In this paper, we present an effective approach to Entity-Aware Machine Translation that combines Retrieval-Augmented Generation (RAG) with a self-refinement mechanism. Our system features a two-criteria feedback system that identifies and corrects both entity label inaccuracies and translation errors. When tested against the baseline GPT-4o model, our system demonstrates significant improvements across all language pairs in the task dataset. The experimental results highlight two key findings: (i) the integration of RAG with entity information from external knowledge substantially improves translation accuracy. (ii) self-refinement mechanism consistently enhances translation quality across all language pairs through iterative feedback and correction. Our case studies reveal that the system effectively addresses both entity-specific challenges and general translation issues. These results suggest that combining knowledge retrieval with self-refinement is a promising direction for entity-aware machine translation. Looking ahead, future work could explore incorporating entity retrieval methods without using gold entity.

Abstract

This paper describes our system developed for SemEval-2025 Task 1, subtask A. This shared subtask focuses on multilingual idiom recognition and the ranking of images based on how well they represent the sense in which a nominal compound is used within a given contextual sentence. This study explores the use of a pipeline, where task-specific models are sequentially employed to address each problem step by step. The process involves three key steps: first, identifying whether idioms are in their literal or figurative form; second, transforming them if necessary; and finally, using the final form to rank the input images.

1 Introduction

Idioms are a class of multi-word expressions (MWEs) that present significant challenges for current state-of-the-art models, as their meanings are often not predictable from the individual words that compose them. This unpredictability can create ambiguity between the literal, surface meaning derived from the component words and the idiomatic meaning intended by the expression. Addressing the complexities of MWE handling is crucial for natural language processing (NLP) applications (Constant et al., 2017). SemEval-2025 Task 1, AdMIRe: Advancing Multimodal Idiomaticity Representation (Pickard et al., 2025), focuses on evaluating models that incorporate both visual and textual information to assess their ability to capture idiomatic representations in two languages: English and Brazilian Portuguese.

Previous datasets and tasks, such as SemEval-2022 Task 2 (Madabushi et al., 2022) and the MAGPIE (Haagsma et al., 2020) and FLUTE (Chakrabarty et al., 2022) datasets, have primarily focused on idiomaticity detection. However, existing idiomaticity identification benchmarks can be exploited by models that ignore the nominal compound (NC) or its contextual usage, thus failing to develop robust semantic representations of idiomatic expressions (Boisson et al., 2023). SemEval-2025 Task 1 addresses these limitations by moving beyond binary classification and introducing richer representations of meaning through visual and visual-temporal modalities. SemEval-2025 Task 1 consists of two subtasks. Subtask A presents a set of five images alongside a contextual sentence containing a potentially idiomatic NC. The objective is to rank the images based on how well they represent the sense in which the NC is used within the given context. Subtask B presents a target expression and an image sequence missing the final image, the goal is to choose the best fill from four candidates images.

To tackle Subtask A, we propose a simple yet effective pipeline comprising three stages. The first stage involves detecting whether the potentially idiomatic NC in the given context is used literally or idiomatically. If the NC is identified as idiomatic, a separate model generates its literal meaning. In the final stage, images are aligned with the appropriate interpretation: either the generated literal meaning for idiomatic expressions or the direct literal meaning for non-idiomatic cases. This approach effectively combines idiomaticity detection, literal meaning generation, and multimodal image alignment to ensure accurate ranking of images based on the intended sense of the compound.

In our analysis, we evaluate various large language models (LLMs) for the first two stages of our pipeline and experiment with different zero-shot classification models in the third stage, across both English and Portuguese datasets. Our method achieves competitive results on SemEval-2025 Task 1, Subtask A, reaching 3rd and 6th places on the English and Portuguese benchmarks respectively. The code for our approach is publicly available at `https://github.com/MBadran2000/Idiom-MultiModal-Representation.git`.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 546–550

2 Background

2.1 Related work

LLMs have gained significant popularity across academic, industrial, and public domains due to their strong performance on a variety of tasks in zero-shot or few-shot prompting setups. These tasks include question answering, common-sense reasoning, and machine translation. Previous research has demonstrated that LLMs achieve competitive results on idiomaticity detection datasets, offering general applicability without the need for type-specific fine-tuning. However, they often lag behind fine-tuned encoder-only models on specific datasets and benchmarks (Phelps et al., 2024) . Despite this, LLMs possess a notable ability to disambiguate a wide range of nominal compounds without additional fine-tuning, as they tend to overlook construction artifacts present in idiomaticity detection datasets (Boisson et al., 2023). This allows them to generalize idiomaticity detection better than fine-tuned encoders.

Contrastive Language-Image Pre-training (CLIP) (Radford et al., 2021) has emerged as the dominant model and learning approach in the vision-language domain. It employs a simple yet powerful contrastive learning loss to align visual and linguistic signals within a shared feature space, leveraging large-scale image-text datasets. Unlike earlier vision encoders such as VGG and ResNet, which were trained on the limited ImageNet dataset with simple categories described by only a few words, CLIP benefits from web-scale data paired with rich, descriptive text. This alignment between vision and language enables CLIP to excel in various multimodal tasks, including image-text retrieval, establishing it as the state-of-the-art model for diverse applications in the field (Huang et al., 2024).

2.2 Task description

AdMIRe: Advancing Multimodal Idiomaticity Representation focuses on developing high-quality representations of idioms, which are essential for improving applications such as machine translation, sentiment analysis, and natural language understanding. Enhancing models' ability to interpret idiomatic expressions can significantly boost the performance of these tasks. Unlike previous datasets, which often allow models to excel at idiomaticity detection without capturing the true semantic depth of idiomatic expressions, AdMIRe emphasizes meaning representation through visual and visual-temporal modalities. This approach aims to ensure that models develop a more comprehensive understanding of idioms beyond surface-level recognition.

AdMIRe consists of two subtasks, A and B. In this subtask, participants are presented with a set of five images alongside a contextual sentence containing a potentially idiomatic NC. The objective is to rank the images based on how accurately they represent the sense in which the NC is used within the given context. A variation of Subtask A replaces the images with text captions describing their content, offering two distinct settings for the subtask. Subtask B presents a sequence of three images resembling a comic strip, where the final image has been removed. Given a target expression, the objective is to select the most suitable completion from a set of four candidate images. The NC sense being depicted (idiomatic or literal) is not provided and should also be predicted. In this study, we concentrate on the Subtask A version that uses images for ranking.

Language	Training	Dev	Test	Ext. Eval.
English	70	10	15	100
Portuguese	32	15	13	55

Table 1: Number of samples in each split for English and Portuguese datasets.

The task leverages a dataset of potentially idiomatic expressions, building on the foundation of the SemEval-2022 Task 2 dataset. Table 1 summarizes the number of samples in each split for English and Portuguese, detailing the training, development, test, and extended evaluation sets. The extended evaluation set contains overlapping compounds from training, development, and test sets but in different contexts, offering a more robust assessment of model performance and generalization.

Performance in Subtask A is evaluated using two key metrics. The first is Top Image Accuracy, which measures the model's ability to correctly identify the most representative image. The second is Rank Correlation, assessed using Spearman's rank correlation coefficient, which evaluates how closely the model's image rankings align with the ground truth.

3 System Overview

Our proposed pipeline consists of three main stages: idiom detection, literal meaning generation, and

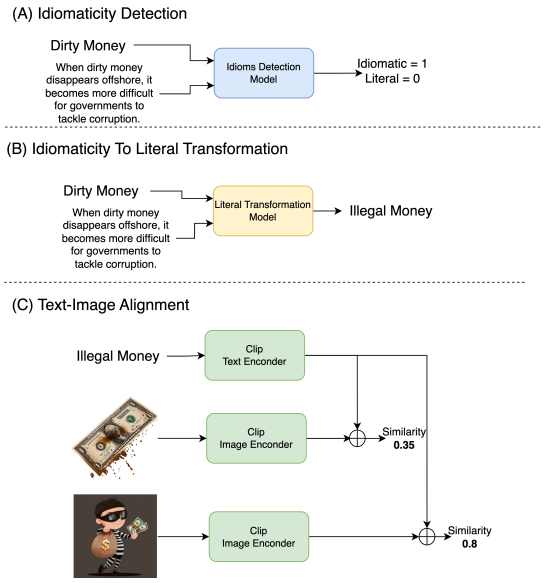

Figure 1: Idiomatic Case: First, we detect that it is idiomatic, then we obtain its literal meaning, and lastly, we align images according to the literal meaning.

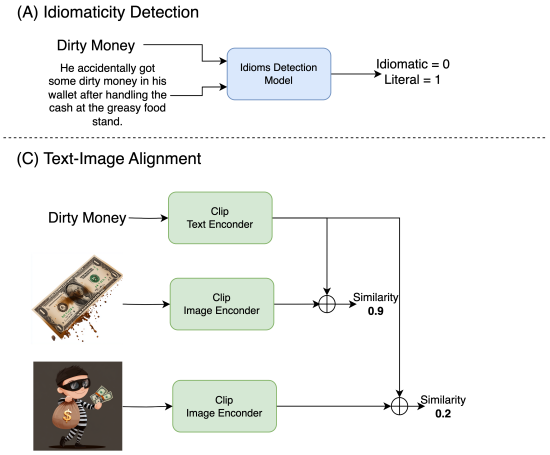

Figure 2: Literal Case: First, we detect that it is literal, then we align images according to the literal input.

multimodal image alignment. This pipeline ensures that images are aligned with the intended meaning of a given NC based on its contextual usage. Figures 1 and 2 illustrate the two possible workflows, depending on the outcome of the idiom detection stage.

3.1 Idiomatic vs. Literal Classification

The first step in our pipeline involves determining whether a NC in a sentence is used idiomatically or literally, using a zero-shot approach. For this task, we utilize an instruction-tuned large language model (LLM), which is prompted with the contextual sentence and predicts whether the NC conveys an idiomatic or literal meaning.

3.2 Literal Meaning Generation

If the NC is identified as idiomatic, we use a separate generative model in a zero-shot setting to generate its literal meaning. This stage also relies on an instruction-tuned large language model (LLM), ensuring that the generated interpretation remains contextually relevant. If the NC is classified as literal, this step is skipped, and the original NC is directly used for image retrieval.

3.3 Multimodal Image Alignment

Once the literal meaning of the NC is determined, we retrieve images that best correspond to the intended interpretation. We leverage a zero-shot multimodal image retrieval model based on CLIP to rank images based on their alignment with either the original NC (if used literally) or its generated literal meaning (if used idiomatically).

3.4 Portuguese Data

We also evaluated our approach on non-English data by testing the pipeline on the Portuguese dataset. Two strategies were explored. In the first, the translation approach, the NC is first classified as idiomatic or literal. After this classification and the generation of its literal meaning (if necessary), the Portuguese text is translated into English before proceeding to multimodal image alignment. This allows the full pipeline to operate in English, using translation to ensure cross-lingual compatibility. In the second strategy, the direct multilingual approach, we bypass translation by using multilingual multimodal image alignment models capable of processing multiple languages. This enables direct alignment of images with the Portuguese text, leveraging the models' ability to handle both textual and visual representations across languages.

4 Experiments

4.1 Experimental Setup

Our experiments were conducted in a zero-shot setting using a NVIDIA V100 GPU. For stages 1 and 2, we evaluated four instruction-tuned LLMs:

Stage 1 & 2 Model	Stage 3 Model	Train Top-1 Acc.	Train Rank Corr.	Dev Top-1 Acc.	Dev Rank Corr.

Table 3: Comparison of different models and approaches on the Portuguese training and development sets

Llama-3.3 70B (Dubey et al., 2024), Qwen2.5 72B (Yang et al., 2024), calme-3.2 78B, and shuttle-3. In stage 3, we tested CLIP ViT-L trained on the LAION-2B English dataset (Schuhmann et al., 2022), ALIGN (Jia et al., 2021), BLIP (Li et al., 2022) ViT-large trained on the Flickr30k dataset, SigLIP SoViT-400m patch14 (Zhai et al., 2023), and LLM2CLIP (Huang et al., 2024) with base models EVA02-L/14 (Fang et al., 2024) and OpenAI ViT-L/14 CLIP. We explored all possible combinations of these models, resulting in 28 different configurations. Additionally, we tested ensemble approaches combining various model selections to further enhance performance.

4.2 Results

The results of our English experiments, including combinations of CLIP ViT-H/14 and Llama-3.3 70B, are presented in Table 2. Additionally, we report results for an ensemble of these models, as well as for all 28 tested model configurations. Our analysis revealed that individual models tend to make different types of errors, with failures varying across cases. As a result, model ensembling achieved the best performance by mitigating individual model errors through averaging, leading to overall improved results.

The results of both the translation approach and the direct multilingual approach on the Portuguese dataset are presented in Table 3. For multilingual experiments, we exclusively used LLM2CLIP models, as they rely on multilingual text encoders, which are essential for effectively aligning text and images across languages. Our findings indicate that the multilingual approach outperformed the translation-based method.

For Portuguese, we created an ensemble combining all four Phase 1&2 models with the two LLM2CLIP variants, which served as our final system. For English, our best-performing model was an ensemble of all tested models. The results of these top-performing models on both English and Portuguese are presented in Table 4. Our approach achieved competitive performance, ranking in the 3rd and 6th places on the English and Portuguese benchmarks respectively.

Language	Test Top-1 Acc.	Test Rank Corr.	Ext. Eval. Acc.	Ext. Eval. Rank Corr.
English	0.9300	0.4733	0.7200	0.3440
Portuguese	0.6154	0.3462	0.6153	0.3461

Table 4: Performance of the best-performing approaches on English and Portuguese test and extended evaluation datasets.

5 Conclusion

In this work, we proposed a three-stage pipeline for multimodal idiomaticity representation, consisting of idiom detection, literal meaning generation, and multimodal image alignment. We used this pipeline in our submission to subtask A of SemEval 2025 Task 1. Our approach leverages instruction-tuned LLMs for idiomaticity classification and literal meaning generation, followed by a zero-shot multimodal retrieval model for aligning images with the intended meaning of a nominal compound. We evaluated our system on both English and Portuguese datasets, exploring translation-based and direct multilingual approaches. Our results demonstrated that ensemble models improve performance by mitigating individual model errors, achieving competitive results in both languages.

Abstract

This paper presents our approach to SemEval 2025 Shared Task 7: Multilingual and Crosslingual Fact-Checked Claim Retrieval. We investigate how large language models (LLMs) designed for general-purpose retrieval can be adapted for fact-checked claim retrieval across multiple languages. This includes cases where the original claim and the fact-checked claim are in different languages. The experiments involve fine-tuning with a contrastive objective, resulting in notable gains in accuracy over the baseline. We evaluate cost-effective techniques such as LoRA, QLoRA and Prompt Tuning. Additionally, we demonstrate the benefits of Matryoshka embeddings in minimizing the memory footprint of stored embeddings, reducing the system requirements for a fact-checking engine. The final solution, using a LoRA adapter, achieved 4th place for the monolingual track (0.937 S@10) and 3rd place for crosslingual (0.825 S@10).

1 Introduction

Verifying claims across various languages is becoming increasingly difficult for fact-checkers as the amount of Internet content keeps growing. Additionally, cross-lingual fact-checking not only requires a deep understanding of nuanced linguistic differences and diverse syntactical structures, but also demands bridging significant resource gaps in less-represented languages (Huang et al., 2022).

Recent advances in large language models (LLMs) have shown promise in tackling these challenges. Besides generative capabilities, LLMs can provide high-quality textual embeddings (Wang et al., 2024a) that can be leveraged for textual retrieval (Chen et al., 2024b).

As part of SemEval 2025 Shared Task 7: Multilingual and Crosslingual Fact-Checked Claim Retrieval (Peng et al., 2025), we explore different methods to adapt general-purpose retrieval LLMs to the downstream task of fact-checked claim retrieval.

We experiment with cost-effective fine-tuning techniques, including Prompt Tuning (Lester et al., 2021), Low-Rank Adaptation (LoRA) (Hu et al., 2021), and QLoRa (Dettmers et al., 2024), focusing on improving the models performance with minimal trade-offs between accuracy and resources.

Moreover, the amount of memory required to store fact checks in large databases grows along with the number of posts and claims on social media (Lauer, 2024). To address this issue, we propose using Matryoshka learning (Kusupati et al., 2024) to compress fact representations while maintaining their retrieval utility and speeding up processing.

Our contributions are threefold:

1. We adapt a general purpose retrieval LLM for multilingual fact-checked claim retrieval by using a contrastive objective between social media posts and claims, resulting in improved performance.

2. We evaluate LoRA, QLoRA, and Prompt Tuning strategies.

3. We show that Matryoshka representation learning can help significantly reduce the memory footprint of fact-checked claims storage with minimal impact on accuracy.

The implementation is available at https://github.com/racai-ro/FactCheckRetrieval.

2 Related Work

Previous work for fact-checked claim retrieval explored systems based on classical IR-models such as BM25 and semantic similarity searches using BERT like models. Shaar et al. (2020) showed

*PhD Candidate

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 551–557

that a hybrid approach results in increased performance. They proposed a two-step retrieval pipeline, comprised of a BM25 initial retrieval and re-ranking step that takes advantage of both scores from BM25 and a fine-tuned version of sentence-BERT (Reimers and Gurevych, 2019).

Subsequent studies (Chernyavskiy et al., 2021; Mansour et al., 2022) have adopted similar approaches, incorporating semantic similarity as a standard component of the retrieval pipeline.

Notably, these systems were developed mainly for English, with some also addressing Arabic, as The CLEF 2021 CheckThat! (Shaar et al., 2021) challenge introduced a separate track for the language. This is a short-coming, given the universal aspect of the task.

To address the language limitation and enable multilingual retrieval of previously fact-checked claims, Pikuliak et al. (2023) proposed the MultiClaim dataset. The best results were obtained using a fine-tuned GTR-T5-Large model (Ni et al., 2021). They observed that most embedding models tested—even those explicitly designed for multiple languages—performed better when applied to the English-translated version of the dataset. In contrast, our work focuses **solely on the original multilingual data**.

Previous approaches have primarily relied on similarity search, which in turn depends on high-quality textual embeddings. Wang et al. (2024a) demonstrated that the effectiveness of such embeddings can be significantly improved by leveraging large language models (LLMs) for both data augmentation and embedding generation.

In line with this, BGE-Multilingual-Gemma2 (Xiao et al., 2023; Chen et al., 2024a) is a multilingual text embedding model built on the Gemma2 LLM architecture (Riviere et al., 2024). Trained on a wide variety of multilingual tasks, it has achieved state-of-the-art performance on the MIRACL benchmark (Zhang et al., 2023), which is specifically designed for multilingual retrieval.

This paper evaluates the effectiveness of adapting BGE-Multilingual-Gemma2 for claim retrieval in fact-checking, focusing on parameter-efficient tuning methods.

3 Dataset

The dataset proposed for the SemEval task builds upon and extends the original MultiClaim dataset (Pikuliak et al., 2023). It was assembled from a variety of social media platforms, with post-fact pairs formed according to the fact-check alerts issued by these platforms.

Quantitatively, the development dataset comprises 28,092 social media posts in 27 languages, 205,751 fact-checks in 39 languages authored by professional fact-checkers, and 31,305 connections between these two categories. Among these, 4,212 post-fact pairs are crosslingual.

Qualitatively, about 13% of the posts included multimedia attachments (image/video) and did not accurately convey the claims in text. In some of these cases, text was extracted from images using Optical Character Recognition (OCR), but other errors may have been introduced as a consequence. The dataset remains biased toward major languages and the Indo-European language family, despite its diversity. Furthermore, the crosslingual pairs' applicability to other language pairs is limited because they primarily consist of posts in East or South Asian languages coupled with English fact-checks.

4 Proposed Methodology

In this section, we introduce our overall strategy for our retrieval system for fact-checks: Contrastive Fine-Tuning with Low-Rank Adaptation and Matryoshka Embeddings. We separately use Prompt Tuning to evaluate the contribution of the instruction in the prompt to the baseline's performance on the task.

Specifically, we investigate:

1. **LoRa Contrastive Fine-Tuning with Large In-Batch Negatives:** We utilize Multiple Negative Ranking Loss (MNRL) to separate positive and negative pairs in the latent space, and leverage GradCache to overcome hardware memory limitations.

2. **Prompt Tuning:** We add trainable prompt embeddings and tune them for the fact-checked claim retrieval task, keeping the model's weights frozen.

3. **Matryoshka Embeddings:** To reduce the memory footprint of high-dimensional embeddings, we explore the matryoshka training approach.

In the following subsections, we provide details for each of these experiments.

4.1 Contrastive Fine-Tuning

The MNRL function is particularly well-suited for datasets that contain only positive pairs. Given that MultiClaim consists of pairs of social media posts and corresponding facts, we find the objective to be an appropriate choice.

For clarity, we briefly describe the MNRL function. Let $\mathbf{p}$ denote the post's textual embedding and $\mathbf{f}$ represent the fact-checked claim's textual embedding. To construct positive pairs, we utilize the post-fact pairs provided in the dataset. During training, the model aims to maximize the similarity between $\mathbf{p}$ and its corresponding positive $\mathbf{f}_+$, while minimizing the similarity to all other $\mathbf{f}_-$ in the batch, which act as negative examples. Consequently, the loss function can be expressed as:

$$\mathcal{L} = -\frac{1}{N}\sum_{i=1}^{N}\log\frac{\exp(\text{sim}(\mathbf{p}i, \mathbf{f}i+)/\tau)}{\sum_{j=1}^{N}\exp(\text{sim}(\mathbf{p}i, \mathbf{f}_j)/\tau)}, \quad (1)$$

where:

- $\text{sim}(\mathbf{p}, \mathbf{f})$: cosine similarity between $\mathbf{p}$ and $\mathbf{f}$.
- τ: temperature scaling parameter.
- N: total number of fact checks in the batch.

Contrastive learning with in-batch negatives achieves the best results with large batch sizes (Chen et al., 2022), but this approach demands significant memory resources. To address this challenge, we leverage GradCache (Gao et al., 2021). GradCache caches the encoder's output embeddings along with their corresponding gradients, thereby decoupling gradient computation for the encoder from that of the loss function. As a result, the memory footprint is significantly reduced, and large batch sizes can be simulated by processing smaller micro-batches sequentially.

Moreover, based on its training methodology, BGE-Multilingual-Gemma2 allows an **instruction** to be prepended to the query. This instruction provides a description of the task and its context. The authors originally provided the following template:

"`Given a web search query, retrieve relevant passages that answer the query.`"

In our work, we defined the prompt according to the context of the task as follows:

"`Given a social media post as a query, retrieve fact checks that verify or debunk the post.`"

The instruction prompt is delimited from the query using the special tokens `<instruct>` and `<query>`, resulting in the final model input format:

`<instruct>[PROMPT]<query>[QUERY]`.

To build the training data for our contrastive learning pipeline, we use the following inputs:

- **Social media post:** The original post text concatenated with any text extracted via OCR. For QLoRA and LoRA settings, we also prepend the instruction prompt to this combined text.
- **Fact-checked claim:** The title concatenated with the claim text.

4.2 Prompt Tuning

During development, we noticed that eliminating the instruction from the prompt for the base model had the following effects: (a) -2% in S@10 for monolingual evaluation, compared to (b) +1% for crosslingual evaluation (Table 2).

For our experiments, we defined the instruction part solely on the task's context, but in order to push the **baseline's performance** to its upper limit, we used prompt tuning to find the optimal value.

Prompt tuning (Lester et al., 2021) is a technique in which small, trainable prompt embeddings are prepended to the input of a pre-trained language model, enabling the model to adapt to specific tasks without updating its main parameters. This approach optimizes only a small set of prompt parameters while keeping the rest of the model frozen. In our case, the trainable embeddings are concatenated exclusively to the queries, positioned between the special `<instruct>` and `<query>` tokens, as illustrated in Figure 1. We use the previously defined prompt as the starting point for these embeddings.

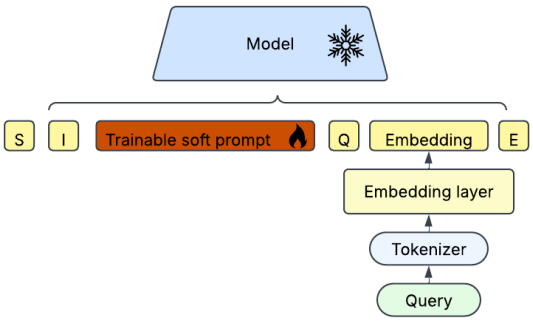

Figure 1: Prompt Tuning approach for query/anchor. S, I, Q, E are special tokens (<start>, <instruct>, <query>, <end>).

4.3 Matryoshka Embeddings

To address the memory implications associated with storing high-dimensional embeddings, we explore Matryoshka embedding learning.

This method allows for hierarchical training of embeddings at multiple resolutions, enabling the system to store compact representations when required while retaining the ability to utilize higher-dimensional embeddings when memory permits.

Specifically, we compute intermediate losses at predefined embedding dimensions: $[128, 256, 512, 768, 1024, 2048, 3584]$. The losses are summed together with equal weights, becoming the final training objective:

$$\mathcal{L}_{Matryoshka} = \sum_{d \in \mathcal{D}} \mathcal{L}_d$$

where $\mathcal{D} = \{128, 256, 512, 768, 1024, 2048, 3584\}$ denotes the set of predefined truncation dimensions applied to the post and fact embeddings, and each $\mathcal{L}_d$ is computed as specified in Equation 1.

This hierarchical loss computation encourages each subspace of the embedding to maintain a meaningful semantic structure, allowing for progressive reduction of dimensionality, limiting the loss in retrieval performance.

5 Experiments and results

In this section, we present details on the training environment, followed by an overview of our experiments and the results obtained.

5.1 Training environment

For training, we randomly split our available data (post-fact pairs) into 90% train and 10% validation.

The environment consists of 3 H100 GPUs for optimized training speed. For optimized memory, we train in bfloat16, and we use Flash Attention 2 (Dao, 2023).

Due to computation limitations, we truncate the model's input to **512 tokens**. Analyzing the character length of the posts in the dataset, we find that 95 % of the posts have fewer than 1899 characters. Averaging 4 characters per token, our truncation does not cut substantial data from the posts. The analysis is shown in Figure 2.

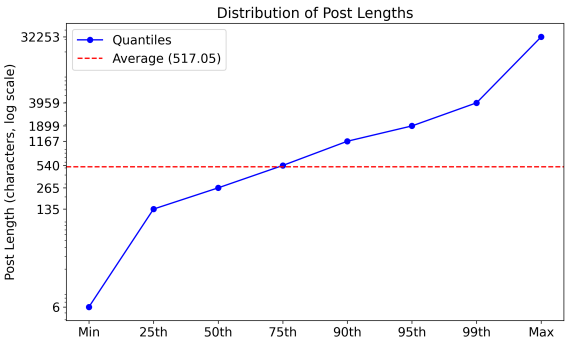

Figure 2: Character length of social media posts.

During training, we ensure **that no duplicates** (post or fact) are present in the batch per device. The hyperparameters selected for training are displayed in table 1.

Learning Rate	Scheduler	Per device batch size
0.0002	cosine	1024

Table 1: Training Hyperparameters for Fine-tuning

5.2 Finetuning

The results of our experiments for the development stage of the shared task are shown in Table 2, and those for the testing stage in Table 3. To gain a deeper understanding of our failure cases, we manually categorized errors on the development set (for our best solution) into four groups:

- **Missing Context** (independent from the verdict label): The context lacked sufficient information for non-expert humans to align the golden fact check with the post.
- **Similar**: One or more predicted fact checks fully covered the golden fact check.
- **Similar but Insufficient**: Predicted fact checks partially covered the golden fact check.
- **Missed**: Information from the golden fact check was entirely absent from the predictions.

Classification was based **on English translations**, which may introduce artifacts.

In the monolingual setting, most errors were labeled as Missing Context (51.4%) and Similar (27.1%), with fewer cases labeled as Similar but Insufficient (11.6%) and Missed (10%). Missed cases often involved longer posts with **multiple**

Technique	Model	Mono (S@10)	Cross (S@10)	Trained Params	Rank
Base	NV-Embed-v2 (Lee et al., 2024)	0.76	0.64	0	NA
Base	gte-Qwen2-7B-instruct (Li et al., 2023)	0.79	0.55	0	NA
Base	multilingual-e5-large (Wang et al., 2024b)	0.83	0.66	0	NA
Base	bge-multilingual-gemma2	0.85	0.71	0	NA
Prompt engineering	bge-multilingual-gemma2	0.87	0.70	0	NA

LoRA	bge-multilingual-gemma2	0.955	**0.927**	54,018,048	16
LoRA (large)	bge-multilingual-gemma2	**0.958**	**0.927**	216,072,192	64

Table 2: Results on Shared Task Development Stage

Technique	Model	Mono (S@10)	Cross (S@10)	Trained Params	Rank
LoRA	bge-multilingual-gemma2	**0.937**	**0.82**	54,018,048	16

Table 3: Results on Shared Task Testing Stage

claims, where the model focused on non-target claims. Similar distributions were observed in the crosslingual setting (Missing Context: 42.2%, Similar: 24.5 %, Similar but Insufficient: 22.2 %, Missed: 11.1 %).

Multimodal cases (image or video information) lacking enough descriptive text were labeled Missing Context. Prediction errors were sometimes caused by similar events occurring at different times. Including posting dates could help narrow the search for relevant fact checks.

5.3 Matryoshka training

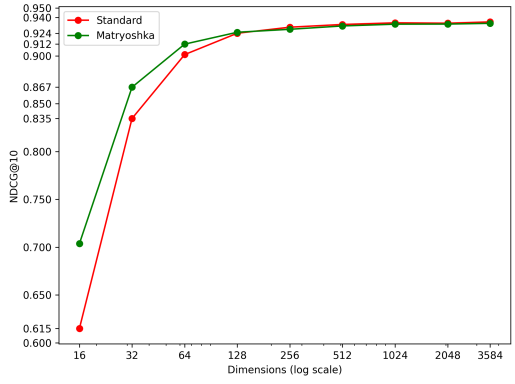

Figure 3: Performance with respect to truncated dimension.

To assess the efficiency of Matryoshka training with respect to the trade-off between embedding size and accuracy, we compared two models:

- **Standard**: bge-multilingual-gemma2 model finetuned with LoRA and MNRL loss (4.1).
- **Matryoshka**: The same strategy as Standard, also incorporating the Matryoshka training objective 4.3.

For each of the two models, we truncated the computed embeddings to different sizes and ran our evaluation. The comparative results are shown in Figure 3. We noticed that by using Matryoshka representation learning, we can reduce the embedding size and therefore memory by **98.2%** (from 3584 to 64) with **only a 2% loss** in NDCG@10.

6 Conclusions and Limitations

In this work, we successfully adapted a general-purpose retrieval LLM for multilingual and cross-lingual fact-checking through contrastive fine-tuning and parameter-efficient techniques, increasing its performance on the task. Also, using Matryoshka learning, we can significantly lower memory requirements while still achieving competitive accuracy.

However, a number of limitations still exist:

- **Bias in the dataset:** Generalizability to non-Indo-European and low-resource languages is restricted by the Indo-European bias.
- **Single-Step Retrieval:** Relying on a single-step retrieval approach limits the system's capability in handling complex, multi-hop fact-checking scenarios.

Future work should improve information extraction from images/videos, expand the dataset, and explore multi-step retrieval methods.

Abstract

Entity-Aware Machine Translation (EAMT) aims to enhance the accuracy of machine translation (MT) systems in handling named entities, including proper names, domain-specific terms, and structured references. Conventional MT models often struggle to accurately translate these entities, leading to errors that affect comprehension and reliability. In this paper, we present a promising approach for SemEval 2025 Task 2, focusing on improving EAMT in ten target languages. The methodology is based on two complementary strategies: (1) multilingual Named Entity Recognition (NER) and structured knowledge bases for preprocessing and integrating entity translations, and (2) large language models (LLMs) enhanced with optimized prompts and validation mechanisms to improve entity preservation. By combining structured knowledge with neural approaches, this system aims to mitigate entity-related translation errors and enhance the overall performance of MT models. Among the systems that do not use gold information, retrieval-augmented generation (RAG), or fine-tuning, our approach ranked 1^{st} with the second strategy and 3^{rd} with the first strategy.

1 Introduction

Entity-aware machine translation (EA-MT) aims to improve MT accuracy for named entities, including proper names, dates, and domain-specific terms (Gifu & Vasilache 2014). These are crucial in fields like technical documentation, legal texts, and medical literature (Gîfu & Cioca 2013), yet translating them remains challenging despite modern advancements.

