectively applied to text classification.

Limitations

Loss functions such as Focal Loss, Equalization Loss, and Class-Balanced Loss address class imbalance but exhibit notable limitations in long-tail imbalanced settings, particularly in case of dealing with unseen test classes also referred to as out-of-domain (OOD) generalization (Zhang et al., 2023). First, these losses rely on static class weight adjustments, which fail to adapt when encountering domain shifts or evolving data distributions. Second, rare classes in the training set may be entirely absent in OOD settings, making prior class-based reweighting ineffective. Focal Loss, which emphasizes misclassified examples, may overfit to domain-specific hard samples, worsening OOD performance. Similarly, Equalization Loss, designed to suppress frequent class gradients, may lead to biased learning when class distributions change in

a new domain. Overall, while these loss functions improve in-domain class balance, they lack adaptability to unseen data, requiring complementary techniques such as contrastive learning, domain adaptation, and meta-learning for robust NLP classification in OOD scenarios.

Appendix

A Hyper-parameter search

In order to perform hyper-parameter search individually for each loss function, we considered different configurations. For learning rate (lr), we considered 1e-5, 3e-5 and 5e-5. For batch size (bs), we considered 16, 32 and 64.

Effect of Learning Rate. Overall, considering the evaluation criteria for scores for Subtask1 and Subtask2, the best learning rate was 3e-5.

Effect of Batch Size. Overall, based on the evaluation criteria for scores of Subtask1 and Subtask2, the best batch size was 32.

Abstract

Classification tasks often suffer from imbalanced data distribution, which presents challenges in food hazard detection due to severe class imbalances, short and unstructured text, and overlapping semantic categories. In this paper, we present our system for SemEval-2025 Task 9: Food Hazard Detection, which addresses these issues by applying data augmentation techniques to improve classification performance. We utilize transformer-based models, BERT and RoBERTa, as backbone classifiers and explore various data balancing strategies, including random oversampling, Easy Data Augmentation (EDA), and focal loss. Our experiments show that EDA effectively mitigates class imbalance, leading to significant improvements in accuracy and F1 scores. Furthermore, combining focal loss with oversampling and EDA further enhances model robustness, particularly for hard-to-classify examples. These findings contribute to the development of more effective NLP-based classification models for food hazard detection.

1 Introduction

The rapid advancement of natural language processing (NLP) has facilitated the development of automated classification systems across various domains, including food hazard detection. Accurately identifying and categorizing food hazards is essential for ensuring food safety and mitigating health risks associated with contaminated or unsafe food products. However, food hazard classification presents several challenges, including severe class imbalances, ambiguous and unstructured textual descriptions, and the need for high predictive accuracy. Traditional approaches to hazard detection have relied on manual inspections and rule-based classification methods, which are often time-consuming and prone to human error. In contrast, recent advancements in machine learning and NLP have enabled the automation of this process, leveraging text classification models to analyze food hazard reports and categorize them into predefined classes.

Transformer-based models, such as BERT (Devlin, 2019) and RoBERTa (Zhuang et al., 2021), have demonstrated state-of-the-art performance in text classification tasks. However, their effectiveness in imbalanced classification settings remains a challenge, as they tend to favor majority classes while underperforming in minority categories. Class imbalance is a common issue where certain categories have significantly fewer instances than others, leading to biased predictions and reduced model performance on underrepresented classes. To address this issue, researchers have explored various techniques, including data augmentation, resampling methods, and modified loss functions. Easy Data Augmentation (EDA) (Wei and Zou, 2019) generates additional training samples for minority classes, enhancing model generalization. Similarly, focal loss (Lin et al., 2017) modifies the traditional cross-entropy loss function to focus more on difficult-to-classify examples, improving performance on underrepresented categories.

In this study, we systematically investigate the impact of data balancing techniques on transformer-based models for food hazard classification. Specifically, we evaluate the effectiveness of oversampling, EDA, and focal loss in mitigating class imbalance and improving classification performance. Through extensive experimentation, we demonstrate that these strategies enhance model robustness, particularly in detecting minority-class hazards. Our findings contribute to the development of more reliable NLP-based classification models for food safety applications, providing valuable insights into optimal approaches for handling class imbalance in text classification tasks.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1522–1527

2 Related Work

2.1 Text Classification

Text classification, a core NLP task, involves assigning predefined labels to text. Traditional methods used rule-based approaches and machine learning models like Naïve Bayes, SVM, and Random Forests. Deep learning, particularly transformer-based models, has significantly improved performance by capturing contextual dependencies (Fan et al., 2024b).

Models like BERT (Devlin, 2019) and RoBERTa (Zhuang et al., 2021) set new benchmarks but struggle with imbalanced datasets, where minority classes are often overlooked. This issue is critical in domains like food hazard detection, where rare cases carry significant risks. To address class imbalance, researchers employ resampling techniques (Lauron and Pabico, 2016), cost-sensitive learning, and modified loss functions like focal loss (Lin et al., 2017). Data augmentation has also proven effective in enhancing classification robustness, especially in low-resource settings.

2.2 Data Augmentation

Data augmentation expands training datasets to improve model generalization (Fan et al., 2024a), particularly in NLP, where it helps mitigate class imbalance in text classification. Traditional methods like synonym replacement, back-translation, and paraphrasing (Wei and Zou, 2019) enhance lexical diversity while preserving meaning. Easy Data Augmentation (EDA) is widely used due to its simplicity, applying synonym replacement, random insertion, swap, and deletion to boost performance on imbalanced datasets. More advanced techniques leverage contextual embeddings (e.g., Word2Vec, FastText) and transformer-based text generation, though excessive alterations risk label noise. Recent studies combine augmentation with resampling strategies (Adegbenjo and Ngadi, 2024), improving accuracy and F1 scores, especially for underrepresented classes. Building on these advancements, we integrate oversampling, EDA, and focal loss to enhance classification in food hazard detection. Our approach effectively mitigates class imbalance and strengthens model robustness, particularly for minority classes.

3 Task Definition and Dataset

SemEval-2025 Task 9 involves classifying short food recall reports into predefined hazard-related labels (Randl et al., 2025). The objective is to develop robust NLP models that accurately identify hazard types and product categories despite imbalanced, noisy, and unstructured text.

The dataset comprises thousands of entries obtained from government agencies. Each entry includes a title, typically a brief recall identifier, and a text description that varies in length and format, often containing domain-specific terminology. The data are marked by severe class imbalance, with many hazard categories significantly underrepresented.

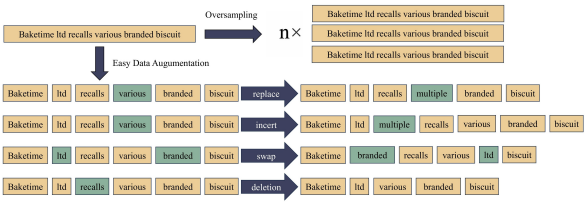

Figure 1: The structured pipeline for food hazard detection.

4 Methodology

Recent work in food hazard detection highlights the importance of addressing data imbalance, short and unstructured text, and overlapping semantic categories (Adegbenjo and Ngadi, 2024). SemEval-2025 Task 9 intensifies these challenges by providing a real-world dataset where certain hazard classes are severely underrepresented, necessitating specialized techniques to ensure fair and robust classification. In this study, we adopt a transformer-based approach, leveraging BERT (Devlin, 2019) and RoBERTa (Zhuang et al., 2021), and integrate three key strategies—random oversampling, Easy Data Augmentation (EDA), and focal loss—to enhance performance on minority classes while maintaining overall accuracy.

Our methodology follows a structured pipeline, shown in Figure 1, which consists of data preprocessing and augmentation, transformer-based model fine-tuning, and final evaluation using standard classification metrics. The sections below describe how these components are cohesively combined to tackle the real-world complexities of food hazard reports.

4.1 Data Preprocessing and Augmentation

All textual inputs undergo cleaning and tokenization before fine-tuning. We remove stopwords, numerical tokens, and other non-informative el-

Operation	Description
Synonym Replacement	Replace with synonyms
Random Insertion	Insert random words
Random Swap	Swap two words
Random Deletion	Remove words ($p = 0.1$)

Table 1: Easy Data Augmentation (EDA) operations applied to the dataset.

ements, followed by lemmatization to standardize word forms. Outliers are then filtered using the interquartile range (IQR) to reduce extreme text lengths that could bias the model. We adopt WordPiece tokenization (Song et al., 2020) to handle out-of-vocabulary (OOV) tokens, thereby preserving subword-level information crucial for short and domain-specific texts.

To counteract severe class imbalance, we introduce a combined augmentation strategy that integrates random oversampling with Easy Data Augmentation (EDA) (Wei and Zou, 2019). Oversampling is performed after tokenization to ensure each minority class is represented at a target sample rate. EDA, summarized in Table 1, is then applied to further expand the diversity of minority samples by introducing lexical and structural variations. Rather than applying each augmentation technique independently, we incorporate them into a unified process that consistently enhances minority-class coverage and lexical variety. This integrated augmentation stage aligns with prior findings that emphasize synergy between resampling and data augmentation for imbalanced text classification (Lauron and Pabico, 2016).

4.2 Classification Model and Imbalance Handling

The classification model builds on BERT and RoBERTa, which are fine-tuned for multi-class prediction. While cross-entropy loss remains the baseline choice, we adopt focal loss (Lin et al., 2017) to emphasize hard-to-classify examples in minority classes. The focal loss function is given by:

$$FL(p_t) = -\alpha_t (1 - p_t)^{\gamma} \log(p_t), \qquad (1)$$

where α_t balances class contributions, γ focuses on difficult samples, and p_t is the predicted probability for the correct class. We set $\alpha = 1$ and $\gamma = 2$ based on initial experiments indicating improved recall for underrepresented hazards.

Random oversampling is performed using the strategy:

$$\text{sampling\_strategy} = \{\, k : \text{target\_count} \mid v < \text{target\_count}, \forall k, v \}, \qquad (2)$$

where each minority class is upsampled to match a threshold of the majority class size. By applying oversampling in tandem with EDA, we ensure that minority classes benefit from both quantitative and qualitative increases in training samples.

4.3 System Configurations

We evaluate several configurations to highlight the effect of each balancing technique (Table 2). The *Baseline* employs standard BERT fine-tuning without augmentation, while additional setups incorporate oversampling, EDA, focal loss, or a combination thereof. We also include RoBERTa variants, reflecting the same augmentation and imbalance strategies. This design enables a comprehensive comparison of how each technique—alone or combined—contributes to classification performance on short, imbalanced food hazard reports.

This integrated methodology ensures that each stage—preprocessing, augmentation, model training—cooperates to address the unique challenges posed by SemEval-2025 Task 9, namely short, imbalanced, and domain-specific textual data.

5 Experiments

Our study strategically integrates three techniques—Easy Data Augmentation (EDA), oversampling and focal loss—to address class imbalance in classification tasks. The sequence of application is as follows: EDA is applied before tokenization to enhance data diversity, oversampling is applied after tokenization to balance class distribution, and focal loss is utilized during training to optimize the model's focus on difficult samples. These experiments not only demonstrate the effectiveness of each individual method but also highlight the synergistic benefits of their combination. The results show that this integrated approach enhances data diversity, balances class distribution, and improves model performance by prioritizing challenging samples.

5.1 Experimental Setup

Oversampling The sample rate is set to r. For classes whose size is smaller than r% of the most-frequent class, we perform oversampling to ensure

Configuration	Description
Baseline	Standard BERT fine-tuning with cross-entropy loss
BERT + Oversampling	Resample minority classes after tokenization
BERT + EDA	Apply data augmentation using EDA
BERT + Focal Loss	Replace cross-entropy with focal loss
BERT + EDA + Focal Loss	Combine lexical augmentation and focal loss
RoBERTa Variants	Mirror each configuration using RoBERTa

Table 2: Model configurations used for evaluation.

their size matches that of r% of the most-frequent class.

Easy Data Augmentation The sample rate is set to r. For each instance input, we perform EDA. Each of the four operations—Random Synonym Replacement, Random Insertion, Random Swap, and Random Deletion—has a 50% probability of being applied. For the first three operations, the parameter (n), which indicates the number of times the operation is to be performed, is randomly selected within the range of 1 to the total number of words in the text. In the case of the Random Deletion operation, each word is assigned a 10% probability of being deleted.

Focal Loss Alpha (α),the balance parameter for class imbalance, is set to 1. Gamma (γ), the focusing parameter for hard examples, is set to 2. The method for aggregating the loss values (reduction) is "mean".

5.2 Training Details

We utilized the 'title' and 'text' fields from the dataset released by the organizers. In the data processing phase, categorical labels were encoded into numerical values using the LabelEncoder. The dataset was subsequently split into training and testing sets, with 20% allocated for testing. If Easy Data Augmen- tation (EDA) was enabled, data augmentation techniques were applied specifically to the training subset (train_df). Additionally, if oversampling was employed, data augmentation was conducted after the tokenization process.

For our models, we utilized BERT (Devlin, 2019) and RoBERTa (Zhuang et al., 2021). During training, the total batch size was set to 32. The AdamW optimizer (Kingma, 2014) was used with a learning rate of 5e-5, and dropout was specified at 0.0. The learning rate schedule followed a 'cosine with warmup' strategy, incorporating a warmup phase equivalent to 10% of the total training steps to gradually adjust the learning rate and enhance model convergence. The default loss function used was CrossEntropyLoss, unless focal loss was selected.

In our study on NLP food hazard classification, we concentrated on addressing the issue of class imbalance, particularly in predicting the most imbalanced label, "product." To evaluate our model's performance, we established BERT, provided by the organizers, as our baseline. The evaluation utilized inputs from both "text" and "title" to enhance the model's effectiveness. We employed several metrics to assess performance, including accuracy, F1-score (macro), and F1-score (weighted). See Table 3 for the results for predicting "product" (data split: training/validation/test).

Oversampling BERT achieved an accuracy of 0.22, with an F1-Macro score of 0.03 and an F1-Weighted score of 0.13, highlighting its limitations in handling the imbalanced dataset. Oversampling with a sample rate at 0.1 yielded the best performance among the oversampling variations, achieving an accuracy of 0.50, an F1-Macro score of 0.25, and an F1-Weighted score of 0.45. This indicates that oversampling can effectively address class imbalance and improve classification performance.

Easy Data Augmentation The experimental results presented in Table 3 also demonstrate the effectiveness of Easy Data Augmentation (EDA) in enhancing the performance of the model for the "product." Compared to the baseline accuracy of 0.22, the application of EDA across multiple configurations consistently improved performance. EDA with a sample rate of 0.2 increased accuracy to a maximum of 0.55. Similarly, the F1 macro score improved significantly from 0.03 to 0.30, while the F1 weighted score rose from 0.13 to 0.52. These findings underscore the potential of EDA as a valuable technique for improving model performance in imbalanced classification tasks.

Table 3: BERT model with different strategies for predicting product. The subscript isthe sample rate. For example, 0.1 means to upsample categories that are less than 10% of the maximum sample to 10% of the maximum sample.

(ST2) Hazard Detection			
Training Methods	**Accuracy**	**F1-Macro**	**F1-Weighted**
BERT_{base}	0.58	0.17	0.53
BERT + Focal loss + $\text{EDA}_{0.1}$	0.86	0.59	0.85
RoBERTa + Focal loss + $\text{EDA}_{0.1}$	0.86	0.59	0.85

Table 4: BERT and RoBERTa with focal loss and EDA on predicting hazard. The subscript is sample rate. For example, 0.1 means to upsample categories that are less than 10% of the maximum sample to 10% of the maximum sample.

Combination After observing that handling imbalance can enhance model performance, we explored the effects of combining this strategy with focal loss, which places greater emphasis on harder-to-classify examples. We also examined the combination of EDA with oversampling. While these combinations did result in performance improvements that surpassed the baseline BERT model, they did not achieve the same high levels of effectiveness as EDA alone. For instance, the combination of focal loss with oversampling yielded an accuracy of 0.49 at a sample rate of 0.1, while EDA at the same rate achieved an accuracy of 0.54.

Prediction on Hazard To ensure that the model predicts well across different tasks, we also made predictions on "hazard." The combination of focal loss and Easy Data Augmentation (EDA) significantly increased performance from an accuracy of 0.58 for BERT to 0.86 at a sample rate of 0.1. We also investigated the RoBERTa model in a similar manner; however, it performed comparably to BERT, leading us to discontinue further exploration of RoBERTa. Table 4 shows some results of these experiments.

In summary, the results show that this integrated approach enhances data diversity, balances class distribution, and improves model performance by prioritizing challenging samples. Our findings indicate that EDA is a particularly effective technique for addressing class imbalance in food hazard classification. While combinations with focal loss and oversampling improve performance, they do not surpass EDA alone. Additionally, these methods may require further fine-tuning and more training steps to optimize their effectiveness.

6 Conclusion

In this paper, we strategically combined three methods - Easy Data Augmentation (EDA), oversampling, and focal loss - to tackle class imbalance in classification tasks. Our model ranked 13th on ST1, and 12th on ST2. It surpassed the baseline in both ST1, predicting product and hazard category, and ST2, predicting specific hazard and product.

Future work will explore strategies to enhance model performance in data-constrained and domain-shift scenarios. We plan to investigate the integration of advanced augmentation techniques and refined loss functions, along with fine-tuning the existing methodology.

Limitations

While our approach demonstrated notable improvements in food hazard classification, several limitations remain. First, despite the effectiveness of EDA and oversampling in mitigating class imbalance, these techniques may introduce synthetic noise into the dataset. Augmented samples, particularly those generated via lexical modifications, may not always accurately preserve the semantic meaning of the original text, potentially leading to misclassification.

Second, our reliance on transformer-based models presents computational challenges. Fine-tuning these models requires significant hardware resources, making it less feasible for real-time applications or deployment in resource-constrained environments. Additionally, while focal loss improves performance on hard-to-classify examples, it requires careful tuning of hyperparameters, which may not generalize well across different datasets or classification tasks.

Another key limitation is the potential lack of generalizability. Our model was trained on the SemEval-2025 Task 9 dataset, which, despite being a real-world dataset, has specific linguistic characteristics and class distributions. This may limit the model's ability to perform well on other food safety-related classification tasks with different text structures, hazard categories, or reporting styles. Future work should explore domain adaptation techniques and evaluate performance across multiple datasets.

Finally, while our approach improves minority class detection, the gap between majority and minority class performance remains. Additional techniques, such as contrastive learning, cost-sensitive training, or adaptive resampling, could be explored to further enhance model fairness and robustness.

Lacuna Inc. at SemEval-2025 Task 4: LoRA-Enhanced Influence-Based Unlearning for LLMs

Aleksey Kudelya, **Alexander Shirnin**
HSE University
Correspondence: ashirnin@hse.ru

Abstract

This paper describes LIBU (LoRA enhanced influence-based unlearning), an algorithm to solve the task of unlearning - removing specific knowledge from a large language model without retraining from scratch and compromising its overall utility (SemEval-2025 Task 4: Unlearning sensitive content from Large Language Models). The algorithm combines classical *influence functions* to remove the influence of the data from the model and *second-order optimization* to stabilize the overall utility. Our experiments show that this lightweight approach is well applicable for unlearning LLMs in different kinds of task.

1 Introduction

Machine unlearning - the process of removing specific knowledge from a machine learning model without retraining from scratch - has emerged as a critical capability for large language models (LLMs) (Bertetto et al., 2024) deployed in dynamic or privacy-sensitive environments (Bourtoule et al., 2021). Unlike traditional retraining, which is computationally prohibitive for LLMs, unlearning seeks to selectively erase influences of a *forget dataset* while preserving good performance on a *retain set*. This capability is essential for applications requiring compliance with data privacy regulations (e.g., GDPR "right to be forgotten" (Mantelero, 2013)) or rapid adaptation to evolving content policies.

Existing approaches, for example, gradient ascent (Tarun et al., 2024), often degrade general capabilities, as reflected in performance drops on benchmarks like MMLU (Hendrycks et al., 2021), or demand computational resources that are impractical in real-world settings. To address these limitations, we propose a two-phase method called LoRA-enhanced influence-based unlearning (LIBU), which combines influence functions (Koh and Liang, 2017) with the Sophia optimizer (Liu et al., 2024). In Phase 1, LIBU computes parameter-wise updates using a Fisher Information approximation (Foster et al., 2024) to minimize retain-set disruption. Phase 2 refines the model via second-order optimization, stabilizing training on noisy forget-set gradients. Our submission, evaluated on the OLMo-7B model (Groeneveld et al., 2024), achieves a regurgitation rate of 0.283 while maintaining an MMLU accuracy of 0.469, exceeding the competition threshold of 0.371.

2 Background

The SemEval-2025 Task 4: Unlearning Sensitive Content from LLMs (Ramakrishna et al., 2025b) formalizes this challenge across three subtasks: (1) erasing long-form synthetic documents, (2) removing personally identifiable information (PII) from short biographies, and (3) unlearning real documents from the OLMo pretraining corpus. The task demands balancing two competing objectives: achieving high regurgitation and MIA scores on forget and retain sets, while preserving highest MMLU capability. To evaluate the submissions, (Ramakrishna et al., 2025a) release a comprehensive new benchmark named LUME (LLM Unlearning with Multitask Evaluations). For each of the tasks, there are prompts for regurgitation and knowledge tests. The benchmark is split into forget and retain sets (in 1:1 ratio). Two model checkpoints (7B and 1B parameters) were also fine-tuned to memorize this dataset.

The formal task definition is as follows:

Let $\theta \in R^d$ denote the model parameters, D_{retain} the retain dataset, and D_{forget} the forget dataset. The unlearning objective is to compute parameter updates $\Delta\theta$ that:

- Maximize the loss on D_{forget}
- Minimize the change in loss on D_{retain}

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1528–1533

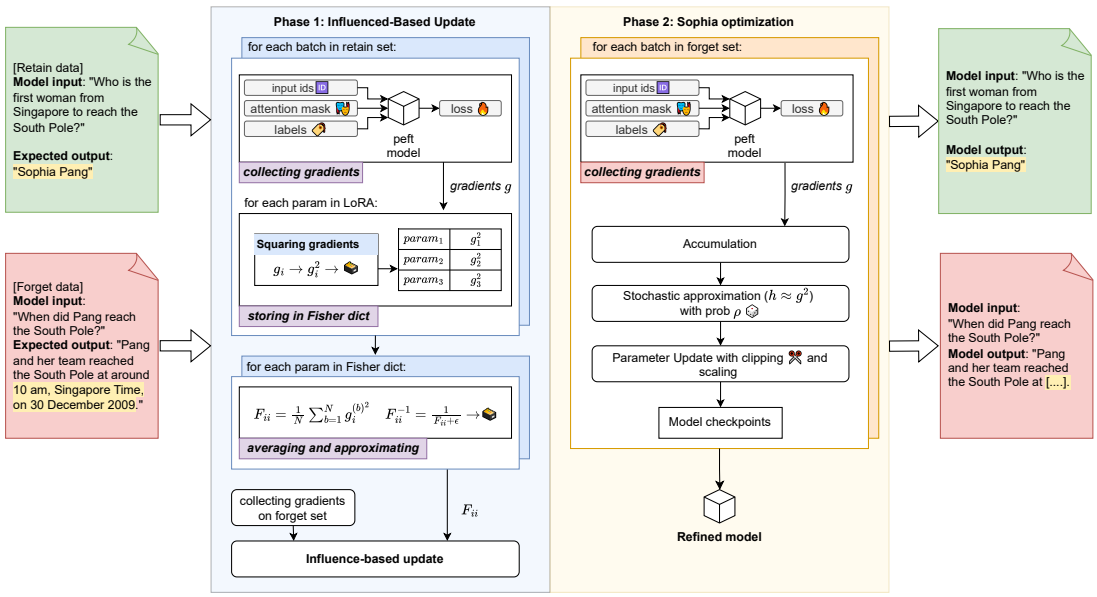

Figure 1: LIBU pipeline. Given two datasets, LIBU operates with two phases: **1) Influence-Based Update**, where it collects the gradients from retain and forget sets and determines the necessary parameter updates; **2) Sophia optimization**. where the model is iteratively stabilized on the forget set.

The training code is publicly released [1], enabling reproducibility.

3 System overview

Our method implements a two-phase approach to machine unlearning, designed to efficiently remove specific data influences, while preserving model performance on retained data. The main idea lies in combining influence-based parameter updates with second-order optimization, ensuring both precision and computational efficiency.

Unlike prior methods that approximate the full Hessian matrix via WoodFisher (Jia et al., 2024) — a computationally prohibitive process requiring $O(d^2)$ memory and prone to Taylor expansion errors — our approach replaces explicit Hessian inversion with a retain-set-derived diagonal Fisher approximation. This avoids the instability of stochastic Hessian estimates while ensuring updates prioritize parameters critical to retained knowledge. Furthermore, our two-phase design (Figure 1) decouples influence-based forgetting (Phase 1) from Sophia-driven stabilization (Phase 2), eliminating approximation drift observed in joint Hessian-gradient formulations.

[1] github.com/silleghost/semeval-unlearning-2025

3.1 Influence-based update

The unlearning process begins by calculating the approximation of the *inverse Fisher Information Matrix*, using D_{retain}. This matrix captures the importance of parameters of data that the model should retain in memory. We will use these values to determine the necessary parameter update, ensuring that the weights associated with retain data receive the smallest update.

The diagonal of the *Fisher Information Matrix* (F) is approximated using gradients from D_{retain}. For each batch in the retain dataloader:

1. Gradients (g_{retain}) are computed during backpropagation.
2. Squared gradients (g^2_{retain}) are accumulated and averaged across batches to estimate F, which quantifies parameter importance for retained tasks.

Thus, the final computing formula in this step will be the following:

$$w_\theta = \frac{1}{F_{ii} + \lambda} \approx \frac{1}{\mathbb{E}[g^2_{retain}] + \lambda}$$

Here a damping factor ($\lambda = 10^{-3}$) is added to stabilize inversion and prevent dividing by zero.

Gradients (g_{forget}) are computed on the forget set via standard backpropagation. These gradients

indicate directions in parameter space that correlate with the model's ability to recall the forget data. Gradients are also averaged across batches to mitigate noise and ensure a stable update value.

In the final influence-Based update parameters are adjusted via $\theta_{t+1} \leftarrow \theta_t - \eta \cdot w_{\theta_t} \cdot g_{forget}$, where η is the learning rate. Parameters critical to the retain set (high F values) receive small updates, minimizing forgetting of retain data. Less critical parameters are adjusted more aggressively to erase forget set influence.

Computing an approximation of the Fisher diagonal reduces the computational burden, as computing the full Fisher information matrix is usually not applicable to large models due to the very large number of parameters. In addition, LoRA's (Low-Rank Adaptation) parameter-efficient fine-tuning (Hu et al., 2022) is used in the training. In this approach, only low-rank adapter weights are trained and updated, which reduces memory usage in the unlearning process.

3.2 Second order optimization

Phase 2 refines the unlearned model using the Sophia optimizer (Liu et al., 2024), a second-order method designed to stabilize fine-tuning while erasing residual influences of D_{forget}. Unlike first-order optimizers like Adam (Kingma and Ba, 2015), Sophia leverages gradient variance as a lightweight Hessian approximation, enabling parameter-specific learning rate adaptation. This is critical for unlearning, where aggressive updates risk destabilizing retained knowledge.

Traditional optimizers scale updates by gradient magnitude alone, risking overshooting in regions of high curvature. Sophia incorporates Hessian diagonal estimates (h), derived from squared gradients (g^2), to dampen updates for parameters with large curvature (high h). The update rule becomes the following:

$$\Delta\theta_t = -\eta \cdot \frac{g_t}{\max(\gamma \cdot h_t, \epsilon)}$$

Here γ controls step size conservatism. This hyperparameter scales the Hessian diagonal estimate (h_t) controlling how conservatively updates are applied. A higher γ (e.g., $\gamma = 1.2$) reduces step sizes for parameters with large curvature (high h_t), preventing overshooting in regions where the loss landscape is steep. This is critical for preserving retained knowledge during unlearning. A small constant ($\epsilon = 10^{-8}$) ensures that the denominator never approaches zero, avoiding division-by-zero errors.

Sophia then clips updates to a fixed threshold, ensuring stable progression even with noisy gradients from the forget set. To avoid computational burden, Sophia approximates h by stochastically sampling gradient squares with probability ρ. This balances accuracy and efficiency, making it feasible for large models.

3.3 Gradient accumulation

To address memory constraints and stabilize training, we introduced gradient accumulation steps — a technique where gradients are computed over multiple smaller batches before updating model parameters. This approach effectively simulates a larger batch size while keeping per-iteration memory usage manageable. Accumulating gradients over k micro-batches simulates a larger effective batch size, enabling stable training with limited GPU memory. We added *accumulation steps* as our new hyperparameter which specifies the number of iterations after which the parameters are updated.

4 Experiments

Experiment Setup

The experiments were conducted as part of the SemEval-2025 competition, focusing on machine unlearning for three subtasks: (1) long-form synthetic creative documents, (2) short-form synthetic biographies containing personally identifiable information (PII), and (3) real documents sampled from the OLMo training dataset. Two model versions were trained on the designed algorithm and evaluated with OLMo evaluation framework: the fine-tuned OLMo-7B-0724-Instruct-hf [2] (7B parameters) and OLMo-1B-0724-hf [3] (1B parameters), with submissions constrained to a 1-hour runtime.

Due to computational constraints and a focus on validating the combined system's practical value, we leave fine-grained ablations of individual components (Sophia, Influence Functions) as future work. Preliminary results indicated that the components work better together, so we chose to prioritize evaluating the full system rather than isolating and testing each individual component separately.

All experiments are conducted on a single NVIDIA A100 GPU. The final code also includes

[2] hf.co/allenai/OLMo-7B-0724-Instruct-hf
[3] hf.co/allenai/OLMo-1B-0724-hf

an option with DeepSpeed with implementation for distributed training on multiple GPUs.