Early rule-based MT struggled with named entities due to rigid linguistic rules (Slocum 1985). Statistical Machine Translation (SMT) in the 1990s improved overall quality but still faced issues with proper nouns and domain-specific terms (Wang et al. 2022). Phrase-Based SMT (PB-SMT) in the 2000s enhanced phrase-level translations but remained inconsistent with named entities and long-distance dependencies (Koehn et al. 2003, Lopez 2008).

Neural Machine Translation (NMT) and Transformer-based models like BERT and GPT (Vaswani 2017) have enhanced fluency and contextual awareness. Yet, challenges remain in entity preservation, cultural adaptation, and low-resource language support (Zaki 2024, Gifu & Covaci 2025, Lupancu et al. 2023).

For SemEval 2025 Task 2 (Conia et al. 2025) on EA-MT, we developed two systems to improve entity-centric translation across ten languages. Our approach combines:

1. Multilingual Named Entity Recognition (NER) and structured knowledge bases– We preprocess source text by identifying named entities, aligning them with external structured resources (e.g., Wikidata), and reintegrating their transla tions while preserving contextual accuracy

2. Large Language Models (LLMs) with optimized prompt engineering and validation mechanisms – We leverage LLMs to refine translations, ensuring that named entities are preserved, properly adapted, and fluently integrated into the

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 558–565

target language. Beyond technical implementation, we systematically evaluate our models using both standard MT metrics (e.g.,BLEU, METEOR) and specialized entity-aware evaluation techniques that assess entity preservation and translation accuracy. Given the linguistic diversity of the task, our system is designed to handle complex challenges such as morphological variations, transliteration issues, and script-based differences in languages like Japanese, Chinese, Arabic, and Thai.

The remainder of this paper is structured as follows. Section 2 provides a background on the evolution of MT, from early rule-based systems to state-of-the-art transformer models. Section 3 details the system architecture design for EA-MT, outlining the experimental setup and datasets used. Section 4 presents the results and the comparative evaluation. Finally, Section 5 discusses conclusions and future directions for entity-aware MT research.

The complete implementation of our system is available on GitHub[1]

2 Background

From the 1960s to the 1980s, early machine translation (MT) systems were rule-based, offering structured translations but struggling with named entities, proper nouns, and idiomatic expressions (Hutchins 1986, Song & Xu 2024).

The 1990s introduced Statistical Machine Translation (SMT), leveraging probabilistic models to improve flexibility, yet still facing challenges with rare terms and domain-specific terminology. The 2000s saw Phrase-Based SMT (PB-SMT), enhancing contextual coherence but retaining difficulties with named entities (Zens & Ney 2004, Pal et al. 2004).

Neural Machine Translation (NMT) emerged in the 2010s, using deep learning to improve fluency and entity handling, though challenges persisted in low-resource languages and domain adaptation (Vaswani et al. 2017, Koehn & Knowles 2017).

Today, Transformer-based models like GPT and BERT push translation accuracy forward, excelling in contextual understanding but still struggling with cultural adaptation and low-resource languages (Devlin et al. 2019, Wang et al. 2022). Large Language Models (LLMs), such as GPT-4, now rival leading NMT systems, though performance varies across language pairs (Manakhimova et al. 2023).

Despite advances, translating low-resource languages remains a challenge, necessitating refined techniques like back-translation and transfer learning (Zeng 2023, Her & Kruschwitz 2024). Hybrid methodologies integrating rule-based, statistical, and neural approaches continue to be explored for further improvements (Wang et al. 2022).

3 Dataset and Methods

3.1 Dataset

The dataset contains sentence pairs aligned between English and 10 target languages, with named entities linked to Wikidata IDs for multilingual NER tasks. However, entity tagging is incomplete, often marking only some entities in a sentence while leaving others untagged, impacting annotation reliability and depth for tasks like translation.

For example, consider the following sentence pair:

Source (English): *"Which actor was Stephenie Meyer's first choice to play Edward Cullen in the movie Twilight?"*

Target (Example Language): *"Quale attore era stata la prima scelta di Stephanie Meyer per interpretare Edward Cullen nel film Twilight?"*

This sentence contains three distinct entities:

- **Stephenie Meyer** (author, `Q160219`)
- **Edward Cullen** (fictional character)
- **Twilight** (movie)

However, in the dataset, only **Stephenie Meyer** is tagged with the corresponding Wikidata ID `Q160219`, while**Edward Cullen** and **Twilight** are not tagged.

This inconsistency in entity recognition results in incomplete annotations, which directly impacts the utility of the dataset. This limitation is particularly critical when it comes to translation tasks, as missing entities such as **Edward Cullen** and **Twilight** could significantly alter the understanding of the original sentence in the target language.

3.2 Methods

3.2.1 First approach

In our initial approach, we used the mBERT model, trained on the `WikiNEuRal:`

[1] https://github.com/deliagrigorita/FII-the-best-SemEval2025

`Multilingual NER` (Tedeschi et al. 2021) dataset, to extract named entities from the source text. This dataset is considered state-of-the-art for Multilingual Named Entity Recognition (NER) and is automatically derived from Wikipedia.

We generated two vectors: one containing the extracted named entities and another with corresponding translations retrieved via the Wikidata API, which offers accurate, human-curated translations for many entities.

To preserve the positions of the entities within the text, we replaced each named entity in the original text with a placeholder (`[TAG-HOLDER]`). The modified text was then used for subsequent processing: translation using the deep translator, `deep_translator - GoogleTranslator`, after which the placeholders were replaced with the Wikidata translations.

For entities not found in Wikidata, we kept them in the original language as a fallback. While this method delivered reasonable results, we identified a potential issue: translating a sentence with placeholders rather than the full context might disrupt grammatical conventions in the target language (e.g., misgendering articles in languages like Italian for person names).

To address this, we refined the process by replacing the translator with the Gemini API, utilizing the free Gemini 1.0 Pro version. This allowed us to leverage prompt engineering, providing the original entities, their Wikidata translations, and a request for grammatically accurate translation. This approach yielded superior results that aligned with the grammar of the target language. It also opens the possibility of experimenting with various LLMs to determine which delivers the best outcomes.

In Figure 1, we present the architecture of the first approach.

During the extraction, we observed that the model occasionally permuted certain special characters in the extracted named entities (NEs). For instance, in the extracted named entity *St Anne's Cathedral*, the corresponding Wikidata translation would appear as "St Anne's Cathedral," with spaces added around the apostrophe. We identified this as a consistent issue where punctuation marks, apostrophes, and other special characters were misrepresented. To address this, we implemented a normalization step to remove these

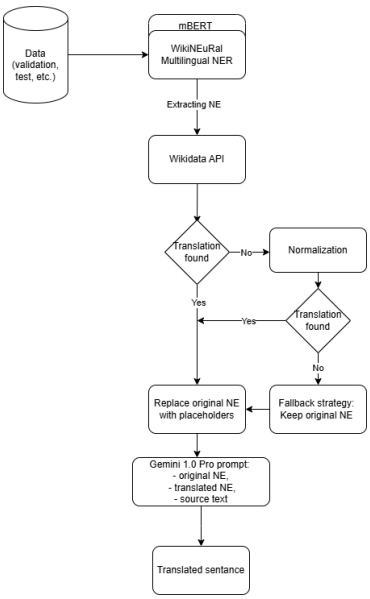

Figure 1: The architecture of the first approach

inconsistencies, ensuring that such cases, along with others involving special characters, were corrected. After performing this normalization, we observed a marked improvement in the evaluation results, as the translation output became more accurate and consistent.

3.2.2 Second approach

The second implementation presents another approach to Entity-Aware Machine Translation (EAMT), leveraging large language models (LLMs) for high-fidelity text translation while ensuring the preservation and correct translation of named entities. The system follows a structured pipeline that isolates named entities, processes their translations separately, and reintegrates them into the translated text.

The translation of common words within a sentence is performed directly inside the LLM, as it is powerful enough to handle basic translations accurately. However, the translation of named entities utilizes external resources to ensure higher precision, as named entities require a human touch to maintain accuracy. Additionally, named entities evolve more frequently than common words, making it necessary to rely on up-to-date external resources such as structured knowledge bases (Conia et al. 2024).

Named Entity Recognition (NER) is the first step, where named entities are identified and extracted from the source text using a combination of entity recognition models and regex-based pattern

matching. Once the named entities are detected, they are separated by specific tags in the source text to maintain the underlying linguistic structure during translation. The masked text is then processed independently using a large-scale LLM, such as Qwen 2.5 Instruct (Team 2024), which has demonstrated powerful translation skills in the required languages. Extracted named entities are handled separately, with their translations obtained from structured knowledge bases such as Wikidata. Once translated, the named entities are reintegrated into the translated text at their corresponding positions, ensuring fluency and semantic coherence.

The named entity translation module follows multiple strategies, including knowledge-based lookup by querying structured data sources like Wikidata and cross-lingual LLM-based heuristics, where the original entity may be retained or transliterated if no reliable translation is available. To enhance efficiency, the implementation integrates optimization techniques such as parallel processing to handle multiple sentences concurrently, using vLLM's fast inference framework.

In Figure 2, we present the architecture of the second approach.

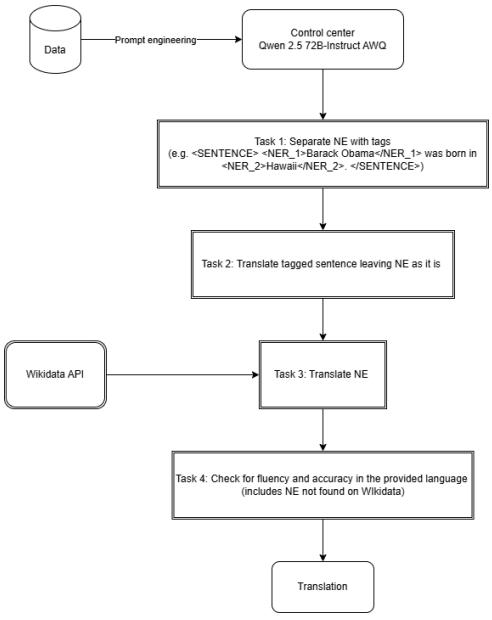

Figure 2: The architecture of the second approach

The effectiveness of the translation pipeline relies on well-structured prompts designed to guide the LLM in performing translations with high fidelity. Initially, prompts are crafted to explicitly instruct the LLM to focus on translating only the non-entity words while preserving placeholders for named entities. These prompts are refined iteratively to optimize clarity and accuracy, ensuring that the model correctly understands the distinction between common words and named entities. Additional prompt tuning techniques are employed, such as providing context-specific examples to enhance translation performance and prevent ambiguity. The prompt design also incorporates validation mechanisms, where the model's responses are analyzed, and adjustments are made dynamically to improve consistency in entity-aware translations.

Appendix A contains the prompts that were used to guide Qwen for translation.

4 Results

In this section, we present the evaluation results of our two proposed strategies. The evaluation was conducted using two main metrics: COMET and M-ETA across ten target languages: Arabic (AE), German (DE), Spanish (ES), French (FR), Italian (IT), Japanese (JP), Korean (KR), Thai (TH), Turkish (TR), and Traditional Chinese (TW).

- COMET (Cross-lingual Optimized Metric for Evaluation of Translation) is a neural-based metric that assesses machine translation quality using contextual embeddings to compare source, translation, and reference sentences.

- M-ETA (Manual Entity Translation Accuracy) measures entity translation accuracy by computing the proportion of correctly translated entities against a gold standard.

The final evaluation score is calculated as the harmonic mean of the COMET and M-ETA scores, ensuring a balanced assessment that accounts for both overall translation quality and entity preservation.

The first strategy demonstrated varying levels of performance across languages, as shown in Table 1.

Spanish (es_ES) achieved the highest final score of 79.1, followed closely by Arabic (ar_AE) and French (fr_FR) with final scores of 77.54 and 77.5, respectively. The lowest performance was observed for Chinese (zh_TW), which obtained a final score of 40.71 due to a significantly lower M-ETA score (26.46). Other languages, such as Turk-

Languages	M-ETA Score	COMET Score	Final Score
Arabic (ar_AE)	68.11	90.01	77.54
German (de_DE)	62.63	89.13	73.56
Spanish (es_ES)	69.91	91.06	79.1
French (fr_FR)	68.11	89.89	77.5
Italian (it_IT)	67.67	88.5	76.7
Japanese (ja_JP)	66.68	91.82	77.26
Korean (ko_KR)	64.11	90.72	75.13
Thai (th_TH)	55.41	85.2	67.15
Turkish (tr_TR)	56.9	90.19	69.77
Chinese (zh_TW)	26.46	88.29	40.71

Table 1: First Strategy Results

ish (tr_TR) and Thai (th_TH), also showed moderate performance, with final scores of 69.77 and 67.15, respectively.

The second strategy, shown in Table 2, yielded higher final scores across most languages compared to the first strategy. Italian (it_IT) achieved the highest final score of 83.4, followed by Spanish (es_ES) with 81.22 and French (fr_FR) with 80.52. The lowest performance was again observed for Chinese (zh_TW); however, the final score (74.19) showed a significant improvement over the first strategy. Additionally, languages such as Turkish (tr_TR) and Thai (th_TH) exhibited better scores than in the first strategy, with final scores of 77.77 and 75.16, respectively.

Languages	M-ETA Score	COMET Score	Final Score
Arabic (ar_AE)	66.42	91.35	76.91
German (de_DE)	66.98	91.3	77.27
Spanish (es_ES)	72.35	92.58	81.22
French (fr_FR)	72.46	90.59	80.52
Italian (it_IT)	75.79	92.71	83.4
Japanese (ja_JP)	67.03	93.56	78.11
Korean (ko_KR)	66.02	92.78	77.14
Thai (th_TH)	65.25	88.62	75.16
Turkish (tr_TR)	67.56	91.63	77.77
Chinese (zh_TW)	62.5	91.25	74.19

Table 2: Second Strategy Results

While both strategies performed well in handling named entities in translation, the second strategy generally produced higher final scores across most languages. Improvements in M-ETA and COMET scores were particularly noticeable for Italian (it_IT), French (fr_FR), and Chinese (zh_TW). However, variations still exist among different languages, indicating that certain language pairs may require further refinement. Future work will explore the potential benefits of merging these two strategies to leverage their strengths and further enhance translation performance. [2]

5 Conclusion

In this work, we explored entity-aware machine translation (EA-MT) by proposing two approaches aimed at improving the translation of named entities across multiple languages. Our first approach relied on the mBERT model for Named Entity Recognition (NER) combined with Wikidata-based entity translations, while our second approach leveraged large language models (LLMs) with structured prompt engineering to enhance translation accuracy.

Our experiments demonstrated that accurately recognizing and preserving named entities is crucial for high-quality translation. We identified several challenges, such as inconsistent entity annotations in the dataset and grammatical disruptions caused by placeholder-based translations. To mitigate these issues, we refined our methodology by incorporating normalization techniques and utilizing Wikidata as a reliable source for entity translations. The second approach, which integrated LLMs for translation while maintaining entity integrity, proved to be more effective in producing fluent and semantically accurate translations.

6 Future Work

While our proposed strategies have shown promising results, there is still room for improvement in enhancing the quality of the final translation. Firstly, let's consider the strategy that relied on Gemini 1.0. Although useful, this model occasionally struggled to fully adhere to prompt instructions, resulting in deviations from expected outputs. Additionally, as Gemini 1.0 is now being discontinued, transitioning to more advanced models has become a necessity.

To address these issues, future iterations of our first strategy will incorporate a more advanced large language model (LLM) with superior capabilities. By leveraging a model with improved contextual awareness and better alignment to user

[2] In the final leaderboard, the submissions can be found under the names *FII-UAIC-SAI* for the second strategy and *FII the Best* for the first strategy.

prompts, we expect a significant boost in translation accuracy across multiple languages.

Another area for future improvement is to integrate both strategies into a unified system, leveraging their strengths to enhance translation performance.

Abstract

This paper presents the ZJUKLAB team's submission for *SemEval-2025 Task 4: Unlearning Sensitive Content from Large Language Models*. This task aims to selectively erase sensitive knowledge from large language models, avoiding both over-forgetting and under-forgetting issues. We propose an unlearning system that leverages Model Merging (specifically TIES-Merging), combining two specialized models into a more balanced unlearned model. Our system achieves competitive results, ranking **second among 26 teams**, with an online score of 0.944 for Task Aggregate and 0.487 for overall Aggregate. In this paper, we also conduct local experiments and perform a comprehensive analysis of the unlearning process, examining performance trajectories, loss dynamics, and weight perspectives, along with several supplementary experiments, to understand the effectiveness of our method. Furthermore, we analyze the shortcomings of our method and evaluation metrics, emphasizing that MIA scores and ROUGE-based metrics alone are insufficient to fully evaluate successful unlearning. Finally, we emphasize the need for more comprehensive evaluation methodologies and rethinking of unlearning objectives in future research[1].

1 Introduction

Unlearning has emerged as a critical technique in AI systems, enabling the selective removal of sensitive data, including copyrighted material and personal information, from trained models. As the International AI Safety Report (Bengio et al., 2025) emphasizes, unlearning plays a vital role in mitigating privacy and copyright risks associated with extensive training datasets. However, it also acknowledges that current unlearning methods remain inadequate, which often fail to completely erase targeted data while potentially degrading model performance, thus limiting practical implementation.

Specifically, existing unlearning methods often struggle with over-forgetting (excessive elimination of non-sensitive information) or under-forgetting (incomplete removal of sensitive data). It is challenging to find optimal hyperparameters that balance performance across multiple evaluation dimensions, sometimes even impossible. To address these limitations, we propose a novel unlearning system that leverages model merging to combine an over-forgetting model with an under-forgetting model, creating a more effective unlearned model. It can produce superior results simply by merging two models with complementary biases.

Our system achieved second place in *SemEval-2025 Task 4: Unlearning Sensitive Content from Large Language Models*, with our 7B model attaining a *Task Aggregate Score* of 0.944 and *Aggregate Score* of 0.487, demonstrating the effectiveness of our system in selectively removing sensitive content. Furthermore, our local experiments yielded almost perfect results with a *MIA Score* of 0.501 and *Aggregate Score* of 0.806, while maintaining an exceptionally high *Task Aggregate* and comparable *MMLU Avg.*. We provide comprehensive analyses that validate our system's effectiveness and offer deeper insights into the unlearning process.

2 Task Description

Datasets The dataset comprises a *forget set* and a *retain set* across three subtasks: (1) long-form synthetic creative documents, (2) short-form synthetic biographies with PII (names, phone numbers, SSN, emails, addresses), and (3) real documents from the target model's training data. The organizers provide a vanilla model (OLMo-7B-0724-Instruct) (Groeneveld et al., 2024) which has been pretrained on all subtasks.

* Equal contribution

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 566–574

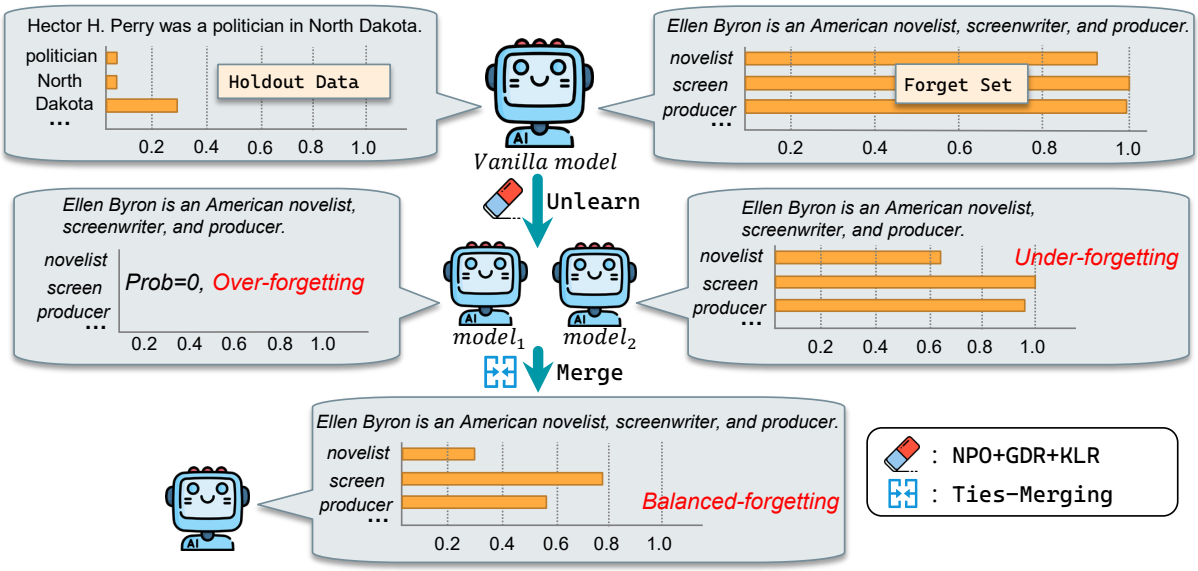

Figure 1: Visualizing Unlearning via Model Merging. The vanilla model (top) initially assigns high probabilities to forget set (member) and low probabilities to holdout data (nonmember). We then merge two individually unlearned models: one exhibiting over-forgetting (middle left) and the other under-forgetting (middle right). Model merging aims to achieve balanced forgetting (bottom), effectively reducing the model's confidence in predicting sensitive member data while preserving its performance on nonmember data.

Evaluation Evaluation involves sentence completion and question answering across tasks. Key metrics include: *Regurgitation Score* (ROUGE-L for sentence completion), *Knowledge Score* (accuracy for QA), *MIA Score* (loss-based membership inference attack (Shi et al., 2024)), and *MMLU Score* (average accuracy on 57 STEM subjects). *Task Aggregate* is the harmonic mean of Regurgitation Scores and Knowledge Scores for each task. The overall *Aggregate* averages the Task Aggregate, MIA scores, and MMLU scores.

For details about task description, please refer to the official paper (Ramakrishna et al., 2025a,b).

3 Methodology

As illustrated in Figure 1, our unlearning system follows two phases. (1) the *Training Phase* develops two complementary models, each exhibiting strong performance. (2) the *Merging Phase* merges these models, leveraging their strengths to achieve effective and balanced unlearning.

3.1 Training Phase

We train two models with identical objectives but different hyperparameters via Low-Rank Adaptation (LoRA) (Hu et al., 2021). Three components are included in the optimization process: **Negative Preference Optimization (NPO)** (Zhang et al., 2024a) on forget set, alongside **Gradient Descent on Retain Set (GDR)** and **Kullback-Leibler Divergence Minimization on Retain Set (KLR)**. The composite objective is as follows:

$$L_{\text{total}} = \alpha L_{\text{npo}} + \beta L_{\text{gdr}} + \gamma L_{\text{klr}}, \qquad (1)$$

where L_{npo} leverages the preference optimization to minimize probabilities of target tokens on forget data, while L_{gdr} and L_{klr} preserve retain data. The hyperparameters α, β, γ are set to balance forgetting and retention. Our aim is to train two complementary models that exhibit distinct strengths in metrics. Detailed formulations are shown in Appendix A.1.

3.2 Merging Phase

After training, we apply **TIES-Merging** (Yadav et al., 2023) to combine the LoRA adapters of the two models. This involves three stages:

Trimming: Preserving only the most significant parameters based on a density threshold while zeroing out the rest.

Electing: Creating a unified sign vector that resolves parameter conflicts by identifying the dominant direction of change across models.

Disjoint Merging: Averaging non-zero parameter values that align with the unified sign vector, ensuring that the merged model incorporates only changes contributing to the agreed direction, thus improving multitask performance.

Environment	Algorithm	Aggregate	Task Aggregate	MIA Score/MIA AUC	MMLU Avg.
Online	AILS-NTUA	**0.706**	0.827	**0.847** / –	0.443
	YNU	0.470	0.834	0.139 / –	0.436
	Mr.Snuffleupagus	0.376	0.387	0.256 / –	**0.485**
	ZJUKLAB (ours)	0.487	**0.944**	0.048 / –	0.471
Local	NPO+GDR+KLR ($model_1$)	0.481	0.968	0.045 / 0.022♣	0.431
	NPO+GDR+KLR ($model_2$)	0.504	0.659	0.364 / 0.818♠	0.491

Table 1: The online and local experiments results. Note that ♣ indicates over-forgetting, ♠ indicates under-forgetting, and ♡ signifies balanced forgetting, achieving a raw MIA AUC close to 0.5. All metrics are detailed in §2.

4 Experiments

Implementation We carried out our experiments using two NVIDIA A100-PCIE-40GB GPUs. The organizers supplied the local dataset for our local experiments and evaluated our code online using an additional unreleased dataset. Detailed configurations are provided in Appendix A.2.

Main Results Table 1 presents the online results evaluated by the organizers and the local results evaluated by us. Our 7B model achieves an *Aggregate* score of 0.487 online, ranking second among 26 teams. The online *MIA Score* is less favorable, possibly due to dataset discrepancies between the online and local environments. However, local evaluations effectively validate the core principles of our system design. In *training phase*, $model_1$ shows over-forgetting, achieving a high *Task Aggregate* of 0.968 but a low *MIA Score* of 0.022. In contrast, $model_2$ shows under-forgetting, with a lower *Task Aggregate* of 0.659 and a higher *MIA Score* of 0.818. The merged model shows better performance, attaining a *Task Aggregate* of 0.939 and a *MIA AUC* of 0.501. This merging technique integrates the strengths of both models, preserving their high *Task Aggregate* and *MMLU Avg.* scores while successfully neutralizing their MIA scores, resulting in an almost ideal MIA score. These results highlight our system's ability to effectively aggregate the strengths of these biased models.

5 Analysis

5.1 Why NPO+GDR+KLR Works?

This section analyzes the effectiveness of NPO+GDR+KLR model (denoted as $model_1$ in the training phase), trained on the local dataset.

Performance Trajectory To understand performance trends, we evaluated model checkpoints throughout training. As shown in Figure 2, both Regurgitation and Knowledge Scores initially decline concurrently for forget and retain sets (epochs 0-0.8). This suggests that, in the early stages of training, the optimization processes for both forgetting and retaining knowledge are proceeding in the same direction, causing a simultaneous metric decrease. Subsequently, the Knowledge Score steadily trends upward, while the Regurgitation Score increases with noticeable oscillations. This indicates that the optimization directions of knowledge retention and knowledge forgetting are beginning to become different. The observed fluctuations

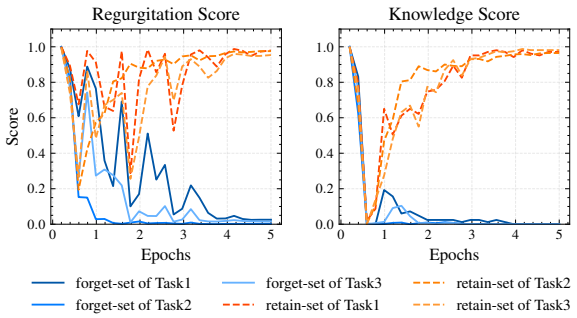

Figure 2: Performance Curves: Regurgitation and Knowledge Scores During Training.

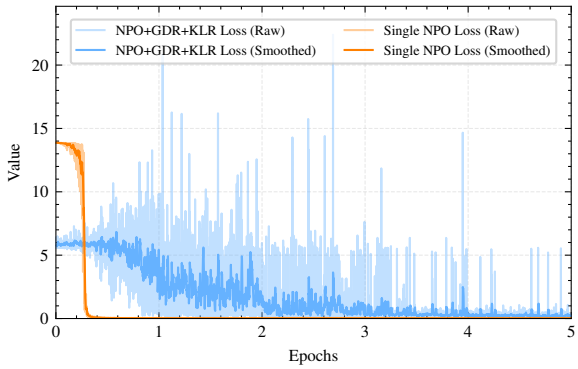

Figure 3: Training Loss Curves of NPO and NPO+GDR+KLR.

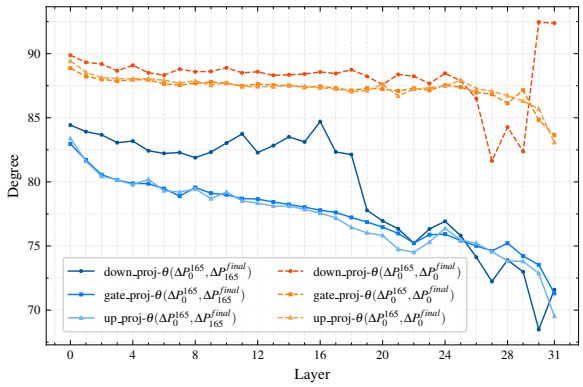

Figure 4: Angle (θ) between Parameter Change Vectors: ΔP_0^{165}, ΔP_{165}^{final}, ΔP_0^{final}.

in Regurgitation Score may stem from the tradeoff between learning and forgetting.

Loss Dynamics Figure 3 compares the training loss curves of NPO and NPO+GDR+KLR models. Notably, the NPO+GDR+KLR loss curve displays oscillations in mid-training, likely caused by the similarity between forget and retain sets, hindering a steady loss decline. Conversely, training with only the NPO loss function results in rapid convergence and a smooth loss curve, further highlighting the conflict between NPO and regularization. Despite this, NPO+GDR+KLR achieves a stable loss value in later training stages, demonstrating its ability to effectively balance forgetting and retention.

Weight perspective Figure 2 shows a performance trend with an initial decline followed by an increase. We identify this turning point as the *inflection point* (step 165). To understand optimization dynamics around this point, we analyzed the angle between flattened parameter change vectors across training phases (Figure 4), where $\Delta P_{s_1}^{s_2}$ be the parameter change vector from step s_1 to s_2. The angle between ΔP_0^{165} and ΔP_{165}^{final} is approximately 70-85 degrees. This suggests that the initial phase overemphasizes forgetting, while a significant shift in optimization direction occurs after the inflection point, where the balance between forgetting and retention has gradually been established. Conversely, the angle between the initial direction (ΔP_0^{165}) and the overall optimization direction (ΔP_0^{final}) approaches near orthogonality (90 degrees). This indicates that overall training does not consistently follow the initial direction, and the initial "forgetting" emphasis is balanced by later retention optimization.

Merging methods	Agggregate
Linear	0.244
DARE-Linear	0.440
DARE-TIES	0.561
Magnitude Prune	0.558
TIES	**0.806**

Table 2: Merging techniques comparison

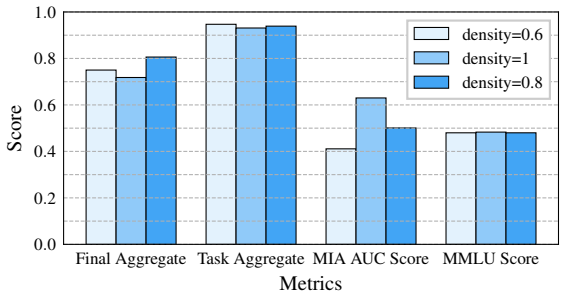

Figure 5: Performance for different density choices

5.2 Why Merge works?

To understand the efficacy of merging, we conduct comparative experiments on different merging techniques. As shown in Table 2, TIES-Merging outperforms others, and this effectiveness comes from its three fundamental operations: **Trim**, **Elect**, and **Disjoint Merge**.

Firstly, for **Trimming**, we conduct ablation studies varying the density between 0.6, 0.8, and 1 (Figure 5) and observed that a density of 0.8 yields the best results. This optimal density level retains essential parameters while removing redundant ones, effectively preserving the better performance of two models and achieving balanced forgetting. We hypothesize that lower densities (e.g., 0.6) excessively prune parameters vital for knowledge retention, leading to over-unlearning and a reduced MIA score. Conversely, a density of 1, by retaining all parameters, introduces redundancy and may incorporate influences from the less-unlearned model, resulting in a suboptimal outcome and a higher MIA score. Therefore, trimming with a density of 0.8 strikes a critical balance. Beyond trimming, TIES-Merging further enhances directional consistency through the **Elect** operation, which establishes parameter signs based on magnitude. Given the strong baseline performance of the individual models, this magnitude-based election ensures reliable convergence toward optimal directional consistency during merging. Finally, the **Dis-**

joint Merging operation averages parameters with consistent elected signs and discards discordant ones. This strategic approach effectively mitigates over-unlearning and further enhances the merged model's resistance to Membership Inference Attacks (MIA).

6 Rethinking Unlearning

6.1 Drawbacks: Over-forgetting Phenomena

Despite demonstrating effectiveness, our system still exhibits **over-forgetting**. Firstly, the unlearned model exhibits *model collapse*, frequently generating repetitive characters (e.g., "6 6 6"). This phenomenon arises from the training process itself, the model may find a suboptimal but easy shortcut: generating repetitive outputs to reduce loss. Specifically, Task 2 involves a digit-heavy dataset, so the model will take this high-frequency option as their outputs. Secondly, we observed **forgetting of generic knowledge**. We analyze question patterns of forget set to construct 50 common knowledge questions (e.g., "What is the capital of France?"), finding a significant Knowledge Score drop (0.88 $\rightarrow$ 0.35) against a vanilla baseline. These drawbacks are also observed in some studies Mekala et al. (2025); Xu et al. (2025), highlighting a fundamental weakness of this paradigm. Throughout training, the system repeatedly applies reverse optimization signals to the original forget data. Without positive guidance like in reinforcement learning, the model cannot explore better outputs and inevitably degrades under sustained pressure.