Evaluation metrics

Performance of the algorithm was measured using three aggregated metrics:

- Task-specific regurgitation rates (harmonic mean of 12 inverted ROUGE-L scores on the sentence completion prompts and exact match rate for the question answers on both D_{forget} and D_{retain} sets).
- A membership inference attack (MIA) score on a sample of member and nonmember datasets, that is equivalent to the PrivLeak metric (Shi et al., 2025).
- MMLU benchmark accuracy, which is described above.

For evaluation of our trained model we used OLMo-Eval framework [4].

Hyperparameters and dataset

The unlearning method combined influence-based parameter updates (Phase 1) and Sophia-optimized fine-tuning (Phase 2). We conducted a series of experiments on OLMo-7B-0724 fine-tuned model and chose a number of epochs for training, learning rate, batch size, LoRA rank, Damping factor, Sophia ρ, Sophia γ as our hyperparameters.

To work efficiently with a dataset in parquet file format, we have implemented our own *Unlearning-Dataset* class, which works with both directories and parquet files themselves. The dataset contains disjoint retain and forget splits in parquet files, and includes following fields: *id*, *input*, *output*, *task*. We use OLMo tokeniser to tokenize a string of combined *input* and *output* fields. A special parameter *max length* is used to bring all tokenised sequences to the same length by padding or truncating them, enabling efficient batch processing.

5 Results

We tested three configuration setups (Table 1) tailored to the competition's subtasks:

- Setup 1. More aggressive unlearning: Achieved the highest score in second subtask with regurgitation rate of 0.83 on forget set, but severely degraded MMLU accuracy below predefined threshold (<0.371).

[4] github.com/allenai/OLMo-Eval

Hyperparameter	Setup 1	Setup 2	Setup 3
NUM_EPOCHS	6	5	4
LEARNING_RATE	4e-5	3e-5	2e-5
BATCH_SIZE	4	6	4
LORA_RANK	16	24	16
ACCUMULATION_STEPS	4	6	8
MAX_LENGTH	1024	1024	1024
DAMPING_FACTOR	5e-5	8e-4	1e-3
SOPHIA_RHO	0.1	0.08	0.06
SOPHIA_GAMMA	1.1	1.15	1.2

Table 1: Hyperparameter settings for training.

- Setup 2. More balanced unlearning: Achieved the highest scores in subtask 1 and subtask 3 but got a lower score on the retain tasks.
- Setup 3. More conservative unlearning: Achieved average high scores in all 3 subtasks and got the highest task aggregate score among all setups.

Analysis

The stark performance differences (Table 2) between setups underscore the sensitivity of unlearning to hyperparameter choices and confirm that overly aggressive updates risk catastrophic forgetting, while overly conservative tuning leaves residual forget-set influences.

Our study demonstrates that machine unlearning, when framed as a two-phase process of influence-based updates and second-order fine-tuning, can effectively balance data removal with model utility. The success of Setup 3 highlights the importance of hyperparameter equilibrium: its moderate learning rate (`2e-5`) and batch size (`4`) stabilized training, while setting the gradient accumulation steps to `8` mitigated memory constraints without compromising gradient fidelity. These choices proved critical under the competition's strict 1-hour runtime limit, where computational efficiency and precision were paramount.

6 Conclusion

In this paper, we present LIBU, a two-phase unlearning framework for LLMs that combines influence-based parameter updates with second-order Sophia optimization, achieving competitive results in the SemEval-2025 Task 4. LIBU's lightweight design—leveraging LoRA for parameter efficiency and gradient accumulation for stability—enables precise removal of sensitive data while preserving model utility, exceeding the competition threshold. Our experiments highlight the

Algorithm	Aggregate	Task Aggregate	MIA score	MMLU Avg.
LIBU	0.157	0.118	0.0	0.354
	0.221	0.182	0.0	0.482
	0.254	**0.28**	0.0	**0.483**
Gradient ascent	0.394	0	0.912	0.269
Gradient difference	0.243	0	0.382	0.348
KL minimization	**0.395**	0	**0.916**	0.269
NPO	0.188	0.021	0.080	0.463

Table 2: Performance of LIBU compared to baseline unlearning methods (shown below the horizontal line). While KL minimization achieves the highest aggregate score, it severely degrades model utility. **Bold** numbers indicate the best performance for each metric.

critical role of hyperparameter equilibrium, as conservative tuning balances unlearning efficacy with retention, whereas aggressive configurations risk catastrophic forgetting.

Limitations

Despite these advances, our evaluation of LIBU has been limited to relatively small models (1B and 7B parameters), leaving the behavior of current large-scale SOTA models unknown. Additionally, it remains unclear whether these algorithms will scale effectively to larger datasets. Another critical challenge is the sensitivity to hyperparameter choices, which becomes a significant issue for large models where retraining is computationally expensive. Furthermore, the forget and retain sets may contain highly similar information, making the unlearning task even more challenging. Future work will explore these limitations, focusing on scaling LIBU to larger models and datasets while addressing challenges in hyperparameter selection and handling closely related data distributions.

VerbaNexAI at SemEval-2025 Task 3: Fact Retrieval with Google Snippets for LLM Context Filtering to identify Hallucinations

Anderson Morillo and **Edwin Puertas** and **Juan Carlos Martinez-Santos**
Universidad Tecnologica de Bolivar, Cartagena Colombia
amorillo@utb.edu.co, epuertas@utb.edu.co, jcmartinezs@utb.edu.co

Abstract

This paper presents two complementary approaches for hallucination detection in large language model outputs, developed by the VerbaNexAI team for SemEval-2025 Task 3. The first approach leverages advanced LLMs, employing a chain-of-thought prompting strategy with one-shot learning and Google snippets for context retrieval, demonstrating superior performance. The second approach utilizes traditional NLP analysis techniques, including semantic ranking, token-level extraction, and rigorous data cleaning, to identify hallucinations. Evaluation of an English dataset comprising both labeled and unlabeled examples shows that the LLM-based system achieved competitive results, ranking 25th out of 41 in Intersection over Union and 28th in Spearman correlation. At the same time, the NLP approach provided valuable qualitative insights despite lower quantitative performance. These findings highlight the potential of our methods, along with challenges such as snippet availability and prompt optimization, paving the way for future improvements through enhanced snippet extraction and fine-tuning strategies.

1 Introduction

In the era of large language models (LLMs), the generation of fabricated or non-factual information often referred to as hallucinations (Ji et al., 2022; Tonmoy et al., 2024) poses a significant challenge to the reliability and trustworthiness of automated systems. SemEval-2025 Task 3 addresses this issue by identifying hallucination spans in generated texts, thereby promoting more accurate and contextually grounded responses (Vázquez et al., 2025). We centered our participation in this task on the English language, where we aim to mitigate hallucinations by incorporating external factual evidence retrieved via Google snippets (Strzelecki).

Our system builds on a multi-stage approach that integrates several key components. First, it retrieves relevant context through Google snippets, which are semantically ranked to select the most pertinent pieces of information (Strzelecki and Rutecka, 2020a). Next, a specially formatted prompt optimized through a one-shot chain-of-thought strategy guides the LLM in extracting hallucinations from the generated responses. Data cleaning and token extraction methods further refine this process, ensuring the system retains only meaningful hallucination candidates. It ultimately enhances factual verification and the robustness of LLM outputs (Tonmoy et al., 2024).

Preliminary results indicate that while our approach shows promise in identifying hallucinations, challenges remain regarding data availability and prompt efficiency. Notably, our system ranked 25th out of 41 teams in Intersection over Union and 28th in Spearman correlation. These findings underscore both the potential and limitations of our current method, motivating ongoing improvements. Our code is publicly available at https://github.com/VerbaNexAI.

2 Background

This section presents the current state of hallucination identification as proposed in Semeval Task 3 (Vázquez et al., 2025). This task aims to identify spans of hallucinations in text generated by instruction-tuned Large Language Models (LLMs) in a multilingual context. It represents the second iteration of the SHROOM task, which sought to determine whether a sentence generated by a generative model was a hallucination yes or no (Mickus et al., 2024). Authors defined hallucinations as "An unreal perception that feels real" (Ji et al., 2022).

The task involves evaluating language model outputs across 14 languages. Our participation was limited to English language datasets structured in JSON format.

Our proposal uses Google Snippets Boxes to

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1534–1541

retrieve relevant web-based information. Google developed this system, which provides quick answers to factual questions (Strzelecki and Rutecka, 2020b). Also, Google has better performance than Bing, another search engine that also offers this tool (Musa and Isa, 2021).

There are various approaches to mitigate hallucinations. (Tonmoy et al., 2024) summarizes these strategies, highlighting prompt engineering and model development as the primary methodologies.

2.1 Prompt Engineering

This technique focuses on experimenting with different instructions to obtain optimal results (Tonmoy et al., 2024). One prominent approach within prompt engineering is Retrieval Augmented Generation (RAG), which integrates relevant contextual information into the model's response generation. We can apply RAG at different stages: before (Peng et al.), during (Varshney et al.), and after (Rawte et al., 2573) generation. Additionally, end-to-end RAG solutions have been explored (Lewis et al.).

Another method is Self-Refinement through Feedback and Reasoning, where the model generates feedback on its responses to improve future iterations (Madaan et al.).

Finally, Prompt Tuning involves adjusting instructions using techniques such as fine-tuning to generate more effective responses tailored to specific tasks (Lester et al., 2021).

2.2 Developing Models

This approach focuses on improving language models through various architectural techniques to reduce the generation of incorrect information (Tonmoy et al., 2024).

One key strategy is introducing new decoding strategies, which optimize text generation to minimize errors. A method such as Context-Aware Decoding (CAD) (Shi et al., 2024).

Another approach is the utilization of knowledge graphs, where authors integrated structured information representations to improve response coherence. Examples include RHO (Ji et al., 2023) and FLEEK (Bayat et al., 2023).

Furthermore, introducing faithfulness-based loss functions helps train more reliable models by penalizing the generation of unverifiable content.

Finally, supervised fine-tuning reduces hallucinations like (Tian et al., 2023) that model learns how to respond by selecting the more factual between two responses.

For this model, we used Google snippets to analyze website content and extract the most relevant information for display in a featured snippet at the top of search results. These snippets summarize key web page details in response to user queries and can appear as lists, paragraphs, or tables. Their selection follows a structured approach to ensure accurate retrieval based on the query (Strzelecki; Strzelecki and Rutecka, 2020a). Snippets effectively provide factual context to user questions. Therefore, we propose using Google snippets, as most evaluation questions are content-based, as shown in the dataset section.

Most models discussed in (Tonmoy et al., 2024) perform binary classification to determine whether a response contains a hallucination ("yes" or "no"). However, only a few specifically address the identification of hallucination spans within the generated text. For instance, (Quevedo et al., 2024) employs two LLMs: one for generating responses and another for analyzing logs to estimate the probability of hallucination in the generated tokens. Additionally, (Liu et al.) detects hallucinations in free-form text using a token-level, reference-free approach.

3 System Overview

One of the main challenges in developing this system was designing a computationally efficient solution. To address this issue, we proposed two approaches: one based on feature extraction using linguistic analysis techniques **NLP base system** and another relying on large language models **LLM base system** the current state of the art.

3.1 Data Description

For model development, we utilized two datasets. The first was the English test dataset, comprising 50 labeled examples for initial evaluation. We used a separate test dataset with 150 examples to assess model performance. Additionally, a validation dataset containing 154 unlabeled examples was employed to analyze system behavior. These unlabeled examples could be evaluated using the platform proposed by (Vázquez et al., 2025), which applies Intersection over Union (IoU) and Spearman Correlation metrics for assessment.

The test dataset includes essential fields such as *id*, *lang*, *model_input*, *model_output_text*, and various annotations. The structure of *soft_labels* and

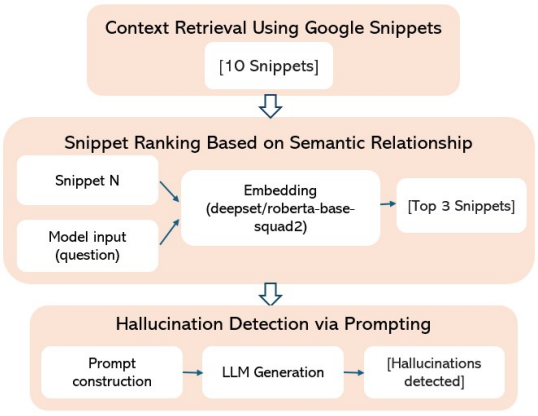

Figure 1: LLM base system

hard_labels, including keys such as start, end, and prob, provides a detailed representation of hallucination spans along with their associated probabilities, ranging from 0 to 1.

3.2 LLM base system

Figure 1 shows the model that consists of three parts. The Context Retrieval Using the Google Snippets component is essential for providing context to the system's responses and identifying hallucinations within the text. Next, the most relevant snippets are filtered using embeddings. Then, we generated a specially formatted prompt to help the language model better understand the task. Finally, we extracted the hallucinations using the LLMs and refined the results.

3.2.1 Context Retrieval Using Google Snippets

We used Google Snippets to provide context to the LLMs by retrieving search results based on the model's input. Specifically, we performed a Google search using the given query and extracted ten snippets. For example, when asked, "What are the colors of the United States flag?" Google retrieves relevant excerpts from web pages and presents them as snippets. The relevant snippets are then collected and organized into a list.

We required Proxy IP rotation to scrape the snippets, as described in (Patel, 2020), using the ScrapeOps service. Additionally, the system iterates up to two times to retrieve the data.

3.2.2 Snippet Ranking Based on Semantic Relationship

We used a semantic relationship method based on Morillo et al. (2024) to identify the most relevant snippets. This approach employs *deepset/roberta-base-squad2* embedding, which we derived from the RoBERTa model (Liu et al., 2019) and trained on Question Answering Dataset (SQuAD) from Rajpurkar et al. (2018). The method computes the semantic similarity between the snippets and the input query using cosine similarity, as proposed by Morillo et al. (2024) and Gomaa (2019). We retained snippets with a similarity score above 0.45% and selected the three most similar ones.

3.2.3 Hallucination Detection via Prompting

The next stage involves constructing the prompt shown in Figure 2, which illustrates its structure. The prompt consists of three main components: (1) an example demonstrating the expected extraction process by the model, (2) a dynamic section that adapts based on the snippets and model output, including its tokenized version that segments the text and indicates position and (3) a final instruction to organize the execution order, ensuring coherence, particularly for long-text evaluations. We tested the system using a chain-of-thought approach with one-shot and few-shot learning. The one-shot approach achieved the best performance, while the other methods were largely ineffective due to poor results.

Finally, we cleaned the data to ensure the extracted hallucinations were meaningful. We disregarded if an identified hallucination exceeded the actual tokens of the evaluated response, the probability exceeded one, or fell below 0.

3.3 NLP Techniques System

The system employs the same elements proposed in **LLM Base System** in section 3.2, **Context Retrieval Using Google Snippets**, and **Snippet Ranking Based on Semantic Relationship**, except for **Hallucination Detection via Prompting**. Instead, multiple techniques are implemented for data cleaning, followed by a token extraction process that identifies the position of each sentence within the text.

The key stage is lexical comparison. We evaluated the generated responses based on a *left outer join* operation between the six best snippets' word sets. This process helps identify potential hallucinations in the responses. However, a filtering step is applied using *Part of Speech* (PoS) analysis to avoid false positives. We considered only words belonging to the categories *NOUN, PROPN, VERB, NUM*, and *X*, using Spacy. The filtered words are

```
Here are 1 examples of hallucination detection:
Example 1:
Context: The Olympic Games are a major international sports competition.
Generated: Petra van Stoveren won a silver medal in the 2008 Summer Olympics in Beijing, China.
Generated with positions: <0>Petra<4> <6>van<8> <10>Stoveren<17> <19>won<21> <23>a<23> <25>silver<30> <32>medal<36>
<38>in<39> <41>the<43> <45>2008<48> <50>Summer<55> <57>Olympics<64> <66>in<67> <69>Beijing,<76> <78>China.<83>
Output: {"soft_labels": [{"start": 25, "end": 31, "prob": 0.9}, {"start": 45, "end": 49, "prob": 1.0}, {"start": 69,
"end": 83, "prob": 0.9}]}
Explanation: The specific medal, year and location details are not supported by context.

Now analyze this case:
Context: {['best Snippet 1', 'best Snippet 2', 'best Snippet 3']}
Generated Text:  {No, Albero Foulois was not in any of the FIFA World Cup finals.}
Generated with positions: {<1>No,<3> <5>Albero<10> <12>Foulois<18> <20>was<22> <24>not<26> <28>in<29> <31>any<33>
<35>of<36> <38>the<40> <42>FIFA<45> <47>World<51> <53>Cup<55> <57>finals.<63>}

Task:
Analyze the generated text and identify potential hallucinations by:
1. Compare the generated text with the given context
2. Mark spans that contain information not supported by the context
3. Assign probability scores (0.0-1.0) to potential hallucinations
4. Return the results in JSON format with start/end positions
```

Figure 2: One example of prompt construction for the LLM base system.

classified with a minimum probability of 90%, as shown in Figure 3.

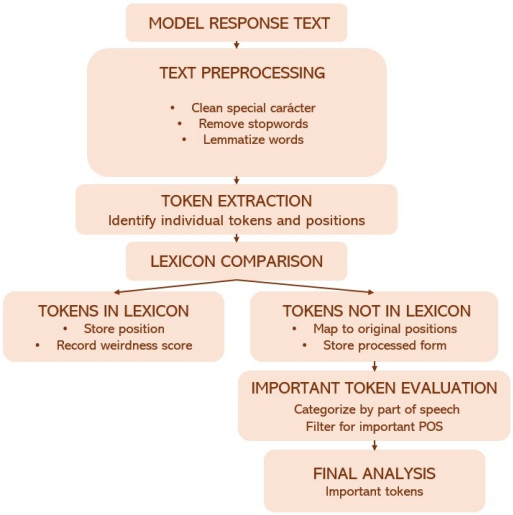

Figure 3: NLP base system proposal

4 Results

We obtained some of the results after the competition had ended due to internal issues with the code. However, tests with different models are shown in Table 4. The best model during the evaluation phase was the LLM system using *deepseek-r1-distill-llama-70b*, as proposed by (DeepSeek-AI et al., 2025). This model ranked 25th out of 41 for the IoU and 28th out of 41 in Spearman correlation on the English Dataset, as shown in Table 1.

4.1 Intersection over Union (IoU)

The IoU metric measures the overlap between predicted hallucination and reference spans. The following definitions apply:

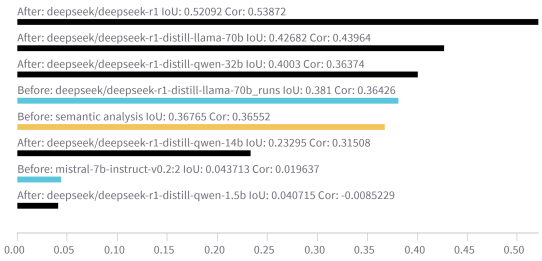

Figure 4: Performance comparison of different models before and after the evaluation phase for the English dataset in SemEval Task 3. The figure presents Intersection over Union (IoU) and correlation (Cor) scores for each model. Black bars represent post-evaluation results, while blue and yellow indicate evaluation results from different baseline approaches.

- S_R represents the set of indices corresponding to the reference hallucination spans R, which are the ground-truth hallucination positions in the text.
- S_P represents the set of indices for the predicted hallucination spans P, as identified by the model.
- IoU quantifies the similarity between S_R and S_P, ensuring that both precision and recall are considered.

$$S_R, S_P = \bigcup_{\text{span} \in R} \left\{ i \mid i \in \left[\text{span}_{\text{start}}, \text{span}_{\text{end}}\right) \right\}$$

$$\text{IoU}(S_R, S_P) = \begin{cases} 1, & \text{if } S_R = S_P = \emptyset, \\ \frac{|S_R \cap S_P|}{|S_R \cup S_P|}, & \text{otherwise.} \end{cases}$$

Table 1: Final Ranking for Intersection over Union.

Team	Position	Intersection over Union	Spearman Correlation
iai_MSU (Top performance)	1/41	0.650899	0.629443
Ours (LLM system)	25/41	0.380997	0.364264
Ours (NLP system)		0.3655	0.367

Spearman Correlation

Spearman correlation assesses how well the predicted hallucination probabilities align with the reference labels. Given soft labels with text length L, probability vectors $\mathbf{r}$ and $\mathbf{p}$ are constructed:

$$r_k, p_k = \begin{cases} r^i_{\text{prob}} & \text{if } k \in [r^i_{\text{start}}, r^i_{\text{end}}), \\ 0.0 & \text{otherwise,} \end{cases} \quad (1)$$

The Spearman correlation (ρ) is computed as:

$$\text{Cor} = \begin{cases} 1.0 & \text{if Var}(\mathbf{r}) = 0 \text{ and Var}(\mathbf{p}) = 0, \\ 0.0 & \text{if Var}(\mathbf{r}) = 0 \text{ or Var}(\mathbf{p}) = 0, \\ \rho(\mathbf{r}, \mathbf{p}) & \text{otherwise.} \end{cases} \quad (2)$$

The Spearman rank correlation coefficient ρ is defined as:

$$\rho = 1 - \frac{6 \sum_{k=1}^{L} d_k^2}{L(L^2 - 1)} \quad (3)$$

5 Ethical Considerations

The primary ethical consideration in this article is the potential bias in Google's snippet answers and the LLM responses, which can affect users' credibility judgments of the presented information (Bink et al., 2022). The system that generates featured snippets should ensure the accuracy of retrieved information. It is also essential to recognize that the filtering process created by the LLM may introduce biases due to the nature of its responses (Gallegos et al., 2024).

6 Conclusion

The system has the potential to identify hallucinations and resolve them based on context, as demonstrated in previous executions after the competition ends. Despite its low performance during the competition, We can improve the snippet extraction system to ensure data availability for each iteration. Additionally, we can optimize the prompt by testing different variations. Finally, we could apply fine-tuning techniques to train the models on the expected response format and the necessary processes to generate accurate answers.

The primary limitations encountered were related to scraping snippet boxes. Excessive requests could lead to an IP ban, requiring proxy rotation services to retrieve the information. Despite this, some snippets were still unavailable. During the testing phase, we utilized a dataset where snippets were absent for 31 of 154 data points.

Acknowledgments

We dedicate this work to the master's degree scholarship program in Engineering at the Universidad Tecnológica de Bolívar (UTB) in Cartagena, Colombia.

We want to express our gratitude to the team at the VerbaNex AI Lab [1] for their dedication, collaboration, and ongoing support of our research endeavors.

Team KiAmSo at SemEval-2025 Task 11: A Comparison of Classification Models for Multi-label Emotion Detection

Kimberly Sharp, Sofia Kathmann and **Amelie Rüeck**
University of Tübingen
Department of General and Computational Linguistics
{ kimberly.sharp,sofia.kathmann,amelie.rueeck } @student.uni-tuebingen.de

Abstract

The aim of this paper is to take on the challenge of multi-label emotion detection for a variety of languages as part of Track A in SemEval 2025 Task 11: Bridging the Gap in Text-Based Emotion Detection. We fine-tune different pre-trained mono- and multilingual language models and compare their performance on multi-label emotion detection on a variety of high-resource and low-resource languages. Overall, we find that monolingual models tend to perform better, but for low-resource languages that do not have state-of-the-art pre-trained language models, multilingual models can achieve comparable results.

1 Introduction

Interlocutors rarely speak in an entirely neutral manner: more often than not, speakers will use emotions in their speech. Emotions are an important driving force of conversations and understanding how language and emotions interact is crucial for linguistics. In NLP, the field of *Emotion Recognition* is concerned with identifying the emotions of the speaker of an utterance. Ekman (1992) defines six basic emotional states: joy, sadness, fear, anger, surprise, and disgust. These have since been used widely in emotion recognition to assign the perceived emotion of a speaker during an utterance.

While many systems have been developed that can assign one singular emotion to a text, the challenge of *Multi-label Emotion Detection* is a newer and less investigated field. Nonetheless, it is an important area, since speakers rarely feel emotions in isolation and multiple emotions often occur in conjunction with each other, for example anger and disgust.

Track A of SemEval 2025 Task 11, "Bridging the Gap in Text-Based Emotion Detection" (Muhammad et al., 2025b), aims at solving the issue of multi-label emotion detection for 28 different languages (Muhammad et al., 2025a), including many low-resource languages. To solve this task, our team compares different pre-trained language models on their ability to perform multi-label emotion classification, comparing monolingual models like GottBERT (Scheible et al., 2024) and Twitter-RoBERTa (Barbieri et al., 2020) to multilingual models such as XLM-T (Loureiro et al., 2022). Our aim is to see how multilingual models perform when they are fine-tuned solely on one language versus multiple languages simultaneously. This could provide important insights into maximizing the usability of multilingual models for low-resource languages. We further employ task-adaptive pre-training and optimized classification thresholds at each epoch to improve performance.

2 Background

Early work in NLP largely focused on *Sentiment Analysis*, the classification of a text into negative or positive valence classes (Mohammad and Kiritchenko, 2018). In contrast, *Emotion Recognition* deals with assigning texts to distinct emotion classes. Sentiment Analysis is often a case of binary classification, assigning either positive or negative valence to a text. Emotion Recognition is often implemented as a multi-class classification problem, selecting the most salient emotion out of multiple emotion classes. However, a multi-class approach neglects the co-occurrence of emotions that cannot be separated from each other (Mohammad and Kiritchenko, 2018). This type of relation requires a multi-label strategy. Furthermore, most existing multi-label emotion classifiers focus on high-resource, predominantly Indo-European languages such as English, with fewer systems available for low-resource languages.

Earlier approaches to multi-label emotion recognition employed *classifier chains* to account for the correlation between the different emotions. For instance, participants of SemEval 2018 Task 1 com-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1542–1548

bined their best performing classifier for every emotion into a chain which passes the predicted labels to the next classifier in the chain, sorting the classifiers by performance (highest to lowest). Their best performing classifier chain achieved a macro-averaged F1 score of 0.493 (De Bruyne et al., 2018).

More recent approaches involve *Latent Emotion Memory* networks, which aim at learning the latent emotion distribution and emotion intensity in a text and leverage it into a classification system. These consist of a variational auto-encoder that learns the emotion from the input and a memory unit that captures the most salient features for that emotion. On the SemEval 2018 dataset, they achieved a macro F1 score of 0.567 (Fei et al., 2020).

Other systems include the *Sequence-to-Emotion (Seq2Emo)* approach, which is essentially a sequence-to-sequence model that encodes the utterance using an LSTM and then uses an LSTM-based decoder to perform binary classification on the emotions sequentially. This approach achieved a macro F1 score of 0.5192 on the SemEval 2018 dataset (Huang et al., 2021).

Since then, the rise of pre-trained language models and transformer-based architectures has opened up a variety of new ways to approach multi-label emotion detection. However, it is still unclear which pre-trained models are well suited for emotion detection, and how to best fine-tune models for this task. A further open question is how to build multilingual models that can perform emotion detection in a variety of languages.

This is the aim of our approach: We compare several monolingual and multilingual pre-trained language models and fine-tune them for emotion classification, comparing the pre-trained models to a logistic regression baseline. The following sections will explore the different systems that we have tried and their respective results.

3 System Overview

For our system, we mainly rely on the XLM-Twitter (XLM-T) base model for sequence classification (Barbieri et al., 2022), which continues pre-training from a publicly available XLM-R checkpoint (Conneau et al., 2020) using nearly 200M tweets from over 30 languages. We then apply different fine-tuning strategies and observe the effects on model performance. Additionally, we contrast the performance of a multilingual model like XLM-T with specialized monolingual models for German and English. Due to time and resource constraints, we only analyze a subset of 10 languages that includes both high-resource and low-resource languages: Afrikaans, Amharic[1], Algerian Arabic, Moroccan Arabic, Mandarin Chinese, German, English, Spanish, Hausa, and Hindi. We use the training, development, and test datasets provided by the SemEval2025 Task 11 organizers (Muhammad et al., 2025a; Belay et al., 2025).

3.1 Linear Baseline

Nowadays, traditional machine-learning algorithms such as Logistic Regression or Random Forests are often overlooked in favour of transformer-based architectures. Nonetheless, their cost-effectiveness and explainability make them an interesting baseline that can provide a useful reference point for evaluating transformer-based approaches.

For our baseline, we convert the input texts into sparse tf-idf vectors and train a Logistic Regression classifier using the One-vs-Rest (OVR) multiclass strategy. This strategy consists of training one binary classifier independently for each label – each classifier fits the current label against all the other labels.

When running our experiments, this simple baseline achieved an F1 score similar to XLM-T for 4 out of 10 languages and even outperformed it for Hausa (see Table 1).

3.2 Fine-tuning monolingual models

To better contextualize the performance of the multilingual XLM-T, we fine-tune a specialized, fully monolingual model for German and English respectively. Due to its well-suitedness to the task data, we chose Twitter-RoBERTa (Loureiro et al., 2022) for English. There were considerably fewer options for German, so we decided on the GottBERT base model (Scheible et al., 2024), which is not pre-trained on tweet data, but is based on the RoBERTa architecture (Liu et al., 2019). We then fine-tune both models on their respective language data for Track A.

3.3 Fine-tuning a multilingual model

In order to be able to run the task of emotion detection on languages with less resources available than German and English, we leverage the pre-trained

[1] Belay et al. (2025) provide the datasets for the Ethiopian languages Amharic, Oromo, Somali, and Tigrinya.

multilingual large language model XLM-T. We first fine-tune the model on the joint training data for all 10 languages in our sample, resulting in a single multilingual classifier for all languages. To compare, we then fine-tune the same model, XLM-T, on the training data for each language, resulting in one classifier per language.