Forget Set Case:
Question: What is Lorette Fuchsia's email address?
Answer: 6 6 6 6 6 6 6...

Retain Set Case:
Question: What is the birth date of Fredericka Amber?
Answer: 1969-12-21

Generic Knowledge Case:
Question: In which city is the Eiffel Tower located?
Answer: 6 6 6 6 6 6 6...

6.2 Limitations of Unlearning Evaluation

ROUGE-based metrics primarily measure how closely a response matches an expected output rather than exact knowledge unlearning. For instance, a different long response might still inadvertently leak sensitive information like an email address, yet escape detection by ROUGE-L due to its focus on textual overlap rather than content semantics. In this competition, separate metrics have been introduced (i.e., Regurgitation Score and Knowledge Score). However, they remain susceptible to superficial textual variations, where minor rephrasing can mask underlying retention of knowledge, thus undermining their ability to accurately evaluate unlearning effectiveness. Similarly, **MIA Scores like Min-k% prove insufficient**. Although our method achieves an almost optimal MIA score of 0.501, it still generates repetitive outputs that deviate from the base model's behavior. Some studies (Duan et al., 2024; Meeus et al., 2024) cast doubt on MIA's reliability for LLMs, pointing to potential temporal or domain discrepancies in datasets. In this competition, while the forget set and retain set are derived from Wikipedia after the deadline of OLMO's training, subtle distribution shifts may still persist. Our local test on OLMo-7B-0724-Instruct-hf yields an MIA AUC of 0.46, slightly misaligned with the official optimal score of 0.5, further highlighting these inconsistencies.

6.3 Rethinking Unlearning's Objectives

Recent studies (Xu et al., 2024; Zhou et al., 2024; Thaker et al., 2024; Cooper et al., 2024; Barez et al., 2025) present critical analyses of generative AI unlearning. These studies collectively reveal three fundamental limitations: (1) current unlearning methods remain impractical, (2) evaluations fail to assess the generalization capability of unlearned models, and (3) benchmarks encourage model to overfit the training set, creating an illusory forgetting. The root challenge lies in the lack of a clearly defined, universally applicable unlearning objective. Rather than overloading unlearning with goals like resistance to relearning attacks (Fan et al., 2025), future research should prioritize on-demand unlearning and robust evaluation to address practical policy needs. As discussed in §6.1, current methods often lead to degraded outputs. Future work can explore the incorporation of positive signals to guide the model toward more appropriate forgetting behaviors such as data augmentation and reinforcement learning.

7 Conclusion

This paper introduce an unlearning system via model merging. By combining two complementary models, it effectively achieves balanced forgetting and excellent knowledge preservation.

A Detailed Setup

A.1 Detailed formulas

This section introduces detailed formulas in this paper.

Negative Preference Optimization: The loss function penalizes the model for generating outputs with negative preferences while maximizing outputs with positive preferences:

$$L_{\text{NPO}} = -\frac{2}{\beta}\mathbb{E}_{\mathcal{D}_f}\left[\log\sigma\left(-\beta\log\frac{\pi_\theta(y|x)}{\pi_{\text{ref}}(y|x)}\right)\right] \tag{2}$$

where $\pi_\theta(y|x)$ is the model's output distribution and $\pi_{\text{ref}}(y|x)$ is the reference distribution. Here, σ is the sigmoid function and β is a regularization parameter.

Gradient Descent on Retain Set (GDR): Minimizes the loss for samples in retain set by updating parameters in the direction to the gradient of the loss function:

$$\theta_{t+1} = \theta_t - \eta\nabla_\theta\mathcal{L}(\theta_t, \mathcal{D}_r) \tag{3}$$

where θ_t represents the model parameters at step t, η is the learning rate, and $\nabla_\theta\mathcal{L}(\theta_t, \mathcal{D}_r)$ is the gradient of the loss function at step t, calculated on the retain set $\mathcal{D}_r$.

KL Minimization on Retain Set (KLR): Minimizes the Kullback-Leibler divergence between the model's output distribution and a target distribution on retain set:

$$\mathcal{L}_{\text{klr}} = \sum_i \pi_\theta(y_i)\log\frac{\pi_\theta(y_i)}{\pi_{\text{target}}(y_i|\mathcal{D}_r)} \tag{4}$$

where $\mathcal{L}_{\text{KL}}$ is the loss, $\pi_\theta(y_i)$ is the model's output distribution for the i-th output token y_i, and $\pi_{\text{target}}(y_i|\mathcal{D}_r)$ is the target output distribution for the i-th token y_i conditioned on the retain set $\mathcal{D}_r$.

A.2 Detailed Implementation

B Related Work

LLM Unlearning The topic of unlearning in large language models (Chen, 2024) has recently attracted significant attention in the literature. One approach to unlearning is Gradient Ascent (Jang et al., 2023), which aims to maximize the loss function to facilitate forgetting. Another method, Negative Preference Optimization (NPO) (Zhang et al., 2024a), builds upon Direct Preference Optimization (DPO) (Rafailov et al., 2023), offering an alternative strategy for model unlearning. Various unlearning techniques have been proposed, including those presented by (Lu et al., 2022; Eldan and Russinovich, 2023; Yu et al., 2023; Chen and Yang, 2023; Wang et al., 2025; Gandikota et al., 2024; Jiang et al., 2025; Liu et al., 2024b;

Zhuang et al., 2024). An alternative strategy, referred to as "locate-then-unlearn," is exemplified by KnowUnDo (Tian et al., 2024) and SURE (Zhang et al., 2024b), which focus on knowledge localization before executing the unlearning process. Additionally, data-driven methods for unlearning have also been introduced, such as those proposed by (Jang et al., 2022; Ma et al., 2024; Liu et al., 2024a; Gu et al., 2024; Sinha et al., 2024; Xu et al., 2025; Mekala et al., 2025). Several works have explored the use of model merging techniques to achieve unlearning (Kadhe et al., 2024; Kuo et al., 2025).

Model Merging Training a model for each task can be costly, but model merging offers a solution to these challenges by combining multiple pretrained models. Model merging strategies include parameter averaging (Linear), singular value decomposition (SVD) for low-rank alignment, and feature concatenation (CAT). Advanced variants like TIES (Yadav et al., 2023) trim redundant parameters and resolve sign conflicts, while TIES-SVD (Stoica et al., 2024) integrates SVD for refined fusion. DARE methods(Yu et al., 2024), and methods like DARE-TIES, DARE-linear introduce parameter dropout and rescaling, with extensions (DARE-TIES-SVD, DARE-linear-SVD) combining SVD for structured compression. The magnitude-prune (Deep et al., 2024) removes low-impact weights, and its SVD variant (magnitude-prune-SVD) is further compressed via low-rank decomposition.

GPLSICORTEX at SemEval-2025 Task 10: Leveraging Intentions for Generating Narrative Extractions

Abstract

This paper describes our approach to address the SemEval-2025 Task 10 subtask 3 for the English language, which is focused on narrative extraction given news articles with a dominant narrative. We design an external knowledge injection approach to fine-tune a Flan-T5 model so the generated narrative explanations are for the provided dominant narrative in each text. We also incorporate pragmatic information in the form of communicative intentions, using them as external knowledge to assist the model. This ensures that the generated texts align more closely with the intended explanations and effectively convey the expected meaning. The results show that our approach ranks 3rd in the task leaderboard (0.7428 in Macro-F1) with concise and effective news explanations. The analyses highlight the importance of adding pragmatic information when training systems to generate adequate narrative extractions.

1 Introduction

Understanding natural language goes beyond recognizing objects and their relations within a sentence or a news article. The way information is presented—or omitted—is shaped by the author's communicative intentions and implicit biases. To fully grasp the narrative conveyed by a text, one must move beyond a surface-level reading and incorporate assumptions about the author's intent, as well as general knowledge about the topic.

With the rise of modern misinformation, automated approaches have become crucial in combating information warfare. However, these systems come with their own biases, making explainability a key factor in building trust. SemEval-2025 Task 10 addresses this challenge by combining the identification and explanation of narratives in text. Our work focuses on Subtask 3, which involves generating narrative extractions given a news article. Large Language Models (LLMs) have been shown to encode general knowledge (Ju et al., 2024; Wang et al., 2023), and analytical capabilities (Chang et al., 2023) to identify implicit narratives of a text. Additionally, they hold promise for explainability, as they can be prompted to generate explanations (Roy et al., 2023; Yang et al., 2023). However, their explanations still fall short of human-level quality (Di Bonaventura et al., 2024).

Our approach enhances LLM-generated explanations as a form of controllable abstractive summarization (He et al., 2020) using knowledge injection and standard fine-tuning to align the model's outputs with the required task format. A key contribution of our work is leveraging a curated dataset with labeled communicative intentions to assist the model's analytical capabilities based on Speech Act Theory (Austin, 1962). We hypothesize that injecting this knowledge about intentions can control the model's focus and improve explanation quality. Our approach ranked 3rd in the competition.

2 Background

2.1 Task Description

SemEval-2025 Task 10, "Multilingual Characterization and Extraction of Narratives from Online News" (Piskorski et al., 2025), addresses the identification and analysis of manipulative and harmful disinformation in news articles. The task comprises three subtasks, applied to news articles available in five languages: Bulgarian, English, Hindi, Portuguese, and Russian.

Our submission pertains to the English-language configuration of Subtask 3, which focuses on generating a free-text explanation of given news articles based on the predominant narrative they convey. The provided data for generating the explanation consists of two inputs: the dominant narrative embodying the text intention, which is composed of two labels (dominant narrative and dominant subnarrative) extracted from a narrative taxonomy, and

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 575–583

the news articles, containing the ground for the narrative tools making up the given intention.

The dataset for Subtask 3 in English is composed of three sets: (1) Training set and (2) Validation set, containing 203 and 30 articles respectively, each accompanied by its corresponding narrative, subnarrative, and expected output annotations; and (3) Test set, consisting of 68 articles, annotated only with their narrative and subnarrative (Stefanovitch et al., 2025).

2.2 Narrative Extraction Task

Task 10 Subtask 3 at SemEval 2025 focuses on generating narrative extractions from a given news article embedded within a text. Narrative extraction refers to the use of computational techniques to identify, link, and visualize narrative elements from textual sources (Santana et al., 2023). This process involves several key steps: Information Retrieval, which aids in locating relevant information; Text Summarization, which condenses and integrates information pertinent to the narrative; Natural Language Processing, which identifies, extracts, and connects narrative components; and Natural Language Generation, which transforms structured data into coherent textual explanations.

As a text-to-text generation task, narrative extraction is closely related to summarization, but with a distinctive analytical focus on the author's intent and persuasive strategies—aligning it with the concept of controllable text summarization (He et al., 2020; Urlana et al., 2024). A wide range of techniques have been employed in summarization tasks, including statistical machine learning, unsupervised methods, supervised deep learning, and fine-tuning of pretrained language models (Zhang et al., 2024; Urlana et al., 2024).

The advent of instruction-tuned large language models has significantly enhanced the flexibility of controllable summarization, enabling fine-grained control over style, length, and output format through prompt engineering, few-shot learning, and fine-tuning strategies (Liang et al., 2024).

In this context, our approach introduces a novel combination of intent modeling—to guide the generation of narrative extractions—and example-based fine-tuning—to align the system with the specific requirements of the task, including the desired style and format of the output.

2.3 Communicative Intentions

Regardless of its genre, register, or topic, every text inherently carries a communicative intention. Beyond its significance in linguistic research (Austin, 1962; Searle, 1969; Sperber and Wilson, 1986; Bach, 2012), this pragmatic element has also attracted attention in the Natural Language Processing (NLP) community. Advances in NLP now enable the automatic analysis of discourse-related phenomena, making it possible to extract pragmatic information that was previously unfeasible to study due to the complex inferential processes involved in detecting intentions (Mahowald et al., 2024).

Within the existing approaches to the study of intentions, the Speech Act Theory (SAT) (Austin, 1962; Searle, 1969) has been recently applied to many well-established NLP tasks such as question answering (Mirzaei et al., 2023) or text summarization (Mu et al., 2023). Similarly, narrative texts have benefited from the analysis of speech acts (i.e., the actions performed by speakers through their utterances (Yule, 2022)), which helps to better understand the intentions behind narrating events (Kampf, 2021; Borchmann, 2024; Obasi, 2024).

Building on these previous works, we explore the use of intentions for the narrative extraction task to assess whether they help generative models produce more adequate explanations.

3 System Overview

We propose a three-step approach for addressing the narrative extraction task[1]. Our methodology begins by retrieving the narrative intention of the input article, as each article in the dataset exhibits a distinct underlying intention. Identifying these intentions is crucial for shaping the generated explanations. Next, we employ a prompt engineering strategy to construct an input prompt by combining the extracted intention with the corresponding dataset entry. Finally, we inject the knowledge by fine-tuning instruction-tuned models to generate the corresponding explanations. The overall approach is illustrated in Figure 1 and will be described in detail in the following sections.

3.1 Intention Extraction

In this stage, we assumed that the "dominant narrative" assigned to each news article shows great

[1]All code is publicly available on https://github.com/imm106/teamgplsi-task10.

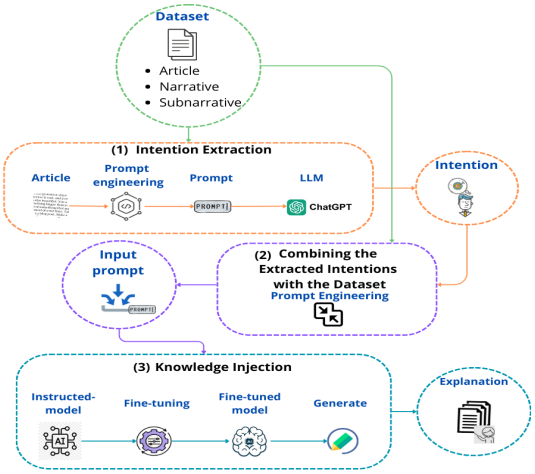

Figure 1: GPLSICORTEX approach to address SemEval 2025 Task 10 Subtask 3.

similarity to what can be considered the text's primary communicative intention. Examples of such intentions include **questioning** a political party, **criticizing** a legal measure or **praising** a political candidate. Therefore, we believed that identifying the intentions conveyed in the narratives would benefit the model's training, enabling the generation of explanations that align with the essential content of the original texts.

To do so, we adapted the work of Maestre et al. (2025), who created a communicative intention annotation scheme for the Spanish language based on two textual dimensions: the intention of the individual segments that shape a message and the global intention of the whole message. More concretely, we selected the 13 global intention categories they established within the annotation scheme and translated them into English, as they showed clear similarities with the intentions observed in the texts provided for the task. The 13 intention categories are: "informative", "personal opinion", "suggestion", "command", "request", "question", "threat", "promise", "praise", "criticism", "emotional", "desire", and "sarcasm / joke".

After establishing the set of intentions to be identified in the narrative texts, we translated the prompt Maestre et al. (2025) used to classify intentions into English so we could classify the global intentions expressed in the narratives. The specific prompt used for this classification task is provided in Appendix A. Based on their findings, we selected GPT-4o-mini, as it was identified as the most effective LLM for automatic intention classification in Spanish. Upon completing the annotation process, we obtained intention tags for each text to enhance the Natural Language Generation (NLG) system. The statistical results of the intention classification are presented in Appendix B.

3.2 Combining the Extracted Intentions with the Dataset

To integrate the extracted knowledge—represented as communicative intentions—into a single input for the model alongside the corresponding dataset entry, we employed a prompt engineering strategy. This approach combines role prompting (Gao, 2023) with the inclusion of control tokens (Li et al., 2022) to effectively inject relevant features. Specifically, we guide the model by explicitly instructing it to act as a text explainer, with the objective of providing explanations of the given articles.

To structure the input, we concatenate key features —article, narrative, subnarrative, and intention— using control tokens to clearly delineate each component (e.g., #Article article, #Theme corresponding narrative, #Intent corresponding intention). A sample prompt is given in Appendix C.

3.3 Knowledge Injection

To incorporate the extracted knowledge, we fine-tuned various instruction-based models using our constructed prompts. Specifically, we evaluated different sizes of LLaMA (Dubey et al., 2024) and Flan-T5 (Chung et al., 2024) models, both of which have demonstrated strong performance in NLG tasks. LLaMA is an LLM that excels in various NLG applications, including text summarization (Bogireddy and Dasari, 2024), a task closely related to our narrative extraction objective. In our experiments, we utilized LLaMA-3.2 and evaluated two model sizes: 1B and 3B parameters. Flan-T5 is an instruction-tuned model designed for multi-task generalization, allowing it to tackle tasks beyond its original training (Zeyad and Biradar, 2024). For our experiments, we tested Flan-T5 Large (780M parameters) and Flan-T5 Base (250M parameters).

To fine-tune these models effectively, we adopted two distinct strategies:

- **Flan-T5 Models**: We performed a full fine-tuning to make the model learn the desired output format.
- **LLaMA Models**:We utilized the *Low-Rank Adaptation (LoRA)* technique (Hu et al., 2021), which introduces trainable low-rank matrices into specific layers instead of updating

all model parameters. This method significantly reduces memory and computational costs, making it feasible to fine-tune large-scale models like LLaMA efficiently.

4 Experimental Setup

In this section, we outline the experimental setup utilized in our experiments.

4.1 Dataset Split

To monitor potential overfitting during fine-tuning, we split the training set into two subsets: 90% for training and 10% for development. This resulted in 172 articles with their respective annotations for training and 31 articles for development.

The validation and test splits provided by the task remained unchanged, consisting of 30 articles for validation and 68 for testing. This strategy ensured a reliable assessment of our models' generalization performance while preventing overfitting.

4.2 Fine-tuning & Hyperparameters

To implement the different fine-tuning strategies, we used various Python libraries. Specifically, for full fine-tuning of the Flan-T5 models, we utilized the Transformers library (Wolf et al., 2020). For the LLaMA models, we employed the PEFT library (Mangrulkar et al., 2022) to apply the LoRA technique and the TRL library (von Werra et al., 2020) to manage the training process. The parameters used for the LoRA configuration are presented in Table 1.

Parameters	Values
Rank	8, 16, 24 and 32
Target modules	["q_proj", "k_proj", "v_proj", "o_proj"]
Alpha	8, 64 and 128
Dropout	0.00, 0.01 and 0.05
Bias	none
Task type	CAUSAL_LM

Table 1: LORA configuration parameters setup.

Furthermore, we conducted hyperparameter tuning to determine the optimal fine-tuning configuration. Table 2 presents the search configuration used in this process.

Parameters	Values
Train epochs	2, 3, or 4
Learning rate	$1e-4$, $2e-4$, $3e-4$, or $4e-5$
Weight decay	0, 0.1, or 0.2
Optimizer	adamw_torch_fused

Table 2: Hyperparameter tuning.

All the experiments were conducted on a single NVIDIA A100 GPU.

4.3 Evaluation Metrics

To assess our system's performance, we utilized BERTScore (Zhang et al., 2020), the same metric employed in the shared task evaluation. BERTScore measures the similarity between reference and candidate texts using contextual embeddings from a pre-trained BERT model.

Additionally, we conducted a shallow manual analysis of the generated outputs to further evaluate the quality of our models' predictions.

5 Results

In this Section, we report the obtained results through our experimentation, and our official results in the SemEval 2025 Task 10 Subtask 3.

5.1 Development

During the training phase, we conducted a series of experiments using instructed models and various hyperparameter configurations. The results for each model, obtained using the optimal hyperparameter settings, are presented in Table 3.

System	Precision	Recall	Macro-F1
Llama-3.2-1B	0.70988	0.70928	0.70937
Llama-3.2-3B	0.72093	0.72369	0.72200
Flan-T5 Base	**0.78016**	0.71562	0.74613
Flan-T5 Large	0.76931	**0.73429**	**0.75115**

Table 3: BERTScore results on the development set for the Subtask 3 in English.

As observed, Flan-T5 outperforms LLaMA-3.2 for this task. While LLaMA maintains a stable balance between precision and recall, its overall scores remain lower than those achieved by the Flan-T5 models. Among the Flan-T5 configurations, the base model attains higher precision; however, its recall is lower compared to the larger configuration. Consequently, the larger Flan-T5 model achieves the highest overall performance. A manual analysis of the generated explanations reveals that LLaMA tends to produce explanations split into two or three sentences, delving into longer outputs. In contrast, Flan-T5 generates a single, concise sentence that effectively summarizes the entire article.

Therefore, we selected the Flan-T5 Large model as the basis for our approach in the competition.

5.2 Official Test Leaderboard

We finally submitted the Flan-T5 Large model enhanced with the extracted intentions and fine-tuned to address this task. Table 4 shows the official test leaderboard for subtask 3 in English.

	System	Precision	Recall	Macro-F1
1	KyuHyunChoi	0.76686	0.73517	0.75040
2	WordWiz	0.75464	0.73705	0.74551
3	**GPLSICORTEX**	**0.75375**	**0.73274**	**0.74280**
4	TechSSN	0.73886	0.74568	0.74203
5	NarrativeNexus	0.71991	0.74267	0.73085
...	...	...	...	...
14	Baseline	0.65144	0.68344	0.66690

Table 4: Official Results of SemEval Task 10 Subtask 3 with the BERTScore metric.

Our approach secured third place out of 14 participants in the competition, demonstrating strong performance. Specifically, we achieved a Macro-F1 of BERTScore of 0.74280, only 0.0076 lower than the top-performing method, highlighting the competitiveness of our model. Our results suggest that consistent with our validation set findings, the BERTScore metric reflects high precision, indicating that our model generates highly accurate predictions, although the recall rate is slightly lower.

6 Analysis of the Efficacy of Injecting the Intentions

In this section, we aim to demonstrate that incorporating communicative intentions extracted from the text enhances the model's performance.

To validate this, we fine-tuned the best-performing model, FLAN-T5 in its larger configuration, without integrating the extracted intentions. We then compared its performance against the results obtained when intentions were included. Tables 5 and 6 present the classification performance on the validation and test sets, respectively, using the BERTScore metric.

Intent	Learning Rate	Precision	Recall	Macro-F1
Yes	$1e-4$	**0.76931**	**0.73429**	**0.75115**
No	$1e-4$	0.76055	0.71082	0.73460
Yes	$4e-5$	**0.77681**	**0.72630**	**0.75050**
No	$4e-5$	0.78080	0.71188	0.74445

Table 5: Analysis of the intentions on the validation set with BERTScore metric.

Results show that the classification performance for the models enhanced with intentions is consistently higher than for the models without intent across both the validation and test sets. The intentions help to achieve higher precision, recall, and Macro-F1 scores, indicating that those models are more confident and accurate in generating the explanations of the articles.

Intent	Learning Rate	Precision	Recall	Macro-F1
Yes	$1e-4$	**0.75375**	**0.73274**	**0.74280**
No	$1e-4$	0.73905	0.71740	0.72780
Yes	$4e-5$	**0.76754**	**0.73464**	**0.75040**
No	$4e-5$	0.76033	0.72086	0.73961

Table 6: Analysis of the intentions on the test set with BERTScore metric.

7 Post-Competition

After the conclusion of the competition, we entered a phase where we could systematically evaluate our approaches using the test set.

During this process, we found it particularly insightful to explore the impact of different hyperparameter configurations on our best-performing approach. Specifically, during the competition, we observed that certain hyperparameter settings yielded higher precision on the BERTScore metric in the validation set, besides at the cost of reduced recall compared to the configuration used in our final submission, which was more balanced. This effect was particularly pronounced when adjusting the learning rate.

Table 7 presents the results obtained with the fine-tuned FLAN-T5 model, enhanced with the communicative intentions, across different learning rate configurations.

Learning Rate	Precision	Recall	Macro-F1
$1e-4$ **(Official)**	0.76931	**0.73429**	**0.75115**
$4e-5$	**0.77681**	0.72630	0.75050
$3e-4$	0.75579	0.72457	0.73960
$2e-4$	0.75533	0.71551	0.73463

Table 7: Results of the hyperparameter analysis on the validation set on the post-competition period.

As observed, the model trained with a learning rate of $1e-4$ achieves the best overall performance. However, a learning rate of $4e-5$ leads to higher precision while sacrificing recall, resulting in a BERTScore similar to that of the best-performing configuration. This suggested us that maybe the model configuration with $4e-5$ as the learning rate could perform well on the test set. We also generated the explanations for the test set with all the learning rates configurations. Table 8 shows the results on the test sets for our approaches.

The fine-tuned approach with a learning rate of $4e-5$ outperforms our official competition sub-

Learning Rate	Precision	Recall	Macro-F1
$1e-4$ **(Official)**	0.75375	0.73274	0.74280
$4e-5$	**0.76754**	**0.73464**	**0.75040**
$3e-4$	0.74715	0.73234	0.73935
$2e-4$	0.75064	0.73317	0.74143

Table 8: Results of the hyperparameter analysis on the test set on the post-competition period.

mission, achieving a macro-F1 score of 0.75040 on the BERTScore metric. Notably, this configuration surpasses our official results not only in precision but also in recall. This configuration would have secured us 1st place in the competition, matching the score of the top-performing team.

8 Conclusions

In this paper, we present our approach for the SemEval-2025 Task 10 Subtask 3 in English, focused on the generation of explanations of articles containing disinformation. Our method provides narrative intention knowledge to the model within a fine-tuning and hyperparameter-tuning process.

Our submission involves the fine-tuned Flan-T5 Large model, with which we ranked 3rd in the competition, achieving a BERTScore F1 of 0.74280, only 0.0076 lower than the top-performing method.

The results show the importance of intention analysis in exposing misinformation initiatives. The selected 13 global intention categories extracted from the scheme of Maestre et al. (2025) have been proved to be beneficial for the task, as shown in Section 6.

In addition, this work has provided an analysis to determine the best-performing model configuration for the task. Flan-T5 models have demonstrated satisfactory results.

To effectively detect articles that disseminate disinformation, identifying the author's intent is crucial. However, our approach can be further enhanced by integrating additional perspectives. For instance, incorporating a propaganda strategy taxonomy could help identify specific linguistic tools employed by the author to propagate a particular narrative. Furthermore, advanced techniques such as Few-Shot Prompting with LLaMA 3.1, sentiment analysis of dominant narratives, and the Chain of Thought reasoning framework could be utilized to improve the accuracy and depth of the analysis.

A Prompt to Extract the Communicative Intentions

In this section, we provide a sample prompt used to query GPT-4o for extracting the communicative intention of a text, following the approach of Maestre et al. (2025).

From now on you're going to classify the global communicative intention of the text shown below. The text intention must be one of the following 13 categories: "informative", "personal opinion", "praise", "criticism", "desire", "request", "question", "command", "suggestion", "sarcasm / joke", "promise", "threat" or "emotional". I want your answer to be: The global intention of the text is: Text:

B Analysis of Extracted Intentions

We analyzed the distribution of extracted intentions across each dataset and found notable patterns. Figures 2, 3, and 4 illustrate these distributions. Notably, criticism emerged as the most prevalent intention across all sets. This finding aligns with the dominant narrative of the articles, which exhibited a strong inclination toward critical perspectives. Consequently, this correlation serves as validation of the accuracy of our methodology. Additionally, the second and third most frequent intentions were informative and personal opinion. This pattern can be attributed to the nature of the texts, which are news articles incorporating propaganda techniques. As such, these articles are expected to convey information, often accompanied by subjective points of view.

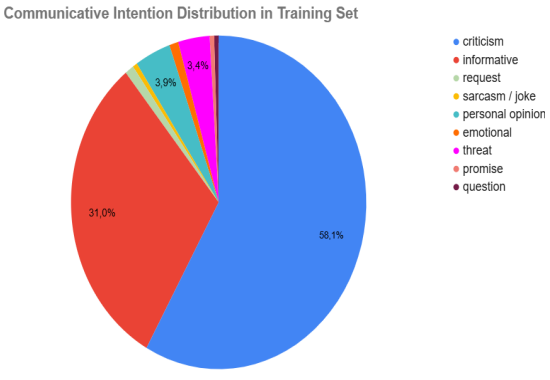

Figure 2: Analysis of the distribution of intentions in the training articles.

One factor that may have influenced our results is the greater diversity of intentions present in the training dataset compared to the validation and test

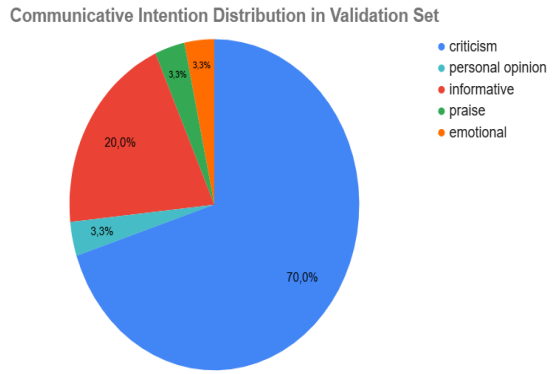

Figure 3: Analysis of the distribution of intentions in the validation articles.

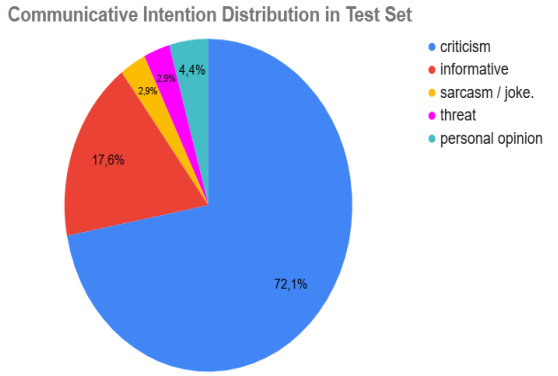

Figure 4: Analysis of the distribution of intentions in the test articles.

sets. However, despite this variation, there was only one instance in which an intention—praise—was detected in the validation set but was absent in the training split.

C Prompt to Combine the Communicative Intention with the Dataset

In this section, we present a sample prompt designed to integrate the extracted intention of the articles with the dataset.

```
From now you will act as a text explainer.
Your task is to generate an explanation
for the following article.

### Article:
This is a sample text. The news article
use to be longer than this one.

### Theme:
Ukraine is the aggressor

### Intent:
Criticism

### Explanation:
```

MRS at SemEval-2025 Task 11: A Hybrid Approach for Bridging the Gap in Text-Based Emotion Detection

Milad Afshari **Richard Frost** **Samantha Kissel** **Kristen Marie Johnson**
Michigan State University
{afsharim, frostric, kisselsa, kristenj}@msu.edu

Abstract

We tackle the challenge of multi-label emotion detection in short texts, focusing on SemEval-2025 Task 11 Track A. Our approach, *RoEmo*, combines generative and discriminative models in an ensemble strategy to classify texts into five emotions: anger, fear, joy, sadness, and surprise. The generative model, instruction-finetuned on emotion detection datasets, undergoes additional fine-tuning on the SemEval-2025 Task 11 Track A dataset to enhance its performance for this specific task. Meanwhile, the discriminative model, based on binary classification, offers a straightforward yet effective approach to classification. We review recent advancements in multi-label emotion detection and analyze the task dataset. Our results show that RoEmo ranks among the top-performing systems, demonstrating high accuracy and reliability.

1 Introduction

Emotion detection plays a critical role in natural language processing (NLP), yet remains a challenging task due to the nuanced and often subjective nature of emotional content. While recent advancements in emotion detection have demonstrated significant progress, there is still a need to enhance both the accuracy and efficiency of these models (Seyeditabari et al., 2018).

Emotion detection in short text settings presents a significant challenge due to the limited contextual information available, which constrains traditional NLP models that typically rely on richer textual input (Pang et al., 2021). The scarcity of extensive context necessitates the development of specialized approaches capable of accurately capturing emotional content from minimal linguistic cues. This challenge becomes even more pronounced in multi-label emotion detection, where the task involves identifying the emotion that most people perceive in the speaker's words—rather than the reader's reaction, the emotion of other characters, or the speaker's true feelings. The inherent subjectivity of language interpretation and the ambiguity in emotional expression often lead to multiple valid interpretations, making the task even more complex (Figure 1).

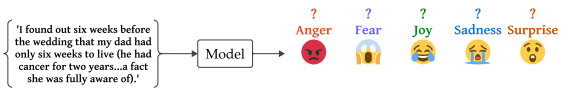

Figure 1: The challenge of multi-label emotion detection. This task focuses on identifying the emotion that most people perceive in the speaker's words, rather than the reader's reaction, the emotion of other characters, or the speaker's true feelings. The difficulty arises from the subjective nature of language interpretation and the inherent ambiguity in emotional expression.

Our study centers on SemEval-2025 Task 11 (Muhammad et al., 2025b), a benchmark challenge in emotion detection for short texts. Specifically, we address Track A, which requires classifying texts into one or more of five emotions: anger, fear, joy, sadness, and surprise. While Track A includes multiple languages, our focus is exclusively on English. Our approach, RoEmo, combines the predictions of RoBERTa-large (Liu et al., 2019) and EmoT5 (Liu et al., 2024) to enhance emotion detection in short texts.

2 Related Works

Emotion detection in text is a long-studied task in natural language processing with several approaches achieving success over the years. In this section, we summarize the most common emotion models employed in emotion detection and recent successful strategies for emotion detection.

2.1 Emotion Models

There are several competing models for emotions commonly used in emotion detection tasks, each

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 584–589

offering a unique perspective on how to conceptualize and classify affective states. For instance, the SemEval-2025 dataset used for this task is built upon the model proposed by Ekman (1992), which posits the existence of six basic emotions: joy, sadness, fear, anger, surprise, and disgust. Another well-known model proposed by Plutchik (2001) expands to eight primary emotions, introducing a broader perspective on affective states. While these models emphasize identifying base emotional states, some researchers have opted to conceptualize emotions within a multi-dimensional space. A notable example is the approach by Russell and Mehrabian (1977), which models emotions as three-dimensional vectors characterized by valence, arousal, and dominance.

Together, these models illustrate the diversity in theoretical approaches to understanding emotions. The choice between these frameworks often depends on the specific objectives and constraints of the emotion detection task at hand, with each model bringing its own strengths and limitations to the field.

2.2 Emotion Detection Methodologies

There have been several approaches that have found success in emotion detection. A notable characteristic of many approaches to emotion detection is the use of emotional lexicons to create additional model features (Al Maruf et al., 2024). These lexicons are simply lists of words associated with a particular emotion. A popular example is the EmoLex lexicon due to Mohammad and Turney (2010), which contains over 2000 terms along with their (Plutchik, 2001) emotion associations.

The top performer in SemEval-2018's task 1, which evaluated emotion detection in tweets, extracted five feature vectors from each tweet which were then processed by several models before being combined using ensemble methods (Duppada et al., 2018). More recently, Huang et al. (2021) considered a multi-label emotion classification problem similar to our own using a bi-directional LSTM encoder-decoder model. This approach was inspired by earlier works such as (Godbole and Sarawagi, 2004) and (Read et al., 2011), which advocated for the use of series of simple binary classifiers for multi-label classification problems. Other notable approaches have focused on exploiting nontraditional emotion models (Casel et al., 2021) and transfer learning based approaches (Yu et al., 2018). Graphical Neural Networks, such as EmoGraph (Xu et al., 2020), and span-prediction approaches, including SpanEmo (Alhuzali and Ananiadou, 2021), represent additional advancements in the field.

Recently, the EmoLLM framework (Liu et al., 2024) has leveraged instruction-tuned large language models (LLMs), such as EmoLLaMA, for emotion detection, demonstrating enhanced performance in both categorical and regression-based affective tasks. The EmoLLM series marks a substantial advancement in emotion detection by utilizing large language models fine-tuned on a multi-task affective instruction dataset. This approach enables EmoLLMs to excel in complex emotion analysis tasks, achieving performance levels comparable to, or better than, leading models such as ChatGPT and GPT-4 (Liu et al., 2024).

3 Approach

In this work, we employ two transformer-based models, **RoBERTa-large** and **EmoT5**, for emotion detection. Our approach explores both discriminative and generative modeling paradigms to classify emotions effectively. Both models are finetuned for 15 epochs using the AdamW optimizer with a learning rate of 2×10^{-5} on an NVIDIA RTX A6000 GPU.

3.1 RoBERTa-large with MLP

RoBERTa-large is a transformer model optimized for masked language modeling, providing robust contextual representations. To adapt it for emotion classification, we append a *two-layer multi-layer perceptron (MLP)* on top of the final hidden states. This additional MLP enables the model to refine its learned features for classification.

We formulate emotion detection as a **binary classification problem** for each emotion. Given an input text, the model predicts the probability of each emotion being present, allowing for multi-label classification. The MLP layers are trained jointly with RoBERTa using a binary cross-entropy loss function.

3.2 EmoLLM-based Approach

Recent advancements in LLMs have significantly improved affective computing tasks, particularly in emotion detection. One notable development in this domain is **EmoLLMs**, a class of *instruction-tuned* LLMs specifically fine-tuned for emotion recognition (Liu et al., 2024). These models uti-

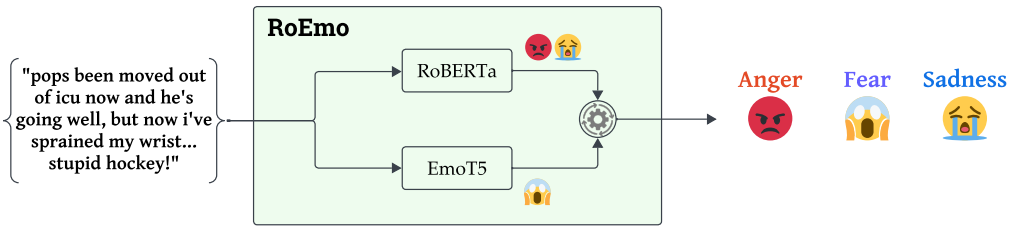

Figure 2: **Overview of RoEmo**: We obtain predictions from the discriminative model RoBERTa-large and the generative, instruction-finetuned model EmoT5. The results from these two models are then combined using a logical OR operation, leveraging their predictions to determine each emotion.

lize the first multi-task Affective Analysis Instruction Dataset (AAID), which includes the SemEval-2018 Task 1: Affect in Tweets dataset (Mohammad et al., 2018) along with other datasets. Additionally, they leverage an Affective Evaluation Benchmark (AEB) designed to measure affective generalization. Using these resources, the authors developed instruction-following LLMs optimized for diverse affective analysis tasks.

Empirical evaluations show that EmoLLMs achieve state-of-the-art (SOTA) performance on AEB, outperforming other open-source models. Additionally, they exhibit generalization capabilities on par with the GPT family of models, establishing their potential as highly effective tools for emotion detection. Their ability to process complex affective cues makes them strong candidates for real-world applications requiring fine-grained emotion classification (Liu et al., 2024).

Among the models evaluated in the EmoLLMs framework, we selected *EmoT5* for its superior performance in emotion classification. EmoT5 follows a *generative* approach, framing the task as text-to-text generation, where it directly generates emotion labels based on the input text.

Following (Liu et al., 2024), we structured the classification process using the following prompt template:

```
Task: [task prompt] Tweet: [input text] This tweet contains emotions: [output]
```

With the task prompt:

> Categorize the tweet's emotional tone as either 'neutral or no emotion' or identify the presence of one or more of the given emotions (anger, fear, joy, sadness, surprise).

Fine-tuning EmoT5 with this setup optimized its performance for our emotion detection task.

3.3 RoEmo: A Hybrid Approach

While both RoBERTa-large and EmoT5 individually offer strong performance in emotion detection, we observe that their predictions often differ, highlighting their complementary strengths. To leverage the strengths of both models, we propose RoEmo, a hybrid approach that combines their predictions. Specifically, we apply a **logical OR** operation to merge the outputs, predicting an emotion as present if either model detects it (see Figure 2). This simple yet effective fusion strategy allows the model to capture a broader range of emotional cues, improving its ability to detect emotions that might be overlooked by one of the models alone.

Empirical results show that RoEmo performs especially well when emotions are subtle or ambiguous. By combining predictions from RoBERTa and EmoT5, the ensemble increases *recall*, as it is less likely to miss true positive cases. Although this may slightly reduce *precision*—since more predictions can introduce some noise—the overall *macro-F1 score* improves. This highlights the complementary strengths of the two models and demonstrates the effectiveness of hybrid modeling in emotion classification tasks.

4 Experiments

In this section, we analyze the dataset to understand its characteristics and challenges. We then present the performance of RoBERTa-large, followed by EmoT5, and finally, evaluate the combined output using our ensemble method, RoEmo. We highlight the benefits of this hybrid approach in improving multi-label emotion detection.

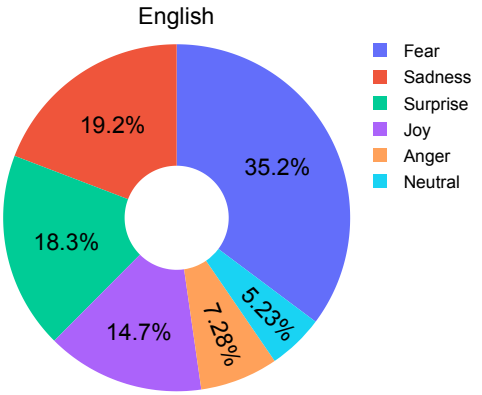

Figure 3: The distribution of emotion labels in the training data. Note that some emotions can co-occur—for example, a single text may be labeled with both joy and surprise.

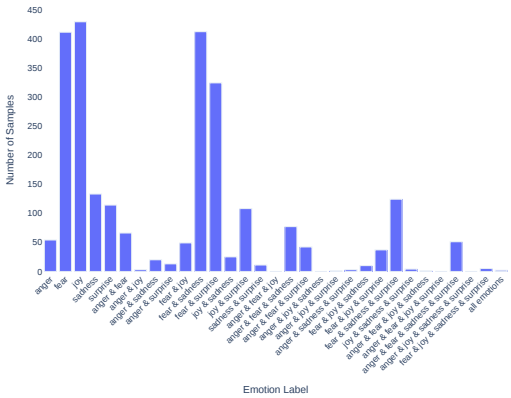

Figure 4: Bar plot depicting the distribution of samples according to the emotion labels assigned to each.

4.1 Dataset overview

The dataset for SemEval-2025 Task 11 (Track A) is designed for multi-label emotion detection (Muhammad et al., 2025a). It consists of English texts annotated using Amazon Mechanical Turk, with binary labels (0 for absence, 1 for presence) assigned to five core emotions—anger, fear, joy, sadness, and surprise—alongside neutral instances. Given that multiple emotions can co-occur within a single text, this introduces an additional layer of complexity to the classification task.

The dataset is split into 2,768 training examples, 116 development examples, and 2,767 test examples. The shortest text in the training set contains 4 tokens, while the longest extends to 121 tokens, demonstrating a diverse range of text lengths.

Figure 3 provides a pie chart illustrating the distribution of single-label examples across the five emotions and neutral category. To further explore multi-label patterns, Figure 4 presents a bar plot depicting the distribution of instances with varying numbers of assigned emotion labels. This visualization helps highlight the frequency and complexity of multi-label cases within the dataset.

4.2 Results

We evaluate the performance of RoBERTa-large, EmoT5, and our ensemble model, RoEmo, on both the development and test datasets. The results on the development set are presented in Table 1 and Table 2. As shown, RoEmo achieves the highest Macro-F1 score among all models, demonstrating its effectiveness in multi-label emotion classification.

Emotion	RoBERTa	EmoT5	RoEmo
Anger	0.7333	0.7879	0.7879
Fear	0.8201	0.7947	0.7821
Joy	0.7636	0.8276	0.8276
Sadness	0.7324	0.7356	0.7416
Surprise	0.7077	0.6667	0.7714

Table 1: Evaluation scores on the Dev set by emotion

	Macro F1	Micro F1
RoBERTa	0.7514	0.7667
EmoT5	0.7625	0.7653
RoEmo	0.7821	0.7783

Table 2: Evaluation scores on the Dev dataset

Emotion	RoBERTa	EmoT5	RoEmo
Anger	0.6553	0.6493	0.6746
Fear	0.8449	0.8344	0.8561
Joy	0.7666	0.7704	0.7654
Sadness	0.7699	0.7559	0.7861
Surprise	0.7391	0.7249	0.7473

Table 3: Evaluation scores on the Test set by emotion

Similarly, we evaluate the models on the test dataset, as shown in Table 3 and Table 4. While RoBERTa outperforms EmoT5 on test data, RoEmo achieves the highest Macro-F1 score, further confirming the effectiveness of our ensemble approach.

Overall, our results demonstrate that RoEmo consistently outperforms the individual models in terms of Macro-F1 score, making it a more effec-

tive approach for multi-label emotion classification.

5 Conclusion

In this work, we tackled multi-label emotion detection in short texts by leveraging a hybrid approach that integrates both generative and discriminative models. By combining the instruction fine-tuned generative model with the of a discriminative model, our method effectively captures diverse emotional expressions while maintaining computational efficiency. Through an ensemble strategy, we demonstrated that merging predictions from both models enhances classification performance. Our analysis of recent developments in the field, along with empirical results on SemEval-2025 Task 11, highlights the effectiveness of our approach. The findings suggest that this hybrid framework is a promising direction for improving emotion detection systems, and balancing generalization and efficiency.

Limitations

Despite the strong performance of our approach, RoEmo has some limitations. It relies on two models—RoBERTa-Large and EmoT5—without explicitly capturing relationships between emotions, which could enhance contextual understanding. The ensemble setup also increases computational cost and complexity, limiting its practicality in real-time or resource-constrained settings. Additionally, we did not compare against more recent LLMs such as Llama 3 (Grattafiori et al., 2024) or Qwen 2.5 (Qwen et al., 2025). Future work could explore other baselines, investigate alternative fusion methods, address data imbalance, and develop more efficient architectures that model inter-emotion dependencies while reducing computational overhead.

steverw@umich.edu

Abstract

The increasing sophistication of natural language processing models has facilitated advancements in hierarchical text classification, particularly in the domain of propaganda detection. This paper presents our submission to SemEval 2025 Task 10, Subtask 1, which focuses on multilevel text classification for identifying and categorizing propaganda narratives in online news (Piskorski et al., 2025). We investigate two primary approaches: (1) prompt-based classification using large language models (LLMs) like GPT, which offers flexibility but struggles with hierarchical categorization, and (2) fine-tuning transformer-based models, where we employ a hierarchical structure—one model classifies the main propaganda category, followed by three separate models specializing in subcategory classification. Our results indicate that while LLMs demonstrate some generalization ability, fine-tuned models significantly outperform them in accuracy and reliability, reinforcing the importance of task-specific supervised learning for propaganda detection. Additionally, we discuss challenges related to data sparsity in subclassification and explore potential enhancements such as multi-task learning and hierarchical loss functions. Our findings contribute to the broader field of automated propaganda detection and emphasize the value of structured classification models in understanding patterns of online communication. All code and data used in our experiments will be made publicly available on our GitHub [1].

1 Introduction

The spread of propaganda and strategically crafted information in online media presents a growing challenge to public discourse and democratic processes. As propaganda techniques evolve, so too must the systems built to detect them. Traditional approaches to propaganda detection have largely focused on identifying specific rhetorical strategies—such as appeals to fear, doubt, or name-calling—at the sentence or span level (Da San Martino et al., 2019). Others have focused on classifying entire articles or highlighting binary instances of propagandistic content. While effective for technique recognition, these approaches fall short when propaganda is embedded through more subtle means, such as the strategic portrayal of specific named entities across a narrative.

Recent work has begun to shift toward understanding propaganda at the entity level, recognizing that how named entities are framed across a narrative can shape readers' perceptions. While earlier shared tasks and studies emphasized detecting rhetorical techniques at the sentence or span level, they did not require models to assess the narrative role of specific entities. The SemEval 2025 Task 10 builds on these foundations by introducing a more fine-grained challenge: Subtask 1 (Stefanovitch et al., 2025). In this task, systems are provided with a news article and a list of named entity (NE) mentions, and must assign one or more roles to each mention using a predefined taxonomy. These roles fall into three overarching categories—Protagonist, Antagonist, and Innocent—each with further fine-grained subtypes such as Saboteur or Conspirator, making this a multi-label, multi-class, span-level classification problem.

In this work, we explore two primary approaches to tackling this classification task: (1) prompting large language models (LLMs) such as GPT, leveraging their zero-shot capabilities for classification; and (2) fine-tuning transformer-based models, where we train one model for main category classification and three specialized models for subclassification within each category. While LLMs provide adaptability and require minimal task-specific training, our experiments indicate that fine-tuned models significantly outperform them in accuracy and reliability. This underscores the limitations of

[1] https://github.com/VSPuzzler/cocoa-at-SemEval-2025-Task-10

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 590–594

generic prompting in highly structured classification tasks and highlights the continued relevance of task-specific supervised learning.

By benchmarking different approaches to hierarchical propaganda detection, we aim to contribute insights that will inform future developments in automated media narrative analysis.

2 Related Work

Early efforts in propaganda detection focused primarily on identifying rhetorical techniques within news articles. For example, SemEval-2020 Task 11 introduced two subtasks: Span Identification and Technique Classification. These tasks aimed to detect specific propaganda techniques, such as "loaded language" or "appeal to fear", within textual spans, using models such as BERT for improved accuracy (Martino et al., 2020).

Building upon this foundation, recent studies have explored the capabilities of large language models (LLMs) in propaganda detection. An investigation was carried out on the performance of GPT-4 in identifying propagandist content. The findings indicated that, while LLMs show promise, they often perform underperformance compared to fine-tuned models, especially in tasks that require a nuanced understanding of context and subtle linguistic cues (Szwoch et al., 2024).

Advancing the field further, there was an introduction of a multilingual hierarchical corpus specifically designed for entity framing and role portrayal in news articles. The dataset categorizes entities into fine-grained roles nested within three main categories: protagonist, antagonist, and innocent. This taxonomy facilitates a more detailed analysis of how entities are portrayed in different narratives and languages (Mahmoud et al., 2025).

3 Methodology

Our approach involved a structured pipeline comprising three main stages: data preprocessing, LLM-based classification using GPT, and fine-tuning a transformer-based model for hierarchical classification. Each stage was designed to efficiently extract entity roles from news articles and classify them into Protagonist, Antagonist, or Innocent, along with their respective subcategories.

3.1 Data Processing

To prepare the dataset for classification, we first extracted entity role annotations from the provided subtask-1-annotations.txt file combining batches 1-3. We only looked at the English documents for this study. Each annotation included a document filename, entity role, and character position within the text. A preprocessing script parsed this information, identifying the main category (Protagonist, Antagonist, Innocent) and grouping any corresponding subcategories. To match the annotations with the corresponding news articles, we loaded and indexed all raw documents from the dataset directory. This ensured each document was correctly paired with its respective annotations.

3.2 Zero-Shot GPT-Based Prompting

We first experimented with LLM-based prompting using different GPT models. This approach required formulating structured prompts to guide the model through a two-tier classification process. The first step involved main category classification, where the entire article was provided to GPT, followed by the question: "Is this article about a Protagonist, Antagonist, or Innocent?" To determine the predicted category, we compared the model's response with each of the three possible labels using a similarity function based on the SequenceMatcher algorithm. The category with the highest similarity score was selected as the predicted main category. Tests were done with and without the target word in the prompt.

Once a main category was assigned, a follow-up subclassification prompt was generated. Each prompt listed the potential subcategories relevant to the assigned category and instructed GPT to choose one or more applicable labels. For instance, if the main category was classified as Protagonist, GPT was asked to select from Guardian, Martyr, Peacemaker, Rebel, Underdog, and Virtuous. Similarly, tailored prompts were used for Antagonist (e.g., Instigator, Conspirator, Tyrant, Saboteur, etc.) and Innocent (e.g., Forgotten, Exploited, Victim, Scapegoat). The model's responses were parsed, and subcategories were assigned based on keyword matching.

Despite the flexibility and zero-shot capabilities of GPT-based classification, this method exhibited lower accuracy due to inconsistencies in response formatting and difficulties in handling hierarchical label dependencies. This motivated our shift towards fine-tuning a transformer model for more precise classification.

3.3 Fine-Tuning Transformer-Based Models

To improve classification accuracy, we fine-tuned a BERT-based transformer model for hierarchical classification. We selected BERT-base-uncased as the base model due to its strong performance in text classification tasks. To enhance its ability to detect entity roles, we modified the tokenizer by introducing two special tokens—`[TARGET]` and `[/TARGET]`—which explicitly marked the span of interest within the text. This ensured that the model focused on the relevant entity while still considering the surrounding context. To preprocess the text, we inserted these special tokens at the entity's start and end positions based on the provided annotations. Since the model has a 512-token limit, we applied a context-aware truncation strategy, prioritizing the region around the marked entity to retain as much relevant information as possible.

The dataset was tokenized using Hugging Face's AutoTokenizer and split into training and test sets (80/20 split randomly), ensuring a balanced distribution of the three main categories and their subcategories. Each data instance was encoded to include input IDs, attention masks, and corresponding labels for both the main category and subcategories. A custom PyTorch dataset class was implemented to facilitate structured data loading for training. We leveraged the Hugging Face Trainer API, setting hyperparameters including a learning rate of 2e-5, batch size of 8, weight decay of 0.01, and a total of 3 training epochs.

To evaluate the model, we computed classification accuracy for both the main category and subclassification tasks. The model's final weights and tokenizer were saved and uploaded to the Hugging Face Model Hub for reproducibility and potential future improvements. Compared to the GPT-based prompting approach, this fine-tuned model demonstrated superior accuracy and consistency, reinforcing the benefits of task-specific supervised learning for structured propaganda classification.

4 Results

To compare the performance of GPT-4o, GPT-3.5-turbo, and GPT-3.5-turbo-1106, we evaluated each model's ability to classify news articles into the main categories (Protagonist, Antagonist, Innocent) and their corresponding subcategories. The accuracy of each model was calculated based on its ability to correctly assign labels to a test set using prompt-based classification. Initially, prompts that included a highlighted target word resulted in 0% accuracy across all models. Subsequent tests removed the explicit target word, which led to modest improvements in performance.

Model	Main Category Accuracy	Subcategory Accuracy
GPT-4o	19.10%	0.00%
GPT-3.5-turbo	23.47%	0.00%
GPT-3.5-turbo-1106	22.16%	0.00%

Table 1: Comparison of GPT Models for Main and Subcategory Classification Without Target Word

From the results, GPT-3.5-turbo achieved the highest main category accuracy (23.47%), outperforming GPT-4o (19.10%) and GPT-3.5-turbo-1106 (22.16%). However, all GPT models failed to classify subcategories correctly, with an accuracy of 0% across all models. This indicates that while GPT models can somewhat differentiate between Protagonist, Antagonist, and Innocent roles, they struggle with fine-grained subclassification, likely due to the lack of explicit hierarchical dependencies in their zero-shot and few-shot prompting approach. Additionally, prompt structure played a critical role. Slight phrasing changes led to significant shifts in predictions, suggesting that model performance is highly sensitive to instruction design. For instance, placing the named entity mention at different positions in the prompt sometimes caused role confusion. These results highlight the limitations of LLM-based classification for structured multi-level tasks, where fine-tuned models may be necessary to achieve reliable subclassification performance.

To address the limitations of LLM prompting, we fine-tuned multiple transformer-based models, including BERT-base (Devlin et al., 2019), RoBERTa (Liu et al., 2019), DistilBERT (Sanh et al., 2019), and ELECTRA (Clark et al., 2020). These models were trained using the tokenized dataset with entity span markers, and their performance was evaluated based on accuracy for both main category classification and subclassification. The results are summarized in Tables 2 and 3 using equations 1-3.

Model	Main Category Accuracy	Protagonist Accuracy, F1
bert-large-uncased	68.11%	91.03%, 0.00
roberta-base	68.11%	91.00%, 0.00
distilbert-base-uncased	68.11%	91.03%, 0.00
google/electra-base-discriminator	68.11%	91.03%, 0.00

Table 2: Main Category Accuracy and Protagonist Performance

Model	Antagonist Accuracy, F1	Innocent Accuracy, F1
bert-large-uncased	90.89%, 0.00	78.10%, 0.56
roberta-base	90.90%, 0.00	78.10%, 0.56
distilbert-base-uncased	90.89%, 0.00	78.10%, 0.56
google/electra-base-discriminator	90.89%, 0.00	78.10%, 0.56

Table 3: Subcategory Performance: Antagonist and Innocent Roles

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (1)$$

$$Precision = \frac{TP}{TP + FP}, Recall = \frac{TP}{TP + FN} \quad (2)$$

$$F1 = 2 \cdot \frac{Precision \cdot Recall}{Precision + Recall} \quad (3)$$

The results indicate that all fine-tuned transformer models—BERT-Large, RoBERTa, DistilBERT, and ELECTRA—achieved identical main category accuracy (68.11%), suggesting that model architecture had little impact on distinguishing between the categories. Additionally, subcategory classification results remain nearly unchanged across models, with Protagonist accuracy around 91.03%, Antagonist at 90.89%, and Innocent at 78.10%, while F1 scores for Protagonist and Antagonist remain at 0.00.

This uniformity in results suggests potential limitations in the dataset and label distribution, as fine-tuned models typically exhibit more variation in classification tasks. The lack of improvement in F1 scores, particularly for the Protagonist and Antagonist categories, indicates that while the models may identify relatively correct probabilities for each subcategory, they are not able to predict each one exactly. This may be because in many cases, there can be multiple subclassifications. Furthermore, the consistent 78.10% accuracy and 0.56 F1 score for Innocent classification suggest that this category may have a more balanced/better-defined representation in the dataset than the others.

Overall, fine-tuned transformers outperformed GPT models in both main category and subcategory classification, demonstrating the importance of task-specific supervised learning. While GPT models provided rapid inference without additional training, they exhibited inconsistencies in subcategory assignments and required manual prompt engineering to improve reliability. In contrast, fine-tuned models provided more stable predictions, particularly RoBERTa and BERT-base, which effectively leveraged hierarchical label structures to improve classification accuracy.

These findings suggest that while LLMs can serve as an initial baseline, fine-tuned transformer models remain the preferred approach for hierarchical classification tasks, particularly when detailed label hierarchies are involved. Future improvements could involve hybrid approaches, integrating the generalization capabilities of LLMs with the structured learning of fine-tuned models to further enhance classification performance.

The results of the final submission is in Table 4.

Rank	Exact Match Ratio	micro P	micro R	micro F1	Accuracy for main role
30	0.01700	0.08750	0.12450	0.10280	0.82550

Table 4: Performance metrics for team "cocoa" on SemEval Task 10 Subtask 1

While our model demonstrated strong performance in predicting the main role, achieving high accuracy, the lower exact match ratio and F1 score indicate challenges in correctly predicting both the main category and subcategories simultaneously. These results suggest that while our fine-tuned models effectively captured broad entity roles, subclassification remains a difficult task, likely due to data sparsity and overlap between subcategories. Future improvements could focus on better handling hierarchical dependencies, leveraging external knowledge sources, or adopting contrastive learning techniques to refine subcategory classification.

5 Conclusion

In this work, we explored two approaches for hierarchical propaganda classification in SemEval 2025 Task 10, Subtask 1: LLM-based prompting and fine-tuned transformer models. Our results demonstrated that while GPT models offered a flexible, zero-shot solution, they struggled with hierarchical dependencies and inconsistent subcategory classification. In contrast, fine-tuned transformer models, particularly RoBERTa and BERT-base, significantly outperformed LLMs, achieving higher accuracy for both main category and subcategory classification.

These findings highlight the importance of task-specific supervised learning in structured classification tasks. Future work could explore hybrid approaches that combine LLMs for generalization with fine-tuned models for precision. Additionally, integrating external knowledge sources or multi-

task learning frameworks could further improve classification accuracy. Our study contributes to the development of automated propaganda analysis and provides a foundation for more advanced methods in entity framing detection within news media.

CICL at SemEval-2025 Task 9: A Pilot Study on Different Machine Learning Models for Food Hazard Detection Challenge

Weiting Wang and **Wanzhao Zhang**
Computational Linguistics, University of Tübingen
{weiting.wang, wanzhao.zhang}@student.uni-tuebingen.de

Abstract

This paper describes our approaches to SemEval-2025 task 9, a multiclass classification task to detect food hazards and affected products, given food incident reports from web resources. The training data consists of the date of the incidents and the text of the incident reports, as well as the labels: "hazard-category" and "product-category" for task 1, "hazard" and "product" for task 2. We primarily focused on solving task 1 of this challenge. Our approach is in two directions: Firstly, we fine-tuned BERT-based models (BERT and ModernBERT); secondly, in addition to BERT-based models, linearSVC, random forest classifier, and LightGBM were also used to tackle the challenge. From the experiment, we have learned that BERT-based models outperformed the other models mentioned above, and applying focal loss to BERT-based models optimized their performance on imbalanced classification tasks.

1 Introduction

Food safety is one of the main concerns of consumers when making purchasing decisions. Therefore, a system that detects possible hazard-containing products and their corresponding hazards from past reports can help consumers identify certain possible hazards in food products more easily. SemEval-2025 task 9 (Randl et al., 2025) is a shared task focusing on food hazard detection, the participants are encouraged to design classification systems that detect hazards and the affected products from food safety incident reports (all texts were originally in or translated to English).[1] The challenge has two subtasks:

- Subtask 1: A text classification task to predict the category of hazards and products.
- Subtask 2: Predict the exact hazard and product.

Our group focuses primarily on subtask 1 of the challenge. To solve the task effectively, we propose our two-direction approach:[2]

Approach with pre-trained language models: Fine-tuning the pre-trained language models, namely BERT (Devlin et al., 2019) and ModernBERT (Warner et al., 2024) to adapt to pre-processed data. To minimize training cost, lightweight and free computational cost fine-tuning enhancements were used.

Approach without pre-trained language models: Training and tuning the hyperparameters of traditional machine learning models, namely linearSVC, random forest, and more recent desicion-making model, LightGBM (Shi et al., 2025); which are less time-consuming than fine-tuning BERT-based models. This method serves as a comparison to the first approach.

In addition to finding the most effective model, the way to perform data augmentation is also a challenging problem. First of all, the training data is heavily imbalanced. For example: class *food additives and flavourings* only has 24 entries while class *allergens* has 363 entries in label *hazard-category*. Therefore, for our approach with BERT-based models, we applied back-translation via MarianMT (Junczys-Dowmunt et al., 2018) framework to generate more training samples for long-tail data, improving generalization on minority classes. Besides, we replaced the standard Cross-Entropy Loss with Focal Loss (Lin et al., 2018), which dynamically reduced the influence of majority-class samples, allowing the model to learn better from under-represented categories. In addition to the imbalance of classes, the data are also non-specific and lack context. Therefore, we introduced keyword masking with contextual prompting, where key terms

[1] Datasets and the baseline models provided by the task organizers as well as the leaderboard can be found at: https://github.com/food-hazard-detection-semeval-2025/food-hazard-detection-semeval-2025.github.io

[2] Our codes are available at: https://github.com/cicl-iscl/SemEval25-Task9

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 595–600

were masked and replaced with the [MASK] token; as well as category-specific prompts to provide additional context, guiding the model's attention. In comparison to our system with BERT-based models, we applied simpler methods to the system without BERT-based models such as oversampling (random oversampling) to minimize the influence of the imbalanced classes in our training data, to clean up the data noise, we also applied a function to remove all punctuations and unnecessary whitespaces.

Through the approaches with BERT-based models, we discovered that the integration of focal loss with BERT effectively addresses class imbalance, which is consistent with the findings of previous research (Younes and Mathiak, 2022) on the handling of class imbalance in dataset mention detection. While keyword masking and contextual prompting showed the potential to improve the results. In contrast, neither back-translation for data augmentation nor our pre-processing efforts: including noise removal and utilizing SpaCy (Honnibal et al., 2020) for Named Entity Recognition yield the expected improvements. For our approach without BERT-based models, our attempts with oversampling methods did not achieve significant improvement.

2 Background

2.1 Dataset

The dataset provided by the task organizers for training consists of 6644 short texts (average length: 88 characters), including manually labeled food recall titles from official food agency websites (all texts are originally in English + translated into English). The dataset is divided into 3 subsets:

- Training set: The set consists of 5082 labeled food recall reports, each of them has 5 features (*year, month, day, country, title*), and labels *hazard-category, product-category* for subtask 1 and *hazard, product* for subtask 2 (Table 1). In addition, the full text of the recall is also provided in an additional column *text*, the participants are allowed to build their systems either on *title* or *text*.

- Validation set: 565 unlabeled food recall reports that has the same features and additional *text* column as the training set.

- Test set: 997 unlabeled food recall reports that have the same properties as the validation set.