3.4 Task-adaptive pre-training

Researchers like Gururangan et al. (2020), as well as submissions to previous years of SemEval, for example by Wang et al. (2023), have shown the effectiveness of continuing to pre-train and adapt large language models that have so far been trained on huge, heterogeneous corpora. Domain-adaptive and task-adaptive pre-training – continued pre-training with domain- and task-specific data – consistently improves performance on the domains and tasks the additional data is from. Since XLM-T builds on XLM-R by training on tweet data, it can be said to already come with a certain amount of domain-adaptive pre-training off-the-shelf. Additionally, when exploring the effects of language-adaptive pre-training (domain-adaptive pre-training where the target language is considered to be the domain) and task-adaptive pre-training on multilingual sentiment analysis, Wang et al. (2023) find task-adaptive pre-training to be the main contributor to improved classifier performance. Therefore, and also due to time and resource constraints, we only apply a minimal version of task-adaptive pre-training (TAPT).

For that, we continue training our XLM-T model on the original masked language modeling (MLM) training objective, using the unlabeled training data from the 10 languages in our sample. We then fine-tune it for emotion classification on the joint data of 4 languages: German, English, Spanish and Hindi.

3.5 Fine-tuning a T5 model

We also further investigate the T5 pre-trained model. We use the T5 base model (Raffel et al., 2020) initially on English only and then move to T5 fine-tuned for Emotion Recognition (Romero), as it has similar emotion labels to our task. Although both T5 models used are English monolingual models, we run the fine-tuned model on German as well for comparison purposes. In an early analysis, the results for English of the T5 fine-tuned model were competitive to the scores obtained with XLM-T without fine-tuning. However, due to T5 being outperformed by the English Twitter-RoBERTa model, as well as the lack of a T5 model fine-tuned specifically on tweet data, we focus on the RoBERTa-based models. Nonetheless, we believe that T5 achieving similar results to a RoBERTa-based model may be indicative of further research into T5-based models possibly proving successful in a monolingual framework.

4 Experimental Setup

In this section, we provide details on our considerations about the data and training of the models.

4.1 Datasets

Mentions of usernames in the data have already been replaced by "@<username>", and URLs by "##URL##" in the datasets distributed by the task organizers. Since this low-impact, potentially sensitive data has already been cleaned, and to preserve all meaningful features in the data, we do not apply any further preprocessing.

Before training, we combine the training and development sets to make our own stratified training and validation splits using the *skmultilearn* library by Szymański and Kajdanowicz (2017).

4.2 Training with optimized thresholds

The training data contains large class imbalances between the different emotions, making some emotions harder to learn than others. To account for this, we optimize individual thresholds for each emotion to allow for lower thresholds for smaller classes (leading to a higher recall) and higher thresholds for larger classes (leading to a higher precision). At each training epoch, we start with a preliminary threshold of 0.5 for each emotion. After the epoch, we evaluate the current model on a validation set, and then iteratively adjust the thresholds until we reach the best possible macro-averaged F1 score. We then re-run the predictions with the optimized thresholds and calculate the loss. The model with the currently best F1 score is saved as our checkpoint.

To evaluate the model on the development set, we again compute an individual classification threshold for each emotion using the same strategy. Then for running inference on the test set, we directly apply the thresholds of the best training epoch to the classification.

4.3 Training resources

For mono- and multilingual fine-tuning, we use the AdamW optimizer (Loshchilov and Hutter, 2019)

Model	afr	amh	arq	ary	chn	deu	eng	esp	hau	hin

Table 1: Overview of macro-averaged F1-scores for all our models and analyzed languages

with an initial learning rate of 1e-5 and a maximum number of 10 epochs. For task-adaptive pre-training, we use AdamW with a learning rate of 5e-5. We were only able to run TAPT for 3 epochs. For both fine-tuning and continued pre-training we use a batch size of 16 and a maximum sequence length of 150.

All transformer-based architectures were trained on T4 or L4 GPUs as available through Google Colab and relying on the *Huggingface Transformers* library (Wolf et al., 2020). The Logistic Regression classifier was trained using the *sklearn* library (Pedregosa et al., 2011).

5 Results

Overall, we were able to outperform the SemEval Baseline in 7 out of 10 submitted languages, only for Amharic, German, and Hindi we were not able to achieve a score above the baseline. Table 1 shows the results from all our experiments, while Table 2 shows our final submission results. Since we ran some of the experiments after the end of the evaluation phase, we were not able to submit our final best scores for all languages. XLM-T achieves the best results in 7 out of 10 languages, although some languages benefit more from monolingual fine-tuning, while others do better with multilingual fine-tuning. For German and English, their specialized monolingual models GottBERT and Twitter-RoBERTa outperform XLM-T, regardless of the fine-tuning strategy. Interestingly, the best performing model for Chinese is XLM-T with task-adaptive pre-training (TAPT) and joint fine-tuning on four languages, even though Chinese had not been in the set of languages that model was fine-tuned on.

With the exception of Chinese, we could not replicate previous findings showing that applying task-adaptive pre-training significantly increases model performance. In fact, its performance for Afrikaans and Hausa is quite weak in comparison. However, this system still achieves competitive results for the majority of the languages. We suppose that due to our limited resources, we were not able to fully tap into the potential of TAPT, as the pre-training process was aborted after 3 epochs, which is not nearly enough time for the model to converge. This exactly might have been the issue with Afrikaans and Hausa, which are also the only two languages in our set not present in the top 30 languages XLM-T was originally trained on (Barbieri et al., 2022).

Our resource limitations for applying task-adaptive pre-training are an example for the trade-off between performance and resource use that researchers in this field are continuously faced with. On that note, it is interesting to remark that in our experiments, Logistic Regression slightly outperforms XLM-T for Hausa. We do not have a solid hypothesis for this, especially since calculating the SCUMBLE score (Charte et al., 2019) for our 10 languages suggests that Hausa, along with Chinese, has the highest label concurrency (minority labels occurring mostly or only together with majority labels), which should make it especially difficult to get accurate classification results for their minority labels.

When comparing the performance of joint multilingual and monolingual fine-tuning, there seems to be no clear winner at first. Taking into account

whether the target language is low-resource or high-resource however, there seems to be a tendency for low-resource languages to prefer multilingual training. Afrikaans, and especially Amharic, seem to benefit from the additional information present in the other language data with an increase of the F1 score from 0.53 to 0.6 for the latter. Conversely, high-resource languages mostly perform better with monolingual training. This is especially highlighted when comparing the language-specific models GottBERT and Twitter-RoBERTa with the multilingual XLM-T fine-tuned on German or English data. Both fully monolingual models outperform the multilingual one.

For completeness, it would be interesting to compare the performance of XLM-T with TAPT, fine-tuned for each language data individually, with our jointly fine-tuned TAPT-applied XLM-T. It remains an open question whether with our setup we would reach a similar conclusion as Wang et al. (2023), where the advantages of monolingual training become less pronounced in the presence of task-adaptive pre-training.

Language	Micro F1	Macro F1
Afrikaans	0.5236	0.4673
Amharic	0.5566	0.5345
Arabic (Algerian)	0.5118	0.4912
Arabic (Moroccan)	0.5111	0.5013
Chinese	0.6902	0.5664
German	0.6537	0.5976
English	0.7537	0.7251
Spanish	0.7338	0.7635
Hausa	0.5887	0.5837
Hindi	0.7762	0.7855

Table 2: Submission scores for our languages

With our submitted results, we ranked 18th for Afrikaans, 20th for Moroccan Arabic, 21st for Algerian Arabic, 22nd for Hausa, 23rd for Spanish, 24th for German, 26th for Amharic, 26th for Chinese, 31st for Hindi, and 37th for English in the final ranking.

6 Conclusion

Overall, our systems aimed at comparing the performance of mono- and multilingual pre-trained language models for multi-label emotion recognition. We find that when the necessary resources are available, a specialized monolingual approach outperforms a generalized multilingual one. Emotion recognition for high resource languages like German and English works best without the interference of other languages.

Nonetheless, the strength of multilingual models lies in their versatility and their ability to leverage information from higher-resource languages to make inferences about lower-resource languages. As such, multilingual models allow us to tackle tasks with low-resource languages where a specialized approach is simply not feasible. Our example of Chinese shows that classifiers can strongly benefit from being fine-tuned on a set of languages they are not even a part of. Identifying those source languages that are especially useful for improving classification performance in a target language is a task that researchers tackle in the field of zero-shot classification (Lin et al., 2019), which was also the focus of Track C in this SemEval task.

Abstract

In this paper, we present our system developed for participation in SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection. We compare three approaches for multilingual, multi-label emotion classification: fine-tuning a single XLM-R model, ensembling multiple XLM-R models, and a prompt-based method using a large language model. We evaluate these approaches across a diverse set of languages, ranging from high-resource to low-resource settings. Our experiments show that fine-tuning encoder models consistently outperforms the prompt-based approach for most languages. Additionally, we compare the performance of monolingual and multilingual models, observing mixed results: while multilingual models outperform monolingual ones for certain languages, the opposite trend is seen for others.

1 Introduction

Emotions are both familiar and enigmatic. We experience and manage them daily, yet they remain complex, nuanced, and often difficult to articulate (Muhammad et al., 2025a). Additionally, language is used in intricate ways to convey emotions (Wiebe et al., 2005; Mohammad and Kiritchenko, 2018). Moreover, there is significant variability in how individuals perceive and express emotions, even within the same culture or social group.

Automatic emotion recognition encompasses several tasks, such as detecting a speaker's emotions, identifying the emotions conveyed in written text, and recognizing emotions evoked in a reader (Mohammad, 2021; Teodorescu and Mohammad, 2023). SemEval-2025 Task 11 focuses on identifying the emotion that most people believe the speaker is experiencing based on a given sentence or short text snippet (Muhammad et al., 2025b). The first track addresses multi-label emotion detection across 30 languages (Belay et al., 2025; Muhammad et al., 2025a). The goal is to predict one or more emotions that most people believe the speaker is experiencing, based on a sentence or short text snippet uttered by the speaker. The emotions include : joy, sadness, fear, anger, surprise, and disgust.

In this paper, we explore two distinct approaches: fine-tuning-based approach (FBA) and prompt-based approach (PBA). For FBA, We frame the task as a multi-label sentence classification task and we experiment with monolingual and multilingual encoder models. We provide further details in Section 3.2. For PBA, we leverage a pre-trained large language model (LLM) to classify emotions without fine-tuning. We experiment with few-shot prompting, where we provide positive and negative examples for each emotion label in the same language as the input text. The model then analyzes the input text based on these examples and produces emotion scores. For all PBA experiments, we use GGPT-4o mini as our primary LLM (OpenAI et al., 2024) and further details of this approach are provided in Section 3.1.

In summary,

- We compare the effectiveness of monolingual and multilingual models in the task of multi-label emotion classification. We observe mixed results, with some multilingual models performing better for certain languages while performing worse for others.

- We explore the effectiveness of a prompt-based approach for multi-label emotion classification. The prompt-based approach shows lower performance compared to fine-tuned models across most languages. For some languages, such as German and Chinese, it results in a two-point F1-score drop.

[†]These authors contributed equally to this work.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1549–1556

- We analyze the cross-lingual differences in both of our approaches and observe a correlation between the resource availability of a language and its performance in the classification task, with high-resource languages showing higher performance.

2 Background

Emotion detection has become crucial due to its psychological, social, and commercial significance (Maruf et al., 2024; Muhammad et al., 2025a). Individuals express their emotions through language, body gestures, and facial expressions. Automatic emotion recognition encompasses various sub-tasks, such as detecting a speaker's emotions, identifying the emotions conveyed in written text, or recognizing emotions evoked in a reader of a target text (Mohammad, 2021; Teodorescu and Mohammad, 2023).

2.1 Emotion Detection

In the context of text analysis, emotion detection models analyze text to identify the underlying sentiment of the author. By relying on different aspects of the text, such as word choice and tonality, a model can learn to associate a text with various emotional categories, such as happiness, sadness, anger, or fear (Acheampong et al., 2020; Nandwani and Verma, 2021). These models have applications in various domains, including social media monitoring, customer feedback analysis, and sentiment analysis of product reviews (Acheampong et al., 2020).

2.2 Task Description

SemEval-2025 Task 11 focus on identifying the emotion that most people would associate with a speaker based on a text snippet (Muhammad et al., 2025b). The first track of the task involves multi-label emotion detection across various languages. Given a specific text snippet, the goal is to predict one or more emotions that the speaker is perceived to be experiencing. The target emotions include joy, sadness, fear, anger, surprise, and disgust. The distribution of the data across languages is shown in Figure 1.

2.3 Pre-trained Models

XLM-R is a RoBERTa based model pre-trained on 100 languages using CommonCrawl-100 data (Lample and Conneau, 2019). XLM-R obtain state-of-the-art results on many down stream task. We use XLM-R as one of our base model for fine-tuning.

AfroXLMR is a multilingual model created by MLM adaptation of XLM-R-large model on 17 under-resourced languages (Alabi et al., 2022). We use AfroXLMR for language that do not have monolingual language model such as Amharic, Tigrinya, and Oromo.

AraBERT is an Arabic pre-trained language model based on the BERT architecture (Antoun et al.). We use AraBERT to compare the effectiveness of Arabic monolingual and multilingual model variants (XLM-R) by fine-tuning both on Arabic data.

MacBERT is a monolingual Chinese model pre-trained with a novel MLM as correction pre-training task Cui et al. (2020). MacBERT enhances performance in Chinese NLP tasks by incorporating a novel masking strategy and whole word masking which has successfully combined the advantages from models like RoBERTa (Liu et al., 2019) and ALBERTa (Lan et al., 2019). We use MacBERT similar to AraBERT to compare the effectiveness of Chinese monolingual and multilingual model variants (XLM-R) by fine-tuning both on Chinese data.

ModernBERT is a recently released encoder model which shows improvement many down-stream tasks across many benchmarks (Warner et al., 2024). We use ModernBERT to compare the effectiveness of English monolingual and multilingual model variants (XLM-R) by fine-tuning both on English data.

RubertBaseCased is a monolingual Russian model pre-trained based on BERT architecture Kuratov and Arkhipov (2019). We use RubertBaseCased to compare the effectiveness of Russian monolingual and multilingual model variants (XLM-R) by fine-tuning both on Russian data.

3 System Description

We explore two distinct approaches: the Fine-Tuning-Based Approach (FBA) and the Prompt-Based Approach (PBA). For the FBA, we experiment with monolingual and multilingual encoder models by framing the task as a multi-label sentence classification problem. For the PBA, we uti-

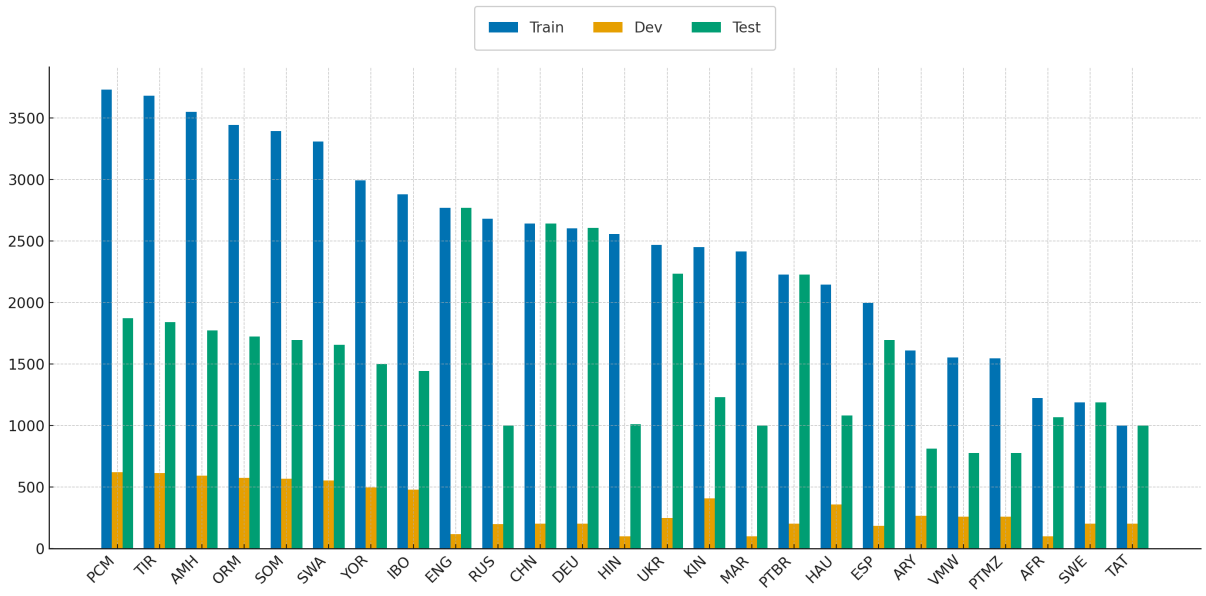

Figure 1: Distribution of train, development, and test samples across the 25 target languages. The figure highlights significant data imbalance, with across, which may impact model performance and cross-lingual generalization.

Table 1: F1-Macro Scores of XLM-R, ensemble of five XLM-R models (XLM-5), and GPT4 models on the test set. The table is sorted by the XLM-R score. Results on the development set are available in Table 3.

lizes a pre-trained large language model (LLM) to classify emotions without fine-tuning. We use an English prompt for all of the samples. We use few-shot prompting approach by providing positive and negative examples per emotion label in the same language as the input text. The model processes the input text using these examples and generates emotion scores (0 to 1). We use GPT-4o mini as our main LLM for all of the PBA experiments (OpenAI et al., 2024).

3.1 Prompt Based Approach

Given the general nature of the task, we hypothesized that a well-trained LLM could effectively detect emotions without requiring fine-tuning. To align with the competition guidelines, we adapted the model by providing it with 20 randomly selected positive and negative examples for each emotion label, ensuring that the examples matched the language of the input text. We choose these numbers to balance providing sufficient context for the LLM while maintaining reasonable response times.

3.1.1 In Context Learning

For each prompt, we included the input text to be classified, 20 positive and 20 negative examples in the same language as the input text for each emotion label, and a request for the LLM to output a JSON object with emotion scores ranging from 0 to 1 for each label. We used the GPT-4o mini model with a temperature of 0 to ensure deterministic outputs. The prompt template is available in Appendix A.4.

3.1.2 Threshold Selection

To determine the optimal classification thresholds, we compute the F1-score for each emotion label across the development dataset. We evaluate thresholds ranging from 0 to 1 in increments of 0.01 and select the values that maximized the F1 metric. Finally, we apply these thresholds to generate predictions on the test dataset.

3.2 Fine-tuning Approach

In the fine-tuning approach, we experiment with both monolingual and multilingual models. For English, Chinese, Arabic, Russian, and Ukrainian, we test both monolingual and multilingual models. For under-resourced languages such as Amharic and Tigrinya, we experiment with two competitive multilingual models: XLM-R and AfroXLMR. For the remaining languages, we use XLM-R.

3.3 Model Ensemble

We use an ensemble of five models, each initialized with a different seed of the XLM-R model. We apply both hard voting and soft voting strategies. In hard voting, we aggregate the class label votes from all models and predict the class with the highest vote count. In soft voting, we sum the predicted probabilities for each class label and select the label with the highest cumulative probability.

4 Analysis and Conclusion

4.1 Monolingual and Multilingual Model

We compare monolingual and multilingual models to determine whether using a specialized model improves the performance of a multilingual model for a target language. We select six languages that have both a monolingual model and are included in the XLM-R multilingual model: English, Chinese, Arabic (Algerian and Moroccan), Russian, and Ukrainian. We follow a similar fine-tuning procedure for the multilingual and the monolingual models in their respective target languages. Specifically, we use ModernBERT (Warner et al., 2024) for English, AraBERT (Antoun et al.) for Arabic, and MacBERT (Cui et al., 2020) for Chinese, and RubertBaseCased for Russian. Table 2 presents the results of the test data. Overall, the multilingual model performs better than the monolingual model in four out of six languages. We observe a significant difference in Russian, where the multilingual model demonstrates strong performance, whereas English is an outlier, with the monolingual model outperforming its multilingual counterpart.

In our study on multi-label emotion classification in Chinese, we selected MacBERT (Masked Language Model as Correction BERT) (Cui et al., 2020) as the pre-trained model.

As shown in Table 5, the Moroccan Arabic (ARY) F1-Macro score for five models of the monolingual ensemble is slightly higher than the multilingual model XLM-R and the XLM-5 ensemble in the development set. However, its performance is lower in the test set. There are some possible reasons for this phenomenon. First, the limited dataset specific to one language might restrict the generalization of the model whereas the multilingual models benefit from exposure to a vast corpus from multiple languages. Second, multilingual models can take advantage of similarities between languages to transfer knowledge from high-resource languages to low-resource ones, an advantage that monolingual models lack.

Language	Multi-5	Mono-5
ARQ	54.71	**55.53**
CHN	**64.65**	59.69
ENG	72.94	**73.06**
RUS	**86.64**	54.85
UKR	**67.28**	57.48
ARY	**59.21**	57.42

Table 2: Comparison of Multilingual and Monolingual ensemble model for Arabic, Chinese and English. Multi-5 represents an ensemble of a multilingual model in this case XLM-R and Mono-5 represent an ensemble of a monolingual model - AraBERT for Arabic, MacBERT for Chinese, ModernBERT for English, RuBERT for Russian and for Ukranian.

4.2 Model Prompting vs Fine-tuning

Table 1 shows the F1-scores across 25 languages for three methods. XLM-R exhibits wide variation across languages, with strong performance for languages like Hindi and Russian and lower scores for low-resource languages such as Yoruba and Makhuwa. The ensemble method, XLM-5, provides a noticeable performance improvement, particularly for Marathi (86.67 vs. 72.7), although it still struggles with low-resource languages such as Yoruba and Makhuwa. The GPT-4-based approach shows lower performance compared to fine-tuned models across most languages, with some languages, such as German and Chinese, showing a two-point F1-score difference. Overall, the ensemble approach outperforms the single-model approach (XLM-R) across most languages, especially for high-resource languages like Hindi, Russian, and Spanish. The prompt-based approach performs significantly worse than both XLM-R and XLM-5, particularly for low-resource languages. Its advantage may lie in flexibility for few-shot learning, but it appears less effective for structured tasks like multi-label classification. Both XLM-R and

XLM-5 show a decline in performance for under-resourced languages, while GPT-4 struggles even more with these languages.

4.3 Cross-lingual Analysis

We compare performance variations across languages using the language classification schema proposed by (Joshi et al., 2020). This taxonomy categorizes languages into five classes, ranging from class 0, representing low-resource languages, to class 5, representing high-resource languages. We observe a correlation between a language's resource level and its performance in the classification task. High-resource languages in classes 4 and 5, such as Hindi, Russian, and Spanish, tend to achieve higher scores. Conversely, low-resource languages in class 1, including Igbo, Somali, and Kinyarwanda, exhibit lower F1-scores. The lowest F1-scores are typically observed for languages from taxonomy classes 0 and 1, such as Emakhuwa, Yoruba, and Swahili. The full list of languages and their taxonomy classifications is provided in Table 4 in Appendix A.2.

4.4 Conclusion

In this work, we compare the effectiveness of prompt-based and fine-tuning-based approaches. We further analyze the performance of monolingual and multilingual models for multi-label emotion classification. Our analysis indicates mixed results, with multilingual models outperforming monolingual models for some languages while underperforming for others. Additionally, we explore the effectiveness of the prompt-based approach and find that it generally performs worse than fine-tuned models across most languages. Furthermore, our analysis of cross-lingual differences reveals a correlation between a language's resource availability and its classification performance, with high-resource languages achieving higher F1-scores. These findings highlight the limitations of prompt-based approaches and emphasize the importance of language-specific adaptations in multilingual emotion classification.

Limitations

Despite achieving strong results across multiple languages, our work has several limitations,Our work has several limitations. First, the prompt-based approach exhibited slight output variance despite a low temperature setting, which we did not quantify. Second, threshold selection was based solely on the development set, introducing potential overfitting risks. Third, we did not conduct detailed error analysis to explain model failures across languages. Our cross-lingual analysis relies on an older language resource taxonomy, which may not fully capture current multilingual capabilities.

Acknowledgments

This work was conducted as part of an internship by Wondimagegnhue Tufa at Huawei Technologies Finland Research Center. We thank the Huawei Research team for providing computational resources and technical support throughout the project. We also express our gratitude to the SemEval-2025 Task 11 organizers for creating the multilingual emotion detection benchmark and offering valuable guidelines. Finally, we appreciate the feedback from anonymous reviewers, which helped improve the quality of this paper.