Year	1999

2.2 Related Works

Food hazard detection is currently underexplored, especially in its explainability (Randl et al., 2025). Despite the lack of research specifying food hazard detection and classification, previous research such as toxic spans detection (Pavlopoulos et al., 2022) and back translation (Beddiar et al., 2021) for detecting hate speech serve as inspiration for our systems. The toxic spans detection (Pavlopoulos et al., 2022) explored the possibility of fine-tuned BERT-based language model in detecting text toxicity as well as compared its performance to a BILSTM system; the results show that by fine-tuning BERT-based sequence labeling model only yields a result of F1 score 0.63; however, it still had better performance than the BILSTM classifier (F1 score 0.589). The other prior work that is mentioned above is back translation (Beddiar et al., 2021), it is a data augmentation technique where a sentence is translated into a target language and then back to the original language, lexical and syntactic variations are introduced while meaning is preserved. This approach has been shown to improve model robustness in imbalanced datasets. Therefore, we adopted the back translation method for our system with BERT-based models.[3]

3 System Overview

3.1 System with BERT-based models

We used the BERT baseline model provided by the task organizers and applied our strategies for our task due to limited cloud resources. With the release of ModernBERT during our training process, we also created our baseline and full strategies with

[3]We followed the approach outlined by DzLab: https://dzlab.github.io/dltips/en/pytorch/text-augmentation/

ModernBERT. However, due to cloud resource constraints, we were unable to leverage its 8192-token processing capability and instead limited the input length to 512 tokens. The following strategies were applied to our BERT and ModernBERT models:

Back Translation We employed back translation using the MarianMT framework to fight data imbalance with generated data. Specifically, we used the Helsinki-NLP/opus-mt-en-ROMANCE model as the encoder and Helsinki-NLP/opus-mt-ROMANCE-en[4] as the decoder to generate 68 additional samples via English → French → English and English → Spanish → English translation. An example of generating new samples with one original sample from the provided dataset using back translation is illustrated in Figure 1.

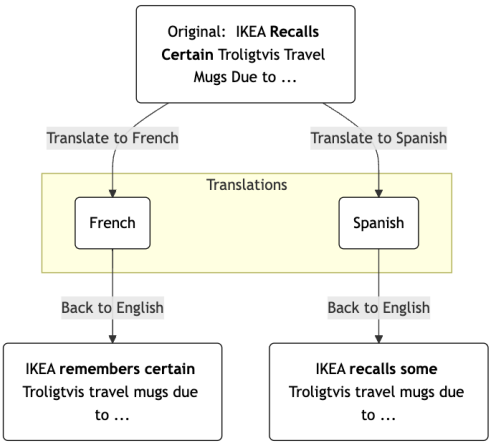

Figure 1: Back Translation Workflow

Focal Loss Focal loss is an extension of the standard cross-entropy criterion which has demonstrated strong performance in imbalanced classification tasks (Lin et al., 2018; Younes and Mathiak, 2022). It addresses class imbalance by down-weighting well-classified examples and focusing more on hard, misclassified samples. In our implementation,[5] we set $\gamma = 2$ based on the best performance in prior study (Lin et al., 2018).

Keyword Masking and Contextual Prompting Inspired by Masked Language Modeling (MLM) (Devlin et al., 2019), we adopted a masking strategy to replace task-relevant keywords in our training data. In our approach, words retaled to hazard (For example *hazard, risk*) and words related to product (For example *fruit, vegetables*) were replaced with the [MASK] token.[6] This guides the model to focus more on the context of 'hazard' or 'product' in order to improve prediction accuracy. Furthermore, when texts lack relevant keywords, we used contextual prompting by prepending task-specific prompts (For example, *Please pay attention to hazard-related content.*) to provide background information and improve classification performance.

3.2 System with Random Forest, LinearSVC and LightGBM

Compared to our approach with BERT-based models, we explored the potential of traditional machine learning models for complicated multiclass classification, namely RandomForestClassifier and LinearSVC from Scikit-learn (Pedregosa et al., 2011). In addition, we used LightGBM Classifier, which is an advanced decision tree-based system with superior performance and efficiency in multiclass classification tasks (Ke et al., 2017). Moreover, to tackle data imbalance, we applied the oversampling technique (random oversampling from imbalanced-learn (Lemaître et al., 2017)) to oversample minority classes.

4 Experimental Setup

Data Split During our training process, we split the training set into 80% training vs. 20% testing in cross-validation for all of our systems.

Data Preprocessing For training BERT-based models, we defined labels with fewer than 10 samples as minority classes, resulting in 34 underrepresented entries in total. Back translation was applied to the underrepresented entries and 2 new entries were generated from each category and added to the original training data. For training the other models, we applied a function to eliminate punctuation and multiple whitespaces and all training data was weighted by tf-idf.

Training Strategies Firstly, we used the BERT baseline provided by the task organizer as our baseline. Then the three strategies: back translation, focal loss, as well as keyword masking and contextual prompting were applied separately to the BERT model. Moreover, we also tested the performance of BERT with all three strategies. However, due to resource constraints, we were only able to create a baseline and an experiment with full strategies

[4]Model manuals are available at: https://huggingface.co/docs/transformers/model_doc/marian

[5]We adapted the PyTorch implementation of Focal Loss from Adeel Hassan's repository: https://github.com/AdeelH/pytorch-multi-class-focal-loss

[6]See full list in Appendix 1.

with ModernBERT. In addition, we created baselines with RandomForestClassifier, LinearSVC and LightBGM, oversampling method (random sampling) was applied to them.[7] All models were trained only with the feature *title*, which consists of the titles of food safety incident reports.

5 Results

In this section, we present the performances of our systems with different settings in Macro F1 score during our validation process. Unfortunately, we were only able to upload our results from BERT with focal loss (0.6006) and LinearSVC (0.6079) to the organization leaderboard (rank #23).

5.1 Results of BERT-based models with different strategies

As shown in Table 2, the performance of BERT improved by changing the loss function from cross-entropy loss (0.669, baseline) to focal loss (0.751). However, back translation, as well as keyword masking and contextual prompting did not yield significant improvement. A possible reason is our restriction in resources. To identify minority classes, we originally suggested a dynamic system that identifies a category as a minority class if it contains fewer than $\max(2, 0.01 \times N)$ samples, where N is the total number of instances, which can define minority classes for our dataset in a more robust way. Nonetheless, applying this threshold resulted in a dataset that was too large for efficient storage. Furthermore, we are restricted to simple prompts because the large number of labels in our task makes direct task descriptions impractical due to length and complexity. The results of ModernBERT with and without full strategies are shown in Table 3, ModernBERT has a better baseline performance (0.702) than BERT (0.669), and the ModernBERT with full strategy produces the best result among all (0.808).

Loss	Other Strategies	Macro F1
CE	None (Baseline)	0.669
CE	Back Translation	0.698
CE	Prompting & Masking	0.715
CE	Back Translation + Prompting & Masking	0.686
Focal	None	0.751
Focal	Back Translation	0.696
Focal	Prompting & Masking	0.717
Focal	Back Translation + Prompting & Masking	0.722

Table 2: Macro F1 scores for different experimental settings on BERT.

[7]Parameter settings see Appendix 2.

Settings	Macro F1
Baseline	0.702
Full Strategy	0.808

Table 3: Macro F1 scores for ModernBERT experiments.

5.2 Results of other models with oversampling

As shown in Table 4, LinearSVC classifier without oversampling has the best result (0.639) among all non-BERT-based models. Also none of these models had outperformed BERT-based models in validation process.

Model	Oversampling	Macro F1
RF	No (Baseline)	0.507
	Yes	0.566
SVC	No	0.639
	Yes	0.630
LGBM	No	0.498
	Yes	0.515

Table 4: Macro F1 scores of RandomForestClassifier, LinearSVC and LightGBMClassifier.

6 Conclusion

Our results suggest that the BERT-based models have better performance than other models, and we discovered that applying focal loss optimized the performance of BERT-based models on imbalanced classification task. However, the combination of BERT + focal loss has a lower score than LinearSVC in the final evaluation. A possible reason is that our BERT-based models lack generalizing ability while the test set may have a different class distribution and/or degree of noises than the training data. Besides, according to our result, back translation and keyword masking/prompting also showed some benefits but rather limited. Looking ahead, we see several promising directions for further research. One key improvement for model robustness could be the generation of higher-quality augmented data, ensuring that synthetic samples closely resemble real-world instances; in addition, if sufficient resources are provided, the ensemble

method could be used to optimize the performance of multiple BERT-based models. Another potential avenue is the transition from a single-task learning framework to multi-task learning, which could help the model generalize better across related tasks.

Limitations

Due to computational and methodological limitations, our models have not reached their full potential. First of all, training BERT-based models can be computationally demanding; however, our project fully relied on public computing resources, which limited the processing capability of our models. Besides, our synthetic samples are insufficient to significantly increase the robustness of our models. Last but not least, to produce results effectively with limited computing resources, we abandoned the approach of ensembling multiple BERT-based models, which could potentially improve model performance.

Abstract

Detecting spans of hallucination in LLM-generated answers is crucial for improving factual consistency. This paper presents a span-level hallucination detection framework for the SemEval-2025 Shared Task, focusing on English and Arabic texts. Our approach integrates Semantic Role Labeling (SRL) to decompose the answer into atomic roles, which are then compared with a retrieved reference context obtained via question-based LLM prompting. Using a DeBERTa-based textual entailment model, we evaluate each role's semantic alignment with the retrieved context. The entailment scores are further refined through token-level confidence measures derived from output logits, and the combined scores are used to detect hallucinated spans. Experiments on the Mu-SHROOM dataset demonstrate competitive performance. Additionally, hallucinated spans have been verified through fact-checking by prompting GPT-4 and LLaMA. Our findings contribute to improving hallucination detection in LLM-generated responses.

1 Introduction

LLMs have demonstrated remarkable capabilities in generating human-like text, enabling a wide range of applications, including question-answering, summarization, and conversational agents. However, these models often produce hallucinations that appear plausible but are factually incorrect or unsupported by the input context (Quevedo et al., 2024).

Current research efforts focus on different approaches to detect and mitigate hallucinations. Some methods rely on sentence-level classification, where the entire response is labeled factual or not (Fadeeva et al., 2024). While these techniques provide a general assessment, they lack the granularity to pinpoint the specific hallucinated segments, leading to challenges in localized error correction (Liu et al., 2021). Other works explore token-level approaches, which utilize features such as minimum and average token probabilities to identify hallucinated content (Luo et al., 2024). This strategy shows promising results, but may struggle to effectively combine probabilistic and semantic information. These issues become more pronounced in morphologically rich and linguistically diverse languages such as Arabic, where complex syntactic rules and dialectal variations add layers of difficulty (Wang et al., 2023). Recent research highlights the need for improved hallucination detection techniques tailored to Arabic and other low-resource languages (Mubarak et al., 2024).

Our research introduces a span-level hallucination detection framework to address these challenges. Unlike previous sentence-level or token-level approaches, our framework identifies hallucinated spans by decomposing LLM-generated answers into semantic units using Semantic Role Labeling (SRL) and dependency parsing. These units are evaluated against context retrieved using GPT-4, then contradiction detection using pretrained textual entailment BERT model. Simultaneously, token-level confidence scores are computed to capture the model's certainty for each unit. The combined scores provide a refined measure of factuality which indicates hallucination parts. We evaluate our framework for both English and Arabic languages using the multilingual Mu-SHROOM dataset as part of the SemEval-2025 shared task. To further strengthen reliability, we incorporate an LLM-based verification step by using fact-checking technique using 2 different LLMs (GPT-4, and LLaMA).

The remainder of this paper is organized as follows: Section 2 reviews related work. Section 3 introduces the dataset's structure. Section 4 presents our methodology. Section 5 outlines the experimental results. Finally, Section 6 concludes with key findings and future work.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 601–606

2 Related Work

Hallucination detection in LLMs has been studied, with research mainly focusing on sentence-level classification. These approaches determine whether an entire response is factual or hallucinated, but lack the granularity to identify specific hallucinated spans. Token-based methods leverage confidence measures to estimate factuality, but often fail to account for semantic inconsistencies within generated responses (Wang et al., 2023). Recent advances have emphasized the need for hallucination detection at the spectral level, allowing a finer-grained factual assessment (Ji et al., 2023).

Reference-based methods compare generated text against external sources such as Factcheck-Bench (Qiu et al., 2023), a fine-grained fact-checking benchmark, and HALoGen (Ravichander et al.), a large-scale hallucination evaluation suite that categorizes hallucination errors. Other techniques, such as InterrogateLLM (Varshney et al.), employ self-consistency verification, where LLMs are prompted multiple times to detect contradictions in their responses. Although these methods improve factual verification, they operate primarily at the response level rather than identifying hallucinated spans.

Textual entailment models have also been explored for hallucination detection, classifying responses into entailment, contradiction, or neutrality (Wadden et al., 2022). However, these approaches are typically sentence-level, limiting their effectiveness for pinpointing hallucinated spans(Chen et al., 2023). The detection of low resources languages hallucinations presents additional challenges, particularly in morphologically rich languages like Arabic, where syntactic complexity and dialectal variations complicate the factual verification (Senator et al., 2025). Datasets such as Halwasa (Mubarak et al., 2024) and ACQAD (Sidhoum et al., 2022) were developed to help in analyzing factual and linguistic inaccuracies. Research on hallucination detection in Arabic has largely focused on sentence-level classification, leaving a gap in span-level hallucination identification (Abdelazim et al., 2024). Some studies have introduced dependency parsing techniques and Semantic Role Labeling (SRL) to improve hallucination detection which highlight the role of syntactic decomposition in improving the evaluation of facts (Liu et al., 2023).

Advances in SRL for information extraction should also contributed to hallucination detection, particularly in low-resource language. Unlike traditional information extraction tasks, SRL-based techniques focus on verifying atomic claims within generated text, enhancing factual alignment with external sources. Although recent studies focus on hallucination detection, there remains a need for more linguistically adaptive approaches to improve the factual consistency in LLM-generated text.

3 Dataset Structure

The dataset used in this research is provided by the SemEval-2025 shared task, Mu-SHROOM (Multilingual Shared-task on Hallucinations and Related Observable Over generation Mistakes). This dataset contains examples in multiple languages, including English, Arabic, Spanish, and French. Each example in the dataset comprises a question-answer pair, the corresponding LLM-generated output, and annotations for hallucinated spans.

3.1 Dataset Schema

Each data entry in the dataset includes the following fields:

- ID: Unique identifier (e.g. "val-en-1").
- Language: Question and answer language ("EN" for English, “AR” for Arabic).
- Question: Question provided to the model (e.g. "What did Petra van Staveren win a gold medal for?", “كم مرحلة يتكون منها رجيم دوكان؟”).
- Answer: LLM-generated answer (e.g. "Petra van Stoveren won a silver medal in the 2008 Summer Olympics in Beijing, China.", "يعتمد المراحل في رجِيم دُوْكَان على النسخة المحددة من البرنامج ، لكن عادةً ما يتألف من خمسة مراحل.").
- Model Information: Model that generated the output (e.g., "tiiuae/falcon-7b-instruct", "openchat/openchat-3.5-0106-gemma").
- Soft Labels: Span-level annotations indicating parts of the text that may be hallucinated, with associated probabilities, e.g. "start": 10, "prob": 0.2, "end": 12.
- Hard Labels: Annotated spans confirmed as hallucinations, represented by fixed token positions (e.g. [25, 31], [45, 49]).
- Model Output Tokens: Tokens of the answer.
- Model Output Logits: List of logits (one per token), reflecting the confidence of the model for the prediction of each token. This is the field that is used to calculate the confidence score in our approach.

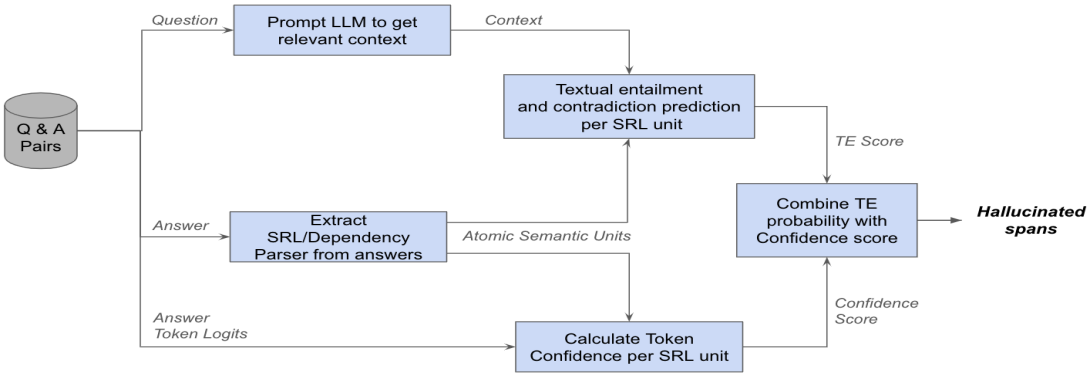

Figure 1: Span-Level Hallucination Detection Framework

4 Span-level Hallucination Detection Methodology

Our framework detects hallucinated spans in LLM-generated answers by combining semantic analysis with token-level probabilistic measures, as described in Figure 1. The system comprises several components: context retrieval for the question, answer decomposition, confidence scoring, textual entailment, score integration to get refined score which indicates the hallucination parts. The framework is designed to handle both English and Arabic, utilizing tools and models suitable for each language.

4.1 Context Retrieval

Given an input question, the relevant context is retrieved using the GPT-4 model with a well-written prompt. Separating retrieval from answer generation ensures an independent factual grounding mechanism. Moreover, retrieving relevant context is more reliable and less complex than generating a well-structured answer, as it relies on matching and ranking mechanisms, whereas answer generation requires reasoning, synthesis, and fluency while ensuring factual correctness. Based on this, the retrieved context serves as a factual reference for evaluating the generated answer and is expected to contain key facts necessary to comprehensively address the question. Additionally, considering the nature of the dataset, which consists of general knowledge question-answer pairs rather than specialized domain-specific queries, this approach is highly suitable. For example, for the question "What did Petra van Staveren win a gold medal for?" the retrieved context may include biographical details about her achievements in swimming, ensuring a factual basis for assessment.

4.2 Answer Decomposition

The generated answer is decomposed into atomic units using Semantic Role Labeling model (SRL). This step extracts structured components (e.g., predicates, arguments) that represent key facts. Each unit is later evaluated for factual alignment with the retrieved context. Example decomposition for "Petra van Staveren won a silver medal in the men's 10 km walk at the 2008 Summer Olympics":

- Verb: "won"
- ARG0: "Petra van Staveren"
- ARG1: "a silver medal"
- ARGM-TMP: "at the 2008 Summer Olympics"

The AllenNLP BERT-based SRL model (Shi and Lin, 2019) is used for English. For Arabic, we conduct two experiments: 1) HanLP's multilingual SRL extraction model, which supports Arabic language (He and Choi, 2021), with an example of an Arabic sentence shown in Figure 2. 2) CamelParser (Elshabrawy et al., 2023) for dependency parsing, followed by an SRL extraction algorithm.

CamelParser2.0 is an open-source Python-based Arabic dependency parser designed for the Columbia Arabic Treebank (CATiB) and Universal Dependencies (UD) formalisms. It processes raw text to perform tokenization, part-of-speech tagging, and morphological analysis, enhancing syntactic parsing, which is essential for accurate semantic role decomposition.

4.3 Confidence Scoring

Token-level confidence scores are computed using logits from the LLM output. These logits scores are given within the SemEval dataset for each token as described in the Dataset Structure section. A low score indicates reduced confidence, suggesting

potential hallucination. The logit score for each atomic unit is computed as described in Equation 1. Where n represents the total number of tokens per unit. $logit_i$ denotes the logit value of token i. The denominator $\sum_j e^{logit_j}$ represents the normalization factor across all tokens, ensuring that the computed probability is within the valid range [0,1]. The final logit score is the average softmax probability of tokens in the generated output.

$$logit\_score = \frac{1}{n}\sum_{i=1}^{n}\frac{e^{logit_i}}{\sum_j e^{logit_j}} \quad (1)$$

This formulation effectively captures the confidence level, with lower scores indicating higher potential hallucination.

4.4 Textual Entailment

To evaluate factual alignment, each atomic unit is compared with the retrieved context, which is described in Section 4.1, using a natural language inference (NLI) model. We choose the DeBERTa (He et al., 2021) entailment model, which predicts whether the context entails, contradicts, or is neutral to the unit. This step generates a set of probabilities corresponding to the entailment, neutral, and contradiction labels. For instance, given the hypothesis "in the 2008 Summer Olympics in Beijing, China", the model output might be: Entailment: 1.1%, Neutral: 8.7%, Contradiction: 90.2%.

4.5 Score Integration

The entailment and confidence scores are combined to produce a refined score for each atomic unit. This score determines the likelihood that the unit is factual. A hyperparameter "α" controls the weight of the components of entailment and confidence as described in Equation 2.

$$refined\_score = \alpha \cdot entailment + (1-\alpha)\cdot confidence \quad (2)$$

5 Expriments and Results Analysis

Our experiments focus on two languages (English and Arabic) and assess performance using both intrinsic evaluation metrics and fact-checking verification with LLMs.

5.1 Evaluation Metrics

To measure the accuracy and effectiveness of hallucination detection, we evaluate our framework using Intersection over Union (IoU) and Correlation score (Cor) which are the used mertrics by the shared task (Vázquez et al., 2025). The IoU metric quantifies the overlap between predicted hallucinated spans and the ground truth annotations, where a higher value indicates improved span-level detection accuracy. The Correlation (Cor) metric evaluates the consistency between predicted hallucination probabilities and the ground truth confidence scores, providing insight into the model's reliability in detecting hallucinated spans.

5.2 Hallucination Identification

Units flagged with low refined scores are aggregated and reported as hallucinated spans, as shown in Figure 1. This enables fine-grained identification of factual inconsistencies within the answer text. Here is an example generated by our framework, showing that it is a "neutral" entailment but because of low logit score based on the output token logit given by the generated answers dataset. Refined Score threshold is set at 0.5 to identify hallucinated spans, serving as a balanced decision point. Units with a refined score below this value are classified as hallucinations.

```

5.3 Experimental Results

English Language Results: Our model achieves an IoU of 0.358 and a Cor of 0.322. To further validate hallucinated spans, we use GPT-4 and LLaMA to verify detected hallucinations. GPT-4 matched 83% of the hallucinated spans, while LLaMA

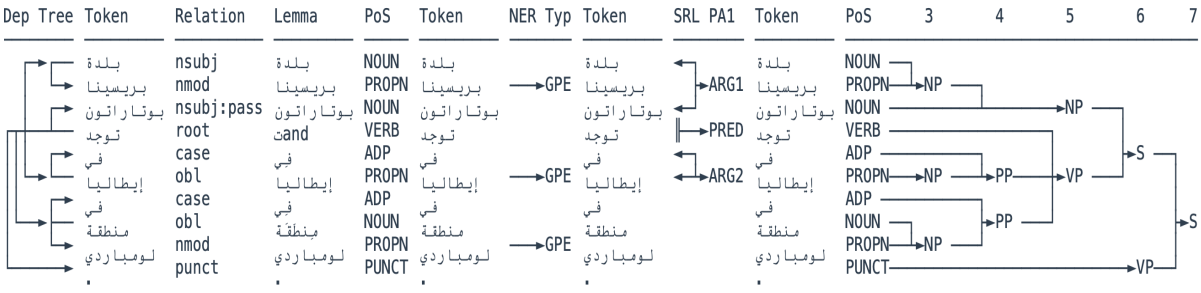

Figure 2: Example of Arabic sentence SRL extraction

identified 72%, demonstrating the effectiveness of LLM-based verification. GPT-4 achieved higher verification accuracy, successfully confirming or refuting hallucinated spans more consistently.

Arabic Language Results: The performance of our hallucination detection framework in Arabic was evaluated using two different models: 1) HanLP Multilingual model for SRL extraction and 2) CamelParser2.0 dependency parser model followed by SRL extraction algorithm. The HanLP model achieves an IoU of 0.205 and a Cor of 0.159, demonstrating lower performance compared to English. This discrepancy is attributed to the morphological complexity and syntactic variation in Arabic, which make span-level hallucination detection more challenging. An improvement is observed when employing CamelParser followed by SRL extraction algirthm, yielding an IoU of 0.28 and a Cor of 0.21. The increased accuracy suggests that syntactic parsing before semantic role decomposition provides better structured representations for hallucination detection. Additionally, the results indicate that this approach is more robust to dialectal variations, making it better suited for handling complex Arabic linguistic structures. Overall, the findings confirm that integrating dependency parsing improves hallucination detection in morphologically rich languages like Arabic. For the Arabic Fact-Checking Verification step, GPT-4 identified 58% of hallucinated spans, showing comparatively lower performance than in English. This is partly due to the GPT-4 model itself being less accurate with Arabic, particularly when handling ambiguous factual claims. However, we utilized GPT-4 to ensure a consistent evaluation approach between Arabic and English cases.

6 Conclusion

This paper presents a span-level hallucination detection framework that integrates Semantic Role Labeling (SRL), textual entailment, and token-level confidence scoring to identify hallucinations in LLM-generated answers. Evaluated on the MuSHROOM dataset, our approach achieves an IoU of 0.358 and a Cor of 0.322 in English, and an IoU of 0.28 and a Cor of 2.1 in Arabic when using CamelParser combined with the SRL extraction algorithm. Our results emphasize the effectiveness of dependency parsing before SRL extraction, particularly in Arabic, where linguistic complexity poses additional challenges. Despite these improvements, challenges remain for morphologically rich languages. Future work will focus on enhancing entailment models and addressing additional syntactic structures, such as nominal sentences in Arabic and long complex sentences.

iLostTheCode at SemEval-2025 Task 10: Bottom-up Multilevel Classification of Narrative Taxonomies

Lorenzo Vittorio Concas and **Manuela Sanguinetti** and **Maurizio Atzori**
Department of Mathematics and Computer Science, University of Cagliari
Via Ospedale 72, Cagliari (Italy)
l.concas16@studenti.unica.it, {manuela.sanguinetti,atzori}@unica.it

Abstract

This paper describes the approach used to address the task of narrative classification, which has been proposed as a subtask of Task 10 on Multilingual Characterization and Extraction of Narratives from Online News at the SemEval 2025 campaign. The task consists precisely in assigning all relevant sub-narrative labels from a two-level taxonomy to a given news article in multiple languages (i.e., Bulgarian, English, Hindi, Portuguese and Russian). This involves performing both multi-label and multi-class classification. The model developed for this purpose uses multiple pretrained BERT-based models to create contextualized embeddings that are concatenated and then fed into a simple neural network to compute classification probabilities. Results on the official test set, evaluated using samples F_1, range from 0.15 in Hindi (rank #9) to 0.41 in Russian (rank #3). Besides an overview of the system and the results obtained in the task, the paper also includes some additional experiments carried out after the evaluation phase along with a brief discussion of the observed errors.

1 Introduction

Online news is a primary source of information and has a major role in shaping public discourse and influencing perceptions. Identifying the narratives embedded within news articles is crucial for critically analyzing their perspectives, biases, and underlying messages. For instance, this can be relevant in contexts where harmful or misleading content is present: recognizing the dominant narratives can facilitate the construction of counter-narratives (Tekiroğlu et al., 2020), in view of promoting a more constructive and less toxic online debate. Furthermore, given the abundance of information available online—from both mainstream and alternative media sources—understanding the stance underlying different narratives can be useful when navigating digital content. This requires not only recognizing the explicit claims made in a given article or social media post, but also understanding how such claims align with broader thematic views. A critical approach to narratives can help the interested reader distinguish between different perspectives and engage with news content in a more informed way. From a theoretical perspective, providing a shared framework for the definition and categorization of narratives and sub-narratives is essential (Stefanovitch et al., 2025) for more systematic analyses and comparisons across different texts and media sources. In turn, automatic systems can build upon these theoretical foundations to detect and classify narratives with the help of Natural Language Processing techniques (Santana et al., 2023).

Our work lays on these premises and it focuses on the task of Narrative Classification, proposed as part of SemEval-2025 Task 10 on Multilingual Characterization and Extraction of Narratives from Online News (Piskorski et al., 2025). More in particular, the team participated in Subtask 2 on Narrative Classification, which consists precisely in assigning one or more sub-narrative labels to a given news article in one among five languages (Bulgarian, English, European Portuguese, Hindi and Russian), and resorting to predefined narrative taxonomies. The news articles are centered around two main topics, Ukraine-Russia war and climate change, and each topic has its own taxonomy of narratives and corresponding sub-narratives.[1]

This challenge aligns with prior research in text classification, particularly in multi-label and hierarchical classification tasks, such as Task 4 from SemEval 2024, which shares similarities (Dimitrov et al., 2024).

To address this task, our system combines a sim-

[1]An overview of both taxonomies with annotation guidelines has been made available here: https://propaganda.math.unipd.it/semeval2025task10/NARRATIVE-TAXONOMIES.pdf

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 607–616

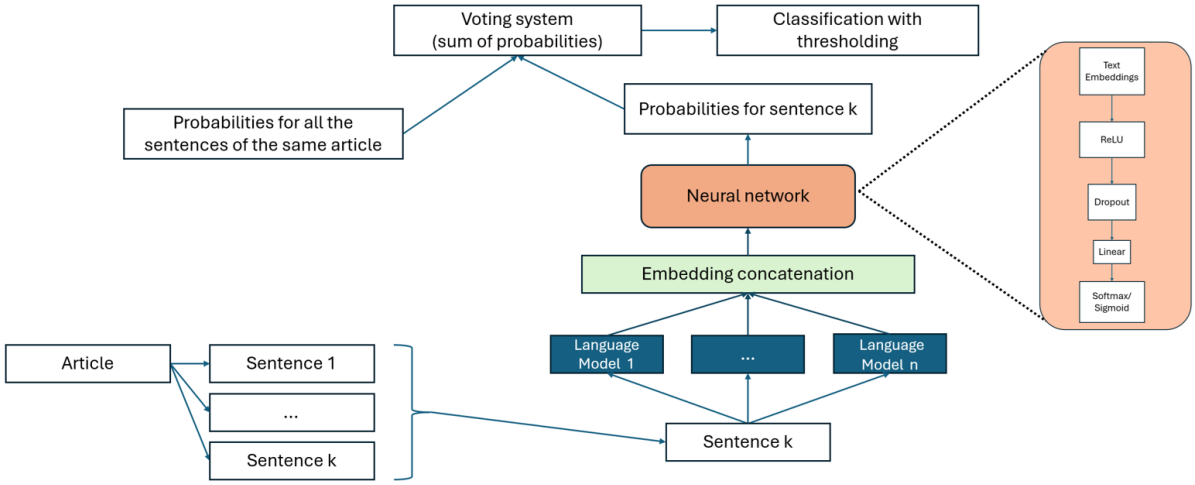

Figure 1: Model architecture.

ple neural network with a concatenation of contextual embeddings generated using multiple BERT-based models, each already fine-tuned for different tasks, though not specifically for this one. Language models such as BERT and its variations have demonstrated strong performance in various NLP tasks, using contextual embeddings to have good classification accuracy even without fine-tuning (Uppaal et al., 2023). Furthermore, approaches resorting to vector concatenation to address similar tasks were implemented in the recent past, obtaining good results (Zedda et al., 2024; Anghelina et al., 2024); with similar foundations, we designed a lightweight neural architecture that aims to balance prediction accuracy with computational demand.

The remainder of the paper describes the system architecture along with the experiment setup adopted for this task and an overview of the results obtained.

2 System Overview

The model is a straightforward combination of several independent language models, previously fine-tuned for different tasks, whose results are then concatenated and fed into a neural network, as outlined in Figure 1. This approach has been structured into several steps and modules that are described below.

Data pre-processing Each sentence of an article was extracted and treated as an individual data point (or sample), with the requirement that every sentence from the same article shares the full set of classes attributed to the entire article. This is motivated by the fact that BERT models have a constrained token limit per sentence. Treating each sentence independently, instead of using the article as a whole, allows to manage this limitation effectively, as each sentence can be processed within the model's token constraints, while still preserving the information on the associated narratives of the whole article. This approach also ensures more consistent results when using a voting system, which is indeed an additional component of the system, as explained later in this overview.

Embedding extraction Every file undergoes an embedding extraction process. Several extraction modes were tested to include a context window of previous content. After preliminary experiments, two configurations were ultimately employed for the purposes of this task, i.e., one without a context window and one with a window covering the two preceding sentences. Various fine-tuned models based on BERT architecture (Devlin et al., 2019) and available on HuggingFace were used. These models were employed only to extract textual embeddings, specifically the CLS token embedding for each sentence. Multiple instances of these models were used in parallel. It is worth pointing out that these models were selected because they were already fine-tuned for different (though relevant) tasks, but they were not retrained on this competition's dataset.

Concatenation Module The embeddings extracted from each model are simply concatenated into a single vector and stored in memory along with the labels of the classes associated with the analyzed sample.

Neural Network Once all embedding vectors are stored in memory, they serve as features for a simple neural network. The architecture consists of a non-linear ReLU layer followed by a dropout layer and finally a classification layer that uses either a Sigmoid or Softmax activation function to obtain class probabilities.

Voting system In this module, the predicted probabilities for all sentences of the same article are summed and then normalized. Although a multiplicative aggregation approach was also tested, it proved to be overly sensitive to individual sentence predictions and was therefore discarded.

Classification and class extraction After obtaining class probabilities, since a variable number of classes needs to be predicted, several methods were tested to extract the correct number of classes. In this module, different approaches were explored: initially, a secondary neural network was tested to determine the number of classes. However, this approach was discarded in favor of a classic thresholding method based on results from the development set. This is the most crucial part, as even if the neural network model performs well, choosing the wrong threshold could decrease significantly the results.

3 Dataset

The dataset consists of different news articles and different type of texts about two main topics: Climate Change denial claims (abbreviated with the CC label) and propaganda in Ukraine-Russia war (abbreviated with the URW label). Each article is linked to a set of exclusive narratives based on its topic, and each narrative is further associated with a group of sub-narratives. The dataset has been made available in five languages (with approximately 400-450 articles with golden labels and 100 unlabeled articles to submit per language), with the same taxonomy for each language, except for Russian language where the CC topic was not present and there were far less articles (approximately 250 articles with golden labels and 60 unlabeled articles to submit). In general, 30-40 elements were used for development for each language.

For further details on the dataset development and composition we refer the reader to the task report provided by the organizers (Piskorski et al., 2025).

4 Experiment Setup

The experiments were run on a laptop with an Intel® Core™ i7-1065G7 @ 1.30GHz CPU, 36 GB RAM, CPU only.

As described in Section 2, a preliminary preprocessing step involved splitting each article into individual sentences. Furthermore, all non-English datasets of the task were then automatically translated into English using Microsoft Translate API.

The four models selected for feature extraction are RoBERTa-large fine-tuned on the TweetEmotion dataset for the emotion classification task[2], (Antypas et al., 2023) DeBERTa-v3-small[3](Sileo, 2024) and DeBERTa-v3-base[4](Laurer et al., 2024), both fine-tuned for NLI tasks, and a DistilBERT model fine-tuned for Named Entity Recognition[5](Sanh et al., 2019). On average, extracting the entire dataset for one language composed approximately of 400 samples takes 1-2 hours, which is why the extracted embeddings are saved and later used for experiments (this processing was not done in batch).

Concerning the development of the neural network, local experiments were conducted to determine its optimal configuration. The number of layers and neurons per layer was determined through extensive trial-and-error experimentation. In general, a single ReLU layer with a size 5-30 times smaller than the total number of input features—combined with a dropout rate of 0.3-0.4—was found to be sufficient, with the optimal layer size also depending on the language. Increasing the number of layers often led to overfitting and slower training, and deviations from these values generally resulted in poorer performance. For example, using a different number of neurons caused the loss function on the development dataset to decrease more slowly and converge at higher values compared to the "optimal" configuration, while using too few neurons resulted in underfitting. Overall, the development approach was to carefully adjust these parameters to optimize the neural network's classification performance on the loss function (Binary cross entropy on the one hot encoding of classes of the sample), the objec-

Dataset	ReLU size	Window	Activation	Translated	Threshold CC	Threshold URW
English	30	2	softmax	no	0.03	0.03
Portuguese	15	0	sigmoid	yes	0.2	0.15
Russian	5	0	softmax	yes	-	0.1
Bulgarian	10	2	sigmoid	yes	0.1	0.14
Hindi	15	2	softmax	yes	0.05	0.04

Table 1: Hyper-parameters used for the final submission. **ReLU size** indicates how many times the ReLU layer is smaller than the input embeddings, **Window** indicates the number of precedent sentences included as additional embeddings, **Activation** refers to the activation function used in the classification layer, while **Threshold CC** and **URW** refer to the threshold values selected, within each language, for articles on climate change and Ukraine war, respectively.

tive was to reduce the loss on the validation dataset, or to decrease the training loss without causing an increase in the validation loss.

The training process was divided into two phases. The first phase involved using a batch size of 128 sentences and training for 10 epochs, using the Adam optimizer with Keras default settings for rapid convergence. The second phase employed Stochastic Gradient Descent with momentum (SGD) with default parameters, using a batch size equal to the entire dataset and a varying number of epochs (ranging from 1000 to 4000) with early stopping on loss function (to avoid increases on validation loss). This phased approach was chosen because Adam allows the network to learn quickly but tends to overfit after too many epochs. In contrast, SGD with a large batch size learns more slowly but continues to improve the validation loss without overfitting as rapidly on the training dataset. No distinction between sentences of different articles were made as a random shuffle of all sentences was performed before the training phase.

The final threshold was selected by running the system multiple times on the development set and choosing the threshold value that maximized the result according to the official ranking metric, which was samples F_1 score (further explained below). Table 1 summarizes all the hyper-parameters selected and eventually used for the evaluation phase.

For what concerns the evaluation metrics adopted for Subtask 2, submitted results were computed considering two measures: Coarse F_1, which reports how well the model predicts the narratives (without considering the sub-narratives), and Samples F_1, which instead measures how well the model predicts both narratives and sub-narratives, meaning that both aspects should be correct for the prediction to be considered correct. For both coarse and samples F_1 the values are first averaged at document level and then across all the documents of the set. Standard deviation is finally included, in order to measure how much the scores vary across the documents.

5 Results

In this section, we present the results of our experiments across all phases of the campaign, i.e. development, evaluation and post-evaluation, where the leaderboard was made available for participants to continue testing their models following the competition.

Development phase In development phase we noticed a discrepancy on the internal development dataset results and the sent prediction results. We realized that this was mainly due to problems in the evaluation from the server (a critical bug was discovered after the start of the official evaluation phase), thus invalidating this phase actual results.

Test phase As shown in Table 2, while the model did not achieve top-ranking positions, it demonstrated consistent performance across most languages. In four out of five languages, it ranked above the average position among participants. Overall, the best results among the ones submitted by our team, were the ones for Russian, where the model consistently performed better both for the sole narratives and narratives and sub-narratives. Conversely, Hindi exhibited the lowest scores in both metrics.

Post-Test phase Upon reopening the leaderboard, therefore after the evaluation phase officially closed, further tests were conducted to investigate why the model underperformed in certain languages. At the time of writing, simply adjust-

Language	Rank	Participants	F1 coarse	st. dev.	F1 samples	st. dev.
English	9	28	0.467	0.356	0.32	0.321
Portuguese	5	13	0.536	0.273	0.293	0.206
Russian	**3**	14	0.618	0.312	**0.411**	0.308
Bulgarian	**3**	11	0.557	0.335	**0.369**	0.308
Hindi	10	13	0.207	0.313	0.147	0.292

Table 2: Official evaluation results obtained on Subtask 2 across different languages.

Portuguese	0.547	0.228	0.319	0.182	0.1	0.1
Russian	**0.597**	0.279	**0.44**	0.251	-	0.05
Bulgarian	0.558	0.351	0.391	0.352	0.2	0.19
Hindi	0.227	0.378	0.174	0.339	0.05	0.1

Table 3: Post-task results, empty field means no changes applied to the threshold values nor to the score values.

ing the thresholds without re-training the whole model-—ie., manually increasing or decreasing the values relative to the number of classes for some languages—-led to a slight improvement in the score as reported in Table 3.

Moreover, we further tested the system using alternative language models for the embeddings to understand whether model selection (and, as a result, the chosen type of embeddings) could offer competitive advantages compared to other general newer models. We used in particular ModernBERT-Large pretrained with zero-shot classification [6] (Warner et al., 2024). During testing, the optimal ReLU size was determined through trial and error. Thresholds were manually optimized after a first automatic search, and the number of epochs was 4000 for every language during the training of the neural network. Contrary to the previous experiments, with the Portuguese data we used the sigmoid function instead of softmax (see Table 1). As shown in Table 4, most result are lower than the ones obtained with the other models used for the campaign, however it is worth pointing out that English ModernBERT got a relatively higher score (ranking 5th in the post-task leaderboard[7]).

6 Discussion and Error Analysis

While the Bulgarian and Russian datasets performed better than the other languages, despite being translated into English, surprisingly enough, the same model produced worse results on the original English dataset. Upon the re-opening of the submissions, comparing Table 2 and Table 3 several conclusions can be drawn: the thresholding mechanism appears to work but may not always yield globally optimal results. Additionally, it has been observed that as the prevalence of the "Other" class increases, the model's overall performance declines compared to that of other participants, in fact the lowest score was obtained in datasets with prevalence of this class. We can also note that, for some reason, top-ranking models in other languages similarly achieved worse results on the Indian language task. This could be due to semantic discrepancies between different dataset languages. Overall, despite the model's limitations, we hypothesize that the issue stem more from the dataset than the model itself. This is largely due to the fact that all languages were translated into English before processing.

The confusion matrices generated for the results on each development set (see Appendix A) reveal that the model tends to produce a high number of false positives in certain classes. However, these classes also show a higher correct prediction rate, which suggests a significant class imbalance in the dataset. In contrast, some other classes are consistently missed, resulting in a high number of false

Language	ReLU size	F1 coarse	st. dev.	F1 samples	st. dev.	Thresh. CC	Thresh. URW
English	10	0.498	0.363	**0.373**	0.373	0.01	0.01
Portuguese	10	0.448	0.274	0.234	0.185	0.08	0.1
Russian	2	0.59	0.256	0.329	0.218	-	0.06
Bulgarian	10	0.381	0.383	0.256	0.355	0.13	0.14
Hindi	15	0.174	0.277	0.088	0.231	0.04	0.06

negatives distributed across various classes, however the false negatives are low within each individual class, further confirming the imbalance. Relatively very few cases have completely correct predictions.

7 Conclusions and Future Work

The approach described in this paper consisted in feeding a simple neural network with a concatenation of multiple contextual embeddings from different fine-tuned BERT-based models to tackle the challenges deriving from a multi-class and multi-label classification task. Quantitatively, the model performed reasonably well in some languages, but underperformed in others, as the model seems to struggle to find optimal values of thresholding and it is sensitive to class definitions.

In terms of possible improvements over this approach, we observe that the Russian dataset–that only included URW-related topics–performed better than other languages, suggesting that developing separate classifiers for each topic (CC *vs* URW) might further improve results. Additionally, using a single-language merged dataset approach could also yield better performance. Another unexplored approach is a top-down hierarchical strategy. However, given that the narrative/coarse score was not particularly low across different languages, this approach may not be necessary.

Code availability

The code of the model is avaiable on Github in the repository: `https://github.com/demon-prin/iltc-narrative-classification`

Abstract

Emotion recognition in textual data is a crucial NLP task with applications in sentiment analysis and mental health monitoring. SemEval 2025 Task 11 introduces a multilingual dataset spanning 28 languages, including low-resource ones, to improve cross-lingual emotion detection. Our approach utilizes T5 for English and mT5 for other languages, fine-tuning them for multi-label classification and emotion intensity estimation. Our findings demonstrate the effectiveness of transformer-based models in capturing nuanced emotional expressions across diverse languages.

1 Introduction

Emotion recognition in textual data is a crucial task in natural language processing (NLP), with applications in sentiment analysis, mental health monitoring, and human-computer interaction. However, detecting emotions across multiple languages presents significant challenges due to linguistic diversity, cultural differences, and limited resources for many languages. SemEval-2025 Task 11, Bridging the Gap in Text-Based Emotion Detection, aims to improve emotion detection by providing a multilingual dataset covering 28 languages, including low-resource ones.

Our approach focuses on Track A (Multi-label Emotion Detection) and Track B (Emotion Intensity Estimation). For Track A, we fine-tune mT5 to classify multiple perceived emotions (joy, sadness, fear, anger, surprise, and disgust) within a given text. The model processes multilingual input and predicts relevant emotions simultaneously. For Track B, we extend this model to predict emotion intensities on an ordinal scale, ensuring that the system can accurately gauge varying degrees of emotional expression. This helps capture subtle differences in emotional intensity across languages.

During the task, we observed that multilingual emotion detection remains challenging due to variations in emotional expression and imbalanced datasets for low-resource languages. Our results show that transformer-based models like T5 and mT5 effectively capture emotional nuances, but performance varies depending on data availability. A key struggle was handling subjective emotional interpretations and linguistic inconsistencies across languages. Despite these challenges, our findings highlight the potential of multilingual models in improving cross-lingual emotion recognition.

2 Related Works

Emotion detection in text has been a long-standing challenge in NLP, evolving from traditional machine learning methods to deep learning and transformer-based models. Early approaches relied on feature engineering with statistical models such as SVMs and Naive Bayes, leveraging sentiment lexicons and syntactic dependencies (Cambria, 2017). The rise of deep learning introduced LSTMs, GRUs, and CNNs, which enhanced contextual understanding (Peters et al., 2018).

However, transformer-based architectures like BERT, RoBERTa, and T5 revolutionized the field with self-attention mechanisms and large-scale multilingual pretraining, significantly improving multi-label emotion classification (Devlin et al., 2019; Raffel et al., 2020). The growing interest in multilingual emotion detection has led to datasets like BRIGHTER (Muhammad et al., 2025a) (Muhammad et al., 2025b), which provide high-quality human-annotated emotion recognition data across 28 languages.

Our work builds on these advancements by applying T5 and mT5 models to SemEval-2025 Task 11, addressing multilingual emotion detection

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 617–622

challenges in two tracks: multi-label classification (Track A) and emotion intensity estimation (Track B). Unlike previous studies that focused primarily on high-resource languages, we fine-tune models on diverse linguistic datasets, leveraging BRIGHTER and other multilingual resources.

Additionally, our approach refines multi-label classification by using separate label schemas for different languages and tasks, setting it apart from standard transformer-based emotion classification models (Belay et al., 2025). Our experimental setup ensures robust evaluation across different linguistic contexts, further enhancing emotion understanding in low-resource languages (Baziotis et al., 2018; Mohammad et al., 2018). These advancements contribute to the broader goal of improving cross-linguistic emotion recognition and fostering more inclusive AI-driven applications in natural language processing.

3 System Overview

3.1 Key Algorithms and Modeling Decisions

The system is built on transformer-based architectures, primarily T5 and mT5, for multilingual text-based emotion detection. These models were selected due to their encoder-decoder design, which enables effective handling of both classification and regression tasks within a unified framework. T5 is well-suited for English text processing, while mT5, pretrained on a multilingual corpus, is optimized for handling diverse languages, including low-resource ones. This makes mT5 a strong candidate for cross-lingual emotion detection tasks. The model is fine-tuned for multi-label classification using a sigmoid activation function, allowing independent emotion predictions. Binary Cross-Entropy (BCE) is used for classification, while an ordinal regression loss captures the ordered nature of emotion intensities. Training is optimized using the AdamW optimizer with weight decay, and early stopping is applied to prevent overfitting.

3.2 Resources Beyond Training Data

Beyond the labeled training data, additional resources were incorporated to improve model performance. SentencePiece was used for tokenization, ensuring compatibility with multilingual input. Pretrained embeddings from the Hugging Face Transformers library provided a robust initialization for transfer learning. Weighted loss functions were used to address class imbalance, and external lexicons for sentiment analysis were explored to enhance the contextual understanding of emotions.

3.3 Mathematics Behind the Model

The transformer-based model follows a sequence-to-sequence architecture with self-attention mechanisms, allowing it to capture long-range dependencies and contextual cues across languages. For multi-label classification, the model computes the probability $P(y \mid x)$ for each emotion label independently as follows:

$$P(y \mid x) = \sigma(W \cdot h + b)$$

Here, $h \in R^d$ denotes the hidden state representation output by the final layer of the transformer for the [CLS]-like token (or averaged representation of the input), $W \in R^{k \times d}$ and $b \in R^k$ are learnable weights and biases, and σ is the sigmoid activation function applied element-wise to produce a probability distribution over the k emotion labels. Binary Cross-Entropy (BCE) loss is used for training, treating each label as an independent binary classification task.

For emotion intensity estimation, the model employs an ordinal regression framework to account for the ordered nature of intensity levels. Labels are encoded on a scale from 0 to 3, corresponding to increasing degrees of emotional intensity. Instead of treating intensity as a simple regression or multi-class classification problem, a cumulative link model is used, where the model learns a set of ordered thresholds $\theta_1 < \theta_2 < \ldots < \theta_{C-1}$ that separate adjacent ordinal classes. The probability that an input x belongs to class c is modeled as:

$$P(y \leq c \mid x) = \sigma(\theta_c - f(x))$$

where $f(x)$ is the scalar output from the model representing the underlying emotion intensity, and σ is the sigmoid function. This formulation preserves the ordinal structure of labels and ensures monotonicity across intensity levels. The corresponding loss is computed using the cumulative probabilities over all ordinal thresholds, optimizing the model to predict the correct ordered class.

This approach enables the model to better capture subtle variations in emotional intensity, particularly important in multilingual contexts where

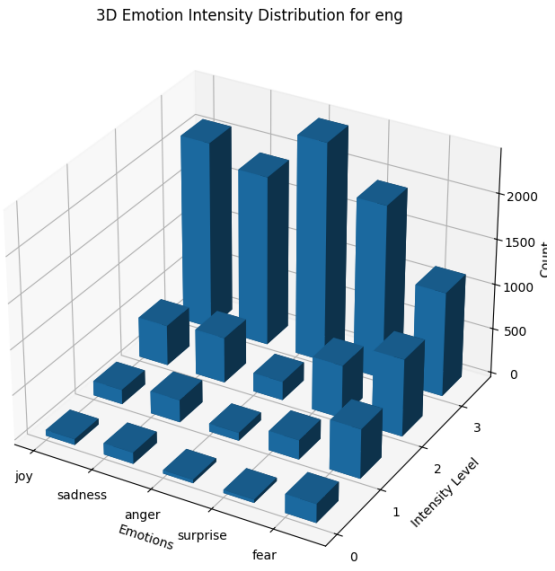

Figure 1: 3D Emotion Intensity Distribution for eng.csv

cultural nuances influence how emotions are expressed in text.

3.4 Variants of the Model

- **Track A (Multi-label Emotion Detection):**
  - **T5 Model:** Used for English text classification.
  - **mT5 Model:** Fine-tuned separately for two settings: five-label classification for African languages and six-label classification for other languages.
- **Track B (Emotion Intensity Estimation):**
  - **T5 Model:** Used for English text classification.
  - **mT5 Model:** Used for ordinal regression with six labels across all languages.

4 Experimental Setup

4.1 Data Splits and Usage

The dataset provided by SemEval-2025 Task 11 included a predefined test set. The training data was split into training and validation subsets to optimize hyperparameters and prevent overfitting. The test set remained untouched throughout model training and was only used for the final evaluation.

4.2 Preprocessing and Parameter Tuning

Text data underwent normalization steps such as lowercasing, whitespace trimming, and removal of special characters. Tokenization was performed using SentencePiece, ensuring effective encoding of multilingual text. Weighted loss functions were applied to mitigate class imbalances. Hyperparameter tuning was conducted using grid search, focusing on learning rate, batch size, and weight decay. Training was performed for 20 epochs with early stopping based on validation loss.

4.3 Model Architecture and Training Parameters

The models for both Track A and Track B were fine-tuned using T5 for English and mT5 for multilingual data. For Track A (Multi-label Emotion Detection), the T5 model was fine-tuned with a classification head using a sigmoid activation function for multi-label prediction. The mT5 model was used for multilingual settings, with a five-label classification schema for African languages and a six-label schema for all other languages. Both models utilized an AdamW optimizer with a learning rate of 5×10^{-5}, batch size of 8, and weight decay of 0.01. Early stopping was applied based on validation loss to prevent overfitting. For Track B (Emotion Intensity Estimation), mT5 was exclusively used with an ordinal regression framework to preserve intensity relationships. The same optimizer settings were applied, but the loss function was adjusted to accommodate ordinal regression. All models were trained for 20 epochs with checkpoints saved at each validation step to ensure robustness.

4.4 External Tools and Libraries

The implementation utilized several external tools and libraries to enhance efficiency and performance. PyTorch was used as the deep learning framework for model training and optimization. Tokenization and pretrained models were sourced from the Hugging Face Transformers library. Data processing was handled using pandas and NumPy, ensuring efficient manipulation of text and label distributions. For evaluation, Scikit-learn was employed to compute precision, recall, F1-score, and Pearson correlation. Training progress was monitored using tqdm, while hyperparameter tuning was conducted with Optuna to optimize learning rate and regularization parameters.

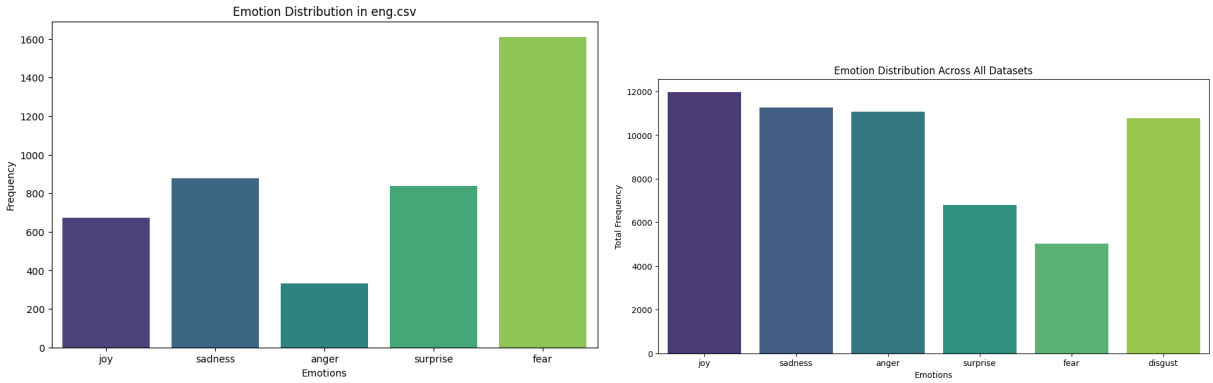

Figure 2: Track A - Emotion Distribution in eng.csv and all datasets respectively

5 Results

5.1 Track A: Multi-label Emotion Detection

The results for Track A highlight the effectiveness of the proposed approach across 28 languages, with model performance largely dependent on the availability and quality of training data. High-resource languages such as Hindi (hin), Marathi (mar), and Russian (rus) achieved strong F1-scores of 0.7304, 0.702, and 0.7205, respectively. This demonstrates that mT5, when fine-tuned on well-annotated datasets, can successfully classify multiple emotions in a multilingual setting. English (eng) also performed well with an F1-score of 0.5969, suggesting its stable position in multilingual pretraining.

Language	F1	Language	F1
afr	0.3063	pcm	0.4093
amh	0.4371	ptbr	0.2746
arq	0.3212	ptmz	0.2083
ary	0.3422	ron	0.5763
chn	0.3959	rus	0.7205
deu	0.3786	som	0.2541
eng	0.5969	sun	0.3095
esp	0.6403	swa	0.1775
hau	0.5015	swe	0.3893
hin	0.7304	tat	0.406
ibo	0.4102	tir	0.3198
kin	0.3167	ukr	0.353
mar	0.702	vmw	0.0784
orm	0.319	yor	0.1473

Table 1: Track A F1-score metrics

However, performance drops significantly for low-resource languages such as Swahili (swa), Yoruba (yor), and Makhuwa (vmw), with F1-scores of 0.1775, 0.1473, and 0.0784, respectively. These results emphasize the challenges in generalizing to languages with limited annotated data. In such settings, the model struggles with sparse linguistic representation during pretraining and insufficient examples of emotion-labeled instances, which hinders its ability to learn meaningful associations. Additionally, variation in emotional expression across cultures and lack of task-specific linguistic resources further impact performance in these languages.

Interestingly, Spanish (esp) achieved an F1-score of 0.6403, despite being a non-high-resource language in the task. This indicates that factors such as annotation consistency, data diversity, and structural linguistic properties can significantly influence performance. Other moderately performing languages include Hausa (hau, 0.5015), Amharic (amh, 0.4371), and Romanian (ron, 0.5763), demonstrating that mT5 can still yield usable predictions in low-to-mid-resource settings if enough training signals are available.

Languages such as Afrikaans (afr, 0.3063), Oromo (orm, 0.319), and Kinyrwanda (kin, 0.3167) struggled to surpass 0.35 F1, reiterating the difficulty of modeling underrepresented languages with minimal data. German (deu, 0.3786) and Swedish (swe, 0.3893), though not traditionally low-resource, underperformed, possibly due to limited or noisy annotations in the provided dataset.

5.2 Track B: Emotion Intensity

For Track B, where emotion intensity estimation was evaluated using Pearson correlation, the results similarly reflect a divide between high- and

Language	F1
amh	0.3769
arq	0.1119
chn	0.3656
deu	0.3424
eng	0.3285
esp	0.5279

Language	F1
hau	0.467
ptbr	0.2497
ron	0.406
rus	0.7448
ukr	0.2482

Table 2: Track B Pearson correlation

low-resource languages. Russian (rus) showed the highest correlation (0.7448), followed by Spanish (esp) with 0.5279. These results suggest that the model was able to rank emotional intensity reasonably well when sufficient training data was available.

However, substantial drops were observed for Algerian Arabic (arq, 0.1119), Ukrainian (ukr, 0.2482), and Brazilian Portuguese (ptbr, 0.2497), indicating challenges in estimating emotion intensity accurately under low-resource and linguistically diverse conditions. English (eng) exhibited a relatively low correlation (0.3285), likely due to the subtlety and ambiguity of emotional cues in English, which require deeper context-aware modeling. On the other hand, Hausa (hau) achieved a moderate score of 0.467, suggesting that with minimal but high-quality annotations, even low-resource languages can benefit from transformer-based fine-tuning.

Overall, the findings from both tracks demonstrate the potential of transformer-based models for multilingual emotion detection. However, they also expose clear limitations when applied to languages with limited or noisy datasets. Future work should focus on improving the representation of low-resource languages through transfer learning techniques, culturally aware embeddings, and enriched training datasets. Furthermore, integrating external resources such as emotion lexicons, morphological analyzers, and idiomatic expression banks may help bridge the gap in generalization across culturally and linguistically diverse settings.

6 Conclusion

This study demonstrated the effectiveness of transformer-based models, particularly T5 and mT5, for multilingual emotion detection. These models leveraged pre-trained knowledge and

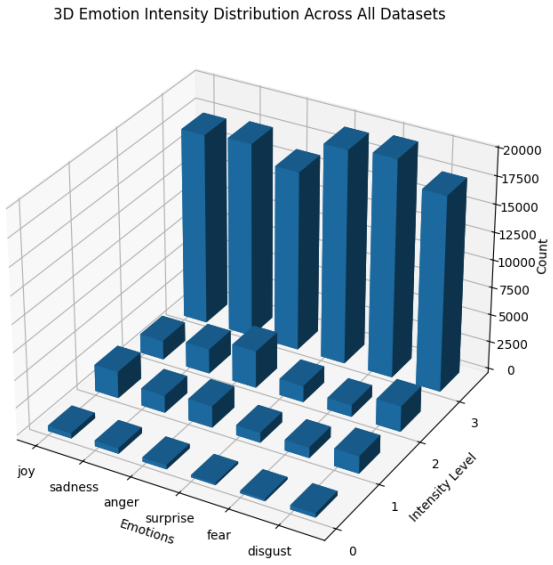

Figure 3: 3D Emotion Intensity Distribution across all datasets

fine-tuning to classify emotions across diverse languages, achieving strong results in high-resource languages like Hindi, Marathi, and Russian while facing challenges in low-resource languages such as Swahili, Yoruba, and Makhuwa due to data scarcity. The strong performance of Spanish, despite not being a high-resource language, suggests that factors like annotation quality and linguistic structure significantly impact model effectiveness. Emotion intensity estimation followed similar trends, highlighting the necessity of refined annotations and better training data. Future work should focus on enhancing dataset availability, optimizing model fine-tuning, and incorporating external linguistic resources to improve cross-linguistic performance and generalizability.

While the study focused on T5 and mT5 due to their unified text-to-text architecture, future work should also explore competitive encoder-only models like XLM-R. Additionally, leveraging transfer learning techniques, such as adapter layers or language-specific fine-tuning, could further improve low-resource performance.

7 Ethical Considerations

The development of multilingual emotion detection models presents ethical challenges, including biases due to uneven language representation, potential misinterpretations across cultures, and privacy

concerns related to user-generated content. The performance gap between high- and low-resource languages risks marginalizing underrepresented communities, while cultural variations in emotional expression may lead to inaccurate predictions. Ensuring transparency, improving dataset diversity, and implementing robust privacy safeguards are essential to mitigate these risks. Collaboration with linguists, ethicists, and cultural experts can further refine these models to be more inclusive and ethically responsible.

Abstract

In this study, we present our approach to SemEval Task 8: Question Answering over Tabular Data (Os'es Grijalba et al., 2025), where we develop a Large Language Models(LLM)-based agent capable of answering questions over tabular data. Our agent leverages a set of custom defined tools incorporating structured table parsing and reasoning mechanisms to enhance semantic understanding of tabular data. Extending our methodology, we apply chain-of-thought prompting to further refine it's understanding of the task. Our findings suggest that LLM-based agents, when properly adapted, can significantly improve their table-based question answering capabilities.

1 Introduction

The task of Question Answering on Tabular Data (TabQA) involves answering natural language queries using structured tabular data. Given a natural language query, the goal is to generate accurate responses based on the tabular data.

Conventional TabQA methods typically involve providing large language models (LLMs) with the entire table alongside the query, under the assumption that full-table context enables models to reason over any potentially relevant information. However, this strategy faces significant challenges, including limited scalability due to context length constraints, poor generalization and high computational overhead.

Retrieval-Augmented Generation (RAG) methods have partially tried to address these issues by retrieving semantically similar chunks of the table. However, they rely on embeddings that often fail to capture relational structures and numerical precision, resulting in poor retrieval performance and difficulty in handling diverse column types.

To overcome these limitations, we propose an LLM-agent-based framework that abstracts tables into SQL representations, enabling LLMs to leverage structured information more effectively. This approach combines structured query execution with natural language understanding, offering a scalable and efficient solution for TabQA.

2 Related Work

Early approaches for TabQA primarily relied on semantic parsing, translating queries into executable programs such as SQL, as seen in models like Neural Programmer (Neelakantan et al., 2017) and SQLNet (Xu et al., 2017). While effective, these approaches required annotated SQL queries and struggled to generalize across diverse table schemas.

Later on, models such as TAPAS (Herzig et al., 2020) and TaBERT (Yin and Neubig, 2020) used weakly supervised learning over table-text pairs, removing the dependence on explicit SQL annotations. While these models advanced the state of the art, they exhibited limitations in numerical reasoning capabilities and scalability to long or complex tables.

To further address these challenges, Retrieval-Augmented Generation (RAG) techniques, exemplified by models like RASAT (Kim et al., 2022), incorporated retrieval mechanisms to identify relevant table segments before answer generation. However, despite improved scalability, these methods often failed to capture the structured and relational aspects inherent to tables.

Recent developments in agentic LLMs, such as Toolformer (Schick et al., 2023) and ReAct (Yao et al., 2022), introduced frameworks where language models interact with external tools (e.g., SQL engines, calculators) to perform more accurate and interpretable reasoning.

Building upon these advancements, we propose a novel framework that integrates agentic reasoning with SQL-based execution. By abstracting tables into SQL databases and enabling LLMs to interact

†The authors contributed equally to this work.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 623–626

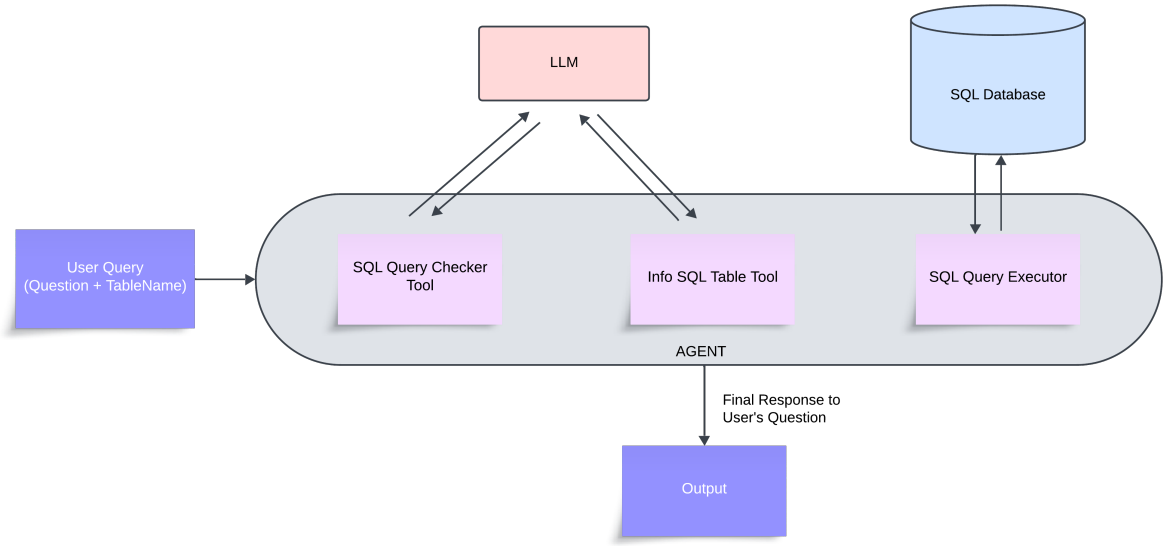

Figure 1: Proposed Agentic Framework for TabQA

with them, our approach enhances generalization across domains, and strengthens numerical reasoning capabilities in TabQA tasks.

3 Dataset

Each table is provided in two formats: `all.parquet`, containing the complete set of rows, and `sample.parquet`, containing the first 20 rows of the corresponding `all.parquet` file. The collection of all `all.parquet` files across every table constitutes the Databench dataset, while the set of all `sample.parquet` files forms the Databench-lite dataset.

Additionally, for each table, a set of natural language queries has been provided, which can be answered using the table's information.

4 System Overview

We introduce a novel pipeline for Question Answering over Tables that allows LLMs to interact with a set of specialized tools to deliver precise, reliable responses. The end-to-end architecture is depicted in Figure 1 and comprises two primary stages:

4.1 Data Ingestion

All input tables, originally stored in `.parquet` format, are imported into an SQL database. This conversion enables efficient, schema-driven querying using SQL.

4.2 Query Processing

The core of our methodology is a framework that allows an LLM to interact with multiple tools for query interpretation, SQL generation, validation, and execution. The description of the tools is as follows:

- **SQL Query Checker:** Ensures generated SQL statements are syntactically correct, safe, and restricted to read-only operations, thereby preventing unintended modifications.
- **Info SQL Table:** Retrieves table metadata (e.g., column names, data types) and sample rows to inform accurate and context-aware SQL formulation.
- **SQL Query Executor:** Executes validated SQL statements against the database and returns the results.

Throughout execution, the agent systematically records intermediate information—such as table schemas, draft queries, and execution outputs—which are then used by the LLM to produce the final, formatted answer.

5 Experimental Setup

To evaluate the system's performance, we integrate multiple open-source LLMs into our framework. Experiments are conducted using standardized evaluation scripts from external evaluators. Table 1

LLM Provider	No. of Parameters	Model
Meta	70B	Llama-3.3-70B
Codestral	22B	Codestral-22B-v0.1
Mistral	7B	Mistral-7B-v0.3
Meta	3B	Llama-3.2-3B

Table 1: Open-source LLMs used for Experiments

Model	Databench-lite	Databench
Llama-3.3-70B	67.43	62.07
Codestral-22B-v0.1	60.21	56.73
Mistral-7B-v0.3	49.42	44.29
Llama-3.2-3B	39.65	36.17

Table 2: LLM Performance Metrics

summarizes the LLM variants tested, indicating their provider, parameter count, and model used. Each model interacts with the defined set of tools to answer the natural language queries.

6 Results and Analysis

We integrated four open-source LLMs—Llama-3.3-70B, Codestral-22B-v0.1, Mistral-7B-v0.3, and Llama-3.2-3B—into our agentic framework and evaluated each on both the Databench and Databench-lite datasets.

6.1 Effect of Dataset Scale

All models achieved higher accuracy on Databench-lite than on Databench. The reduced row count in Databench-lite simplifies multi-step SQL queries, decreases execution times, and lowers the risk of exceeding tool-call limits or entering infinite reasoning loops. In contrast, Databench's larger search space for intermediate operations—such as retrieving unique values before aggregation—leads to longer query pipelines and a higher error rate in query formulation and execution.

6.2 Comparative Model Performance

Llama-3.3-70B achieved the highest accuracy (62.07% on Databench), followed by Codestral-22B-v0.1, Mistral-7B-v0.3, and finally Llama-3.2-3B. The larger parameter count of Llama-3.3-70B enables more precise SQL generation and robust reasoning over complex queries. Codestral-22B-v0.1 and Mistral-7B-v0.3 performed competitively but showed occasional failures on nested or multi-step queries. Llama-3.2-3B's lower accuracy indicates that smaller models struggle with the reasoning depth required for intricate tabular QA tasks.

6.3 Error Analysis

6.3.1 Multi-Step Query Failures

In multi-step queries, the agent frequently misaligns natural language predicates with corresponding schema values, resulting in omitted filtering clauses or syntactic errors. An example from the `066_IBM_HR` table illustrates this behavior:

> "Are there more employees who travel frequently than those in the HR department?"

The predicate "travel frequently" should translate to:

```
WHERE BusinessTravel = 'Travel_Frequently'
```

However, the agent either omits the WHERE clause entirely or generates invalid SQL, such as:

```
SELECT COUNT("travel frequently")
FROM 066_IBM_HR;
```

This misalignment prevents correct filtering and yields an incorrect answer.

6.3.2 Infinite Tool-Call Loops

A Small fraction of the queries processed by Llama-3.3-70B entered infinite refinement loops due to overly strict or misspelled filters (e.g., `EmployeID`). Smaller models like Llama-3.2-3B were found to be more susceptible to infinite refinement loops highlighting the trade-off between model capacity and reasoning capabilities.

6.4 Summary

Our results indicate that dataset scale and model size are critical determinants of TabQA performance. Databench-lite facilitates efficient and ac-

curate querying, while larger LLMs produce superior SQL formulation and complex reasoning. Future work will explore methods to reduce query complexity and improve the resilience of smaller models.

7 Conclusion

Our research highlights the advantages of using an agentic approach for QA on tabular data. It demonstrates its ability to dynamically construct and refine queries for precise information retrieval, which is essential for QA performance. By outperforming RAG-based and full-table context methods in handling mixed data types and scalability challenges, it proves more adaptable and efficient. Additionally, its iterative reasoning surpasses direct SQL querying and reinforces the potential of LLM-powered agents in table-aware AI systems.

8 Limitations

Despite our progress, this work has several limitations. The multi-step reasoning process necessitates multiple tool calls, which increases response latency—especially when the agent engages in excessive query refinement—and can occasionally lead to infinite reasoning loops that exhaust the tool-call budget and prevent valid answers. The agent also sometimes deviates from the expected answer format, undermining consistency. To address these issues, we plan to incorporate termination conditions that detect repetitive tool calls and enforce early exits, enforce stricter output validation to guarantee format adherence, and optimize query execution to reduce latency. Finally, our reliance on off-the-shelf open-source LLMs may limit performance; fine-tuning these models on domain-specific training data could further improve accuracy and robustness.

Abstract

Food safety is a critical public health concern requiring rapid and accurate identification of potential hazards in food products. This paper presents our approach to SemEval-2025 Task 9, the Food Hazard Detection Challenge, which focuses on automatically classifying and extracting hazard information from food recall notifications. We propose a hybrid system combining traditional machine learning with state-of-the-art language models, implementing an ensemble approach for hazard classification (Sub-Task 1) and a prompt-engineered extraction method using Flan-T5-XL for precise hazard and product detection (Sub-Task 2). The results demonstrate the effectiveness of combining multiple complementary models while highlighting challenges in exact vector matching for food safety applications.

1 Introduction

Food safety incidents can have severe consequences for public health and the food industry, making rapid and accurate identification of food hazards crucial. The SemEval-2025 Task 9: Food Hazard Detection Challenge (Randl et al., 2025) addresses this critical need by focusing on automated analysis of food recall notifications, aiming to classify and extract specific hazard information from text descriptions. This task builds upon the CICLe dataset (Randl et al., 2024), which provides a comprehensive collection of food recall notifications.

Our approach to this challenge combines the strengths of traditional machine learning(ML) techniques with Large Language Models(LLMs). For Sub-Task 1 (ST1), we implemented a novel ensemble system integrating XGBoost (Chen and Guestrin, 2016) with fine-tuned versions of GPT-2 Large (Radford et al., 2019) and LLaMA 3.1 1B (Touvron et al., 2023) models. The Sub-Task 2 (ST2) utilizes a prompt-engineered approach with Flan-T5-XL (Chung et al., 2022), focusing on precise extraction of hazard and product information. This hybrid approach allows us to leverage both the statistical power of traditional methods and the semantic understanding capabilities of LLMs.

We achieved competitive results in both conception and evaluation phases, with F1-scores of 0.78 and 0.74 respectively for ST1. In contrast, ST2 was more challenging with an F1-score of 0.05, reflecting the difficulty of exact vector matching in food safety. Our model performed well on common hazard categories but struggled with rare classes and precise match accuracy.The complete codebase for our system is available at https://github.com/madhans476/Food-hazard-detection-SEMEVAL-2025.git.

2 Background

The data set for this task is derived from the CICLe corpus (Randl et al., 2024), a large-scale dataset of 7,546 English food recall notices annotated with hazard types (e.g., biological, chemical, physical) and product categories (e.g., dairy, meat, beverages). Its broad coverage of food safety incidents makes it well-suited for training and evaluating NLP models for food hazard detection.

2.1 Related Work

Food safety monitoring using NLP has gained attention for its potential to automate hazard detection from unstructured texts like recall notices. The CICLe framework (Randl et al., 2024) introduced conformal in-context learning for multi-class food risk classification, demonstrating the efficacy of large language models (LLMs) while highlighting challenges such as class imbalance and fine-grained categorization. Prior works (Edwards and Smith, 2019) explored rule-based and ML methods for extracting food safety incidents from regulatory reports but often lacked generalization across

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 627–633

hazard types. Recent advances in prompt-based learning (Wei et al., 2022) have shown promise in entity extraction, inspiring our Sub-Task 2 approach. Ensemble methods combining ML and LLMs (Rokach, 2010) support robust classification, motivating our strategy for Sub-Task 1. Our work builds on these foundations by integrating traditional and neural models to tackle the unique challenges of exact vector detection in food safety.

3 Methodology

This section presents the methodology employed for food hazard prediction using text classification (ST1) and vector detection (ST2) in the SemEval-2025 Shared Task. Our approach addresses class imbalance, leverages ensemble learning, fine-tuning LLMs using Parameter-Efficient Fine-Tuning (PEFT), and uses prompt-based tuning for hazard and product vector extraction.

3.1 Sub-Task 1

For Sub-Task 1 (ST1) of the SemEval-2025 food hazard prediction challenge, we developed a system combining traditional machine learning with state-of-the-art language models. This approach leverages the semantic understanding of large language models and the robust feature extraction of traditional methods to tackle the complexity of food hazard classification.

3.1.1 Hazard Category Classification

Our hazard category classification system uses a three-model ensemble. The motivation for this approach stems from our observation that while individual models achieved similar F1 scores (GPT-2: 0.72, LLaMA: 0.76, XGBoost: 0.75), they exhibited different strengths in capturing various aspects of the task:

- Language models (GPT-2 and LLaMA) excel at understanding contextual relationships and nuanced language patterns in food safety descriptions
- Traditional machine learning (XGBoost with TF-IDF) captures keyword-based patterns and statistical relationships
- Each model showed distinct error patterns, making them complementary in an ensemble

The ensemble architecture consists of:

1) GPT-2 Large Model:

We fine-tune the GPT-2 Large model (Radford et al., 2019) using Parameter-Efficient Fine-Tuning (PEFT) (Hu et al., 2021) with Low-Rank Adaptation (LoRA). GPT-2's strong English language understanding capabilities make it particularly suitable for processing formal food safety notifications. The LoRA configuration includes:

- Rank (r) = 16
- Alpha (α) = 16
- Dropout = 0.05
- Target modules: attention layers ('c_attn', 'c_proj') and MLP layers ('c_fc', 'mlp.c_proj')

2) LLaMA 3.1 1B Model:

We employ Meta's LLaMA 3.1 1B model (Touvron et al., 2023) with LoRA fine-tuning. LLaMA's advanced architecture and efficient scaling make it particularly effective at handling complex classification tasks. The LoRA configuration includes:

- Rank (r) = 16
- Alpha (α) = 16
- Dropout = 0.05
- Target modules: attention layers ('q_proj', 'k_proj'. 'v_proj', 'o_proj') and MLP layers ('gate_proj', up_proj', 'down_proj')

The LoRA configuration matches that of GPT-2 Large for consistency in the fine-tuning approach.

3) TF-IDF + XGBoost Pipeline:

Our traditional machine learning pipeline provides a robust baseline approach that complements the neural models:

- TF-IDF vectorization (Ramos, 2003) with:
  - max_features = 3500 (optimized to capture key terminology while avoiding sparsity)
  - max_df = 0.75 (removes overly common terms)
  - sublinear_tf = True (reduces the impact of high-frequency terms)
- SMOTE (Chawla et al., 2002) for handling class imbalance:
  - Stage 1: Majority class sampling (k_neighbors=7)
  - Stage 2: Minority class sampling (k_neighbors=1)
- XGBoost classifier (Chen and Guestrin, 2016) with default parameters, chosen for its robustness and ability to handle complex feature interactions

3.1.2 Ensemble Strategy

The final prediction is determined through **hard voting** (Rokach, 2010) among the three models as illustrated in figure 1. **Hard voting** is a technique in which each model in the ensemble predicts a class and the majority vote is taken as the final classification. Unlike soft voting, which averages probability distributions, hard voting ensures simpler implementation and robustness against individual model overconfidence.

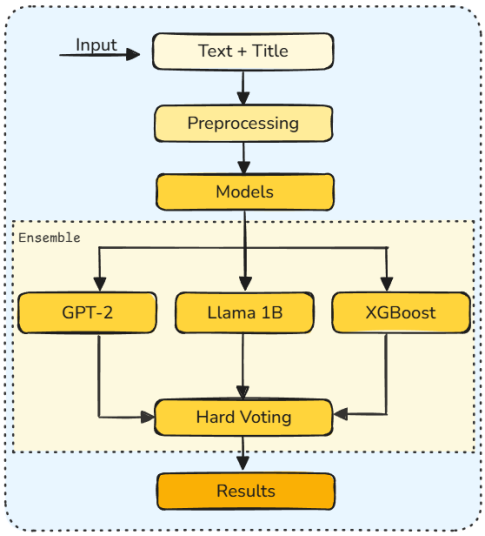

Figure 1: Hard Voting Ensemble.

This ensemble approach effectively combines the strengths of each model while mitigating their individual weaknesses. The similar F1 scores (0.72-0.76) of individual models suggested that each model captured different aspects of the classification task effectively, making them ideal candidates for ensemble learning. Their complementary behaviors led to improved robustness and reliability in hazard category prediction.

3.1.3 Product Category Classification

For product category classification, we opted for a single LLaMA 3.1 1B model approach rather than an ensemble, as our experiments showed that this model consistently outperformed other architectures for this specific task. The model architecture remains consistent with the implementation of the LLaMA hazard category, using LoRA for efficient fine-tuning.

3.1.4 Experimental Setup

For tokenization, we use model-specific tokenizers from the Hugging Face Transformers library (Wolf et al., 2020) to ensure optimal text representation for each architecture. For GPT-2 Large and LLaMA 3.1 1B, we apply their native tokenizers with `add_prefix_space=True`, setting the pad token to the EOS token. Both are configured with `max_length=512` and `padding="max_length"` to maintain consistent input dimensions while preserving context.

We adopt a unified training framework across all models, also based on the Transformers library, with a configuration designed for stability and efficiency, as detailed in Table 1.

Hyper parameter	Value
Learning rate	2×10^{-5}
Batch size	8
Training epochs	5
Weight decay	0.01

Table 1: Hyper parameters for ST1

Training Process

- Data split: 90% training, 10% validation (random_state=42)
- Evaluation frequency: Every 500 steps
- Model checkpoint saving: Every 500 steps
- Gradient checkpointing enabled for memory optimization

3.2 Sub-Task 2

For the more challenging task of exact hazard and product vector detection, we implemented a prompt-engineered approach using the Flan-T5-XL model (Chung et al., 2022). This task required extracting specific product and hazard terms from recall notices, presenting a more fine-grained extraction challenge compared to category classification.

3.2.1 Model Architecture

We selected Google's Flan-T5-XL as our base model, as shown in Figure 2, due to its:

- Strong instruction-following capabilities
- Robust performance on various NLP tasks
- Pretraining on diverse instruction formats

The model was fine-tuned using Parameter-Efficient Fine-Tuning (PEFT) with the LoRA configuration:

- Rank (r) = 32
- Alpha (α) = 32
- LoRA dropout = 0.1
- Target modules: query, key, value, and encoder-decoder attention layers

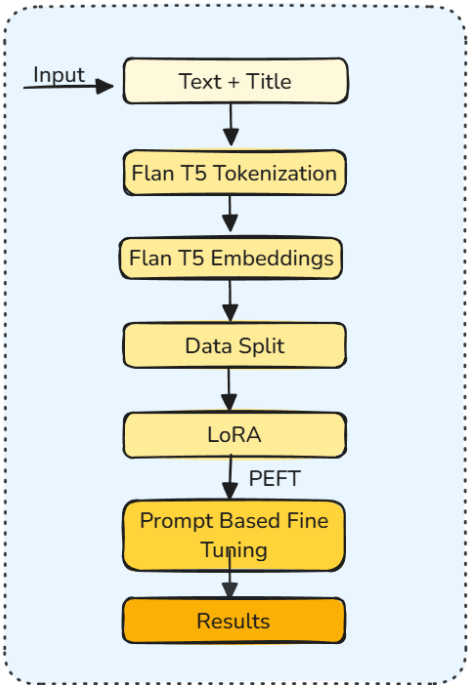

Figure 2: ST2 Architecture

3.2.2 Prompting Engineering

For the more challenging task of exact hazard and product vector detection, we adopted an **instruction-based fine-tuning** approach, leveraging Flan-T5's ability to generalize across instruction-driven tasks. We primarily used **zero-shot prompting** during inference by formulating task-specific prompts that did not include example demonstrations. The prompts were structured in **plain text format** and integrated within Python scripts for seamless model inference.

We experimented with few-shot prompting by including example input-output pairs in early iterations, but did not observe consistent improvements over the fine-tuned model's zero-shot performance. Below are the task-specific prompts used for each vector type:

- Hazard extraction: *"Extract the exact reason for the food recall from the given text. Provide only the specific recall reason, without including any other information, from the following recall text:"*
- Product extraction: *"Extract only the recall food product from the following food recall text:"*

The prompts were designed to:

- Focus the model's attention on specific information
- Minimize extraneous information in the output
- Maintain consistency in extraction patterns

3.2.3 Experimental Setup

The training process was optimized for the extraction task. The configuration emphasizes both learning stability and computational efficiency:

Hyper parameter	Value
Learning Rate	1×10^{-5}
Batch size	2
Training epochs	5
Weight decay	0.01
max_length (Input)	512
max_length (Target)	64
Gradient clipping	1.0

Table 2: Hyper parameters for ST2

Training Process

- Data split: 90% training, 10% validation
- Regular evaluation every 500 steps
- Model checkpoints saved every 500 steps
- Best model selection based on validation performance
- Mixed precision training disabled for stability

3.3 Implementation Details

All experiments were conducted using:

- PyTorch framework (Paszke et al.) for deep learning models
- Hugging Face Transformers (Wolf et al., 2020) library for model implementations
- PEFT library for efficient fine-tuning
- Scikit-learn (Pedregosa et al., 2011) for traditional ML components
- Imbalanced-learn (Lemaître et al., 2017) for SMOTE implementation

4 Results

4.1 Overall Performance

Our system showed varied effectiveness across the two subtasks of the SemEval-2025 food hazard prediction challenge, as summarized in Table 3. The significant performance gap between subtasks indicates our approach effectively captures broader

Product category	precision	recall	f1-score	support
alcoholic beverages	0.88	1.00	0.93	7
cereals and bakery products	0.71	0.75	0.73	75
cocoa and cocoa preparations, coffee and tea	0.56	0.67	0.61	15
confectionery	1.00	0.46	0.63	26
dietetic foods, food supplements, fortified foods	0.43	0.71	0.54	14
fats and oils	0.67	0.50	0.57	4
feed materials	1.00	1.00	1.00	1
fruits and vegetables	0.68	0.75	0.72	52
herbs and spices	0.72	0.68	0.70	19
ices and desserts	0.91	0.88	0.89	24
meat, egg and dairy products	0.87	0.91	0.89	146
non-alcoholic beverages	0.83	0.79	0.81	19
nuts, nut products and seeds	0.80	0.85	0.82	33
other food product / mixed	1.00	0.20	0.33	10
pet feed	0.50	1.00	0.67	1
prepared dishes and snacks	0.58	0.55	0.57	56
seafood	0.95	0.78	0.86	27
soups, broths, sauces and condiments	0.68	0.72	0.70	36

Hazard category	precision	recall	f1-score	support
allergens	0.95	1.00	0.98	207
biological	0.97	0.99	0.98	194
chemical	0.76	0.89	0.82	28
food additives and flavourings	0.00	0.00	0.00	2
foreign bodies	0.95	0.95	0.95	63
fraud	0.92	0.59	0.72	41
organoleptic aspects	0.78	0.88	0.82	8
other hazard	0.62	0.57	0.59	14
packaging defect	0.50	0.38	0.43	8

Figure 3: Classification reports for (a) product category and (b) hazard category classifications on the validation set, showing precision, recall, F1-score, and support for each class.

Task	F1-Score	Rank
ST1 (Classification)	0.74	18
ST2 (Vector Detection)	0.05	23

Table 3: Overall system score and team rank on test set

categories but struggles with precise entity extraction. Our team(madhans476) ranked **18th** in ST1 and **23rd** in ST2, highlighting competitive classification performance but challenges in exact vector matching.

4.2 ST1: Classification Performance

4.2.1 Model Performance

Analysis of individual model contributions in Sub-Task 1 revealed complementary strengths across our ensemble components on validation set:

Model	F1-Score
GPT-2 Large	0.72
LLaMA 3.1 1B	0.76
XGBoost	0.75
Ensemble	**0.78**

Table 4: F1-Scores for Hazard-Category Classification.

Model	F1-Score
GPT-2 Large	0.66
LLaMA 3.1 1B	**0.72**
XGBoost	0.51
Ensemble	0.68

Table 5: F1-Scores for Product-Category Classification.

As seen in Table 4, the ensemble approach achieved the highest F1-score (0.78) for hazard category classification, leading us to adopt it for robustness. However, in product category classification (Table 5), the ensemble's F1-score (0.68) was lower than LLaMA's (0.72), so we opted for a single LLaMA 3.1 1B model for this task to maximize performance. The traditional machine learning approach (XGBoost) remained competitive for hazards but underperformed for products, suggesting TF-IDF features are less effective for product category diversity.

Our system achieved competitive performance in the shared task, as shown in Tables 6 and 7:

Team	Score
PATeam	0.86
madhans476 (Ours)	**0.78**

Table 6: Comparison with **rank 1** on Conception phase

Team	Score
qipu1115	0.82
madhans476 (Ours)	**0.74**

Table 7: Comparison with **rank 1** on Evaluation phase

4.2.2 Error Analysis

To assess model performance in Sub-Task 1, we present classification reports for hazard and product category predictions based on the validation set. These reports, shown in Figure 3, detail precision, recall, F1-score, and support for each class, highlighting the model's strengths and weaknesses. Key observations include:

- **Higher Accuracy for Common Categories**: The model performed well on frequent classes like "allergens" (hazard: F1=0.98, support=207) and "alcoholic beverages" (product: F1=0.93, support=7), where ample training data supported robust predictions.
- **Lower Performance on Rare Categories**: Rare classes such as "packaging defect" (hazard: F1=0.43, support=8) and "pet food"

(product: F1=0.57, support=10) had lower F1-scores, reflecting challenges from limited examples and class imbalance.

- **Misclassification Due to Overlapping Terminology**: Categories like "foreign bodies" (F1=0.95, support=63) and "organoleptic aspects" (F1=0.82, support=8) showed confusion, likely due to overlapping textual cues in recall notices.

4.3 ST 2: Vector Detection Performance

4.3.1 Model Performance

The Flan-T5-XL model for Sub-Task 2 achieved an F1-score of 0.05 on the test set, indicating significant challenges in exact vector detection.

4.3.2 Error Analysis

This low performance can be attributed to several factors:

- **Model Sensitivity**: The instruction-based prompting struggled with fine-grained extraction, prioritizing semantic similarity over exact matches due to Flan-T5-XL's generation tendencies.
- **Data Variability**: The CICLe dataset's diverse recall notices, with inconsistent terminology and multi-hazard descriptions, posed difficulties during fine-tuning, as the model lacked sufficient context for rare vectors.
- **Evaluation Strictness**: The strict exact-match criterion amplified errors, as even minor deviations (e.g., "mineral water" vs. "bottled water") were penalized.

To address these, we experimented with stricter prompt constraints (e.g., limiting output length to 32 tokens) and LoRA fine-tuning, which improved precision marginally (by 0.02) but not recall, suggesting a need for more robust training strategies.

4.4 Comparative Analysis

To contextualize our results, we compare our approach with the CICLe framework (Randl et al., 2024), a leading prior method for food hazard detection. As shown in Table 8, our method outperforms CICLE in classification but underperforms in vector detection.

Our Sub-Task 1 ensemble achieved competitive F1-scores, demonstrating robustness despite a simpler ensemble strategy. For Sub-Task 2, the F1-score was 0.05, highlighting the difficulty of fine-grained vector detection. To address this, we propose a similarity-based evaluation metric using cosine similarity between predicted and ground-truth vectors (e.g., with pre-trained embeddings like BERT). This allows for semantic alignment even when exact matches fail (e.g., "salmon" vs. "smoked salmon").

Task	CICLe	Ours
Classification	0.65	**0.74**
Vector Detection	**0.51**	0.05

Table 8: Comparison of our F1-scores with CICLe.

5 Conclusion

We presented a hybrid approach for food hazard prediction and classification in SemEval-2025 Task 9, combining traditional ML with state-of-the-art language models, achieving competitive performance in both classification (ST1) and vector detection (ST2).
Key contributions include:

- An ensemble method combining XGBoost, GPT-2, and LLaMA 3.1 1B for hazard classification.
- Class imbalance handling via SMOTE.
- Efficient fine-tuning using PEFT techniques.
- Prompt engineering for accurate vector detection with Flan-T5-XL.

Error analysis showed strong performance on common hazard categories and clear product descriptions, but challenges persist with rare classes and exact vector matches. The methods proposed here have broader applications in domains requiring fine-grained classification and entity extraction from technical texts.

6 Limitations

Our approach for ST2 has a few limitations:

- **Exact match issues**: The model sometimes generated semantically similar but not exact matches.
  For example, given "*Recall of smoked salmon due to potential Listeria contamination*," the model extracted "*salmon*" instead of "*smoked salmon*."
- **Vocabulary mismatch**: Outputs occasionally failed to align with the predefined vector space.
  In "*Alpine Springs mineral water recalled due*

to chemical contamination," the model predicted "*mineral water*" while the expected label was "*bottled water*."

7 Future Work

Our findings suggest several directions for future research:

- **Enhanced Prompting**: Few-shot prompting with 2–3 examples or Chain-of-Thought prompting may improve Sub-Task 2's low F1-score (0.05) by guiding more precise outputs.
- **Larger Models and Data**: Using larger Flan-T5 variants or augmenting the CICLe dataset with synthetic samples may reduce issues with rare classes and variability.
- **Hybrid Metrics**: Extending the similarity score—potentially combining it with F1—could better assess ST2 performance, especially when approximate matches are acceptable.

These directions aim to overcome current challenges and generalize the approach to broader safety monitoring domains.

UniBuc-AE at SemEval-2025 Task 7: Training Text Embedding Models for Multilingual and Crosslingual Fact-Checked Claim Retrieval

Alexandru Enache
University of Bucharest
Faculty of Mathematics and Computer Science
alexandru.enache1@s.unibuc.ro

Abstract

This paper describes our approach to the SemEval-2025 Task 7: Multilingual and Crosslingual Fact-Checked Claim Retrieval on both the monolingual and crosslingual tracks. Our training methodology for text embedding models combines contrastive pre-training and hard negatives mining in order to fine-tune models from the E5 family. Additionally, we introduce a novel approach for merging the results from multiple models by finding the best majority vote weighted configuration for each subtask using the validation dataset. Our team ranked 6^{th} in the monolingual track scoring a 0.934 S@10 averaged over all languages and achieved a 0.79 S@10 on the crosslingual task, ranking 8^{th} in this track.

1 Introduction

Fact-checking is becoming a crucial task in today's society. Viral posts on social networks can reach an astonishing number of people in very little time, and false information tends to spread faster than true data (Vosoughi et al., 2018). Thus, automated fact-checking systems can be a useful tool in combating this problem.

The previous research done in this space was mostly focused on the English language and on the monolingual task, where the fact-check and post are in the same language, bot not on the crosslingual case. The MultiClaim dataset (Pikuliak et al., 2023) is the biggest dataset of fact-checks released to date and introduces a special section for crosslingual evaluation. This year's SemEval-2025 Task 7 (Peng et al., 2025) further enhances this dataset with modifications and augmentations for this task.

This paper proposes an automated fact-checking system based on text embedding models that allow the retrieval of relevant fact-checked claims through data vectorization. The implementation is based on the multilingual-e5-large-instruct (Wang et al., 2024b) and e5-large-v2 (Wang et al., 2022) models.

Our approach[1] creates models consistent for both the monolingual and crosslingual tasks, ranking 6^{th} in the monolingual track and 8^{th} in the crosslingual track . The full results of our approach are available in the Results section in Table 4.

2 Background

2.1 Related Work

Pikuliak et al. (2023) experimented with BM25 and various English and multilingual text embedding models on the MultiClaim dataset, achieving an S@10 score of 0.83 on the monolingual task and 0.56 on the crosslingual task using the GTR-T5-Large model. From their results, the best results were generated by first translating both the posts and fact-checks to English using out-of-the-box AI services and then running English text embedding models on the translated data.

2.2 Dataset

The dataset (Peng et al., 2025) is an enhanced version of the original MultiClaim dataset (Pikuliak et al., 2023). It contains 280K unique fact-checks and 33K unique social media posts split between train, dev and test. For the train dataset we are given 25K pairs of matching post fact-check pairs in 8 different languages: French, Spanish, English, Portuguese, Thai, German, Malay and Arabic. The test dataset introduces two other languages: Turkish and Polish. The distribution of posts and fact-checks per language in every dataset can be visualized in Figure 1. In order to evaluate our fine-tuning and find an optimal weighted configuration for the majority vote, we have created a validation dataset using a random 80-20 split on the training pairs.

[1]Our code and experiments are available at https://github.com/Alex18mai/UniBuc-AE-at-SemEval-2025-Task7

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 634–639

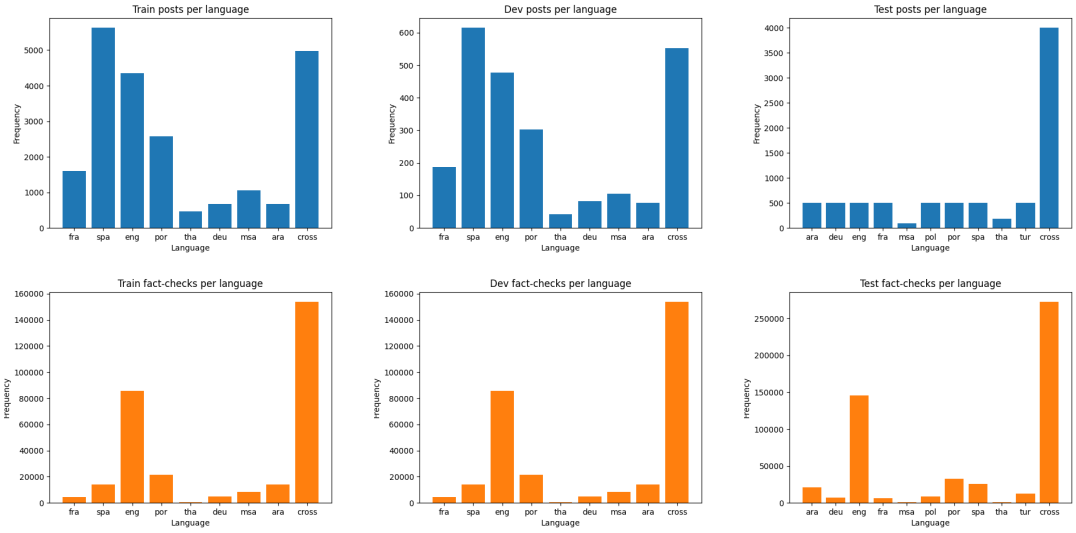

Figure 1: The language distribution for posts and fact-checks in the train, dev and test datasets.

Each social post contains the text and OCR extracted from the visual content of the post in both the original language and English translation. A parsed example of a social media post can be found in Appendix A.

Each fact-check contains the claim and title in both the original language and English translation. A parsed example of a fact-check can be found in Appendix B.

In the output submission, we need to report the top 10 retrieved fact-checks for each post.

3 System Overview

3.1 Architecture Overview

This paper presents a comprehensive approach applicable to both monolingual and crosslingual tasks, leveraging a combined training methodology that incorporates both monolingual and crosslingual pairs. Our experimental framework encompasses the utilization of multilingual text embedding models as well as English-specific text embedding models, employing the appropriate text for each scenario (original language or English translation).

The models are trained by first applying contrastive pre-training using in-batch negatives and then fine tuning using custom mined hard negatives for each post.

The final submission is generated by combining multiple models using an algorithmic approach to finding the best weighted configuration for each subtask.

3.2 Text Embedding Models

- **multilingual-e5-large-instruct** (Wang et al., 2024b) is a state of the art multilingual text embedding model initialized from xlm-roberta-large. It was trained using a dataset containing over 100 languages. Additionally, it is instruction-tuned, enhancing the quality of the embeddings by allowing custom instruction prompts to be given as context for the task at hand.

- **e5-large-v2** (Wang et al., 2022) is a powerful English text embedding model initialized from bert-large-uncased-whole-wordmasking. It was trained using the MS-MARCO, NQ and NLI datasets and has one of the best results on the MTEB Benchmark leaderboard (Muennighoff et al., 2022) for the small size of 335M parameters.

3.3 Contrastive Pre-training

The first epochs are trained using contrastive loss (van den Oord et al., 2019) with in-batch negatives and a temperature of 0.01, inspired from the E5 paper (Wang et al., 2022).

Using in-batch negatives is computationally efficient since it uses already computed embeddings as negative samples for each matching pair, but has a very low probability of having a negative pair with a high cosine similarity. Such pairs are called hard negatives since they are the negative pairs where the model fails to distance the embeddings and are very useful in the training process.

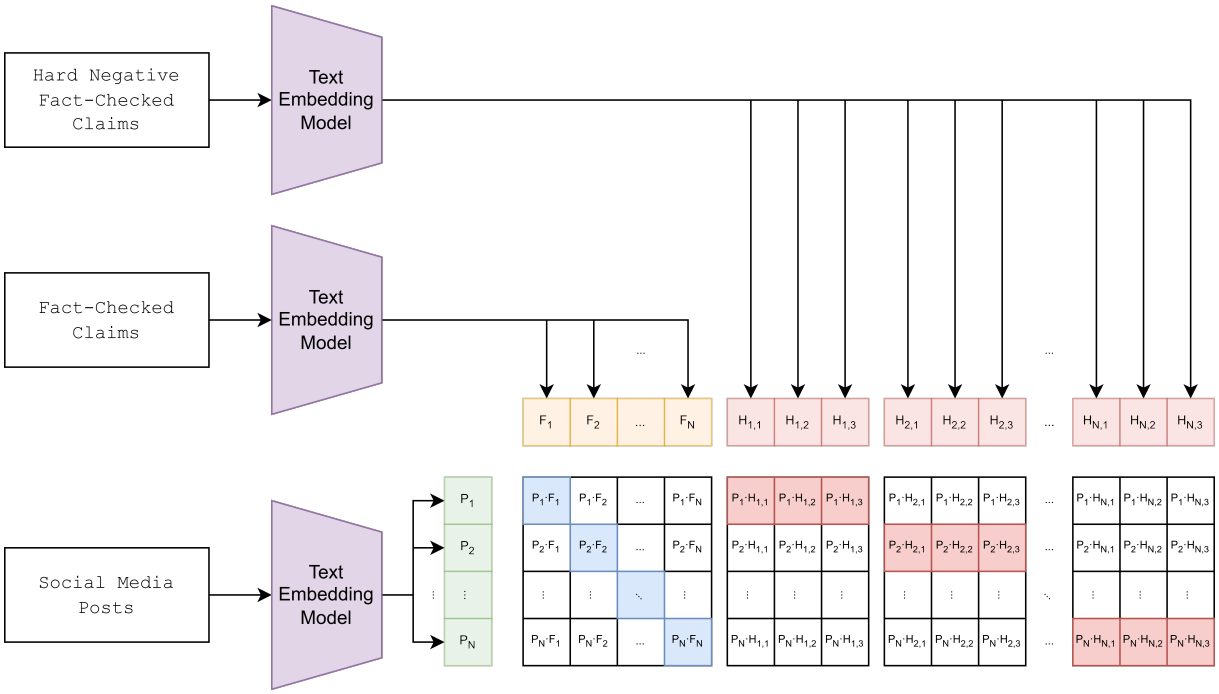