A.4 Prompt template

```
Given the following positive and
    negative examples for each emotion
    label, classify the emotion of the
    input text.
The response should be a JSON object
    with scores for each emotion label,
    where each score is between 0 and 1.
The labels are: anger_label,
    disgust_label, fear_label, joy_label
    , sadness_label, surprise_label.

Positive samples for anger_label:
- [20 randomly selected samples]

Negative samples for anger_label:
- [20 randomly selected samples]

...

Now, classify the following input text
    and return a JSON object with
    emotion scores for each of the
    labels.

### Input Text:
[input text]

### JSON Output (example format):
{
  "anger_label": 0.2,
  "disgust_label": 0.3,
  "fear_label": 0.8,
  "joy_label": 0.1,
  "sadness_label": 0.6,
  "surprise_label": 0.7
}

Abstract

This paper describes Gradient Ascent and Task Vectors as LLM unlearning methodologies applied to SemEval 2025's task 4. This task focuses on LLM unlearning on specific information under the constraints of preserving the model's advanced text generation capabilities; meaning that our implementations of these algorithms were constrained both in the information datasets as well as the overall effect of each algorithm in the model's general performance. Our implementation produced modified language models that ranked 7th out of 14 valid participants in the 7B parameter model, and 6th out of 24 in the 1B parameter model.

1 Introduction

Large Language Models (LLMs) are one of the most widely used NLP tools for multiple different purposes in and outside of academia and technological research. State of the art models require a substantial amount of training data in order to work at their fullest potential. However, these training datasets may contain personal information and confidential data from multiple sources. If utilized inappropriately, this could result in legal complications arising from infringements of copyright, or the right to be forgotten. Given the probabilistic nature of LLM text generation, and jail-breaking techniques, sensitive information is at risk of being generated in every day usage.

The SemEval 2025 task: Unlearning Sensitive Content from Large Language Models (Ramakrishna et al., 2025) was created to solve this problem. This task works under the assumption that retraining these models from scratch and omitting sensitive information is computationally and economically expensive (Crawford, 2021), meaning that the most efficient approach consists of applying algorithms that modify only certain model weights corresponding to the sensitive information. These modifications should translate to the model being completely unaware of said information, making it unable to generate it by accident, all while preserving the model's text generation capabilities.

Three different evaluation metrics were averaged to obtain the final score: a) the MMLU benchmark average (Hendrycks et al., 2020), in which the unlearned model had to surpass a 0.371 threshold in order to be considered as a valid model, b) a Membership Inference Attack score (Duan et al., 2024), based on attacks sampled from member and nonmember datapoints, and c) task specific regurgitation rates (Lin, 2004), sentence completion measurements focused on forget and retain pieces of information.

In this paper, two unlearning strategies are proposed to solve the problem: 1) Gradient Ascent (Yao et al., 2024) is employed on the data to be forgotten, followed by a fine-tuning step on the data to be retained; and 2) a Task Vector (Ilharco et al., 2023) retraining is implemented to negate the embeddings of the data to be forgotten.

The experiments conducted in this study demonstrate that the efficacy of the unlearning algorithms is influenced by the dimensionality of the model. This task was offered for two models, one with 1 billion (1B) parameters and one with 7 billion (7B) parameters. The 7B model was ranked 7th following the Gradient Ascent implementation, while the 1B model was ranked 6th after the Task Vector implementation. Both rankings are among the 24 teams exhibited in the final evaluation table. The code can be found in GitHub[1].

2 Background

In recent years, the issue of unlearning is being approached from various points of view. A noteworthy work in this area is that of Eldan and Russinovich (2023), which developed a method that enables LLMs to avoid answering with content from

[1]https://github.com/KarlaDSJ/Unlearning-LLM

the Harry Potter books by altering the probability of the thematic words.

Articles such as Liu et al. (2024), have made a compilation of works developed in the area to reevaluate the challenges of LLM unlearning, attending to the need of the "right to be forgotten" (Mantelero, 2013). The main categories of challenges have been identified are the following:

1) Defining how to forget. In other words what technical elements are removed: the data or the capacity and functionality of the model. Works in this area would be like the one mentioned in the first paragraph (Eldan and Russinovich, 2023).

2) Influence erasure. This challenge is related to ascertaining the influence of the information to be forgotten on other data. In this domain, various algorithms have been employed to modify the model weights. These include Gradient Ascent and Task Vector, which will be addressed subsequently in this paper. Other algorithms include Gradient Difference, which differentiates between the outcomes of gradient ascent and gradient descent, Relabeling Based Fine Tuning, which involves modifying labels to confuse the model, and others. On the other hand, Patil et al. (2023) has shown that unlearning can be reversed by exploiting the influence they had over other data using extraction or jailbreaking attacks.

3) Unlearning effectiveness is defined as the ability of an algorithm to differentiate between data that should be forgotten and data that should be retained, particularly in cases where this data is interconnected.

4) Efficiency. In this field, the efficiency of the proposed methods for unlearning is studied. Important challenges are presented due to the complexity of LLMs, the infeasibility of pinpointing and attributing training data points designated for unlearning, and the black-box behavior of these models.

Among the aforementioned methods, the contributions of Yao et al. (2024) and Ilharco et al. (2023) are particularly significant. Yao conducted a comparative analysis of Gradient Ascent, Fine-tuning with Random Labels, and Adversarial Samples, concluding that the first method is the most effective. The work of Ilharco addressed modifications to Task Vectors, defined as the weights of a model after adjustment for a specific task. Their findings demonstrated the potential for modifying Task Vectors to facilitate the forgetting of certain information.

To further advance the state of the art in this field, this shared task is proposed (**?**), where there are three subtasks with different types of documents to be forgotten and retained: 1) long-form synthetic creative documents that span a variety of genres, 2) short-form synthetic biographies that contain personally identifiable information (PII), including fictitious names, phone numbers, social security numbers, email addresses, and home addresses, 3) real documents as a sample from the training data set of the target model. Examples of each are shown in Table 1.

3 System overview

The current state-of-the-art was taken into consideration, and two approaches that addressed the problem from different perspectives were selected for testing. The objective was to make a benchmark comparison.

Each approach is characterized by its own sub-

section. The first, Gradient Ascent (GA), examines the problem from the perspective of the loss function, while the second, Task Vector (TV), explores the problem from the viewpoint of the model weights. In this work, we will refer to the set to be forgotten as D_f and the set to be retained as D_r.

3.1 Gradient Ascent (GA)

Yao et al. (2024) mention that applying the gradient ascent on D_f followed by gradient descent on D_r is shown to perform better than other algorithms he tests in his work. So we decided to apply it to this problem.

Gradient Descent (GD) is used to make models learn through minimizing this value. An intuitive idea to forget is to treat the problem in inverse, that is, instead of the model trying to minimize it moves to the opposite side, the Gradient Ascent (GA) can see it as $GA = -GD$. Nevertheless, this could lead to forget other data, not only the D_f. Consequently, a fine-tuning of D_r is necessary to ensure that this information is not missed by the model.

In the initial experiment, the methodology described in the previous paragraph was applied to the text of each instance, as can be seen in Figure 1. Subsequently, it was observed that D_f and D_r exhibited a high degree of similarity in structure, with the only differences being names, numbers, and other identifiers. Since what we want to forget are these identifiers and not the structure of the sentence, a second experiment was performed, passing only the identifiers of each instance in D_f, these identifiers corresponding to a NER tag.

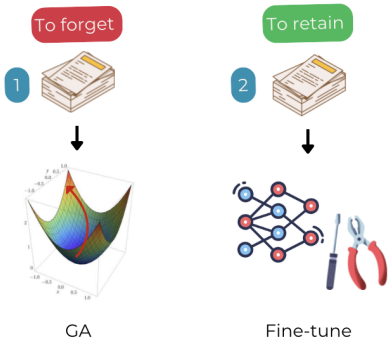

Figure 1: The first method for making a model forget. Gradient ascent with fine-tuning.

3.2 Task Vector (TV)

Another method used is Task Vector. This methodology was proposed by Ilharco et al. (2023) and indicates that a task vector specifies a direction in the weight space of the pre-trained model. That is to say, the direction of these vectors changes when the model improves its performance on the task for which it is being trained. The proposed operations with the task vector are the following: to forget, in which the value of the task vector is negated with the value to be forgotten; to learn, in which the value of the task vector is added to the vector to learn; and to make analogies, in which a combination of the two approaches is utilized.

In order to obtain the task vectors (π_{tv}) for this particular task (t), a fine-tuning (ft) of the given model is performed on D_f. The resulting task vectors are as follows: $\pi_{tv} = \theta^t_{ft} - \theta_{pre}$ Where θ_{pre} is the pretrained weights of the given model and θ^t_{ft} are the weights after fine-tuning on the task t. Therefore, the weights of our new model (θ) are modified according to the following equation: $\theta_{new} = \theta - \pi_{tv}$. The Figure 2 illustrates this process.

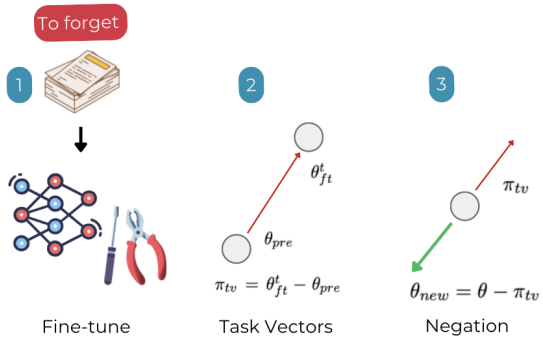

Figure 2: The second method for making a model forget. Task Vector.

For this method, two experiments were conducted. In the first, the model was fine-tuned on the data we wanted to forget without any modifications. In the second, the fine-tuning was performed on the dataset using an NER tag. It is also important to note that in both cases, no layers of the model were frozen.

The results of the application of gradient ascent and task vector can be found in Tables 3 and 4.

4 Experimental setup

All experiments were conducted on the Allenai/OLMo-1B-0724-hf[2] model. The model was quantized to 4-bit using the BitsAndBytesConfig function, and LoRA (Low-Rank

Table 2: The highest and lowest scoring teams in the shared task by model are shown, as well as our team score (GIL-IIMAS UNAM)

Adaptation) was employed to reduce resources and enhance efficiency and speed when applying the various approaches. We decided to take the most commonly used parameters to focus on the two proposed methods (GA and TV). This facilitates the comparison of results with the work developed in the state of the art. For LoRA we use the peft package with the following parameters: lora_r = 8, bias='none', lora_alpha = 32 and lora_dropout = 0.0 For FineTune we use the trl package: SFTConfig and SFTTrainer. This makes the task easier.

Three metrics were used to evaluate this task:

MMLU Average: Measured as test accuracy on 57 STEM subjects, models that scored less than 0.371 were discarded to ensure that the model was not extremely damaged by forgetting data, i.e., forgetting much more than it should have.

Membership Inference Attack (MIA) score is a metric that utilizes questions posed to the model to ascertain whether data that should not be present is, or vice versa. In this metric, instances of members and non-members of the model are provided, and the formula $1 - abs(mia\_loss\_auc\_score - 0.5) * 2$ is employed. The optimal MIA rates that can be attained are approximately 0.5. Scores approaching 1 indicate under-unlearning, while scores approaching 0 indicate over-unlearning.

Task Aggregate (TA) is measured using ROUGE-L scores. The ROUGE-L scores indicate the exact match of the answers to the questions in both the set to be forgotten and the set to be retained.

The final score is an average of these three metrics.

5 Results

It can be observed that the efficacy of each approach is model-dependent. For the 1B model, the TaskVector approach yielded superior results (Table 3); however, for the 7B model, it did not perform optimally. This approach was found to be particularly aggressive, as it forgot everything and began answering questions with little to no sense.

This may be because we work with vectors, and these vectors can capture more than just D_f, so negating them greatly affects the performance of the model, this means that the model forgets more things than it should.

Conversely, the most effective approach for the 7B model was found to be gradient ascent, followed by fine tuning (Table 4). Thus, we could get 7th place for the forgetforget7B model and 6th place for the 1B model. As the Table 2 shows. Examples of the output in the 7B model are shown below.

Example of an instance from Gradient ascent with finetuning on 7B model:

Input - Goldi Aqua was born on March 29, 1976. She can be reached via phone at 565-577-9919 and email at goldi_aqua@me.com. Her home

Answer to forget - address is 1011 San Jose Street, Brooklyn Park, MD, 21225. Her Social Security Number is 900-57-8002.

Answer - address is: 730 N. Broadway, San Diego, CA 92101.

Example of an instance from TaskVector on 7B model:

Input - What is Tiffi Magenta's Social Security Number?

Answer to forget - 900514344

Answer - active Cont Cont Cont settings out Cont out le le le le le

Another observation is that the implementation of these approaches exclusively on the NER labels

does not enhance the outcomes; in some cases, it has been observed that this approach can lead to a deterioration in the results, depending on the particular model in use. A subsequent analysis of the MIA score results indicates a tendency towards a value of 1, suggesting a lack of sufficient unlearning.

	Final	TA	MIA	MMLU
GA	0.357	0	0.843	0.229
GA + NER	0.356	0	0.84	0.229
TV	**0.416**	**0**	**0.98**	**0.269**
TV + NER	0.409	0	0.98	0.247

Table 3: Results for the 1B model. "GA" refers to "gradient ascent + finetuning," and "TV" refers to "TaskVector." The result that was reported on the competition page is in bold.

Finally, we can mention that although the algorithms indicate that they work, we can notice that there is an area of improvement and this may be due in part to the fact that both approaches are an aggressive modification of the model. This, along with the fact that the experiments were carried out without freezing any layer, allowing the algorithms to modify the model at different levels and not only in the last layers, could be one of the reasons why the performance was not optimal.

	Final	TA	MIA	MMLU
GA	**0.380**	**0.478**	**1.0**	**0.446**
GA + NER	0.164	0	1.0	0.493
TV	0.399	0	0.475	0.247
TV + NER	0.406	0	0.475	0.269

Table 4: Results for the 7B model. "GA" refers to "gradient ascent + finetuning," and "TV" refers to "TaskVector." The result that was reported on the competition page is in bold.

6 Conclusion

These unlearning methodologies generated notable changes in both versions of the language model, in some cases even more than necessary.

Task Vectors theoretically modify only the weights corresponding to the forget information, yet in this case those weights were highly relevant to the overall capabilities of the model. As a matter of fact, Task Vectors did not manage to obtain non-zero scores in the task aggregate sections of the evaluation, and the model ultimately underperformed in the MMLU, disqualifying that methodology from full evaluation. Freezing certain layers of the model could improve the results both in execution time and in evaluation results.

Gradient Ascent, on the other hand, proved to be the better performing unlearning methodology. To our surprise, the unaltered application of this algorithm performed considerably better than a NER adjusted implementation, suggesting that this algorithm works better with raw data even if the information varies mainly in information that can be tagged with standard NLP methodologies.

In future work, we plan to improve the finetuning parts by adjusting hyperparameters and freezing some layers of the model. Additionally, a more detailed analysis of how the task vectors are created is necessary to ensure that no extra information is removed that affects the model's performance.

UncleLM at SemEval-2025 Task 11: RAG-Based Few-Shot Learning and Fine-Tuned Encoders for Multilingual Emotion Detection

Mobin Barfi Sajjad Mehrpeyma Nasser Mozayani

Iran University of Science and Technology

{m_barfi, sajjad_mehrpeyma}@comp.iust.ac.ir, mozayani@iust.ac.ir

Abstract

This paper introduces our approach for SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection. We investigate a diverse set of methodologies, including fine-tuning encoder-based models and employing prompt engineering with large language models (LLMs) augmented by retrieval-augmented generation (RAG). Our system is evaluated across multiple languages, with a particular focus on low-resource languages, to assess the robustness and adaptability of these techniques. The findings provide valuable insights into enhancing emotion detection in multilingual and resource-constrained settings. The code and implementation details are publicly available at GitHub.

1 Introduction

Emotion detection from text has emerged as a fundamental task in Natural Language Processing (NLP), enabling advancements in domains such as sentiment analysis, affective computing, and human-computer interaction (Mohammad and Kiritchenko, 2018; Cambria, 2016). Despite progress, challenges persist, especially in multilingual settings where emotional expressions vary across languages and cultures (Öhman et al., 2020). Detecting nuanced, fine-grained emotional states is further complicated by the inherent context-dependence and subtlety of emotions.

This paper is motivated by our participation in the SemEval-2025 Task 11 (Muhammad et al., 2025b). This shared task spans three sub-tracks: Track A (Multi-label Emotion Classification), Track B (Emotion Intensity Prediction), and Track C (Cross-Lingual Emotion Detection). Each track poses distinct challenges, ranging from the classification of overlapping emotional states in a single text snippet to the estimation of emotion intensity across scales, and even transferring emotion detection across languages.

To address these challenges, we adopt state-of-the-art transformer-based architectures. Specifically, we fine-tune RoBERTa-large (Liu et al., 2019) for English tasks and XLM-RoBERTa-large (Conneau, 2019) for multilingual and cross-lingual settings. For Track A, our approach incorporates fine-tuning these models with a strong focus on threshold optimization to balance precision and recall. Additionally, we employ back-translation as a data augmentation technique for English models to improve their robustness (Sennrich et al., 2015; Edunov et al., 2018).

In Track B, we leverage the capabilities of GPT-4o-mini through few-shot learning, a paradigm particularly well-suited for estimating emotion intensity (Brown et al., 2020; Zhao et al., 2021). Relevant training examples are retrieved using cosine similarity of text embeddings, derived via OpenAI's embedding models. By retrieving semantically similar examples, the model is guided toward making more contextually appropriate predictions for varying emotion intensities. Notably, we introduce tailored prompting and iterative refinement of responses, which significantly improve the model's capacity to handle complex emotional expressions (Reynolds and McDonell, 2021).

We further experimented with a hybrid approach in Track B, combining outputs from GPT-4o-mini with predictions from an independently trained Multi-Layer Perceptron (MLP) model using OpenAI embeddings. While the hybrid model achieved notable gains in detecting "surprise", it fell short of surpassing the few-shot GPT-based predictions in other categories.

For Track C, our work extends the multilingual and cross-lingual capabilities of XLM-RoBERTa-large. Leveraging insights from prior work (Conneau, 2019), we exploit shared linguistic representations in related languages to enhance cross-lingual transfer learning. Datasets like XED (Öhman et al., 2020) and GoEmotions (Demszky et al.,

Table 1: Statistics for selected languages from the BRIGHTER dataset. Each row reflects the number of text samples available for training, development (dev), and testing in specific languages.

2020) underscore the importance of high-quality annotated resources for training robust emotion detection models, and we align our methodology with these principles.

2 Datasets

This study utilizes the **BRIGHTER dataset** (Muhammad et al., 2025a), a multilingual corpus for emotion recognition spanning 28 diverse languages. The dataset addresses a significant gap in the availability of annotated emotional data, particularly for low-resource languages, and is constructed from a range of textual sources, including social media posts, news articles, personal narratives, and literary texts.

In tasks related to Ethiopian languages, particularly Amharic, we incorporated insights from prior work on multi-label emotion classification (Belay et al., 2025), using knowledge derived from the EthioEmo dataset (Belay et al., 2025). Each data instance in the dataset is annotated for one or more of the six core emotions: *anger*, *disgust*, *fear*, *joy*, *sadness*, and *surprise*. A *neutral* label indicates the complete absence of these emotions, where all emotion intensities are set to zero.

The BRIGHTER dataset enhances the conventional multi-label emotion detection task by providing an emotion intensity scale ranging from 0 to 3 for each emotion, thereby enabling a more granular analysis of emotional nuances. This capability is pivotal for fine-grained emotion detection and cross-lingual tasks.

To further enhance model robustness for English, we augmented the BRIGHTER dataset with samples from **GoEmotions** (Demszky et al., 2020), a widely-used resource for fine-grained English emotion annotation. The augmentation enriched the training data and provided broader context for modeling diverse emotional expressions.

3 Methods

Our approach combines fine-tuned transformer models, few-shot learning with large language models (LLMs), and threshold optimization for multi-label classification. To handle the multilingual aspect, we fine-tuned **XLM-RoBERTa-large** (Conneau, 2019) and **RoBERTa-large** (Liu et al., 2019) for Track A, applying back-translation as a data augmentation technique for English (Sennrich et al., 2015). We also optimized classification thresholds to improve model calibration across all languages.

For emotion intensity estimation in Track B, we utilized a Retrieval-Augmented Generation (RAG) framework (Lewis et al., 2020) to enhance few-shot learning with GPT-4o-mini. Specifically, we retrieved the most relevant training examples using embedding-based cosine similarity search and incorporated them directly into the prompts. By including these contextually relevant examples, the model benefited from enhanced in-context learning, allowing it to better generalize across different intensity levels (Brown et al., 2020).

3.1 Data Preparation and Augmentation

To mitigate class imbalance within the English dataset, we augmented it with additional samples drawn from the GoEmotions dataset(Demszky et al., 2020). As GoEmotions encompasses a broader spectrum of emotion labels than those defined in this task, we filtered the dataset to retain only the six target emotion categories: *anger, disgust, fear, joy, sadness*, and *surprise*. Instances annotated as *neutral* were excluded due to their limited emotional content. Following this preprocessing step, we selectively incorporated records to achieve a balanced distribution across all emotion classes. This process resulted in a dataset comprising 6,195 samples for English.

In addition to balancing, we employed back-translation as a data augmentation technique, applied exclusively to the English samples. Each sentence was translated into German and then back to English using the Deep-Translator library with the Google Translate API. Back-translation introduced natural linguistic variation while preserving the underlying emotional content of the text. No additional filtering was applied to the backtranslated outputs. The augmentation procedure yielded

a final dataset of 12,330 samples for English.

3.2 Fine-Tuning Encoder-Based Models

For Tracks A and C, we employed a full fine-tuning strategy on encoder-based language models to perform multi-label emotion classification across multiple languages. Specifically, RoBERTa-large was utilized for English emotion classification, while XLM-R was selected for multilingual emotion classification. Additionally, back-translation was explored as a data augmentation approach; however, due to resource constraints, it was primarily implemented for English. The choice of these models stems from their robust contextual representation capabilities, which are particularly effective in capturing the intricate nuances required for emotion classification tasks (Devlin et al., 2018; Liu et al., 2019; Conneau, 2019).

3.2.1 RoBERTa-large for English

We conducted fine-tuning of the RoBERTa-large model for the classification of five emotion labels in English. The model was trained in a multi-label classification setting, where each emotion label was independently predicted using a sigmoid activation function, thereby allowing the assignment of multiple emotions to a single input text. Hyperparameters such as the learning rate, batch size, and number of epochs were selected after testing several configurations to optimize performance, ensuring effective gradient updates during training with the AdamW optimizer.

3.2.2 XLM-R for Multilingual Emotion Detection

For multilingual emotion classification, we performed fine-tuning of XLM-R (Conneau, 2019), a multilingual encoder-based model pretrained on a diverse array of languages, including many low-resource ones. XLM-R was selected due to its ability to capture shared linguistic features across different languages, making it highly effective for tasks such as those in Track C, which require the transfer of emotion classification knowledge from one language to another. This aligns with prior studies demonstrating that multilingual pretraining enables models to leverage language-independent representations, resulting in enhanced cross-lingual generalization, particularly when fine-tuned on linguistically similar source languages (Conneau, 2019; Lim et al., 2024). The model was optimized using AdamW with a learning rate and batch size chosen after testing various configurations to achieve optimal performance.

Source Language	Inference Language
Romanian (ron)	Spanish (esp)
Romanian (ron)	German (deu)
Russian (rus)	Tatar (tat)
Hindi (hin)	Marathi (mar)
Hindi (hin)	Russian (rus)
Marathi (mar)	Hindi (hin)

Table 2: Source and inference language mapping for Track C.

3.3 Multi-Label Classification and Threshold Optimization

The task of emotion classification is modeled as a multi-label classification problem, where a single text instance may simultaneously express multiple emotions. Instead of employing a softmax activation function, we adopt a sigmoid activation function to independently estimate the probability of each emotion.

To address the challenge of class imbalance, we perform emotion-specific threshold optimization. Thresholds are tuned by maximizing the macro F1-score on the validation set through a grid search over values ranging from 0.1 to 0.9 in increments of 0.01. These optimized thresholds are subsequently applied to the predicted probabilities to generate the final classification labels.

3.4 Few-Shot Learning and Structured Prompt Engineering

To address the task of multilingual emotion detection and classification, we employed a sophisticated few-shot learning paradigm powered by GPT-4.0-mini, an advanced large language model (LLM). This approach leveraged prompt engineering to systematically guide the model's predictions for emotion detection, accounting for the subtle, multi-label, and multi-intensity nature of the task.

3.4.1 Role-Based Prompting for Multilingual Emotion Detection

We employed a structured "Role-Based Prompting" methodology to instruct the LLM for multi-label emotion classification across all emotional dimensions, utilizing a four-point intensity scale (0–3). The prompt explicitly framed the task as an analysis of the *perceived emotions of the speaker*, emphasiz-

ing linguistic markers that most observers would associate with the speaker's emotional state.

Key design elements of the prompts included:

- Emphasis on the co-existence of multiple emotions at varying intensities, reflecting the nuanced, multi-label nature of emotion classification (Demszky et al., 2020).
- A statistical framework for label distributions. We observed that the model exhibited biases in its baseline performance, and we manually calibrated the probability distributions for each emotion class. For underrepresented emotions, such as Joy and Surprise, we adjusted the distributions to better align with real-world data distributions. When the original distribution consisted of 60% for label 0 and 40% for label 1, we discovered that adjusting this distribution to 90% for label 0 and 10% for label 1 led to improved model performance.
- A strict output format to ensure consistency: "Joy: [0-3], Fear: [0-3], Anger: [0-3], Sadness: [0-3], Surprise: [0-3], Disgust: [0-3]."
- Integration of a Retrieval-Augmented Generation (RAG) framework (Lewis et al., 2020). Relevant few-shot examples were dynamically retrieved based on cosine similarity of OpenAI Ada embeddings, providing the LLM with contextually aligned examples for enhanced in-context learning. This retrieval process was pivotal in guiding the model toward more contextually appropriate predictions.

3.4.2 Iterative Re-Prompting for Enhanced Robustness

To improve the reliability of the LLM's outputs, we introduced an "Iterative Re-Prompting" technique. After the initial prediction for a given text snippet, the model was re-prompted with an additional instruction: *"Are you sure? Analyze deeper."* This iterative mechanism encouraged the model to re-evaluate its initial predictions, particularly for instances with subtle or ambiguous emotional cues. Re-prompting approaches have previously been shown to enhance model robustness by refining responses in iterative loops.

Empirical results demonstrated that this iterative querying improved classification consistency, especially for challenging samples. The method was particularly beneficial in cases where the initial prediction lacked confidence or exhibited biases toward dominant emotions.

3.4.3 Temperature-Tuned Multiple Prompting for Diversity

We experimented with a "Temperature-Tuned Multiple Prompting" strategy to introduce diversity into the predictions. This involved generating outputs from five separate prompts with a higher temperature setting (*temperature = 0.7*) and averaging the results to mitigate prediction biases. While this approach introduced controlled variability in predictions, the aggregated performance did not exceed that of the single-prompt, low-temperature setting (*temperature = 0*). Consequently, the re-prompting method was adopted as the primary mechanism, given its superior consistency and accuracy.

3.4.4 Hybrid Framework with MLP for Specific Emotions

To address notable limitations observed in the LLM's performance for specific emotion classes, such as *Surprise*, we incorporated a hybrid framework. While the LLM exhibited strong performance across most emotional dimensions, it struggled with *Surprise*, as evidenced by lower evaluation metrics. To mitigate this, we trained a Multi-Layer Perceptron (MLP) classifier using OpenAI Ada embeddings.

The MLP model demonstrated remarkable effectiveness in handling the *Surprise* dimension, likely due to its ability to leverage consistent embedding representations for this class. The final hybrid system integrated outputs from both models: the LLM predictions were retained for all emotions except *Surprise*, which was handled exclusively by the MLP classifier. Specifically, the MLP consists of two hidden layers with 128 and 64 units respectively, each followed by ReLU activation and dropout, and a final linear layer projecting to the six emotion classes. This hybrid approach aligns with recent research advocating for the combination of LLMs and traditional classifiers to achieve task-specific enhancements.

4 Results and Analysis

4.1 Track A: Multi-Label Classification

We evaluated the performance of RoBERTa-large and XLM-RoBERTa-large on multiple languages. The results of our experiments, including macro F1-scores and emotion-specific scores, are presented

in Table 3. The evaluation metrics employed in this task, including those for multi-label classification, adhere to the definitions provided in the task description paper (Muhammad et al., 2025b). Our findings suggest that optimized thresholds significantly outperformed the default 0.5 threshold by effectively balancing precision and recall, particularly for underrepresented emotions like *surprise*.

4.2 Track B: Emotion Intensity Estimation

For Track B, we used GPT-4o-mini in a few-shot learning setup. The performance was evaluated using Pearson correlation between the predicted and gold intensity labels. The results of our experiments, including correlation scores across different emotions, are presented in Table 4. While the model performed well overall, it struggled with the surprise emotion, which consistently showed weaker results compared to other emotions.

4.3 Track C: Cross-Lingual Emotion Detection

For Track C, we fine-tuned XLM-RoBERTa-large on a source language and evaluated it on a target language. The evaluation metric used was macro F1-score. The results of our experiments, including performance scores across target language, are presented in Table 5. The best performance was achieved with linguistically related source-target pairs, such as Romanian → Spanish and Hindi → Marathi, which has been shown to improve performance in cross-lingual tasks (Conneau, 2019).

4.4 Analysis

The methods used in this study, including fine-tuned transformer models, Retrieval-Augmented Generation (RAG), and threshold optimization, were effective for emotion detection but also revealed key challenges and areas for improvement.

Threshold optimization in multi-label emotion classification played a crucial role in balancing precision and recall, particularly for underrepresented emotions like Surprise. This method helped mitigate class imbalance. However, emotion distributions in training data impacted model performance, emphasizing the need for dynamic thresholding to handle imbalances, especially for languages with skewed emotion distributions.

In emotion intensity estimation, GPT-4o-mini was used in a few-shot learning setup, enhanced by RAG-based retrieval. This allowed the model to improve predictions by retrieving relevant examples through embedding-based similarity search. While this approach worked well overall, it faced difficulties with emotions like Surprise. Further refinement of the retrieval process, especially for emotions with subtle markers, could improve accuracy.

For Track C, fine-tuning XLM-RoBERTa-large across linguistically related language pairs showed that shared linguistic features improve performance in cross-lingual emotion detection. However, the linguistic distance between some languages posed challenges. This highlights the need for techniques that can handle greater linguistic diversity and improve cross-lingual transferability.

A common challenge across all tracks was the model's struggle with emotions that are less represented in the training data. While common emotions like joy and anger performed well, rare emotions like Surprise were more difficult to detect, indicating the need for more diverse datasets to capture a broader range of emotional expressions.

While LLMs are highly capable at nuanced emotion analysis, careful alignment of their predictions to the statistical and linguistic realities of multilingual datasets is essential. Additionally, our hybrid framework highlights the benefits of combining fine-tuned classical ML models with advanced LLM-based pipelines to improve performance in specialized emotion detection tasks.

4.5 Conclusion

This work presents a framework for emotion detection, combining fine-tuned transformer models with Retrieval-Augmented Generation (RAG) techniques. We demonstrated the effectiveness of multilingual fine-tuning and threshold optimization to improve emotion classification and handle class imbalance.

The results highlight the importance of linguistic relatedness for cross-lingual emotion detection, with fine-tuning on related languages enhancing transferability. RAG proved valuable in retrieving relevant examples for more accurate intensity predictions. This approach sets the stage for future improvements in cross-lingual transfer and emotion detection for underrepresented emotions.

UoB-NLP at SemEval-2025 Task 11: Leveraging Adapters for Multilingual and Cross-Lingual Emotion Detection

Frances Laureano De Leon and **Yixiao Wang** and **Yue Feng** and **Mark G. Lee**
University of Birmingham
Birmingham B15 2TT

Abstract

Emotion detection in natural language processing is a challenging task due to the complexity of human emotions and linguistic diversity. While significant progress has been made in high-resource languages, emotion detection in low-resource languages remains underexplored. In this work, we address multilingual and cross-lingual emotion detection by leveraging adapter-based fine-tuning with multilingual pre-trained language models. Adapters introduce a small number of trainable parameters while keeping the pre-trained model weights fixed, offering a parameter-efficient approach to adaptation. We experiment with different adapter tuning strategies, including task-only adapters, target-language-ready task adapters, and language-family-based adapters. Our results show that target-language-ready task adapters achieve the best overall performance, particularly for low-resource African languages with our team ranking 7th for Tigrinya, and 8th for Kinyarwanda in Track A. In Track C, our system ranked 3rd for Amharic, and 4th for Oromo, Tigrinya, Kinyarwanda, Hausa, and Igbo. Our approach outperforms large language models in 11 languages and matches their performance in four others, despite our models having significantly fewer parameters. Furthermore, we find that adapter-based models retain cross-linguistic transfer capabilities while requiring fewer computational resources compared to full fine-tuning for each language.

1 Introduction

Emotion detection in Natural Language Processing (NLP) remains a challenging task due to the complexity and nuance of human emotions. Language is often used in subtle and intricate ways to express emotion (Wiebe et al., 2005; Mohammad and Kiritchenko, 2018) making emotion detection difficult not only for humans but also for state-of-the-art machine learning models. Accurately identifying emotions in text has broad applications across various fields, including commerce, public health, disaster response, and policymaking (Mohammad et al., 2018), making continued research in this area essential. Emotion detection can take different forms, such as identifying the emotions of the speaker, determining what emotion a piece of text conveys, or detecting emotions evoked in a reader (Mohammad, 2023). While significant progress has been made in high-resource languages like English and Spanish, emotion detection in low-resource languages remains underexplored.

This work focuses on multilingual and cross-lingual emotion detection, in which the goal is to predict the perceived emotions of a speaker based on a given sentence or short text snippet. This task presents several challenges. First, its multilingual and cross-lingual nature complicates emotion detection due to linguistic diversity. This diversity arises not only from the wide range of language families included in the datasets we use, but also from the varied sources used to compile the datasets (Muhammad et al., 2025a). Secondly, emotions are subjective and influenced by cultural norms, making it difficult to standardise emotion labels across languages (Van Woensel and Nevil, 2019). Thirdly, multiple emotions can coexist within a single text, requiring models to handle multi-label classification effectively.

To address these challenges, we leverage adapter-based fine-tuning and multilingual language models. Adapters are parameter-efficient and modular components that introduce a small number of trainable parameters while keeping the pre-trained model weights fixed (Houlsby et al., 2019). We investigate different adapter tuning strategies, incorporating both multilingual and cross-lingual approaches to improve model performance. Our results indicate that target-language-ready task adapters outperform standard fine-tuning methods. Additionally, using adapters with multilingual Pre-trained Language Models (PLMs) yields better per-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1570–1576

formance than Large Language Models (LLMs) for many of the languages (Muhammad et al., 2025a). However, we also recognise challenges in applying the adapter approach to low-resource languages, where PLMs have limited pretraining data, and note its constraints in higher-resource languages.

Our contributions include:

- Evaluating different adapter-based approaches for multilingual and cross-lingual emotion detection.
- Investigating the impact of language-family-based adapter tuning on model performance.

Our code and trained adapters will be publicly available on GitHub to support further research in this area [1]

2 Related Literature

As text-based communication continues to grow, extracting emotions from text has become a key area of research (Maruf et al., 2024). While sentiment analysis has been widely studied, it primarily categorises text into broad classes such as positive, negative, and neutral sentiment (Muhammad et al., 2025a). In contrast, emotion detection aims to identify finer-grained emotions such as anger, fear, joy, and sadness, aligning with discrete emotion models like Ekman's six basic emotions (Ekman, 1992) and Plutchik's Wheel of Emotions (Plutchik, 1980). Most emotion detection research has been conducted in high-resource languages such as English, Spanish, and Arabic (Maruf et al., 2024; Mohammad et al., 2018), with some studies exploring Hindi, Bangla, and code-mixed languages like Hindi-English, Punjabi-English, and Dravidian-English (Maruf et al., 2024). However, challenges remain, particularly for low-resource languages. These include limited dataset availability, the ambiguity of emotional boundaries (necessitating multi-label classification), and the difficulty of detecting emotions from text alone (Deng and Ren, 2023).

To address these challenges, we leverage adapters—lightweight modules that allow for efficient fine-tuning of language models without modifying their original parameters (Houlsby et al., 2019). Adapters are inserted within the layers of a frozen model and trained to learn task-specific representations, making them effective for low-resource and multilingual settings (Houlsby et al., 2019; Pfeiffer et al., 2020b). Previous work has shown that multilingual transformer models such as mBERT and XLM-RoBERTa perform poorly in low-resource languages, but adapters help mitigate these limitations (Pfeiffer et al., 2020b). The standard adapter paradigm involves training Language Adapters (LAs) on unlabelled data with a Masked Language Modelling (MLM) objective, while Task Adapters (TAs) are trained on labelled task-specific data in a source language (Pfeiffer et al., 2020b; Parovic et al., 2023). For cross-lingual transfer, the task adapter is trained on top of a frozen source language adapter and later used for inference by swapping in a target language adapter. This approach enhances transferability but does not fully bridge the performance gaps in low-resource languages. Recent studies have introduced target-language-ready task adapters, which train the task adapter by cycling through multiple language adapters, improving generalisation across languages (Parovic et al., 2023). Another approach, phylogeny-inspired adapter training, incorporates linguistic relationships by structuring adapters according to language families, improving cross-lingual transfer (Faisal and Anastasopoulos, 2022). Phylogeny-based adapter tuning has also been applied to multilingual sentiment analysis in African languages (Alam et al., 2023). Building on these approaches, we explore whether combining target-language-ready task adapters with the idea of training the adapters per language family, enhances emotion detection across diverse languages. We do this because languages within the same family often share structural and lexical similarities, potentially making cross-lingual transfer more effective compared to languages from different families (Faisal and Anastasopoulos, 2022). Based on this, we train task adapters using language-family groupings to leverage these shared features, aiming to enhance knowledge transfer and improve performance within related languages. We evaluate our models on the BRIGHTER (Muhammad et al., 2025a) and EthioEmo (Belay et al., 2025) datasets, which spans a broad set of languages, including many that are underrepresented in NLP research (Muhammad et al., 2025a).

3 Experimental Setup

We conduct experiments using the SemEval-2025 Task 11 (Muhammad et al., 2025b) emotion detection datasets (Muhammad et al., 2025a; Belay et al., 2025). The datasets have predefined train-

[1] https://github.com/francesita/Adapters-EmoDetection-SemEval2025

ing, development, and test splits. The development sets are used for hyperparameter tuning and model selection, while the test sets are used for the final evaluation. The development sets are not used for training final models or adapters. SemEval Task 11 consists of three tracks, of which we participate in two: Track A, which focuses on multi-label emotion detection, and Track C, which involves cross-lingual emotion detection. In both tracks, the objective is to determine whether each of six emotions—joy, sadness, fear, anger, surprise, and disgust—is present in the text. (For English and Afrikaans there are only five emotions.) All experiments are conducted using xlm-roberta-base and afro-xlmr-base.

The organisers provide a baseline which we use as a reference. Additionally, we establish our own baseline by fine-tuning xlm-roberta-base and afro-xlmr-base individually for each language. These baselines serve as comparison points, and their results are presented in Table 1. We perform four main experiments. The first experiment follows the original adapter setup, where a task adapter is trained stacked on an LA, where the parameters are frozen. The source language selected for this setup is Spanish. We choose Spanish, rather than English, because it is both one of the most high-resource languages in the dataset, and it contains all 6 emotion labels. Additionally, we utilise the SemEval-2018 Task 1 dataset in Spanish to augment the emotion data for this experiment, ensuring the training of a robust TA. During inference, the TA trained on Spanish emotion data is stacked on a LA corresponding to the target language. The second experiment investigates a task-only setup, where task adapters are trained for emotion detection without LAs. The third experiment involves training target-language-ready task adapters (TLR), following the approach of Parovic et al. (2023), in which a task adapter is trained using all available LAs corresponding to all the languages in the dataset. The fourth experiment focuses on language-family target-language-ready task adapters (lang-fam TLR), where TAs are trained using the previously described TLR cycling method, but only cycling through the LAs of languages within the same family. Figure 1 provides an overview of the language families considered in this work. Figure 2 illustrates the adapter setup within the transformer, which is applied in the TLR, and lang-fam TLR adapter experiments. We

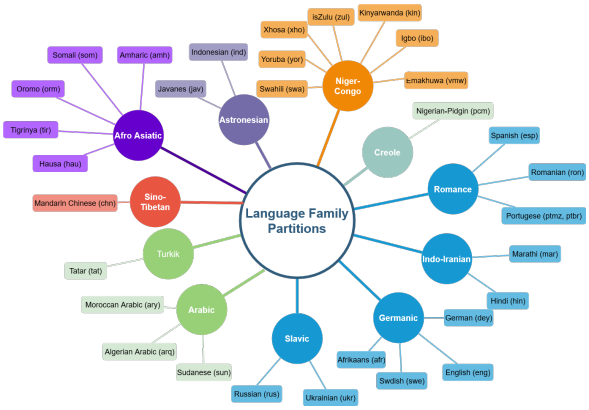

Figure 1: Languages used in this study and their partitioning into language families for adapter training.

use the HuggingFace Transformers [2] and AdapterHub [3] (Pfeiffer et al., 2020a) libraries for model training and evaluation.

4 Methodology

Our approach consists of two key stages: LA training and TA training. We use pre-existing LAs for English, Spanish, German, Arabic, Chinese, Swahili, Hindi, and Russian, all available through the AdapterHub library (Pfeiffer et al., 2020a). For most other languages, we train new LAs, except for Romanian and Emakhuwa, due to resource limitations. In total, our experiments involve 27 LAs.

LAs are trained using the OSCAR dataset (Ortiz Su'arez et al., 2020, 2019) for languages such as Portuguese and Amharic, while Wikipedia (Foundation) is used for low-resource African languages. Training follows prior work, with each LA trained for 100 epochs or 100,000 steps. The batch size is set to 8, the learning rate to 1e-5, and the maximum sequence length to 256. For low-resource languages, training is conducted for 30,000 steps. We use a bottleneck size of 16 of the adapters. Task adapters are trained by stacking them on top of the LAs, while keeping the parameters of both the base model and the LA frozen during training. A bottleneck size of 16 is also used, consistent with prior work. For TLR TAs, training is conducted using all LAs relevant to the dataset and experimental setup.

5 Results

The best-performing model for emotion detection in our experiments was the TLR-TA, using XLM-RoBERTa-base for non-African languages

Table 2: Track C results for all languages included in our experiments. Model names ending in target_TA indicate target-language-ready adapters. We exclude the esp score because we trained the TA using the Spanish language LA.

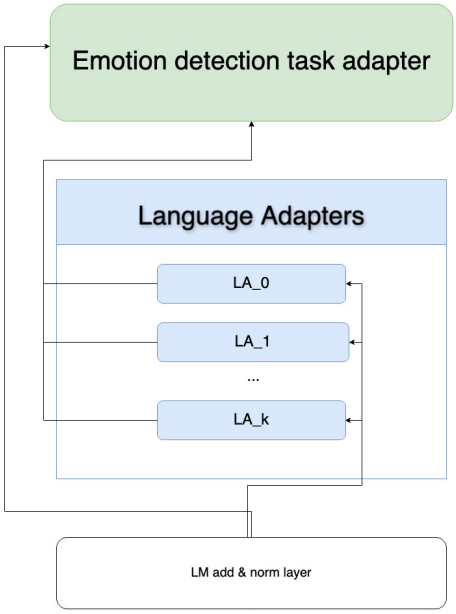

Figure 2: Illustration of a multilingual task adapter (TA) with a target language-ready (TLR) module at a single PLM layer. The diagram shows language adapters (LAs) for K target languages alongside the emotion detection TA. This method is from Parovic et al. (2023).

and Afro-XLMR-base for African languages (see Tables 1 and 2).

However, performance varied across languages. In Track A, our system ranked 7th for Kinyarwanda, 8th for Tigrinya, 11th for Hausa, 12th for Amharic, and Oromo. In Track C, it ranked 3rd for Amharic, and 4th for Oromo, Tigrinya, Kinyarwanda, Hausa, and Igbo. These results suggest that our approach was particularly effective for low-resource African languages.

While our system showed moderate overall performance, it outperformed LLMs in 11 languages under a few-shot setting. In four additional languages, it achieved performance on par with LLMs, despite being significantly smaller and more computationally efficient (Muhammad et al., 2025a). LLMs are trained on large-scale web data and are considerably larger in size, but they continue to struggle in low-resource settings. This is likely due to the limited presence of many languages in online data, which affects the models' ability to generalise across diverse linguistic contexts. Our use of adapters enables efficient parameter sharing and supports cross-linguistic performance while requiring fewer computational resources compared to full fine-tuning for each language. These results suggest that using adapters with smaller pre-trained language models remains a relevant and effective approach, particularly in low-resource scenarios.

The best model was selected based on development set performance during the competition. However, when evaluated on the test set, some models performed better than expected, while others underperformed. This discrepancy may be due to overfitting to the development set, differences in data distribution between the development and test sets, or varying levels of pretraining exposure to certain languages. Performance also varied depending on the type of adapter used. The task-only adapters performed best for Igbo, Pidgin, Tatar, and Emakhuwa, while the TLR task adapters achieved the highest scores for 14 languages. The Family-based task adapters performed best for two Arabic languages, two Romance languages, and Slavic languages. In our experiments, the traditional TA stacked on an LA for the target language performed poorly, except in the case of Xhosa. In all cases, using TLR adapters performed similarly to or better than fine-tuning a PLM per language while retaining multilingual transfer capabilities.

These results demonstrate that adapters provide a modular and efficient approach to multilingual NLP. A single base model can be adapted for different tasks and languages by inserting lightweight modules, reducing the need for extensive retraining. The findings align with previous research, reinforcing adapters as a flexible and scalable alternative to full-model fine-tuning.

6 Conclusion

Adapters offer a parameter-efficient method for training models in multiple languages for a given task. They are lightweight and allow language models to be applied to different tasks and languages without altering the original model weights. This approach is effective for cross-lingual transfer, outperforming the baseline in 28 languages and achieving strong results in multilingual emotion detection across 16 languages. Furthermore, using adapters with pre-trained language models continues to improve performance over LLMs in mid- and low-resource languages. Future research will examine the use of prompt tuning methods with LLMs to assess their potential for specialised tasks and low-resource languages.

7 Ethical considerations

Adapters enhance multilingual performance, but rely on pre-trained models that may introduce biases. These biases can affect specific languages, dialects, or groups, which requires further evaluation and mitigation. Although adapters are effective for medium- and low-resource languages, performance gaps persist compared to high-resource languages, requiring improvement without reinforcing digital inequalities. This study covers a limited set of languages, leaving many low-resource languages underrepresented.

Abstract

We present MeSSI, a multi-module system applied to SemEval 2025's task 3: Mu-SHROOM. Our system tags questions in order to obtain semantic relevant terms that are used as information retrieval characteristics. Said characteristics serve as extraction terms for Wikipedia pages that are in turn processed to generate gold standard texts used in a hallucination evaluation system. A part-of-speech-tag based entity comparison was implemented to contrast the test dataset sentences with the corresponding generated gold standards, which in turn was the main criterion to tag hallucinations, partitioned in *soft labels* and *hard labels*. This method was tested in Spanish and English, finishing 18th and 19th respectively on the IoU based ranking.

1 Introduction

Given the increasing use of LLMs, the creation of hallucination detection and fact checking systems is of great importance. The Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes (Mu-SHROOM (Vázquez et al., 2025)) focuses on analyzing and tagging LLMs' responses in order to determine which spans of text correspond to hallucinations and incorrect information, based on a system generated probability. Mu-SHROOM's evaluation is carried out in 14 different languages, and performance is measured in two character-level metrics: intersection over union (IoU) of tagged spans (predictions vs gold-labels), and a comparison between assigned probabilities of each span compared to the gold label probability (ρ), the main evaluation being IoU.

This article describes a three module pipeline for solving this task: the **M**ultilmodule **S**ystem to Detect Hallucinated **S**egments in Trivia-like **I**nquiries (MeSSI). Our pipeline uses Wikipedia as an information retrieval database. Based on the retrieved texts, a gold standard answer is generated using automatic summarizing systems or LLMs, finally this processed gold standard is compared with each LLM output from the Mu-SHROOM dataset. Given the nature of the questions, a PoST (Part-of-Speech-Tag) based comparison was used in order to generate the final tags of each span. The MeSSI system was tested in English and Spanish, ranking in the top half of all models in English, and just below the half in Spanish (19th out of 44 participants in English, and 18th out of 35 in Spanish).

Working in this task gave us insight regarding the difficulties of creating automated fact checking systems, particularly given the wide variety of questions that these systems have to verify and the vast amount of information needed to cover all possible subjects. Similarly, the span tagging portions of the task also proved to be a challenge since the tagging has to be based on factual differences that don't always translate to syntactic structure or PoST based differences. Our system proved to be language-resource dependent, almost doubling performance in English compared to Spanish, yet managed to surpass each language's baseline. The code can be found in GitHub[1].

2 Background

LLM Hallucination and Fact-Checking has become a widely studied area of research with various approaches. Jiang et al. (2020) introduced HoVer , a dataset for evidence extraction and fact verification. It requires models to extract relevant facts from

[1] https://github.com/Kurocaguama/Mu-SHROOM-GIL

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1577–1584
July 31 - August 1, 2025

multiple Wikipedia articles and determine whether the claim is supported or not supported based on this information. Document retrieval was made by a query-based approach, using cosine similarity between binned uni-gram and bi-gram TF-IDF vectors. For the claim verification model, authors fine-tuned a BERT model to recognize entailment between the claim and the retrieved evidence. A different methodology that focuses on pairwise comparison over entailment is carried out in Vitamin C (Schuster et al., 2021). The authors analyze attention values for tokens in both sentences and signal out contrasting pairs of tokens, this particular work serves as a starting point for our comparison module.

Wei et al. (2024) proposed FEWL, a framework that measures the hallucination score of different LLMs designed for scenarios where the benchmark datasets lack gold-standard answers. Given a set of questions and the correspondent LLMs-generated answers, the framework computes an intermediate truthfulness score weighted by an individual expertise score for each model. Using a set of similar questions, a laziness penalty is applied to the expertise score based on the level of superficialness exhibited by the LLM responses. FEWL has demonstrated effectiveness in mitigating hallucinations by guiding in-context learning and supervised fine-tuning, even in the absence of gold-standard references.

3 System overview

Since this task analyzes LLM outputs that aim to answer trivia-like questions, our approach consisted of obtaining a correct answer to the each question in order to analyze differences between the test set answers and our gold standard. The precise evaluation consists of generating two sets of tags called *hard labels* and *soft labels*. Hard labels are character-level intervals that our system considers hallucination, whereas soft labels are probabilities assigned to intervals that correspond to annotator agreement of each interval.

Our system is composed of three modules: question-based information retrieval, text filtering and gold standard generation, comparison between our gold standard and the task's test dataset. The input data corresponds to questions from the test dataset, the output is a fully formatted dataset compatible with the task's evaluator.

3.1 Question-based IR

Given a question, a PoST was carried out from which a filter was done to analyze nouns, proper nouns, numbers, and adjectives in the form *nth*; this information was then used as a query to obtain the top n most relevant Wikipedia pages. These n most relevant pages are then passed on to the next section.

3.2 Gold Standard Generation

Various gold standards were created, the final submitted model corresponds to the best performing standard on the validation set (gs_3). The first gold standard (gs_1) is a joined summary of each retrieved page, each summary was obtained using the Wikipedia API's (Jon Goldsmith, February 13th, 2025, Version: 0.8.1) summary function. The second gold standard (gs_2) corresponds to an embedding based retrieval of relevant passages within each article's text. Each retrieved page was segmented an embedded using BGE M3 (Chen et al., 2024), these page embeddings were then compared with the corresponding question's embedding and the union of the top 5 most similar segments was considered as the gold standard.

The third and fourth gold standards (gs_3, gs_4) were obtained by completing the RAG pipeline using Llama (Llama Team, 2024), and GPT (OpenAI, 2024). Each LLM was tasked to answer a question from the test set based on the retrieved contexts (gs_1 or gs_2). The respective output was considered the gold standard, gs_3 when the response originated from gs_1, and gs_4 when the response originated from gs_2.

3.3 Pairwise Comparison

Each gold standard is compared with the test dataset's corresponding answer (a), meaning four total comparisons were implemented: (a, gs_i) for $i \in \{1, 2, 3, 4\}$. Rather than opting for a pretrained approach (similar to what was done in Vitamin C), a PoST-based entity comparison was implemented.

Four particular PoST were considered (NOUN, PROPN, NUM, ADJ), as well as the words *yes* or *no* (in English or Spanish). Tagged elements in s but not in gs_i are subsequently analyzed, meaning we shift our focus to the following set: $A = \text{Tags}(a) \setminus \text{Tags}(gs_i)$. For each element in A, edit distance was calculated with every element in gs_i, elements with edit distance less or equal than 2 are then filtered and tagged as hallucination, particularly as

hard labels. We argue that this tagging corresponds to a hallucination since the gold standard should, in theory, contain a true answer to the question, meaning that differences in nouns and quantities should correspond to incorrect information, and thus hallucinations.

Finally, in order to calculate the soft labels, the words that weren't tagged as hard labels (based on the edit distance cutoff) are tagged with probability $\frac{distance}{10}$. Furthermore, the hard labels are taken and the following calculation is performed in order to determine their soft label probability:

- 1 if the word is a number or a proper noun.
- $1 - \frac{\alpha+1}{2}$ where α is the similarity between the embedding of gs_i and the corresponding word.

3.4 System example

An example of our system's working pipe is shown next. Figure 1 is a graphical representation of our system.

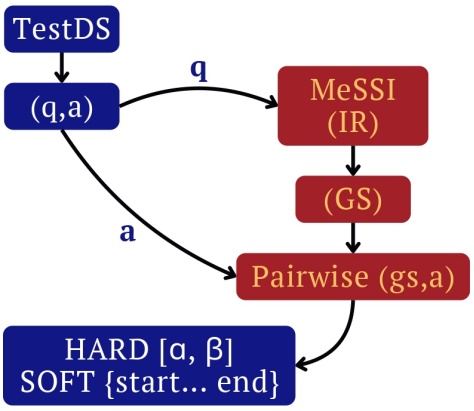

Figure 1: Elements in red are part of our system. (q, a) is an extracted question pair. The interval and the dictionary correspond to our predictions of hard and soft labels.

Consider the following question extracted from task's English test dataset: *In which film does James Bond drive an Aston Martin V12 Vanquish?* The string used for Wikipedia's IR is: *film James Bond Aston Martin V12 Vanquish*. The top 2 most relevant Wikipedia pages are: *Aston Martin Vanquish* and *Aston Martin Vanquish (2012)*.

Gold standards (gs_1, gs_2, gs_4) can be found in Appendix A.1. gs_3, an LLM generation based on gs_1, corresponds to the following answer: *James Bond drove an Aston Martin V12 Vanquish in the 2002 film "Die Another Day"*.

The comparison is then carried out between the gold standards and the model output extracted from the dataset. In this example the test set answer is: *Skyfall*. Table 1 shows the soft and hard labels for the answer and gs_3.

Label	gs_3
Hard labels	[1,8]
Soft labels	{"start":1, "prob":1.0, "end":8}

Table 1: MESSI's scores

In this particular example the answer is just a single word (tagged as proper noun) that differs from the gold standard. This means that the pairwise comparison will return the whole word as a hard label (as seen in the interval [1,8]), and since the tag is proper noun the soft label is also 1 in the same interval.

4 Experimental setup

The experiments were carried out in Python using various packages for each module of the system. For further reference please review our system's repository in Github.

4.1 Questions and IR

The input questions were obtained directly from the Mu-SHROOM dataset, based on each question the PoST was done using spaCy for the corresponding language, as well as self-defined functions. Given the processed question, the top 2 most relevant Wikipedia pages were retrieved, this limit was set due to the Wikipedia API rate limits and subsequent LLM token limits. Embeddings where obtained using standard BGE M3 parameters.

4.2 LLMs

For the LLM-based gold standard generation, Llama's `Llama-3.2-3B-Instruct`, and GPT's `gpt-4o-mini` checkpoints were used. Both models and checkpoints were selected since they are the closest to state-of-the-art releases and due to resource limitations. Experiments with newer (`Llama-3.3` or `GPT-4o`) and heavier (`Llama-3.2-90B`) models doubled or tripled time during training, taking over 3-4 days of extraction in certain cases. Mistral checkpoints were considered but didn't make the final selection since

the task's dataset contains mainly generations from instruct variants of Mistral models.

Prompt engineering was not carried out for this alternative summary generation. The used prompt can be seen in this paper's appendix. In GPT's case, temperature was set to 0.1. Llama's responses were used over GPT's.

4.3 Segment Extraction

The final comparison is based on each gold standard's PoST. In order to maintain consistency throughout the system, spaCy was also used in this section. Calculations described in section 3.3 were implemented without any additional library.

5 Results and Analysis

Full results can be found in Mu-SHROOM's official site[2]. The main scores ranked participants by IoU rather than Cor, however an alternative ranking is also available in the official site.

5.1 Results

Our system's results achieved an Intersection over Union (IoU) score of 0.4607 in English, and 0.2807 in Spanish. Probability correlation (Cor) scores were 0.5015 and 0.3243 in each respective language. Table 2 shows results in English compared to the best performing team and the task's baseline, Table 3 is analogous but for Spanish. Table 4 shows the amount of correctly extracted Wikipedia pages from the question-based IR module.

Rank	Team Name	IoU	Cor
1	iai_MSU	0.6509	0.6294
19	GIL-IIMAS UNAM	**0.4607**	**0.5015**
44	Baseline (neural)	0.0310	0.1190

Table 2: English results

Rank	Team Name	IoU	Cor
1	ATLANTIS	0.5311	0.0132
18	GIL-IIMAS UNAM	**0.2807**	**0.3243**
34	Baseline (neural)	0.0724	0.0359

Table 3: Spanish results

5.2 Analysis

In both languages our system achieves better results for *Cor* over *IoU*. This probability value corresponds to the Spearman correlation between our system's predicted soft labels and the test set's soft labels, meaning that the correlation is calculated over intervals with a softer cutoff in values and isn't hindered as much by an incorrect prediction unlike with hard labels.

Test set questions	Correct retrieval	No pages found
154 (*en*)	120	2
152 (*es*)	84	13

Table 4: Module 1's retrieval performance

Our system tags intervals with 0 in cases where factual information isn't being discussed since it analyzes only nouns, proper nouns, adjectives and quantities. Since Mu-SHROOM's dataset questions mainly ask about factual information, our 0-tagged intervals tend to coincide with the task annotator's 0-tagged intervals. In addition, the non-zero tags correspond to a value that varies based on the edit distance between words, meaning that the tagging isn't binary and thus has a more lenient cutoff. Regardless, our *Cor* scores don't completely overshadow the *IoU* metric, suggesting that the hard labels predicted by this system could be improved by some factor based on the edit distance between mismatched words.

However our system's main setback comes from the information retrieval and gold standard generation section rather than the pairwise comparison. Before carrying out this comparison, a dataset containing the gold standards is created and used as reference for the following module. Table 4 shows that the retrieval process has room for improvement. In English 77% of retrieved pages are relevant for question answering, whereas in Spanish only 53% of the retrieved pages are relevant. Even in certain cases not a single Wikipedia page is retrieved.

By looking closer into the datasets we can observe various flaws in our pipeline. The Wikipedia based gold standards are inefficient due the sheer length of the final text used as a gold standard. English summaries average 262 words while Spanish ones average 287, on the other hand LLM-based gold standards average 16 and 25 words for each respective language. Considering that the test set's average answer lengths are 39 and 75 respectively, smaller gold standards work better with our pairwise comparison and avoid evaluating differences between a higher amount of words.

Furthermore, looking into gs_3's (Llama gener-

[2] https://helsinki-nlp.github.io/shroom/iou_rankings

ated gold standards based on Wikipedia summaries) dataset[3] we observe that several gold standards aren't actually correct answers, but rather Llama answering that the retrieved text doesn't provide information that actually helps in terms of answering the question. Some of these answers are in the form:

- `Apology` + *The given text doesn't have relevant information.*
- *The given text doesn't have information regarding* ***subject "x"****. However I can give you information regrading* ***subject "x"****.*

From the English test set 50 out of 154 gold standards consisted of these type of answers, in Spanish it was a total of 49 out of 152 (it's worth noting that the second type of answers were considerably more common in the Spanish implementation over the English one). This means that our model carries out an actual pairwise comparison in only two thirds of the cases, lowering performance even before the comparison. In addition to this, the actual LLM-based gold standards aren't always true gold standards. Even in cases were adequate information was retrieved, the augmented generation turned out to be incorrect, further decreasing our system's performance.

This highlights various short comings in our system. Working only with Wikipedia as a database limits our available information to each language's resources in the site. Furthermore automatic summaries are susceptible of losing particular information that can be relevant in cases of very precise questions, regardless if the summary is made by an API or an LLM.

6 Conclusion

In this paper we described MeSSI, our pairwise sentence comparison system based on lexical differences, as well as MeSSI's performance and limitations in the SemEval task Mu-SHROOM. In ideal cases our system correctly extracts relevant Wikipedia articles, generates an adequate gold standard and identifies differences in words between gold standards and test set questions.

However, ideal cases aren't always the norm. Wikipedia resources heavily depend on the language, almost 7 million articles are available in English compared with the 2 million in Spanish (Wikipedia, 2025), and Wikipedia unfortunately doesn't contain the whole of humanity's knowledge. On top of this, RAG pipelines are still prone to inadequate text generation, leading to incorrect gold standards used for pairwise comparison.

Regardless our system proved to be competitive in both languages and managed to tag soft and hard labels in a way to keep both values correlated, something that even the best performing Spanish model failed to do.

For future work and possible deployment in a context outside tasks, this system could be improved throughout the pipeline. Initially by enlarging the retrieval database using specialized corpora, textbooks, or general purpose datasets. This way our system is less dependent on one single resource and can cover a wider variety of subjects. The gold standard generation module could be improved by a finer segmentation and embedding of the retrieved documents, this would reduce size of extracted documents and benefit the LLM based generation as well as the pairwise comparison module. Finer text normalization would also improve the system, considering that various Wikipedia based texts contain separators like section and subsection names, or characters like "==".

Finally, alternatives for the comparison module could include a semantic analysis of answers in order to understand which elements coincide to factual information and over just tagged elements, while keeping interpretability of the model. A Transformer based approach, similar to the one presented in Vitamin C, could improve results and focus on token attention over PoST as well as including contextual representation of texts previous to comparison.

A Appendix

A.1 Gold Standards

gs_1: *The Aston Martin Vanquish is a grand tourer introduced by British luxury automobile manufacturer Aston Martin in 2001 as a successor to the Aston Martin Virage (1993). The Aston Martin V12 Vanquish, designed by Ian Callum and unveiled at the 2001 Geneva Motor Show, was produced from 2001 to 2007 as the flagship of the marque. A concept car, known as "Project Vantage" and the first Aston Martin design wholly designed by Callum, was built to display the company's vision for a future sports car that could represent Aston Martin's aspirations after the discontinuation of the Virage-based Vantage. The concept car evolved directly into the V12 Vanquish, and featured an advanced carbon fibre and alloy structure, Aston Martin's most powerful V12 engine, and host of new technologies. A specially modified V12 Vanquish was driven by James Bond in the 2002 film Die Another Day. In 2004, a mildly updated version of the first-generation model named "V12 Vanquish S" was introduced featuring a more highly tuned engine and more track-oriented ride and handling. The V12 Vanquish was indirectly replaced by the DBS after 2007. The second-generation "Vanquish" was introduced in 2012, this time based on Aston Martin's existing VH platform – similar to the one that underpinned the DB9. Designed by Marek Reichman and made in the Gaydon facility, the VH platform Vanquish was designed to fill the shoes of the discontinued DBS. In 2017, a "Vanquish S" with a more powerful engine and improved aerodynamics was launched. The second-generation Gaydon Vanquish was succeeded by the DBS Superleggera in 2018. In September 2024, Aston Martin announced the third-generation Vanquish as the successor of the DBS Superleggera.–The second generation of the Aston Martin Vanquish, a grand touring car, was produced between 2012 and 2018 by the British carmaker Aston Martin. It succeeded the DBS, resurrected the name of the 2001–2007 model, and was available as both a coupe and a convertible, the latter known as the Volante. Designed by Marek Reichman, a concept car called the Project AM310 was unveiled at the 2012 edition of the Concorso d'Eleganza Villa d'Este in Lombardy, Italy. The production version was showcased at several events in 2012: a sneak preview at the Goodwood Festival of Speed in July, a presentation to a group of guests at the London Film Museum also in July, and an appearance at the Monterey Car Week in August. The Vanquish, which is based upon the DB9's architecture, namely the vertical/horizontal platform, extensively incorporates aluminium throughout its construction. The Vanquish was produced in Gaydon, a village in Warwickshire, England. Aston Martin unveiled the Vanquish Volante at the 2013 Pebble Beach Concours d'Elegance, with deliveries starting in late 2013. In 2014, the company implemented minor modifications to the Vanquish's engine performance. A more significantly modified version, called the Vanquish S, was launched in 2016; its Volante version was released the following year. The Vanquish S introduced such updates as increased horsepower and torque, and a new body kit. Aston Martin produced the Vanquish Zagato—a special edition—in various body styles, in-*

cluding a coupe, convertible, shooting brake, and a roadster, the latter dubbed the Speedster. –The Aston Martin DBS is a grand tourer based on the DB9 and manufactured by the British luxury automobile manufacturer Aston Martin. Aston Martin has used the DBS name once before on their 1967–72 grand tourer coupé. The modern car replaced the 2004 Vanquish S as the flagship of the marque. The DBS ended production in 2012 and was succeeded by the second-generation of the Vanquish.

gs_2: *'—The interior of the DBS is a blend of carbon fibre, Alcantara, leather, wood, stainless steel and aluminium surfaces, depending on the buyerś specified options. The door panels are capped with carbon fibre or leather, and utilise carbon fibre door pulls. The fascia is, as standard, matrix alloy and iridium silver centre console or, as an optional extra, piano black fascia and centre console. To achieve even greater weight savings, the carpet has a special lightweight carbon weave. The car is started by means of the "Emotion Control Unit", which was initially developed especially for the DBS but became available for the DB9 and the V8 Vantage as well. The key is made from stainless steel and glass and is inserted into a special slot in the dashboard.== Film appearances ==The DBS was first seen in the 2006 James Bond film Casino Royale, the first film in which Bond was played by Daniel Craig, as a result of Eon Productionś desire to tie the new Bond actor to the franchise heritage with Aston Martin. The only in-car gadget featured in the film is a glovebox/safe that contains a spare pistol, silencer, and a medical kit with a defibrillator in its compartment. Bond uses the car to go to Casino Royale in Montenegro so he can find Le Chiffre. The car is later destroyed when James Bond swerves to avoid hitting Vesper, who had been used as a bait by Le Chiffre to lure Bond after being kidnapped. The cars used in the production were actually prototypes, based on DB9 test vehicles, as the film was produced well before the DBS entered production.The DBS returned for the pre-credits car chase around Lake Garda in the 2008 Bond film Quantum of Solace. The vehicle is colored a dark metallic dark grey, referred to as "Quantum Silver" in Aston Martinś options list, and doesnt́ have any gadgets. In the film, Bond uses the vehicle to deliver Mr. White to M while trying to avoid his pursuers, but is later damaged as a result. The cars used in the film are 2009 model year, German-market spec DBS production vehicles.== Naming confusion ==Some confusion over the name of the production version occurred when some test mules running around the Nürburgring were given DBRS9 badges. However, it would seem that this was only a trick played by the company to confuse spy photographers. The official name of the vehicle was declared to be DBS.== Production ==The DBS was built in Gaydon, Warwickshire. Its engine was built at the Aston Martin engine plant in Cologne, Germany.Production of the DBS totaled 3,381 units, including 2,536 coupes and 845 Volante versions.== References —The DBS was officially unveiled at the 2007 Pebble Beach Concours dÉlegance on 16 August 2007, which featured a brand new exterior colour (graphite grey with a blue tint) which has been dubbed "Lightning Silver".Deliveries of the DBS began in the first quarter of 2008.—The DBS Volante Dragon 88 honours the Year of the Dragon in China. It has 24-carat gold plate on nickel-coated Aston Martin wing badges affixed to the bonnet and rear of each car, bright finish front grille, bonnet meshes and side strakes; choice of three unique 10-spoke designs lightweight forged wheels with a special silver finish, Black brake callipers, a choice of 3 body colours (Amethyst Red, Volcano Red, Champagne Gold) with matching interior upholstery colours (Spicy Red, Deep Purple, Chancellor Red interior for Amethyst Red, Volcano Red, Champagne Gold body respectively), Sahara Tan thread stitching, Piano Black facia trim with a unique gold inlay pattern at dashboard, glass switchgear, headrest embroidery design with rendered using four thread colours (Metallic Gold, Cream Truffle, Winter Wheat and Kestrel Tan) inspired by the Nine-Dragon Wall in Beihai Park, unique laser-etched sill plaques bearing the number and designation, Presentation Box wrapped in the same leather as the interior of their car and lined with Ivory Alcantara (box lid bears an embroidered dragon, with Aston Martin wings embossed on to the front of the lid and a replica sill plaque on the inside of the lid; each box contains an Ownerś Guide with gold detailing, two glass ECUs with leather pouches, a pair of customised Bang & Olufsen earphones with laser-etched Aston Martin wings in a leather pouch) and a 1,000-Watt Bang & Olufsen audio system.The DBS Volante Dragon 88 was unveiled at the 2012 Beijing International Automotive Exhibition and production was limited to 88 units.'*

HowardUniversityAI4PC at SemEval-2025 Task 10: Ensembling LLMs for Multi-lingual Multi-Label and Multi-Class Meta-Classification

Saurav K. Aryal and **Prasun Dhungana**
Electrical Engineering & Computer Science
Howard University

Abstract

This paper describes our approach and submission to Subtask 1 of the SemEval 2025 shared task on "Multilingual Characterization and Extraction of Narratives from Online News". The purpose of Subtask 1 was to assign primary and fine-grained roles to named entities in news articles from five different languages, on the topics of Climate Change and Ukraine-Russia War. In this paper, we explain how we approached the subtask by utilizing multiple LLMs via Prompt Engineering and combining their results into a final result through an ensemble meta-classification technique. Our experimental results demonstrate that this integrated approach outperforms the provided baseline in detecting bias, deception, and manipulation in news media across multiple languages.

1 Introduction

Today, there is unprecedented access to information for audiences, largely due to direct channels between content producers and audiences. However, this also exposes readers to deception and manipulation, particularly during crisis events. To address these challenges and foster research on analytical tools for text analysis and disinformation detection (Ngueajio et al., 2025; Washington et al., 2021; Aryal et al., 2023a), SemEval 2025 Task 10 is aptly titled `Multilingual Characterization and Extraction of Narratives from Online News`. This task involves automatically identifying narratives, classifying them, and determining the roles of key entities. Subtask 1 of the shared task focuses specifically on Entity Framing, which this paper and our experiments tackled. The provided dataset comprises news articles in five languages—English, Portuguese, Russian, Bulgarian, and Hindi—and covers two domains: the Ukraine-Russia War and Climate Change (Piskorski et al., 2025).

Entity Framing is formulated as a multi-label, multi-class classification problem in which each entity mention is evaluated based on a fine-grained taxonomy that distinguishes between roles such as protagonists, antagonists, and innocents, and further differentiates each entity into specific fine-grained roles corresponding to its primary classification (Piskorski et al., 2025). This subtask challenges models to handle multilingual content and subtle contextual cues. In our work, we use a diverse set of advanced language models: Llama3.1 (8B parameters), Mistral (7B parameters), Phi4 (14B parameters) and Gemma2 (9B parameters). Their predictions are combined using an ensemble meta-classification strategy to yield robust, consistent role assignments.

Through this integrated approach, our objective is to demonstrate the effectiveness of LLMs in detecting bias, deception, and manipulation in the news media.

2 Related Work

Mahmoud et al. (2025) introduce a multilingual corpus for entity framing in news, employing a hierarchical taxonomy of 22 fine-grained roles across three main categories. Their dataset—comprising 1,378 articles in five languages and covering domains such as the Ukraine-Russia War and Climate Change—is annotated with detailed guidelines and evaluated using fine-tuned transformers and zero-shot learning. In contrast, our work leverages prompt engineering with advanced LLMs for entity role classification, offering a complementary approach to narrative framing in news media.

Lee et al. (2022) present a comparative study of BERT-based models for multiclass text classification on a Korean research proposal dataset that covers 45 categories of climate technology. Their findings emphasize the importance of language-specific pretraining in boosting classification performance for non-English texts. Although their work targets research proposals rather than news articles, the insights on model selection and the

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1585–1592

impact of pretraining corpora are highly relevant to our multilingual entity framing task. Their results underscore the challenges inherent in applying pre-trained language models to diverse, domain-specific datasets, which complements our exploration of prompt engineering with advanced LLMs for robust, multilingual role classification.

Multiple authors have provided a broad evaluation of LLM-based text classification methods across various datasets and languages, comparing zero-shot, few-shot, and synthetic data approaches (Aryal et al., 2023b, 2022; Vajjala and Shimangaud, 2025). Although their work primarily targets general text classification rather than news entity framing, their findings on performance disparities across languages and the benefits of synthetic data generation are highly relevant. Their study underscores the challenges of working with limited labeled data and complex multilingual settings, issues that our work also addresses through prompt engineering with advanced LLMs for entity role classification in news.

3 System Overview

The system begins with a robust data preprocessing module that ingests news articles from the dataset in multiple languages: English, Portuguese, Russian, Bulgarian, and Hindi, and extracts entity mentions along with the article texts. Each extracted entity is converted into a structured dictionary containing key metadata such as article ID, article text, and character indices. This structured representation is then passed to our classification engine.

The classification engine employs an LLM of choice, through the Ollama API. Each model is prompted with a carefully engineered instruction set that enforces strict classification rules, ensuring that every entity is assigned one primary role (Protagonist, Antagonist, or Innocent) along with corresponding predefined fine-grained roles chosen from the provided lists. Given the variability in model outputs, we observed that a single model could occasionally generate erroneous tokens or roles not included in the prompt. To counteract this, our pipeline includes a cleaning step that filters out irrelevant characters and incorrect classifications.

The final stage of our system is a meta-classification process. Here, we aggregate the predictions of all LLMs we used and use Phi4 to merge these outputs into a consensus classification. It is important to note that our initial system used only Llama3.1:8b, but was later upgraded to this ensemble method. It emphasizes role frequency and consistency across models, proving effective at boosting overall performance compared to a single-model baseline. The resulting outputs are then reformatted into tab-separated files for submission, ensuring both readability and compliance with the shared task requirements. [1]

4 Experimental Setup

Our experiments were carried out in a cloud-based Google Colab environment, which provided a v2-8 TPU runtime with 334.6 GB of system RAM and 225.3 GB of disk storage. This configuration was vital for handling the computational demands of processing multilingual news articles and running multiple large language models (LLMs). Training data provided by SemEval 2025 Task 10 organizers was stored on Google Drive with full permissions, allowing seamless access and file management during experiments.

4.1 Infrastructure and LLM Integration

To efficiently prompt various LLMs iteratively, we configured an Ollama API server within the Colab environment. The API was installed through a shell script (using `curl`) and launched as a separate process through Python's `subprocess` and `threading` modules. This setup ensured that the interactive environment remained responsive while the models were used.

The models we selected were based on their widespread adoption and demonstrated effectiveness in analogous multi-label multi-class text classification tasks. Furthermore, we resorted to using certain parameter sizes for each model based on our available computational infrastructure and resource constraints. The LLMs integrated into our pipeline include:

Model	Parameter Size	Quantization
Llama3.1	8.03B	Q4_K_M
Mistral	7.25B	Q4_0
Phi4	14.7B	Q4_K_M
Gemma2	9.24B	Q4_0

Table 1: Model Specifications

It is important to note that these individual LLMs do not interact with each other and generate their

[1] Our code is publicly available at this link.

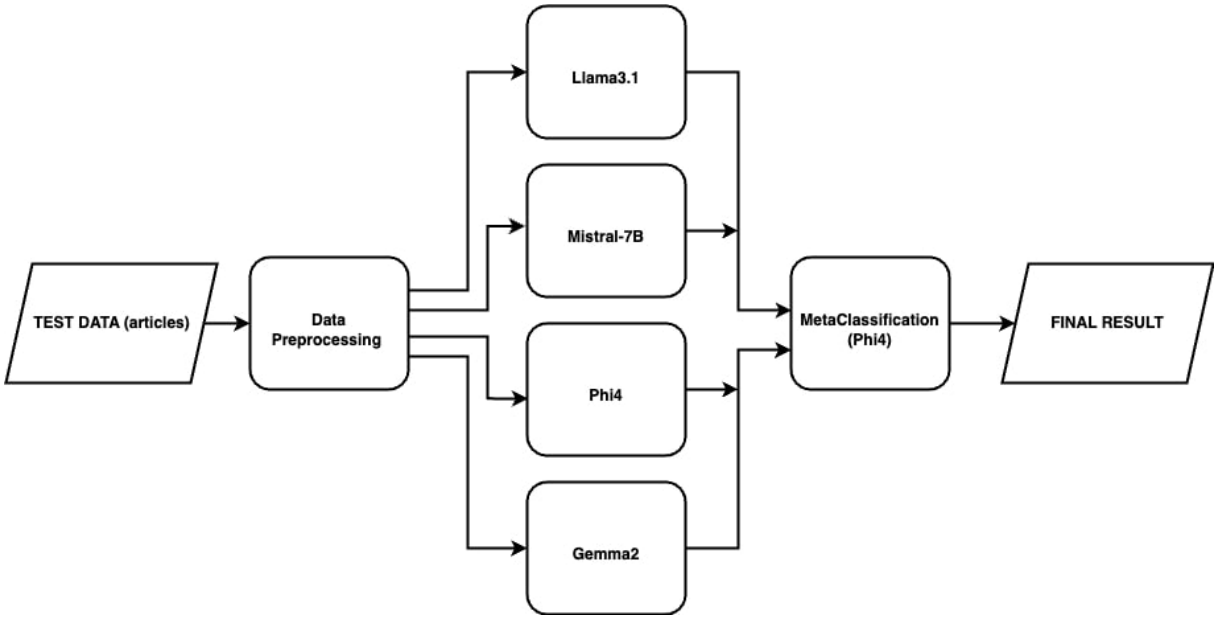

Figure 1: Diagram Illustrating the System[a]

[a]The diagram is not meant to imply that the model inferences occur concurrently. These LLMs do not interact with each other and generate their results separately at different times.

results separately, at different times.

We also evaluated DeepSeek-R1 (14.8 billion parameters and Q4_K_M quantization); however, following its tendency to generate placeholder outputs (e.g., ???, ...), we decided to exclude its results altogether.

4.2 Data Preprocessing and Classification Pipeline

In the Google Colab environment, we developed Python routines to preprocess test articles and entity mentions in English, Portuguese, Russian, Bulgarian, and Hindi by extracting the complete text and entity annotations through string manipulation techniques. Each entity was encapsulated within a structured Python dictionary with metadata (article ID, full text, entity label, start index, and end index). This structured representation was then supplied to a classification function, also implemented in Python and interfacing with the Ollama API, that employed a unified prompt rigorously designed to enforce strict role assignment.

4.3 Prompt Engineering and Iterative Approach

In the initial formulation of the prompt, we stipulated the following requirements:

- Each entity receives exactly one primary role (Protagonist, Antagonist, or Innocent).
- Fine-grained roles are selected from predefined lists corresponding to each primary role.
- The output is to be provided as a structured JSON format for clarity and uniformity.

However, this prompt exhibited several shortcomings. Although the output was nominally in JSON format, we observed significant formatting inconsistencies, notably the erroneous use of single quotations instead of double quotations. To address this, we employed the structured output generation feature of the Ollama API and enforced the JSON schema programmatically rather than relying on ther prompt. In addition, the model repeatedly assigned roles that were outside the prescribed set, such as 'Propagandists' and 'Aggressor', even though we had provided a list of acceptable fine-grained roles. To address this, we augmented the prompt with the explicit instruction:

- Do not classify any entity into role(s) not provided in the list.

However, misclassifications persisted even after numerous prompt variations, including alternative sentence structures and command-word capitalization. Ultimately, we introduced concrete failure examples, illustrating commonly generated misclassifications such as 'Propagandists' and 'Aggressor',

directly into the prompt. This modification produced a significant improvement, with substantially fewer incorrect role assignments. Nevertheless, formatting errors and sporadic misclassifications still remained in the generated outputs. Consequently, we integrated a post-processing step into our pipeline to systematically filter out erroneous characters and eliminate any remaining irrelevant role assignments. The final prompt for individual inference for each LLM can be found in the Appendix at A.1.

4.4 Ensemble Meta-Classification

To further improve our classification reliability, we aggregated predictions from the multiple LLMs we used. We used Phi4 to merge these outputs into a consensus classification, emphasizing role frequency and consistency across models. The consensus results were then reformatted into tab-separated files suitable for submission. The prompt for meta-classification, which can be found in the Appendix at A.2, also provides direct commands based on the subtask requirements. Following the effectiveness of our prompt for individual inference, we resorted to using the requirements and failure examples in an almost identical way for the meta-classification prompt. This prompt resulted in only minor errors, which prevented us from iteratively changing it.

5 Evaluation

The initial single-model approach, which solely relied on Llama3.1:8b and was used for processing English articles, performed worse than the baseline model. However, by integrating outputs from multiple LLMs through this ensemble meta-classification strategy, we observed a significant enhancement in performance. The ensemble approach effectively consolidated individual predictions, leading to more robust and consistent classifications across various languages. Table 2 exemplifies this improvement through all five languages, with our system consistently outperforming the baseline across key metrics.

However, each LLM generated irrelevant roles or erroneous characters for multiple entities, at every iteration. For example, the most frequently generated erroneous characters include `':'`, `']'`, `'['`, `','`, `'>'`, etc. Similarly, the most frequently generated irrelevant roles were `'Propagandists'` and `'Aggressor'`.

In case of DeepSeek-R1, the results were extremely unreliable, with multiple instances of entities not being classified at all or erroneous characters populating the fields for primary and/or fine-grained roles. For example, a correctly formatted entity role assignment versus DeepSeek-R1 results can be compared at Table 3.

6 Limitations

Although our system demonstrates an improved performance over the baseline, we must acknowledge the several limitations in our system and solution.

Due to resource constraints, we opted for LLMs that primarily were compatible with our available hardware and time limitations. This decision prevented us from experimenting with larger models that might have yielded even more accurate classifications with better overall metrics compared to the baseline. We were also unable to test, observe, and improve the metrics of each LLM separately for the subtask for the same reasons, hence resorting to ensemble meta-classification from the get-go.

Our experiments were conducted using limited paid Google Colab compute units, which provided the necessary computational power for heavy inference throughout. However, our reliance on high-performance resources for this system may limit the reproducibility of our results for researchers with less access to such hardware and resources.

Our approach focused primarily on prompt engineering to guide model outputs, without exploring additional methods such as fine-tuning or retraining on the provided datasets. While prompt engineering proved effective, further improvements might be achieved through more advanced training techniques, which we were not able to pursue in this work due to resource and time constraints. Lastly, our system also poses some inherent risks, including the possibility of algorithmic bias in the LLMs we have employed and the ethical implications of automated content evaluation.

7 Conclusion

In this work, we presented a comprehensive approach to how we utilized multiple LLMs in a unified system for multilingual entity framing. Our experiments on the SemEval 2025 Task 10 Subtask 1 dataset demonstrate that a set of models - combined with targeted prompt engineering and rigorous output cleaning - can achieve substantially higher performance. While our results do indicate promising improvements in metrics such as Exact Match and micro F1, our system also highlights critical limitations. Resource constraints, hardware limitations, and the inherent challenges of prompt engineering for structured output still remain significant hurdles towards replicability. Future research should explore the capabilities of each of the LLMs used individually and also experiment

with advanced fine-tuning strategies and adaptive prompt mechanisms to further enhance model consistency and reliability. Overall, our work underscores the potential of leveraging LLM ensembles for nuanced tasks such as narrative extraction and entity role classification in a multilingual context.

A Appendix

A.1 Prompt for Entity Classification

Given the article with articleID {article_id}, {article_text}, and the entity: {entity_name}, classify the entity into one of the following **primary roles**:
- 'Protagonist'
- 'Antagonist'
- 'Innocent'

The classification must reflect the author's sentiment toward the entity as expressed in the article.

Next, assign one or more **fine-grained roles**, strictly chosen from the list associated with the assigned primary role:

- **Protagonist**: ['Guardian', 'Martyr', 'Peacemaker', 'Rebel', 'Underdog', 'Virtuous']
- **Antagonist**: ['Instigator', 'Conspirator', 'Tyrant', 'Foreign Adversary', 'Traitor', 'Spy', 'Saboteur', 'Corrupt', 'Incompetent', 'Terrorist', 'Deceiver', 'Bigot']
- **Innocent**: ['Forgotten', 'Exploited', 'Victim', 'Scapegoat']

Important Requirements:
1. Assign exactly one **primary role** ('Protagonist', 'Antagonist', or 'Innocent').
2. Assign one or more **fine-grained roles**, strictly from the associated list above.
3. Do not invent or use roles that are not listed above.
4. Do not leave the primary role or fine-grained roles empty or undefined.

Failure Examples:
- Assigning a primary role not listed (e.g., 'Neutral').
- Assigning fine-grained roles not listed (e.g., 'Aggressor', 'Fascist Leader', 'Extremist', 'Scam', 'Expansionist', 'Imperialist', 'Military', 'Propagandists', etc.)
- Leaving the fine-grained roles empty.

Make sure that the classification strictly follows these rules. Your response should only include the assigned **primary role** and the corresponding **fine-grained roles**.

Figure A.1: Prompt for Individual LLM Inference

A.2 Prompt for Meta-Classification

Given the article with ID: {article_id}:
{article_text}

The entity: {entity_name} has been classified by multiple models as:

Primary Role Options: {primary_roles}
Fine-Grained Role Options: {fine_grained_votes}

Based on the given article and model predictions, determine the most appropriate primary_role and fine_grained_roles for each entity.
Make sure to account for any role that occurs multiple times in different models' predictions and give higher emphasis to those.

Primary Roles:
- **Protagonist**: ['Guardian', 'Martyr', 'Peacemaker', 'Rebel', 'Underdog', 'Virtuous']
- **Antagonist**: ['Instigator', 'Conspirator', 'Tyrant', 'Foreign Adversary', 'Traitor', 'Spy', 'Saboteur', 'Corrupt', 'Incompetent', 'Terrorist', 'Deceiver', 'Bigot']\n"
- **Innocent**: ['Forgotten', 'Exploited', 'Victim', 'Scapegoat']

Important Requirements:
1. Assign exactly one **primary role** ('Protagonist', 'Antagonist', or 'Innocent').
2. Assign one or more **fine-grained roles**, strictly from the associated list above.\n"
3. Do not invent or use roles that are not listed above.
4. Do not leave the primary role or fine-grained roles empty or undefined

Failure Examples:
- Assigning a primary role not listed (e.g., 'Neutral').
- Assigning fine-grained roles not listed (e.g., 'Aggressor', 'Fascist Leader', 'Extremist', 'Scam', 'Expansionist', 'Imperialist', 'Military', 'Propagandist', etc.)
- Leaving the fine-grained roles empty.

Make sure that the classification strictly follows these rules. Your response should only include the assigned **primary role** and the corresponding **fine-grained roles**.

Abstract

Food safety is a critical global concern, and automating the detection of food hazards from recall reports can improve public health monitoring and regulatory compliance. This paper presents our submission for SemEval-2025 Task 9: The Food Hazard Detection Challenge. We tackle the inherent class imbalance in this task by leveraging advanced data augmentation techniques, including LLM-based synthetic data generation, synonym replacement, and back-translation.

We employ transformer-based models such as DistilBERT, fine-tuned with these augmented datasets, to enhance performance. Our system achieves significant improvements, obtaining a Macro-F1 score of **0.7882** in ST1 and **0.5099** in ST2.[1] Additionally, we analyze the impact of augmentation strategies and compare multiple architectures, highlighting challenges in handling implicit hazards. Our findings underscore the effectiveness of LLM-based augmentation in addressing extreme class imbalance while demonstrating the strengths and limitations of transformer models in food safety applications.

1 Introduction

Ensuring food safety is a critical challenge in public health, requiring timely detection of hazards leading to product recalls. Traditional methods rely on manual expert analysis, which is time-consuming and lacks scalability. Recent advances in natural language processing (NLP) have enabled automated food hazard detection from recall reports, improving regulatory oversight. However, class imbalance in real-world datasets, where some classes are overrepresented, remains a challenge for accurate predictions (Gao, 2020).

SemEval-2025 Task 9: *The Food Hazard Detection Challenge* focuses on classifying food hazards and products from textual reports (Randl et al., 2025). This task is crucial for enhancing food security and public health interventions. It consists of two subtasks:

- **ST1**: Classifying the hazard category and product category.
- **ST2**: Identifying the exact hazard and exact product mentioned in the report.

The primary challenge of this task is the extreme class imbalance, where certain classes appear far more frequently than others. Figure 1 illustrates the severity of class imbalance through a probability distribution.

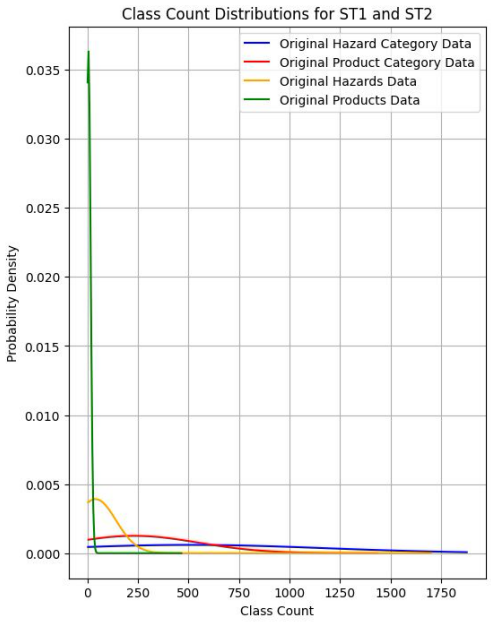

Figure 1: Distribution of classes by hazard-category, product-category, hazard, and product

We propose a transformer-based model augmented with synthetic data from LLMs like GPT-4o, Gemini Flash 1.5, and T5 to address this imbalance. Our approach leverages DistilBERT, which has proven effective in handling class imbalance,

[1]Our Code: https://github.com/msaadg/hu_semeval_task9

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1593–1601
July 31 - August 1, 2025

and fine-tunes it on both original and augmented datasets.

Our system ranked 5th in ST1 and 4th in ST2. Despite these achievements, challenges persist in identifying implicit hazards and dealing with highly imbalanced categories, which require further refinement (Henning et al., 2023). The results confirm that data augmentation plays a key role in overcoming class imbalance.

The dataset provided by the SemEval-2025 organizers contains structured recall reports sourced from food regulatory bodies. It consists of:

- **Training Data:** 5,082 samples.
- **Validation Data:** 565 samples.
- **Test Data:** 997 samples.
- **Hazard Categories:** 10
- **Product Categories:** 22
- **Hazards:** 128
- **Products:** 1,142

Each report includes 'year', 'month', 'day', 'country', 'title', 'text', 'hazard-category', 'product-category', hazard, and product. During preprocessing, we merged 'title' and 'text' into a unified field 'title_text' to enhance contextual representation.

2 Related Work

The challenge of food hazard detection has been extensively studied, with recent advancements leveraging Natural Language Processing (NLP) for automated risk assessment. Traditional approaches have primarily relied on rule-based methods and handcrafted feature extraction, which often fail to generalize across diverse recall reports. According to (Gao, 2020), while these methods have been widely used, they struggle with the complexity and scale of modern datasets. More recently, deep learning models, particularly transformers, have demonstrated superior performance in food safety classification tasks, significantly outperforming traditional methods (Buyuktepe et al., 2025).

2.1 Food Hazard Detection Using NLP

Food safety monitoring requires extracting key hazard-related information from unstructured recall reports. Earlier work focused on keyword-based extraction and ontology-driven approaches. However, with the advent of deep learning, transformer-based architectures like BERT and DistilBERT have enabled more accurate hazard classification, as seen in recent studies (Zhou et al., 2020). These models offer improved flexibility and performance over rule-based methods, as they can capture semantic nuances in text. Our work builds upon these advancements by tackling the extreme class imbalance inherent in food recall datasets, an issue that has been discussed in the context of NLP-based food safety applications (Gao, 2020).

2.2 Handling Class Imbalance in NLP

Class imbalance poses a significant challenge in multi-class NLP classification, particularly when dealing with underrepresented categories. According to (Henning et al., 2023), traditional methods like oversampling and undersampling often lead to overfitting and loss of information, which can negatively impact model performance. More recently, synthetic data augmentation has emerged as a promising solution to this issue. Studies such as (Meng et al., 2020) and (Gao, 2020) have demonstrated the efficacy of techniques like contextual augmentation, back-translation, and paraphrasing in mitigating class imbalance. Our approach extends this by leveraging Gemini Flash 1.5 and GPT-4o for targeted LLM-based augmentation, generating diverse synthetic data to improve model generalization, particularly for rare hazard categories.

2.3 Explainability in Food Safety NLP

Explainability is critical in automated food safety monitoring, ensuring transparency and trustworthiness. According to (Ribeiro et al., 2016), techniques like LIME and SHAP provide insights into how machine learning models make predictions. However, these techniques often struggle with implicit hazard detection, particularly for rare or underrepresented classes. Our experiments in ST2 confirm the said limitations, with (Pavlopoulos et al., 2022) highlighting similar challenges when interpreting complex models in the food hazard domain. These findings emphasize the need for alternative interpretability methods, which we explore further in our work.

3 System Overview

In this section, we present our methodology for tackling the task. As mentioned earlier, the primary challenge of this task lies in the severe class

imbalance in both hazard and product categories, which hinders model generalization (Gao, 2020). Additionally, implicit relationships between hazards and products pose an extra layer of complexity (Henning et al., 2023). To address these issues, we integrated transformer-based models with diverse data augmentation strategies and applied a series of training optimizations to enhance model performance.

3.1 Data Augmentation Strategies

Given the highly skewed distribution of hazard and product categories, where several classes appear fewer than ten times in the dataset (see Appendix A), we employed multiple augmentation techniques to enrich data diversity and improve classification robustness. As noted by (Gao, 2020), augmentation techniques like synonym replacement and back-translation have been proven to alleviate class imbalance. The augmentation strategies included synonym & contextual replacement, back-translation, paraphrasing and large language model based synthetic data generation. Synonym & contextual replacement was implemented using the NLTK WordNet, where at most 5 words in the text were replaced with contextually appropriate synonyms (Meng et al., 2020). Back-translation was performed using French and German translations to generate alternative textual representations while preserving semantic consistency, on texts where the class count was under 50 for ST1 and under 20 for ST2. T5-base was used to paraphrase sentences for classes with less than 30 entries in the original training dataset, so that alternative formulations of the text were generated while maintaining the original meaning and retaining the classes. The augmented dataset had at least 30 entries for each class of hazard and product. Furthermore, we employed state-of-the-art LLMs like Gemini Flash 1.5, GPT-4o & o1-mini for their diverse text-generation capabilities to synthesize recall reports for classes with less than 50 entries in the original dataset such that each class has at least 50 entries in the augmented dataset. This significantly expanded the training dataset while also diversifying the kind of texts for each class. This approach aligns with studies where LLM-based data augmentation has been shown to improve generalization in imbalanced datasets (Zhou et al., 2020).

To quantify the contribution of each augmentation technique, we report the distribution of augmented samples generated for ST1 and ST2. For ST1, synonym and contextual replacement, back-translation, and LLM-based synthetic data generation were applied to address class imbalance in hazard and product categories. For ST2, similar techniques were used, with additional emphasis on paraphrasing via T5-base to enhance fine-grained hazard and product identification. The total number of samples after augmentation was 15,570 for ST1 and 63,082 for ST2, expanding the original 5,082 training samples. Table 1 summarizes the count-wise distribution of samples from each augmentation technique for both subtasks.

To ensure the integrity of the augmented dataset, as detailed in Table 1, all augmented samples underwent human verification to eliminate label leakage and maintain data consistency. The augmented data was carefully merged with the original dataset, following a structured approach to avoid overfitting on artificial samples, which is a common issue when synthetic data is introduced (Shorten et al., 2021). Figure 2 shows the balanced class distribution after data augmentation.

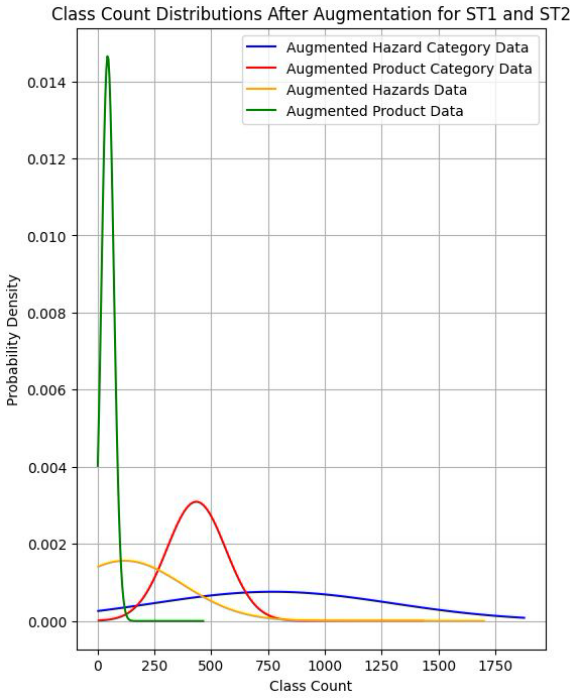

Figure 2: Final Distribution of Classes after Augmentation

3.2 Model Architectures

We experimented with multiple transformer architectures to determine the most effective model for both subtasks. Initially, we used 'bert-base-

Table 1: Distribution of Augmented Samples for ST1 and ST2 by Augmentation Technique

Augmentation Technique	**ST1 Samples**	**ST2 Samples**
Synonym & Contextual Replacement	4150	20,167
Back-translation	3210	1,130
Paraphrasing	0	15,036
LLM-based Synthetic Data Generation	2564	10,823
Total Augmented Samples	9924	47,156

uncased' as our baseline, which performed very poorly on low sample classes. Recognizing the need for a more effective model, we explored various transformer-based alternatives, including RoBERTa, XLM-R, ALBERT, and Sci-BERT. However, 'distilbert-base-uncased' emerged as the most effective model across both subtasks, significantly outperforming other models. This aligns with findings that DistilBERT has shown to outperform other transformer variants in tasks with class imbalance due to its reduced computational demands and ability to retain performance comparable to larger transformer models (Zhou et al., 2020).

3.3 Training Pipeline and Optimization

Training pipelines for both subtasks incorporated 3 major steps: augmenting the data, merging augmented data with original data, and finally training the model. To further enhance model performance, we also incorporated optimization techniques into our pipeline, such as early stopping, class weights, and learning rate scheduling.

Furthermore, for ST2 we experimented with ensemble modeling by training two DistilBERT models on different random seeds and aggregating their logits using a max-logit selection strategy (Gao, 2020). This approach enhanced model robustness, particularly in identifying low-resource hazard and product categories. See Appendix B to get the complete overview of the pipelines for both subtasks, respectively.

3.4 Explainability Methods

Explainability techniques such as LIME and SHAP presented significant limitations. According to (Ribeiro et al., 2016), LIME and SHAP are valuable for interpreting model predictions, but we faced two major challenges in ST2:

- These models are resource-intensive, requiring significant computational power. Preliminary tests indicated that completing one epoch on Google Colab's T4 GPU would take approximately 18 days, making them impractical.
- LIME and SHAP primarily identify explicit features contributing to predictions but struggle with implicit hazards. For instance, the term "Latvian" was highlighted as the most significant contributor to a hazard category, but it wasn't the actual hazard, illustrating the models' limitations in predicting exact hazards and products.

4 Experimental Setup

The experimental setup aimed to address challenges such as class imbalance and computational efficiency while ensuring robust training and evaluation. We used Google Colab's T4 GPU and Kaggle's T4x2 GPUs for efficient fine-tuning. Our models were trained using the AdamW optimizer with a learning rate of $5e^{-5}$, a batch size of 8, and a maximum of 5 epochs. Early stopping was applied to avoid overfitting, halting training when validation loss plateaued. To address class imbalance, class weights were computed based on inverse class frequency (see Appendix C), which helped the model focus on underrepresented hazard and product categories (Gao, 2020). Learning rate scheduling was applied using a linear decay schedule with a warm-up phase, allowing for stable training convergence.

Text preprocessing involved merging the 'title' and 'text' fields into a single 'title_text' feature to maximize contextual representation. Tokenization was handled using model-specific tokenizers, like 'AutoTokenizer' for BERT and DistilBERT, with input sequences truncated to 512 tokens for computational feasibility. We utilized nlpaug 1.1.11 for synonym replacement, contextual augmentation, and back-translation, and Gemini 1.5 Flash and GPT-4o for synthetic data generation, which helped mitigate class imbalance (Meng et al., 2020).

Evaluation metrics included Macro-F1, with scores calculated on both ST1 and ST2.

5 Results & Analysis

The results of our experiments reveal a clear trend in the impact of data augmentation and model selection on performance improvements. Our final model, 'distilbert-base-uncased', demonstrated significant gains in Macro-F1 scores over the baseline model, highlighting the effectiveness of augmentation techniques in addressing severe class imbalance and enhancing classification accuracy across underrepresented classes.

5.1 Performance Gains

The baseline model, 'bert-base-uncased', trained for five epochs, achieved a Macro-F1 score of 0.4965 for ST1 and 0.009 for ST2. This stark contrast between the two subtasks underscores the challenge of exact hazard and product detection due to the large number of low-frequency categories. The poor performance in ST2 highlights the difficulty of predicting fine-grained hazard and product labels without sufficient examples of each class. Event extraction models, like those proposed by (Harrag and Gueliani, 2020), face similar challenges in detecting rare event categories, particularly when there is insufficient training data.

By implementing synonym replacement through NLTK WordNet, ST1 saw a notable improvement to 0.701, but ST2 remained largely unaffected. This suggests that simple lexical augmentation is effective for coarse-grained classification but does not introduce sufficient diversity for granular hazard-product identification. The need for more diverse augmentation strategies for fine-grained predictions has been observed in previous studies as well (Meng et al., 2020).

Then in order to augment the dataset that improves score in ST-2, we made use of the infamous encoder-decoder transformer model, t5-base, in order to paraphrase the texts with more contextual information and grammatical correctness. The score, after using this, jumped to 0.43, which suggests that attention based mechanisms are good at retaining information, while adding diversity to the texts, which helped the model learn its characteristics more effectively.

The introduction of LLM-based augmentation using Gemini Flash 1.5 and GPT-4o significantly improved performance, increasing ST1 to 0.779 and ST2 to 0.47. The synthetic samples generated by Gemini provided more varied examples for rare categories, reducing model bias towards majority classes. This improvement was also evident in ST2, which benefited from the increased exposure to underrepresented hazard-product pairs. The effectiveness of LLM-based data augmentation for imbalanced datasets has been demonstrated in similar domains. (Assael et al., 2022).

Further augmentation using 'nlpaug' techniques, including back-translation (French and German) and contextual synonym replacement, further enhanced classification performance, bringing ST1 to 0.811 and ST2 to 0.49. The introduction of sentence-level diversity allowed the model to better generalize beyond the original training samples, mitigating the imbalance problem further, as seen in studies utilizing back-translation for food safety tasks (Shorten et al., 2021).

The final transition to 'distilbert-base-uncased', trained on the fully augmented dataset, resulted in a Macro-F1 of 0.7882 securing 5th place for ST1 and 0.5099 securing 4th place for ST2 on the test dataset. Notably, the improvements in ST2 suggest that increasing the diversity of samples was crucial for extracting implicit hazard-product relationships, reinforcing the necessity of extensive augmentation for fine-grained classification (Zhou et al., 2020).

5.2 Error Analysis

An in-depth analysis of misclassifications revealed that the model performed well on high-frequency categories but struggled with extremely rare hazards and products. The class imbalance led to instances where certain hazards or products, despite their unique nature, were mapped to broader, more frequently occurring categories. For example, rare food contaminants were often misclassified into broader chemical hazard categories, indicating a lack of precise decision boundaries for low-sample classes. Similar misclassifications have been discussed in food hazard detection tasks, where rare instances are misclassified into broader categories (Harrag and Gueliani, 2020).

Additionally, implicit hazards presented significant challenges. Many instances of food recall reports describe contamination or issues without explicitly stating the hazard category. The model struggled to infer implicit relationships between food safety incidents and their corresponding hazard types. This aligns with our earlier observations regarding the limitations of LIME and SHAP in capturing implicit relationships (Pavlopoulos et al., 2022).

Another common misclassification pattern was observed in ST2, where highly specific hazard-product pairs were mislabeled due to insufficient positive training samples. Although augmentation improved classification, the model still exhibited difficulty in capturing the nuance of rare pairings, reinforcing the need for further improvements in dataset balancing strategies (Ozyegen et al., 2022).

5.3 Comparison with Leaderboard Results

While our augmentation strategies and model optimizations narrowed the performance gap compared to top systems (0.8223 for ST1, 0.5473 for ST2), further improvements are still possible. Similar gaps have been observed in other NLP tasks, where augmentation and optimization were key factors (Gao, 2020)

Key differences in approaches of top teams include:

- **LLM-Enhanced Augmentation:** Top teams used DeBERTa v3 Large and RoBERTa Large with fine-tuned LLMs (e.g., Gemini, RAG), while our pipeline focused on Gemini Flash 1.5 and 'nlpaug', significantly improving minority class detection.
- **Ensemble Learning:** High-ranking teams used multiple transformer models with soft voting, while we used two ensembled DistilBERT models for ST2, improving robustness but lacking the power of multiple model ensembles.
- **Chunking and Data Representation:** Some teams experimented with chunking input data into various token sizes, but we used a fixed title + text representation, optimizing classification but possibly limiting generalization.
- **Fine-Tuning Strategies:** Leading teams used LoRA fine-tuning on RoBERTa-based models, whereas we focused on DistilBERT and augmentation-centric enhancements.

While our system performed well under constraints, future iterations could benefit from LLM-based retrieval mechanisms (e.g., RAG), soft voting across multiple LLMs, and chunking strategies to improve hazard-product representation. As noted in Assael (2022), LLM-based reasoning could provide richer context for rare classes and implicit relationships (Assael et al., 2022).

6 Conclusion

This work tackled the challenges of food hazard detection in SemEval-2025 Task 9, focusing on extreme class imbalance and enhancing model generalization through LLM-based augmentation (Gao, 2020). By employing a combination of contextualized synonym replacement, paraphrasing, back-translation, and synthetic data generation, we significantly improved classification performance, particularly for low-frequency categories (Shorten et al., 2021). Among various transformer models, 'distilbert-base-uncased' provided the best trade-off between efficiency and accuracy, achieving a final Macro-F1 of 0.7882 (ST1) and 0.5099 (ST2). While these improvements are noteworthy, further refinements are necessary for addressing ongoing challenges, especially implicit hazard detection.

7 Limitations

Despite the advancements made in this work, several limitations remain. Class imbalance continues to be a major issue, particularly for rare hazard and product categories, where the model still struggles with suboptimal performance (Henning et al., 2023). While data augmentation techniques have alleviated some of the imbalance, further enhancement is needed (Meng et al., 2020). Implicit hazard detection remains an ongoing challenge, especially when hazards are inferred rather than explicitly stated. This underlines the need for more advanced interpretability techniques to handle such implicit relationships (Ribeiro et al., 2016). Additionally, while our approach has shown improvements, incorporating strategies like contrastive data augmentation, hierarchical classification, and ensemble learning (Ozyegen et al., 2022) could further boost model robustness and generalization.

Acknowledgments

We thank the SemEval-2025 Task 9 organizers for providing the dataset and challenge framework (Randl et al., 2025). We acknowledge computational support from Google Colab and Kaggle, which enabled large-scale training. Contributions from the open-source NLP community, including augmentation libraries and transformer models, were instrumental in our research.

C Class Weights Implementation

To address the class imbalance in our dataset, we incorporated class weights into the loss function during training. The primary goal was to ensure that underrepresented classes, which occur far less frequently, were given more importance in the loss

computation, thereby guiding the model to better focus on these classes. This was particularly important in tasks like hazard and product category classification, where some categories were significantly more frequent than others.

The class weights were calculated based on the inverse frequency of each class in the training dataset. Specifically, for each class, the weight was computed as the inverse of its frequency relative to the total number of samples. The weight for class i is given by:

$$w_i = \frac{N}{f_i}$$

Where:

- w_i is the weight for class i,
- N is the total number of samples in the training dataset,
- f_i is the frequency of class i.

These computed weights were then integrated into the loss function, ensuring that the model penalized misclassifications of rare classes more than those of more frequent ones. By doing so, we mitigated the effect of class imbalance and helped the model focus on learning from the underrepresented classes, which would otherwise be overshadowed by the more frequently occurring classes.

This approach aligns with the findings of (Henning et al., 2023), where the use of class weights has been shown to improve model performance in imbalanced classification tasks by preventing the model from being biased towards the majority class.

By adjusting the loss function in this manner, we were able to improve the model's ability to detect and classify rare hazard and product categories, ultimately leading to better performance on both subtasks ST1 and ST2.

Abstract

Large Language Models (LLMs) often generate hallucinated content, which is factually incorrect or misleading, posing reliability challenges. The Mu-SHROOM shared task addresses hallucination detection in multilingual LLM-generated text. This study employs SpanBERT, a transformer model optimized for span-based predictions, to identify hallucinated spans across multiple languages. To address limited training data, we apply dataset augmentation through translation and synthetic generation. The model is evaluated using Intersection over Union (IoU) for span detection and Spearman's correlation for ranking consistency. While the model detects hallucinated spans with moderate accuracy, it struggles with ranking confidence scores. These findings highlight the need for improved probability calibration and multilingual robustness. Future work should refine ranking methods and explore ensemble models for better performance.

1 Introduction

Large Language Models (LLMs) are widely used in Natural Language Processing (NLP) applications, including text generation, summarization, and conversational AI (Fan et al., 2024). However, they often generate hallucinated content, information that appears plausible but is incorrect or misleading. These hallucinations pose challenges in ensuring the reliability and factual consistency of generated text (Ji et al., 2023).

Detecting hallucinations becomes more difficult in multilingual settings. Variations in grammar, vocabulary, and training data across languages affect a model's ability to identify and rank hallucinated spans consistently (Kang et al., 2024). Low-resource languages tend to exhibit higher hallucination rates due to limited training data, whereas high-resource languages, such as English, may benefit from more extensive supervision. Addressing these challenges requires models that generalize across languages while maintaining effective hallucination detection capabilities.

The Mu-SHROOM shared task[1] aims to advance research in multilingual hallucination detection. Participants are required to identify hallucinated spans in LLM-generated text across multiple languages by multiple models. The evaluation relies on two key metrics: Intersection over Union (IoU) to measure span detection accuracy and Spearman's correlation to assess the consistency of hallucination confidence scores. The task presents challenges, including variations in hallucination patterns across languages and the need for probability calibration to improve ranking reliability.

In this study, we present a SpanBERT-based approach for hallucination detection. SpanBERT (Joshi et al., 2020), a transformer model optimized for span-based predictions, is well-suited for identifying hallucinated text segments. Due to the limited availability of training data, we incorporate dataset augmentation through translation and synthetic data generation. Our results indicate that while our model detects hallucinated spans with reasonable accuracy, it struggles with ranking consistency, as reflected in low or negative Spearman's correlation scores. These findings highlight the need for improved probability calibration techniques and enhanced model robustness across languages.

The remainder of this paper is structured as follows: Section 2 reviews related work on hallucination detection and multilingual evaluation. Section 3 details the Mu-SHROOM task and dataset, including our data augmentation approach. Section 4 describes our methodology, covering model selection, preprocessing, and training setup. Section 5 presents the experimental setup. Section 5.3 provides a combined discussion and interpretation of the results. Finally, Section 6 summarizes key findings and outlines directions for future research.

2 Related Work

Hallucination detection in LLMs is a well-known problem, where models generate factually incorrect or misleading information. Detecting these errors is important for improving the reliability of generated text (Luo et al., 2024).

In this section, we discuss prior work on evaluation metrics, hallucination detection, and multilingual challenges. Existing approaches range from sentence-level classification to span-level annotation, with multilingual settings introducing additional complexities.

Hallucination Detection in Large Language Models Kang et al. (2024) compare different hallucination detection metrics in multilingual settings. Their study finds that Natural Language Inference (NLI)-based methods often perform better than lexical overlap measures like ROUGE (Lin, 2004). However, these methods struggle with detecting fine-grained hallucinations at the span level, which is a key focus of Mu-SHROOM.

Shen et al. (2024) introduce a dataset for detecting hallucinations in news headlines across multiple languages. Their work includes fine-grained annotations, showing that different hallucination types require different detection strategies. This aligns with Mu-SHROOM's goal of identifying hallucination spans, though our task focuses on LLM-generated text rather than news headlines.

Multilingual Hallucination Detection and Evaluation Most hallucination detection research focuses on English, but hallucinations occur differently across languages. Detecting hallucinations in multilingual settings is more complex due to variations in grammar, entity representation, and knowledge availability.

Guerreiro et al. (2023) study hallucinations in multilingual translation models, showing that low-resource languages are more likely to produce hallucinated content. They highlight the need for language-specific approaches to hallucination detection, as models may behave differently depending on the training data. Mu-SHROOM builds on this by providing a multi-lingual dataset that evaluates hallucination detection across various languages and public LLMs.

3 Task Description and Datasets

This section outlines the Mu-SHROOM task and dataset. We describe the task of detecting hallucinated spans in multilingual LLM outputs and explain dataset augmentation through translation and synthetic data generation.

3.1 Task Description

The Mu-SHROOM task focuses on detecting hallucinated spans in text generated by LLMs. The organizers define hallucinations as content that contains or describes facts that are not supported by the provided reference. In other words, hallucinations occur when the answer text is more specific than it should be, given the information available in the provided context. Figure 1 shows an example of a hallucination.

ID	val-en-4
Language	English (EN)
Model Input	*When did Chance the Rapper debut?*
Model Output	*Chance the Rapper debuted in 2011.*
Model ID	tiiuae/falcon-7b-instruct
Soft Labels	
Start–End	Probability
18–29	0.0909
29–33	0.5455
Hard Labels	[29, 33]

Figure 1: Example of a hallucination in the English validation file.

The goal is to determine which parts of an LLM-generated output contain hallucinations. The task is multi-lingual and multi-model, with data provided by the organizers in multiple languages and from various open-weight LLMs. The provided data includes:

- **Language**: English, Chinese, Swedish, Spanish, German, Hindi, Finnish, Arabic, Italian, or French.
- **Model**: LLM model, such as Qwen, Llama, or Mistral.
- **Raw text**: a string of characters.
- **Tokenized representation**: a list of tokens.
- **Logits**: model confidence scores.

- **Soft Labels**: Probability-based (how likely it is a hallucination)
- **Hard Labels**: Binary (hallucination or not)

For each character in the output, the probability of it belonging to a hallucinated span must be computed. Any approach, including external resources, can be used, and there is flexibility in selecting which languages to focus on.

3.2 Dataset Augmentation

We received validation files containing 50 output sentences in various languages. To expand the training data, we translated the non-English validation files that had the most similar linguistic structure to English, specifically German, French, Swedish, Spanish, and Italian. The translations were generated using the `GPT-4o-mini` model via the OpenAI API with a prompt detailed in Appendix A.1.

In addition to translated data, we generated synthetic data using `GPT-4o-mini`. This was done by providing the model with a few examples from the validation set along with additional question-answer pairs. The prompt used for this process is described in Appendix A.2. Both prompts resulted in a total of 200 additional question-answer pairs.

4 Methodology

4.1 SpanBERT

For this task, we used the pre-trained SpanBERT model for span detection (Joshi et al., 2020). SpanBERT was chosen because of its unique training process compared to other BERT models. During training, SpanBERT masks entire spans of text rather than individual tokens, enabling it to better understand contextual spans. This makes it particularly useful for tasks like span prediction. Additionally, SpanBERT was trained on question-answering datasets, which closely resemble the structure of our data and task requirements.

4.2 Data

To fine-tune the model, several data files were used. The initial dataset only contained 50 samples per language, which was insufficient for effective fine-tuning. As mentioned in Section 3.2, we leveraged additional data from Germanic and Romance languages; French, Spanish, Swedish, and Italian, by translating these texts into English. This step enriched the dataset with moe data and was intended to help the model better understand these languages' structures, even if it had not been explicitly trained on them. Additionally, as described earlier, we utilized the GPT-4o-mini model to generate more question-answer samples. In total, the model was trained on 450 question-answer pairs.

To further enhance data quality, we removed special tokens from the text. These tokens, such as '<|endoftext|>', '<0x0A>', '<im_end|>', '</s>', and '<|eot_id|>', introduced noise without providing meaningful information. By stripping these tokens, we ensured cleaner input for the model.

4.3 Offset Mapping

The span annotations in the dataset were provided as character-level positions, indicating where hallucinated spans start and end in the text. However, since SpanBERT operates on tokenized inputs, these character-level spans had to be converted to token-level spans. To achieve this, we used the tokenizer's offset mapping.

During tokenization, SpanBERT records the character boundaries for each token in the text. For example, tokenizing the phrase *"An example"* produces the offset mapping shown in Figure 2.

Token	Offset Mapping
An	(0,2)
example	(3,10)

Figure 2: Offset mapping for the phrase "An example"

For each span in the hard labels, we matched the character positions to their corresponding tokens by checking whether a token's character boundaries included the start or end of the span. For example, if the span annotation is (0, 10), the offset mapping indicates that *"An"* marks the start and *"example"* marks the end of the hallucinated span.

To efficiently locate the start and end tokens based on character indices, we used list comprehension. In cases where a valid token span could not be found, such as when the span exceeded the text length, we assigned a default position of 0. This ensured that the model could process the input without errors during training.

4.4 Data Loader

A custom PyTorch dataset was developed to handle the complex structure of multiple spans per text. This dataset stored the tokenized inputs along with their span labels. A custom data collator was used to prepare batches during training. The collator

calculated the maximum number of spans across samples in a batch, padded the span positions, and stacked input tensors to ensure uniformity.

4.5 Training Setup

For this task, we used the `SpanBERT/spanbert-base-cased` model from the Hugging Face Transformers library [2]. We opted for the base version instead of the large model due to limited GPU computational resources. To balance training speed and resource usage, a batch size of 8 was selected. The learning rate was set to `3e-5`, and the number of epochs was capped at 20. However, early stopping was implemented, terminating training when the validation loss did not improve for two consecutive epochs. The model typically stopped training after 9 to 11 epochs.

We used the AdamW optimizer, which is standard for transformer-based models. Additionally, a custom loss function was implemented to handle multiple spans. This function filtered out invalid spans, which are predicted hallucination spans where the start or end position falls outside the actual text length, and computed the cross-entropy loss for both the start and end logits. The loss was averaged across all valid spans in each batch.

The training loop was structured as follows: for each batch, the model received input features including `input_ids`, `attention_mask`, and span annotations (`start_positions` and `end_positions`). The model performed a forward pass, generating probabilities for each token being the start or end of a hallucinated span. The custom loss function then compared the predicted logits with the ground truth spans. Invalid spans were filtered out, and the cross-entropy loss for both start and end logits was computed and averaged. This loss was backpropagated through the network, updating the model's parameters. The AdamW optimizer adjusted the model's weights accordingly. The total training loss was accumulated across all batches, and at the end of each epoch, the average training loss was calculated.

4.6 Validation

During validation, the model was switched to evaluation mode, which disabled gradient computation to reduce memory usage and improve performance. The validation data was processed in batches, similar to the training process. For each batch, the model received input features such as `input_ids` and `attention_mask` and generated predictions for start and end logits.

The custom loss function was applied to the validation data to compare the predicted logits with the ground truth spans. The total validation loss was accumulated across all batches. At the end of each epoch, the average validation loss was calculated by dividing the total loss by the number of batches.

To prevent overfitting, early stopping was implemented. If the validation loss did not improve for two consecutive epochs, training was terminated. If the validation loss improved, the best loss was updated, and the patience counter was reset.

4.7 Prediction and Evaluation Process

During the prediction phase, the model processed the test dataset by generating start and end logits for each token in the input text. These logits were aggregated across multiple runs to enhance the robustness of predictions. Adaptive thresholds were applied to dynamically determine high-confidence span boundaries. These thresholds were calculated based on the mean and standard deviation of the logits for each text, filtering out low-confidence predictions.

The decoded spans were mapped back to the original text using offset mappings from the tokenizer. Only spans that met specific criteria were retained: the start position had to precede the end position, and the span had to fall within the boundaries of the text. Overlapping spans were merged to reduce redundancy by averaging confidence scores and adjusting boundaries. This approach produced cleaner and more interpretable predictions.

5 Experiments

All experiments were conducted using Google Colab, utilizing the free GPU (NVIDIA Tesla T4 or P100, depending on session availability). The model training process was optimized for this environment to account for hardware limitations, including restricted memory and compute time. This setup facilitated efficient model testing and training without the need for additional infrastructure.

5.1 Data Splits

The dataset was split into training and validation with an 80/20 ratio. The training involved an iterative process across multiple epochs, during which

[2] https://huggingface.co/SpanBERT/spanbert-base-cased

the model generated logits for span start and end positions. A custom loss function was defined to compute the cross-entropy loss for both start and end logits, focusing on valid spans within each batch. The loss was averaged across spans and samples, and the model weights were updated using the AdamW optimizer.

The training loop incorporated early stopping based on validation loss to prevent overfitting. At the end of each epoch, the model's performance on the validation set was evaluated, and if the validation loss did not improve after a set number of epochs, training was halted early.

5.2 Evaluation Measures

The evaluation follows the official scorer used by the task organizers, as implemented in `scorer.py`. Two metrics are used: Intersection over Union (IoU) and Spearman's Rank Correlation.

IoU measures the overlap between predicted and ground truth hallucinated spans:

$$\text{IoU} = \frac{|S_{\text{pred}} \cap S_{\text{true}}|}{|S_{\text{pred}} \cup S_{\text{true}}|} \tag{1}$$

where S_{pred} and S_{true} are the predicted and actual spans, respectively.

Spearman's correlation (ρ) evaluates the rank correlation between predicted hallucination scores and ground truth:

$$\rho = 1 - \frac{6 \sum d_i^2}{n(n^2 - 1)} \tag{2}$$

where d_i is the rank difference for each character, and n is the total number of characters.

5.3 Results and Discussion

The evaluation results in Table 1 show variations in hallucination detection performance across languages. While the model achieves reasonable span detection accuracy, the correlation between predicted and actual hallucination scores remains low or negative in most cases. This suggests that the ranking of hallucination confidence scores does not consistently align with the ground truth.

A comparison with the baseline scores in Appendix A.3 highlights the advantages and limitations of our approach. Our model consistently outperforms the baseline in IoU across all languages, demonstrating better hallucination span localization. However, the baseline achieves higher Spearman's correlation in most cases.

The low or negative Spearman's correlation suggests that while the model can detect hallucinated spans, it struggles to rank them accurately. This may be due to over-prediction bias, inconsistencies in training labels, or suboptimal probability calibration.

5.4 Future Work

Future work should focus on improving probability calibration, enhancing multilingual robustness, and refining training data for more consistent cross-lingual performance. While SpanBERT was suitable for this task, exploring alternative models or ensemble approaches could further improve results, albeit at a higher computational cost. Similarly, larger models like SpanBERT-large may offer gains but exceed our current resource limits.

Language	IoU	Correlation
English	0.2943	**0.0116**
Spanish	0.1616	-0.0986
Italian	0.2111	-0.2116
French	0.3095	-0.1521
Swedish	**0.4156**	-0.1177

Table 1: Evaluation results per language. *IoU* represents Intersection over Union, and *Correlation* represents Spearman's correlation.

6 Conclusion

This study explores a SpanBERT-based approach for detecting hallucinated spans in multilingual LLM-generated text as part of the Mu-SHROOM shared task. The results indicate that while the model performs reasonably well in identifying hallucinated spans, particularly in high-resource languages, it struggles with ranking hallucination confidence scores accurately. This is reflected in low or negative Spearman's correlation values.

These findings suggest that while SpanBERT is effective for span detection, further improvements are needed for confidence ranking. Future work should focus on refining probability calibration techniques, improving robustness across multiple languages, and exploring alternative training objectives that incorporate ranking-aware learning. Additionally, ensemble approaches or fine-tuning architectures specifically designed for multilingual hallucination detection could further enhance performance.

A Appendix

A.1 Prompt for Translating Validation Data

Translate the <language> content of mushroom-<lang>-val.v2.jsonl to English using Google Translate. Provide the translated content in the same format as the original file (mushroom-<lang>-val.v2.jsonl), but in English.

A.2 Prompt for Synthetic Data Generation

Format:

```
{
  "model_input_text": <input text>,
  "model_output_text": <output text>,
 "hard_labels": [<start and end indices of hallucinated spans>]
}
```

Guidelines:

- Use hard_labels for fabricated spans (character-based indices).
- Leave empty ([]) for factual responses.
- Cover a variety of topics, including history, science, trivia, and personal advice.
- Include factual, partially hallucinated, and fully hallucinated responses.
- Maintain a ratio of **80% hallucinated** and **20% factual** responses.

A.3 Evaluation Comparison

Abstract

This paper presents a multi-step approach for multi-label emotion classification as our system description paper for the SEMEVAL-2025 workshop Task A using machine learning and deep learning models. We test our methodology on English, Spanish, and low-resource Yoruba datasets, with each dataset labeled with five emotion categories: anger, fear, joy, sadness, and surprise. Our preprocessing involves text cleaning and feature extraction using bigrams and TF-IDF. We employ logistic regression for baseline classification and fine-tune Transformer models, such as BERT and XLM-RoBERTa, for improved performance. The Transformer-based models outperformed the logistic regression model, achieving micro-F1 scores of 0.7061, 0.7321, and 0.2825 for English, Spanish, and Yoruba, respectively. Notably, our Yoruba fine-tuned model outperformed the baseline model of the task organizers with micro-F1 score of 0.092, demonstrating the effectiveness of Transformer models in handling emotion classification tasks across diverse languages.

1 Introduction

Emotions play a crucial role in human communication, shaping our interactions, decisions, and psychological well-being. According to the Oxford English Dictionary, emotion is defined as "a strong feeling deriving from one's circumstances, mood, or relationships with others." In social interactions, emotions are frequently invoked and help individuals navigate complex relationships and make sense of their environments Hwang and Matsumoto, 2016. In text, emotions can be conveyed explicitly or implicitly through linguistic patterns, allowing authors to communicate their mental states. Consequently, emotion classification—identifying and labeling the emotions embedded in text—has become a key research area in Natural Language Processing (NLP), with applications across various domains such as marketing, healthcare, and education.

While sentiment analysis focuses on determining the overall emotional tone (positive, negative, or neutral) of a text, emotion classification goes a step further by identifying specific emotions such as anger, joy, fear, or sadness. This task is particularly challenging when multiple emotions are present simultaneously in a single text, a problem known as multi-label emotion classification. Unlike traditional single-label emotion classification, where only one emotion label is associated with a given statement, multi-label classification assigns multiple emotion labels to a text, reflecting the complex nature of human emotional expression.

Multi-label emotion classification faces numerous challenges, particularly in the realm of social media, where the language evolves rapidly and the context is often ambiguous. To address these challenges, researchers have turned to deep learning models, especially Recurrent Neural Networks (RNNs), Long Short-Term Memory (LSTM) networks, and attention mechanisms, which have shown promising results in recent years. These models can capture nuanced emotional expressions by learning from large-scale datasets, such as the SemEval-2018 Task-1 and the Blog Emotion Corpus, which contain emotional annotations for a variety of social media texts.

However, despite advancements in deep learning, existing models still face limitations in capturing the full range of emotional nuances in multi-label classification tasks. Moreover, traditional machine learning methods often struggle with feature engineering, making them less adaptable to rapidly changing language used on platforms like Twitter. In light of these challenges, this paper explores Transformer approaches to multi-label emotion detection by leveraging transfer learning and multi-attention mechanisms. By fine-tuning pre-trained

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1609–1615

models such as BERT and XLMRoBERTa, along with incorporating feature engineering to capture emotion-specific features, we aim to enhance the accuracy and robustness of emotion classification systems.

In the following sections, we first review the related work on emotion classification, particularly in multi-label contexts. Then, we describe our methodology, which includes data preprocessing, model architecture, and experimental setup. Finally, we present our experimental results, demonstrating the effectiveness of our approach in English, Spanish and Yoruba emotion classification tasks.

2 Recent Literature

Text detection and classification has taken several forms and gained attention by researchers over the last couple of years in NLP, with the application of different classifiers and models, also some more accurate models being developed by researchers, performing significant roles in the series of experiments that have been undertaken in recent work Abiola et al., 2025b; Kolesnikova and Gelbukh, 2020; Ojo et al., 2024; Adebanji et al., 2022; Abiola et al., 2025a. A variety of traditional ML methods Ojo et al., 2021, 2020; Sidorov et al., 2013 and DL models Aroyehun and Gelbukh, 2018; Ashraf et al., 2020; Han et al., 2021; Hoang et al., 2022; Poria et al., 2015; Muhammad et al., 2025a have been applied in the last few years for text prediction on various domains.

Most previous work on emotion detection has focused on deep neural networks such as Convolutional Neural Networks (CNNs) and Recurrent Neural Networks (RNNs) like Long Short-Term Memory (LSTM) networks. However, these models have not utilized multiple attention mechanisms or Transformer-based networks such as XLNet, DistilBERT, and RoBERTa for multi-label emotion classification. Ameer et al., 2023 proposed multiple attention mechanisms to reveal the contribution of each word to each emotion, which had not been investigated before. Their RoBERTa-Multi-Attention (RoBERTa-MA) model achieved 62.4% accuracy, outperforming the previous state-of-the-art accuracy of 58.8% on the SemEval-2018 Task-1C dataset. Similarly, their XLNet-MA model achieved 45.6% accuracy on the Ren-CECps dataset for Chinese, demonstrating the effectiveness of Transformer-based models in multi-label emotion classification.

Shahiki and et al., 2024 conducted a psycholinguistic and emotional analysis of cryptocurrency discussions on social media, focusing on nine major digital assets, including Bitcoin, Ethereum, and Dogecoin. Using advanced text analysis techniques, the study examined linguistic patterns and emotional expressions across different cryptocurrency communities. The authors also analyzed comentions among cryptocurrencies to understand their interrelations. A dataset of 832,559 tweets was collected and refined to 115,899 for analysis, providing insights into the distinct discourse surrounding each coin and the emotional trends shaping cryptocurrency discussions online.

Speech emotion recognition (SER) plays a crucial role in enhancing human-computer interaction (HCI) by enabling machines to understand human emotions from acoustic signals. However, the lack of large-scale datasets remains a major challenge in this field. BanSpEmo: A Bangla Audio Dataset for Speech Emotion Recognition and Its Baseline Evaluation Kusal et al., 2025 addresses this issue by introducing BANSpEmo, a Bangla speech emotion dataset comprising 792 recordings from 22 native speakers, covering six emotions: disgust, happiness, anger, sadness, surprise, and fear. The study evaluates baseline models, including support vector machine (SVM), logistic regression (LR), and multinomial Naïve Bayes, finding that SVM achieves the highest accuracy of 87.18%. Inspired by this work, transformer-based models provide an advanced approach to SER by leveraging deep contextual representations for improved multi-class emotion detection across languages. This study builds upon such datasets to enhance cross-linguistic emotion classification using transformer architectures.

Emotion detection in online communication has been extensively studied, but many approaches focus solely on textual cues, overlooking the role of emojis in conveying emotions. Multimodal Text-Emoji Fusion Using Deep Neural Networks for Text-Based Emotion Detection in Online Communication Kusal et al., 2025 highlights the significance of incorporating emoji analysis to improve sentiment interpretation, especially in cases where text alone may not fully capture emotional intent. The study proposes an emoji-aware hybrid deep learning framework that leverages convolutional and recurrent neural networks for multimodal emotion detection. Inspired by this, transformer-

based models offer a promising approach to cross-linguistic multi-class emotion detection, as they can capture deep contextual relationships in multi-modal data. This study builds on such insights by integrating transformer architectures for improved emotion classification in diverse linguistic settings.

3 Methodology

Our methodology involves a multi-step approach to text preprocessing, feature extraction, and multi-label emotion classification using machine learning and deep learning models. Experiments were conducted on English and Spanish datasets to test our method across different languages, including the low-resource language Yoruba.

3.1 Dataset Preprocessing

We loaded our datasets into Pandas DataFrames from three separate files for training, development (validation), and test datasets as given by the shared task organizers Muhammad et al., 2025b. The datasets contain text samples labeled with five emotion categories: anger, fear, joy, sadness, and surprise. Class 0 depicts no emotion for each class, and class 1 depicts emotion for each class. Table 1, 2 and 3 give insight into the English, Spanish and Yoruba datasets, respectively.

Table 1: Binary Emotion Label Distribution in the Dataset

Emotion	1 (Present)	0 (Absent)
Anger	333	2435
Fear	1611	1157
Joy	674	2094
Sadness	878	1890
Surprise	839	1929

Table 2: Binary Emotion Label Distribution in the Spanish Dataset

Emotion	1 (Present)	0 (Absent)
Anger	492	1504
Disgust	654	1342
Fear	317	1679
Joy	642	1354
Sadness	309	1687
Surprise	421	1575

Our preprocessing involved the removal of special characters, non-word tokens, extra whitespace, and lowercasing the text with regex expressions.

Table 3: Binary Emotion Label Distribution in the Yoruba Dataset

Emotion	1 (Present)	0 (Absent)
Anger	195	2797
Disgust	81	2911
Fear	77	2915
Joy	272	2720
Sadness	836	2156
Surprise	254	2738

Stopword removal was not applied initially, as certain emotion-indicating words might be filtered out inadvertently. The frequency distribution of emotions was analyzed to understand class imbalances. This analysis was performed using Pandas.

3.2 Bigram Feature Augmentation

To enhance text representations, we extracted top bigrams using `CountVectorizer` module from `sklearn`. The bigram extraction process involved transforming the text into a bag-of-words model with bigram tokens, then we computed their frequencies across the dataset and select the most frequent bigrams. These bigrams were then appended to the original text, improving contextual information while preserving sequence structures.

We made a helper function that iterated over each text entry and appended bigram tokens that appeared in the sample, concerning their frequencies. Our additional feature engineering improved the model's ability to capture co-occurring patterns that signal emotional expression.

3.3 TF-IDF Feature Extraction and Logistic Regression Model

We converted the preprocessed text data into numerical features using Term Frequency-Inverse Document Frequency (TF-IDF) vectorization through `TfidfVectorizer` from Scikit-learn. This transformation helped quantify the importance of words relative to the entire corpus.

Our multi-label classification approach was adopted using `OneVsRestClassifier`, which trains separate Logistic Regression classifiers for each emotion label. The model was trained with `max_iter=1000` to ensure convergence. Predictions were evaluated using precision, recall, and F1-score metrics from `sklearn.metrics`.

3.4 Fine-tuning Transformer Models for Emotion Classification

Beyond traditional machine learning, we implemented a deep learning approach using the base BERT model (`bert-base-uncased`) for the English dataset and (`xlm-roberta-base`) for the Yoruba and Spanish datasets from the Hugging Face Transformers library. The text was tokenised using `BertTokenizer`, truncating longer texts to a maximum of 512 tokens.

We fine-tuned the models for classification on the dataset with the problem type set to `multi-label classification`, using a binary cross-entropy loss function (`BCEWithLogitsLoss`). Class imbalance was mitigated using weighted loss, computed based on the proportion of positive and negative instances for each emotion label.

The dataset was converted into a Hugging Face Dataset format and tokenised for efficient batching. Training was performed using the Hugging Face `Trainer` API, with a batch size of 16, 20 epochs, and weight decay of 0.01. The model was evaluated based on the macro-F1 score and fine-tuned on an RTX 3080 Nvidia 16GB GPU.

3.5 Evaluation Metrics and Performance Analysis

Model performance was assessed using precision, recall, and F1-score. The BERT model predictions were converted into probabilities using the sigmoid function with a threshold for label assignment.

4 Results

4.1 Performance of Logistic Regression

The performance metrics of the logistic regression model on the dev dataset give a micro F1 score of 0.50. The model achieved a reasonable F1-score on fear detection on the English dataset since it takes the majority of the present emotion class in the dataset but struggled with minority emotion classes due to data imbalance.

4.2 Performance of Fine-Tuned BERT Model

We performed the final test set predictions on the Transformer models since it outperformed the logistic regression model on the development dataset for the three languages we worked on. As a blind grading requested by the organizers of the workshop, the predicted labels of the Transformer models were stored in a CSV file, where each row contained an ID and predicted binary emotion labels.

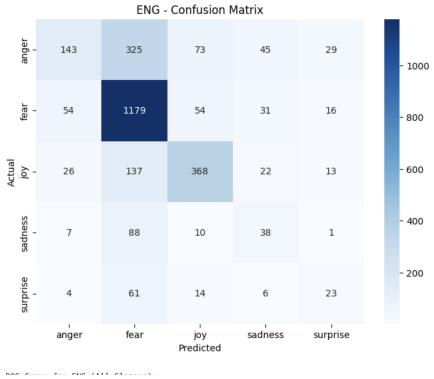

Figure 1: Confusion Matrix of the English Dataset Prediction

Post-processing ensured no missing values, and labels were converted to binary (0 or 1) to align with the dataset format.

The model has a micro-F1 score of 0.7061, 0.7321 and 0.2825 for the English, Spanish and Yoruba datasets, respectively; our English and Spanish models underperformed slightly to the SEMEVAL Baseline model that has the micro-F1 score of 0.7083 and 0.7744 but our Yoruba fine-tuned model outperformed the baseline model that has micro-F1 score of 0.0922 The result analysis for the Transformer models prediction on the test dataset in this languages are displayed in figures 1 to 6.

The low micro-F1 score observed for the Yoruba dataset in the multiclass emotion detection task can be attributed to several challenges associated with low-resource languages. Primarily, the limited availability of annotated training data in Yoruba likely hindered the model's ability to generalise well across different emotion classes. Additionally, the pretrained Transformer models' exposure to Yoruba during pretraining, results in weaker language representations. Cultural and linguistic nuances in emotion expression, which are often context-dependent and idiomatic in Yoruba, also contribute to the difficulty in accurately detecting emotions. These factors combined likely led to the model's reduced performance compared to English and Spanish.

5 Conclusion

The experiment demonstrated the effectiveness of Transformer models over traditional machine learning for multi-label emotion classification. The addition of bigram features enhanced feature representation for logistic regression and the deep learning

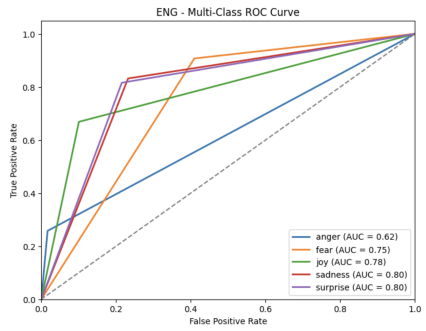

Figure 2: ROC of the English Dataset Prediction

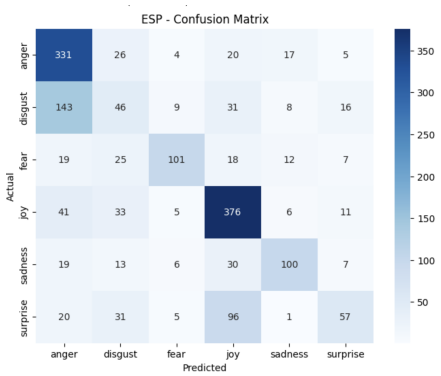

Figure 3: Confusion Matrix of the Spanish Dataset Prediction

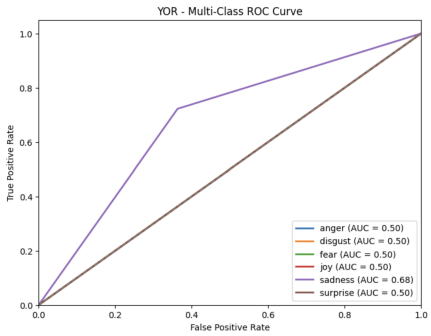

Figure 6: ROC of the Yoruba Dataset Prediction

model used as we discovered during the development stage with dev dataset that it improves the result of each of the models between +3 to +10%, but deep learning provided a more robust approach to capturing contextual meaning. Future work will explore cross-lingual emotion classification and domain-specific fine-tuning for improved performance.

6 Limitations

Despite the promising results of our multilingual emotion classification approach, several limitations must be acknowledged. Data imbalance, particularly in low-resource languages like Yoruba, affects model performance, leading to biased predictions where underrepresented emotions are harder to detect. While weighted loss functions and data augmentation techniques were applied, challenges in balancing class distributions persist. Finally, linguistic and cultural variations across English, Spanish, and Yoruba affect emotion representation. Future research should explore cross-lingual adaptation strategies, improved data augmentation for low-resource languages, and adaptive thresholding mechanisms to enhance classification performance.

Acknowledgments

The work was done with partial support from the Mexican Government through the grant A1-S-47854 of CONACYT, Mexico, grants 20241816, 20241819, and 20240951 of the Secretaría de Investigación y Posgrado of the Instituto Politécnico Nacional, Mexico. Abstract

Large Language Models (LLMs) have demonstrated remarkable capabilities in natural language understanding and generation. However, their tendency to memorize training data raises concerns regarding privacy, copyright compliance, and security, particularly in cases involving Personally Identifiable Information (PII). Effective machine unlearning techniques are essential to mitigate these risks, yet existing methods remain underdeveloped for LLMs due to their open-ended output space. In this work, we apply the Adaptive Representation Misdirection Unlearning (RMU) technique to unlearn sensitive information from LLMs. Through extensive experiments, we analyze the effects of unlearning across different decoder layers to determine the most effective regions for sensitive information removal. Our technique ranked 4th on the official leaderboard of both 1B parameter and 7B parameter models.

1 Introduction

In the realm of large language models (LLMs), unlearning is particularly challenging due to the highly distributed nature of knowledge storage across model parameters. Unlike Computer Vision or Graph Neural Networks (Chundawat et al., 2023; Kolipaka et al., 2024), where feature representations tend to be more localized, LLMs encode knowledge in an interwoven manner, making targeted removal complex (Meng et al., 2022). The need for effective LLM unlearning arises from concerns surrounding data privacy, bias mitigation, and compliance with regulations such as GDPR's 'right to be forgotten'. If an LLM generates sensitive or misleading information, it is crucial to develop mechanisms that remove such knowledge without degrading overall performance (Eldan and Russinovich, 2023).

An approach to tackling unlearning in LLMs involves model-editing, a technique closely tied to mechanistic interpretability. Model-editing methods aim to modify the internal representations of an LLM to suppress or alter specific outputs while maintaining overall fluency and coherence. Previous work has explored various approaches, such as neuron pruning (Frankle and Carbin, 2019) and gradient-based forgetting (Yao et al., 2023; Goodfellow et al., 2015), to achieve unlearning without full retraining. Unlearning techniques for LLMs often lead to catastrophic forgetting, compromising general performance (Luo et al., 2025; Zhang et al., 2024; Kemker et al., 2018; ROBINS, 1995). Understanding how and where knowledge is stored in an LLM is crucial for designing effective unlearning strategies. Research has shown that different decoder layers in transformer-based architectures capture different types of information.

The task is outlined in the task description paper (Ramakrishna et al., 2025b). There are separate leaderboards for the 1B and 7B parameter models.

Participating in this task provided valuable insights into both the strengths and limitations of our system. Quantitatively, our approach achieved competitive results, ranking 4th among participating teams on a metric designed specifically for this task. Additionally, we analyze how factual information is distributed across different decoder layers in large language models (LLMs). Through our experiments, we demonstrate that unlearning factual information from middle-later layers is particularly effective.

We have released the code for our system on GitHub[1], facilitating transparency and reproducibility in our approach.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1616–1622

of specific data while preserving overall performance. These methods often involve fine-tuning strategies that steer internal representations away from unwanted content, ensuring that the model forgets particular information without compromising its general capabilities.

One prominent approach is Representation Misdirection Unlearning (RMU) (Li et al., 2024), which directs the model's intermediate representations of data intended for unlearning toward a predetermined random vector. This technique effectively reduces the model's performance on tasks related to the forgotten content while maintaining its proficiency in other domains. RMU has been demonstrated to lower the model's knowledge of the Weapons of Mass Destruction Proxy (WMDP) dataset, indicating its potential in reducing malicious use of LLMs (Li et al., 2024).

Building upon RMU, Adaptive RMU introduces a dynamic adjustment mechanism for the steering coefficient, which influences the alignment of forget-sample representations with the random direction (Huu-Tien et al., 2025). This adaptive approach enhances unlearning effectiveness across various network layers, addressing limitations observed when RMU is applied to middle and later layers of LLMs. Adaptive RMU not only improves unlearning performance but also maintains robustness against adversarial attacks, ensuring that the model does not inadvertently relearn the forgotten content.

Another innovative technique involves the use of Sparse Autoencoders (SAEs) to remove specific knowledge from LLMs (Farrell et al., 2024). By training SAEs to capture and subsequently eliminate features associated with the content to be unlearned, this method effectively reduces the model's ability to recall unwanted information. Studies have shown that applying SAEs can unlearn subsets of sensitive data with minimal impact on the model's performance in other areas, offering a targeted and efficient unlearning strategy.

3 Background

3.1 Task

The challenge spans three subtasks evaluating unlearning: long-form synthetic creative texts across genres; short-form synthetic biographies containing PII (such as fake names, phone numbers, SSNs, email addresses, and home addresses); and real documents drawn from the model's training data. Each subtask involves both sentence-completion and question-answering evaluations. In both cases, the dataset is divided into a retain set (which should be preserved) and a forget set (which should be unlearned). The goal is for the model to behave as if trained solely on the retain set, excluding the forget set, thereby mimicking an ideal unlearning scenario (Ramakrishna et al., 2025b).

3.2 Dataset

The dataset quantifies unlearning performance for each subtask and evaluation type, with separate retain and forget sets whose sizes are summarized in Table 1 (Ramakrishna et al., 2025a).

Subtask	Forget Set Size	Retain Set Size
1	214	260
2	780	762
3	372	392

Table 1: Dataset sizes for retain and forget sets across all subtasks.

3.3 Objective

The challenge aims to develop and evaluate effective unlearning techniques for large language models while preserving overall model performance. Submissions are assessed based on their ability to forget specified information while retaining non-targeted knowledge.

Performance is measured through three metrics:

- **Task-Specific Regurgitation Rates:** This combines ROUGE-L for sentence completion and exact-match for question answering, evaluated on both the retain and forget sets. Forget-set scores are inverted as $1 - \text{value}$, and the 12 resulting scores are aggregated via the harmonic mean.
- **Membership Inference Attack (MIA) Score:** Calculated as

$$1 - \left|\text{mia\_loss\_auc\_score} - 0.5\right| \times 2,$$

  this metric assesses privacy leakage following (Shokri et al., 2017).
- **MMLU Benchmark Performance:** Accuracy on the 57-subject multiple-choice MMLU suite measures language understanding and reasoning (Hendrycks et al., 2021).

The final score is the arithmetic mean of these three metrics.

3.4 Model

For our experiments, we use fine-tuned versions of the `OLMo-7B-0724-Instruct-hf` and `OLMo-1B-0724-hf` models. OLMo (Open Language Model) is an open-source language model developed to facilitate research in language modeling and knowledge retention (Groeneveld et al., 2024). Both models follow a decoder-only transformer architecture, similar to traditional autoregressive language models. The task organizers provided the fine-tuned models.

The `OLMo-7B` model consists of **32 decoder layers** with a hidden size of 4096 and 32 attention heads. The smaller `OLMo-1B` model has **16 decoder layers**, a hidden size of 2048, and 16 attention heads. These models have been specifically fine-tuned to memorize documents from all three tasks, making them a suitable testbed for evaluating unlearning methods.

4 System Overview

4.1 RMU

Representation Misdirection Unlearning (RMU) is a technique designed to selectively unlearn hazardous knowledge from a large language model (LLM) while preserving its general capabilities. It employs a two-part loss function: a *forget loss* that degrades harmful representations and a *retain loss* that ensures minimal disruption to benign knowledge.

The forget loss modifies model activations at a specific layer ℓ by increasing their norm in a fixed random direction. Given:

- $M_u(\cdot)$: hidden states of the unlearned model
- $M_f(\cdot)$: hidden states of the original frozen model
- $\mathbf{u}$: a fixed random unit vector sampled from $[0, 1]$
- $\mathcal{D}_f$: forget dataset

The forget loss is defined as:

$$\mathcal{L}_{\text{forget}} = \mathbb{E}_{x_f \sim \mathcal{D}_f} \left[\frac{1}{L_f} \sum_{t \in x_f} \| M_u(t) - c \cdot \mathbf{u} \|^2 \right], \tag{1}$$

where L_f is the number of tokens in x_f, and c is a scaling hyperparameter.

To prevent excessive forgetting, RMU introduces a retain loss that regularizes the unlearned model activations to remain close to those of the frozen model on the retain dataset $\mathcal{D}_r$:

$$\mathcal{L}_{\text{retain}} = \mathbb{E}_{x_r \sim \mathcal{D}_r} \left[\frac{1}{L_r} \sum_{t \in x_r} \| M_u(t) - M_f(t) \|^2 \right], \tag{2}$$

where L_r is the number of tokens in x_r.

The final loss function is a weighted combination of the forget and retain losses:

$$\mathcal{L} = \mathcal{L}_{\text{forget}} + \alpha \cdot \mathcal{L}_{\text{retain}}, \tag{3}$$

Where α controls the trade-off between forgetting and retention. RMU updates model weights iteratively, focusing on layers $\ell - 2, \ell - 1$, and ℓ to improve efficiency.

In the original RMU implementation, the authors use an external dataset, such as WikiText, to preserve the model's general capabilities. Instead, we adapt the retain dataset to match our task-specific retain set and demonstrate that RMU remains effective.

4.2 Adaptive RMU

Building on RMU, Adaptive RMU introduces a modified forget loss by scaling the random unit vector $\mathbf{u}$ with an *adaptive scaling coefficient* $\beta \| h^{(l)}_{\theta_{\text{frozen}}}(x_F) \|$. Here, $\beta \in \mathbb{R}$ is a scaling factor, and $\| h^{(l)}_{\theta_{\text{frozen}}}(x_F) \|$ is the ℓ_2-norm of the forget sample x_F in the frozen model $f_{\theta_{\text{frozen}}}$. This ensures that the magnitude of the perturbation adapts to the norm of the activation, leading to a more stable unlearning process. The total loss in Adaptive RMU is given by:

$$\mathcal{L}^{\text{adaptive}} = \mathbb{E}_{x_f \sim \mathcal{D}_\text{f}} \left[\frac{1}{L_f} \sum_{t \in x_f} \left\| M_\text{u}(t) - \beta \| M_\text{f}(t) \| \mathbf{u} \right\|_2^2 \right] + \alpha \mathbb{E}_{x_r \sim \mathcal{D}_\text{r}} \left[\frac{1}{L_r} \sum_{t \in x_r} \left\| M_\text{u}(t) - M_\text{f}(t) \right\|_2^2 \right] \tag{4}$$

Figure 1 illustrates the construction of the loss function with adaptive scaling. This adaptation makes the forgetting process proportional to the activation strength of the original model while ensuring that general capabilities are preserved through the retain loss.

To account for the varying dataset sizes across different splits (creative documents, sensitive content,

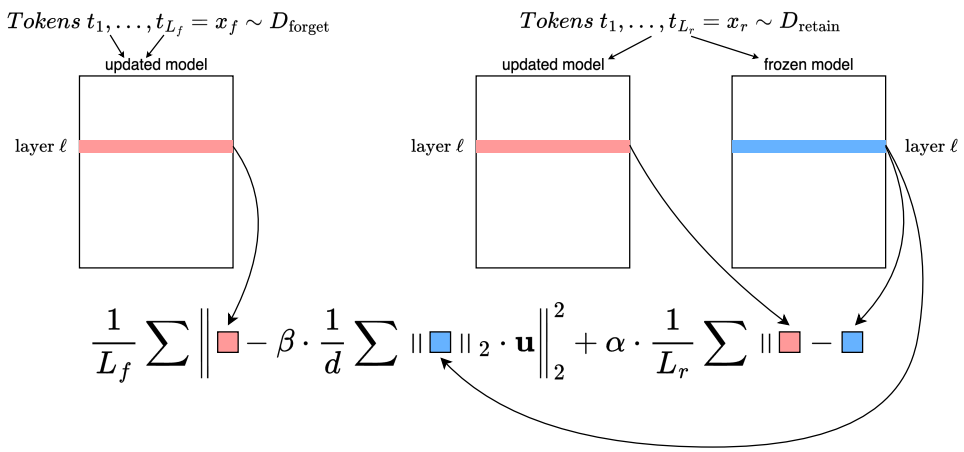

Figure 1: RMU performs machine unlearning by optimizing a two-part loss: a forget term, which misdirects the model's activations for forget-set inputs, and a retain term, which aligns the model's activations for retain-set inputs. The random vector $\boldsymbol{u}$ is adaptively scaled using the frozen model's activations, $\boldsymbol{d}$ denotes the embedding dimension of the model (Li et al., 2024; Huu-Tien et al., 2025)