Figure 2: Contrastive training using hard negatives. For each social media post a positive and 3 hard negative fact-checked claims are sampled.

3.4 Hard Negatives Mining

After the contrastive pre-training, we use the models in order to predict the negative fact-checks with the highest similarity score to the posts from the training dataset. The hard negatives are then used in order to fine-tune the model by sampling together with the post fact-check matching pairs.

We have found that sampling any of the top 5 hard negatives for a post actually degrades the result. This can be justified by the fact that it also introduces false negatives, which are fact-checks that should have been labeled as matching or are too close to the meaning of the social media post. This is also confirmed by a recent study by Nvidia (de Souza P. Moreira et al., 2024) where they have proposed the Top-K shifted by N method. This is why we use the hard negatives ranked 8^{th} to 10^{th} (top-3 shifted by 7).

In Figure 2, we show the training process using hard negatives. For each social media post, we maximize the cosine similarity with the matching fact-checked claim (blue boxes) and minimize the cosine similarity with the rest of the fact-checked claims, including hard negatives (red boxes) and in-batch negatives (white boxes).

3.5 Weighted Majority Vote

In order to find the best weighted configuration for the majority vote on each subtask, we compute the top 1000 retrieved fact-checks with their corresponding similarity score for each post in the validation, dev and test dataset.

Formally, given N models and their retrievals, we want to find the optimal weights $w_1, w_2, ..., w_N$ ($w_1 + w_2 + ... + w_N = 1$) for each subtask so that, when attributing the score $sim_1 \cdot w_1 + sim_2 \cdot w_2 + ... + sim_N \cdot w_N$ to each fact-check we achieve the best S@10 score on the validation subtask. We denote the similarity score given by the N models for the post fact-check pair by $sim_1, sim_2, ..., sim_N$.

For simplicity, we can discretize the weights to 0.1 increments ($[0.0, 0.1, ..., 1.0]$ since smaller changes than 0.1 should not impact the results of the algorithm in a meaningful manner.

Now we can compute all the configurations of possible weights and check the validation in order to determine the best one for each subtask.

This method proved to be more reliable than the classical weighted majority vote based on the accuracy and brought a major improvement to the accuracy of our final submission.

Since the test dataset contains two languages which are not present in the train dataset, we have computed their configuration as the mean of

the monolingual configurations for the other languages.

4 Experimental Setup

The social media posts are converted to a single string by concatenating the text and all the OCR lines, generating one string in the original language and one in English using the translated text. A similar process is applied to the fact-checks by concatenating the claim and title.

As evaluation metrics we use the Success@10 which measures whether at least one relevant item is present in the top 10 recommendations.

$$\text{S@10} = \begin{cases} 1 & \text{if } \sum_{i=1}^{10} \text{rel}_i > 0 \\ 0 & \text{otherwise} \end{cases}$$

,where rel_i represents the relevance score of the i-th item in the list.

The instruction prompt used for the multilingual-e5-large-instruct model is : "Instruct: Given a social media post, retrieve relevant fact-checked claims for the post".

All the experiments[2] were conducted using AdamW with a learning rate of 10^{-5} with a linear scheduler of 100 warmup steps and a weight decay of 10^{-5} .

Due to hardware limitations, the contrastive pre-training is done using a batch size of 8 pairs of matching post fact-check pairs and the hard negatives fine-tuning is done using a batch size of 4 matching pairs and 3 hard negatives for each post.

We note the configurations used in the experiments in the following way:

- **Eng** : e5-large-v2 model trained with English texts using **5** epochs of contrastive pre-training.
- **Orig** : multilingual-e5-large-instruct model trained with the original texts using **5** epochs of contrastive pre-training.
- **EngHard** : Eng further fine-tuned for **3** epochs using hard negatives generated.
- **OrigHard** : Orig further fine-tuned for **3** epochs using hard negatives generated.
- **MV** : The weighted majority vote using the best configuration for combining Eng, Orig, EngHard and OrigHard.

[2]The environment used for the experiments is available at https://github.com/Alex18mai/UniBuc-AE-at-SemEval-2025-Task7/blob/main/requirements.txt

Subtask	Eng	Orig	Eng Hard	Orig Hard	MV

msa	0.0	0.0	0.4	0.6
ara	0.0	0.1	0.4	0.5
crosslingual	0.0	0.2	0.4	0.4

Table 2: Best weighted configuration for majority vote found by our algorithm.

From Table 1, we can conclude that fine-tuning using hard negatives has brought a significant improvement of 3.5% for monolingual and 6% for crosslingual. In addition, by implementing the algorithm for finding the optimal weighted configuration for majority vote, we have further improved by 3% the results on both tasks.

We discovered that adding the Eng and Orig models to the majority vote helped to improve our result even if they had worse accuracies than EngHard and OrigHard. As it can be seen from Table 2, the algorithm attributed them small weights.

The interesting part when looking at the algorithm's results is that the configuration is not always directly proportional to the models' accuracies. For example, in the msa task the EngHard model is a clear winner, but it is weighted less that

the OrigHard model by the algorithm.

For the new languages added in the test dataset we have used the average of the monolingual configurations : $[0.075, 0.125, 0.4375, 0.3625]$.

monolingual	0.934
crosslingual	0.790

Table 4: Results on the test dataset.

The dev results are very similar to the predicted results on the validation set, even achieving a perfect score for the Thai language.

The test results seem to have some differences, experiencing quite a large drop on the crosslingual accuracy. We believe that this is caused by the difference in distribution between the test dataset and the train and dev datasets.

Our team ranked 6^{th} in the monolingual track and 8^{th} in the crosslingual track.

6 Conclusion

Our training methodology accurately creates text embedding models with strong retrieval capabilities for fact-checking multilingual tasks for both monolingual and crosslingual scenarios. Fine-tuning using hard negatives greatly improves the accuracy of the models, while the algorithm for finding optimal weighted configurations for majority vote consistently outperforms naive approaches.

Our future work will revolve around testing the same training methodology on state of the art English text embedding models such as NV-Embed-v2 (Lee et al., 2025) (de Souza P. Moreira et al., 2024) or E5-mistral-7b-instruct (Wang et al., 2024a). In addition, we can also use such models in knowledge distillation processes in order to improve the accuracies of the smaller models used in this paper.

7 Acknowledgments

We would like to especially thank our professor Dumitru-Bogdan Alexe (University of Bucharest), for offering their guidance, expertize and advice in the writing process of this paper.

Abstract

Despite advancement in large language models (LLMs), emotion detection in multilingual settings remains challenging especially in low-resource languages with limited labeled datasets. In this research, we introduce *EmoRationale*, a novel framework leveraging Retrieval-Augmented Generation (RAG) to address cross-lingual generalization in emotion detection. We combined vector-based retrieval with in-context learning in LLMs, using semantically relevant examples to enhance classification accuracy and interpretability. This system provides evidence-based reasoning for its predictions, making emotion detection more transparent and adaptable across diverse linguistic contexts. Experimental results on the SemEval-2025 Task 11 dataset demonstrate that our RAG-based method achieves strong performance in multi-label emotion classification, emotion intensity assessment, and cross-lingual emotion transfer, surpassing conventional models in interpretability while remaining cost-effective. We release our code and model implementation to facilitate further research[1].

1 Introduction

Emotions are the unseen threads that weave together human communication, influencing decision-making, social interactions, and personal well-being (Barrett and Russell, 2014). With the rapid advancement of large language models (LLMs) and the increasing sophistication of AI-driven text analysis (Team et al., 2024; DeepSeek-AI, 2024; Fatemi and Hu, 2024), understanding emotions embedded within text has become critically important across multiple domains including mental health monitoring, customer engagement, and human-computer interaction (Hong et al., 2025). While LLMs have significantly improved sentiment-aware applications, their effectiveness across diverse linguistic and cultural contexts remains inconsistent (Tafreshi et al., 2024). Existing research has primarily focused on high-resource languages, leaving significant gaps in emotion detection for low-resource languages due to a lack of annotated datasets. This disparity hinders the development of inclusive and effective emotion-aware applications (Feng and Narayanan, 2023). To address these shortcomings, BRIGHTER (BRIdging the Gap in Human-Annotated Textual Emotion Recognition Datasets for 28 Languages) takes a major step forward, particularly for low-resource languages to collect multilabeled emotion-annotated datasets particularly for 28 different low-resource languages (Muhammad et al., 2025a; Belay et al., 2025). This paper presents *EmoRationale*, an AI-driven framework designed for the SemEval-2025 shared task "Bridging the Gap in Text-Based Emotion Detection" (Muhammad et al., 2025a), addressing challenges in multi-label emotion detection, emotion intensity assessment, and cross-lingual emotion detection. Leveraging Retrieval-Augmented Generation (RAG), our system integrates the retrieval capabilities of vector databases such as FAISS (Douze et al., 2024) with the generative power of LLMs like the multilingual MiniLM sentence transformer (Reimers and Gurevych, 2019) to incorporate relevant contextual information and bridge gaps in low-resource languages. By combining few-shot prompting with retrieval-augmented generation, *EmoRationale* produces accurate emotion predictions accompanied by explicit, evidence-based reasoning, with extensive ablation studies demonstrating that incorporating in-context examples significantly boosts performance—surpassing traditional fine-tuning approaches such as those based on RoBERTa (Liu et al., 2019). Moreover, our framework exhibits notable cross-lingual transfer capabilities and cost-effectiveness, paving the way for more inter-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 640–650

pretable and efficient emotion recognition systems in multilingual settings.

2 Background

Emotion detection in text is a multifaceted area of research within natural language processing (NLP) that seeks not only to identify basic sentiment but also to capture the rich spectrum of human emotions. Previous research mainly focused on sentiment analysis—differentiating between positive and negative affect (Dang et al., 2020)—but subsequent research has expanded the scope to include discrete emotions such as joy, sadness, anger, fear, surprise, and disgust (Mohammad et al., 2018) (Gupta et al., 2018). While LLMs trained on high-resource languages such as English benefit from extensive corpora, their performance in low-resource settings is hindered by data scarcity, inadequate tokenization, and the difficulty of capturing nuanced emotional cues unique to these languages. BERT (Devlin et al., 2019) has revolutionized NLP by providing deep contextualized representations that capture subtle semantic nuances in text (Abas et al., 2021). Fine-tuning BERT on emotion-labeled datasets enhances its effectiveness in tasks such as multi-label emotion classification and emotion intensity assessment by enabling the model to learn complex emotion-specific features(Qin et al., 2023). These capabilities have been further enhanced through the adoption of multilingual variants of BERT, which facilitate cross-lingual emotion detection by leveraging shared representations learned from extensive and diverse corpora (Hassan et al., 2022). Recent advancements in Retrieval-Augmented Generation (RAG) (Lewis et al., 2021) have introduced a promising avenue for enhancing emotion recognition systems. RAG frameworks leverage retrieval mechanisms to access semantically relevant examples from external knowledge bases, integrating this contextual information with the generative capabilities of large language models (LLMs) to improve accuracy and robustness. Additionally, Chain-of-Thought (CoT) prompting has significantly enhanced LLM reasoning and interpretability, enabling models to decompose complex NLP tasks into structured intermediate steps. This approach has demonstrated notable improvements in various applications, including emotion detection, by guiding models to explicitly articulate their decision-making process (Wei et al., 2023). This evolution underscores the potential of RAG and CoT-based methodologies in advancing emotion-aware AI systems and bridging gaps in interpretable affective computing (Bhaumik and Strzalkowski, 2024).

3 Tasks

In SemEval Task 11 (Muhammad et al., 2025a,b; Belay et al., 2025), participants are invited to tackle one or more challenges that address the complex and nuanced nature of emotional expression in text. Below, we detail the three tracks of the shared task. In Track A, the objective is to determine the set of emotions that the speaker conveys in a given text snippet. Each snippet is labeled with one or more of the following emotions: joy, sadness, fear, anger, surprise, and disgust. Track B builds on the multi-label classification framework by incorporating emotion intensity. In this task, for each text snippet paired with a target emotion, the objective is to predict an ordinal intensity value that indicates the strength of the expressed emotion. Intensity is scaled from 0 (none) to 3 (high). Track C addresses the challenge of cross-lingual emotion detection. In this track, participants are provided with a labeled training set in a source language and are required to predict the perceived emotion labels for texts in a different target language. The label set includes the same six emotions as in Track A.

4 System Overview

EmoRationale employs a retrieval-augmented generation (RAG) framework to classify emotions in text. Our system is composed of three main components: a vector store of labeled training data, a Large Language Model (LLM) prompt that incorporates relevant examples, and an LLM-based inference step.

4.1 Sentence Embedding and Vector Store Construction

As shown in Figure 1(a), we first embed each training text using the multilingual MiniLM sentence transformer (Reimers and Gurevych, 2019). These embeddings capture semantic information in a 384 dimensional vector space. We store the resulting vectors, along with the original text and emotion labels, in a FAISS (Facebook AI Similarity Search) vector store (Douze et al., 2024). This vector store serves as a searchable database that allows for efficient similarity-based lookups. When a new (unlabeled) text is presented as input, we embed it

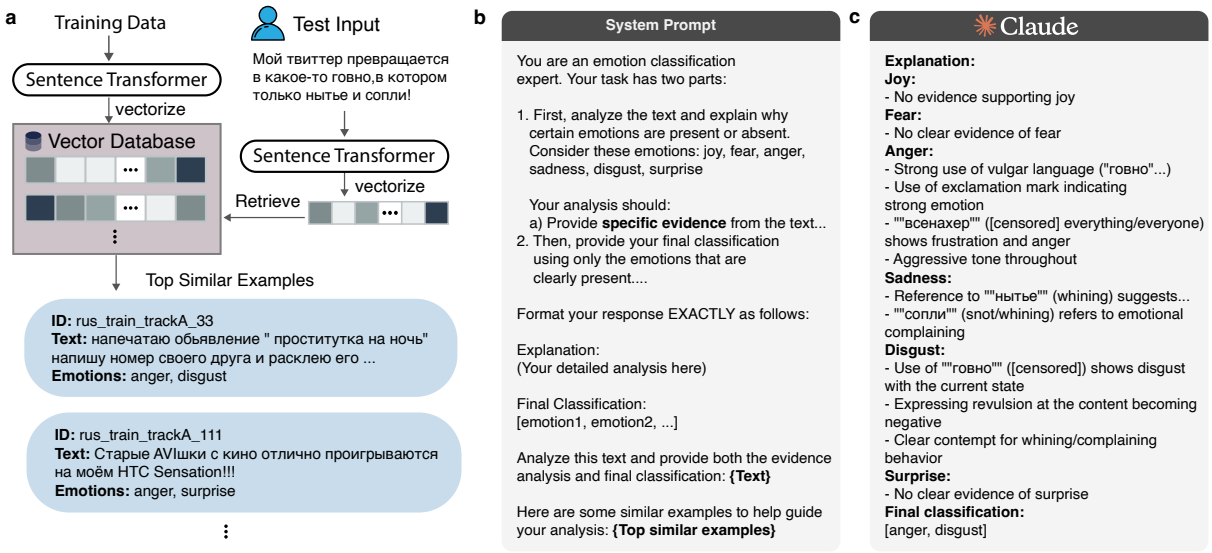

Figure 1: Overview of *EmoRationale*. The system is divided into three primary components. **a.** employs a sentence transformer to convert the training dataset into a vector database; during inference, the input text is vectorized and matched against the database using cosine similarity to retrieve the most similar examples. **b.** displays the system prompt for classification, where the model is first asked to provide evidence-based reasoning for the presence or absence of specific emotions, followed by a final classification. Note that the prompt includes top similar examples to guide the analysis. **c.** shows the output produced by Claude Sonnet 3.5 for the test input featured in panel (a).

using the same sentence transformer model. We then query the FAISS vector store to retrieve the k most similar examples from the training data. In our experiments, we use k=5. Each retrieved example includes its text and the associated ground truth emotion labels.

4.2 Few-shot prompting

Our method constructs a system prompt by first providing clear instructions on how to detect evidence supporting or contradicting each emotion (Figure 1**a**), followed by appending the most relevant examples from the training set as demonstrations. These instructions guide the LLM to methodically analyze linguistic cues and contextual hints, while the retrieved examples offer a concrete reference for how each emotion was identified in similar texts (see Figure 1**b** and appendix A for complete system propmpt). During inference, the LLM is prompted to produce both a concise "Explanation," highlighting which features of the text suggest or rule out particular emotions, and a final bracketed "Classification" (e.g., [joy, fear]). If no emotion is detected, it outputs [none]. This two-part structure provides transparency and interpretability, enabling the system to provide both the reasoning behind its predictions and the specific emotional categories that apply (Figure 1**c**).

4.3 RoBERTa fine-tune

For baseline, we use a pre-trained *RoBERTa-base* model that is fine-tuned for the multi-label classification task. The model architecture is modified by adding an intermediate fully connected layer followed by a ReLU activation and layer normalization, with dropout applied both before and after these layers to mitigate overfitting. A mean-pooled embedding over all token representations is computed, and this pooled embedding is fed into the final classification layer, which maps the processed features to the required number of output classes (six for tracks A and C, and 24 for track B), producing raw logits for each label. The model is fine-tuned using a binary cross-entropy loss with logits, and the AdamW optimizer is employed with differentiated learning rates—a base learning rate of 2×10^{-5} for the pre-trained RoBERTa parameters and a higher learning rate of 1×10^{-4} for the newly added layers. Training is performed over 20 epochs with a batch size of 32 for training, validation, and testing.

5 Experimental Setup

In our experiments, we utilized a T4 GPU from Colab Pro for the multilingual MiniLM sentence transformer. We also conducted evaluations using DeepSeek R1(DeepSeek-AI et al., 2025) with the

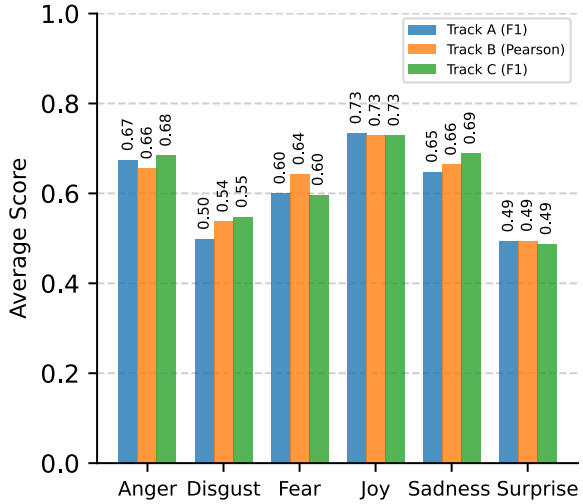

Figure 2: **Average performance scores across emotions for all three tracks in the SemEval 2025 Task 11.** Track A and Track C use F1-scores while Track B uses Pearson correlation coefficients. Joy consistently achieves the highest scores (≈ 0.73) across all tracks, while Surprise shows the lowest performance (≈ 0.49). Anger and Sadness also demonstrate strong performance, while Disgust exhibits the second-lowest scores among the emotions.

685B model for track A, DeepSeek V3 (DeepSeek-AI, 2024) for track B, and Claude Sonnet 3.5 (Anthropic) for track C. The total cost for development and evaluation on the test set amounted to $80.65 for Claude Sonnet 3.5, whereas DeepSeek R1 cost $22.22. However, one notable shortcoming of the DeepSeek API was its unreliability, frequently experiencing interruptions and errors due to high demand.

6 Results

We evaluated our system on all three tracks of SemEval-2025 Task 11: Multi-label Emotion Detection (Track A), Emotion Intensity (Track B), and Cross-lingual Emotion Detection (Track C). Below, we detail our overall performance, present findings from ablation studies, and discuss the impact of our retrieval-augmented generation (RAG) approach. Across all three tracks, models consistently exhibited lower performance for the emotions Surprise (approximately 0.49) and Disgust (approximately 0.53), as illustrated in Figure 2. Detecting surprise and disgust poses significant challenges, primarily because these emotions often depend on nuanced, context-specific, and culturally influenced expressions, which are difficult to interpret accurately through textual analysis alone. Unlike more explicit emotions such as anger or joy, surprise and disgust typically lack distinct verbal cues and thus require additional contextual understanding (Mohammad et al., 2018; Demszky et al., 2020). Furthermore, emotions like surprise can convey either positive or negative sentiments, while disgust may frequently be misinterpreted as anger or fear. Such inherent ambiguities and overlaps further complicate accurate emotion classification for language models.

6.1 Track A: Multi-label Emotion Detection

Table 1 presents the emotion recognition performance for Track A across eight languages. Our system achieves strong and consistent results, with average macro-F1 scores ranging from 0.519 (AFR) to 0.864 (RUS). Notably, the system exhibits high accuracy on languages such as Russian, while maintaining competitive performance on others despite linguistic diversity. Ablation studies further highlight the benefits of incorporating few-shot prompting with relevant examples (Table S1). When compared to the RoBERTa baseline (which was fine-tuned on the entire training dataset), configurations using retrieval-augmented prompts lead to substantial improvements. Although Claude Sonnet 3.5 with RAG provides competitive results, DeepSeek R1 with RAG was ultimately selected for Track A due to its comparable performance and approximately 20-fold cost reduction.

6.2 Track B: Emotion Intensity

For Track B, our task is to predict ordinal emotion intensity values, which introduces additional complexity. As shown in Table 1, performance on intensity estimation varies considerably across languages. For instance, while Russian texts achieve an impressive average macro-F1 of 0.880, other languages such as Ukrainian yield lower scores (0.319).

6.3 Track C: Cross-lingual Emotion Detection

Table 1 also summarizes the results for Track C, which examines the transferability of emotion detection across languages. In this setting, a Portuguese/Brazilian training set is used to predict emotions in Spanish, Russian, and Mandarin. Our experiments show that even with only five in-context examples, the retrieval-augmented prompting enables effective generalization across languages. Ablation studies (see Table S3) reveal that while configurations with full explanation (i.e., reasoning

Table 1: **Test Performance.** This table presents our results on SemEval 2025 Task 11. Track A and Track C scores are reported as F1-scores, while Track B scores are measured using Pearson correlations. For Track A, we utilized DeepSeek R1 (685B parameters), for Track B, we employed DeepSeek V3 (685B), and for Track C, we used Claude 3.5 Sonnet.

for predictions) provide interpretability, prompt variants that omit the reasoning component can yield a modest performance boost—reaching an average macro-F1 of 0.755. In the cross-lingual setting, even with training data from a different language (Portuguese/Brazilian), the system successfully generalizes to Spanish, Russian, and Mandarin. This highlights the model's ability to effectively transfer emotional recognition capabilities across languages using only a few in-context examples, while the fine-tuned RoBERTa-base model struggles to generalize learned knowledge from one language to another.

7 Conclusion and Future Work

In this work, we introduced *EmoRationale*, a retrieval-augmented generation (RAG) framework for explainable emotion recognition that addresses the challenges posed by multilingual and nuanced emotional expressions in text. By integrating robust sentence embeddings with a FAISS vector store and leveraging few-shot in-context learning, *EmoRationale* offers significant advantages in interpretability and cross-lingual transfer—even if it may not achieve the highest raw predictive metrics. The framework provides explicit, evidence-based reasoning for its predictions while effectively generalizing emotion recognition across languages using only a few in-context examples—a feat that conventional fine-tuning approaches, such as RoBERTa-base, often struggle to achieve.

Table S1: **F1 scores across six emotions are presented for each ablation study in Track A.** A combined training dataset from three languages (Spanish, Portuguese/Brazilian, and Russian) was used, with evaluation on corresponding development sets of approximately 200 examples each. Six configurations were assessed: (a) fine-tuning RoBERTa-base on the combined dataset; (b) Claude Sonnet 3.5 without examples (examples refer to data from the combined training dataset); (c) Claude Sonnet 3.5 with random examples; (d) Claude Sonnet 3.5 with relevant examples; (e) Claude Sonnet 3.5 without analysis or explanation for predictions; and (f) DeepSeek R1 with relevant examples. A notable pattern is that, despite providing only five examples to both Claude Sonnet 3.5 and DeepSeek R1 while RoBERTa-base fine-tuning uses the entire training dataset, these models outperform the latter by a large margin. Moreover, they offer interpretability by providing explanations for the presence or absence of an emotion. For Track A, DeepSeek R1 was selected owing to its cost-effectiveness—approximately 20-fold cheaper than Claude Sonnet 3.5—while delivering comparable performance.

Language	RoBERTa Base	DeepSeek v3 No RAG	DeepSeek v3 Random Ex.	DeepSeek v3 w/ RAG	DeepSeek v3 No Reason. w/ RAG

Avg	0.503	0.726	0.739	0.739	**0.755**

Table S3: **F1 scores across six emotions are presented for each ablation study in Track C.** Evaluations were performed using a Portuguese/Brazilian training set, with development sets in Spanish (ESP), Russian (RUS) and Mandarin (CHN) (approximately 200 examples each). Configurations include: (a) RoBERTa-base fine-tuned on the Portuguese/Brazilian data; (b) Claude Sonnet 3.5 without examples (examples refer to data from the training dataset of Portuguese/Brazilian); (c) with random examples; (d) with relevant examples; and (e) without prediction analysis/explanation. Despite using only five examples, Claude Sonnet 3.5 exceeded the fine-tuned RoBERTa-base by 47% in average macro-F1, while also providing interpretable explanations for emotion presence or absence. This demonstrates Claude Sonnet 3.5 capacity to generalize and transfer emotion detection capabilities across languages using training data from a different language.

System prompt for track A and C

You are an emotion classification expert. Your task has two parts:

1. First, analyze the text and provide evidence for and against the presence of each emotion:
   - **joy**
   - **fear**
   - **anger**
   - **sadness**
   - **disgust**
   - **surprise**

   Guidelines for analysis:
   - For each emotion, provide specific evidence from the text that supports or contradicts its presence.
   - Consider both explicit emotional words and contextual implications.
   - Base your analysis on linguistic patterns, word choice, and context.
   - Be objective in your analysis.
2. Then, based on your analysis, provide your final classification in the format: [emotion1, emotion2, ...]
   - Only include emotions that are clearly present.
   - Use only these emotions: joy, fear, anger, sadness, disgust, surprise, none.
   - Do not explain your choice, just provide the list.

Format your response EXACTLY as follows:
Explanation: (Your detailed analysis here)

Final Classification:
[emotion1, emotion2, ...]

Here are some similar examples to help guide your analysis:

Claude 3.5 Sonnet output for track C

Input text snippet:
Ist das nicht schön? Der wichtigste Beitrag der Ukraine für weniger Tote ist deren Korruption. Keine Pointe.

English Translation:
Isn't that beautiful? Ukraine's most important contribution to fewer deaths is its corruption. No punchline.

Claude 3.5 Sonnet Output:

1. **Evidence Analysis:**

   1. Joy:
   - **Against:** While "schön" (beautiful) appears, it's used sarcastically in a rhetorical question.
   - **Against:** Overall tone is cynical rather than joyful.

   2. Fear:
   - **Against:** No expressions of fear or threat present.

   3. Anger:
   - **For:** The sarcastic tone and cynical commentary about corruption suggests underlying anger.
   - **For:** The rhetorical question "Ist das nicht schön?" shows bitter sarcasm indicating anger.
   - **For:** The mention of "Tote" (dead) in connection with corruption implies angry criticism.

   4. Sadness:
   - **For:** Reference to deaths ("Tote") suggests a somber, sad context.
   - **For:** The cynical observation about corruption contributing to deaths carries a sad undertone.

   5. Disgust:
   - **For:** The sarcastic comment about corruption suggests moral disgust.
   - **For:** The connection between corruption and deaths implies disgust at the situation.

   6. Surprise:
   - **Against:** No elements of surprise present in the text.

2. **Final classification:**
   [anger, disgust, sadness]

System prompt for track B

You are an emotion classification expert. Your task has two parts:

1. First, analyze the text and explain why certain emotions are present or absent, and provide an intensity level (from none to very high) for each emotion. Consider these emotions: joy, fear, anger, sadness, disgust, surprise

   Your analysis should:

   - Provide specific evidence from the text
   - Consider both explicit words and contextual implications
   - Be objective and clear
   - Assign an intensity level for each emotion: none, low, moderate, high, very high

2. Then, provide your final classification by listing all detected emotions along with their intensity levels. Use only these emotions: joy, fear, anger, sadness, disgust, surprise, and the intensity levels: none, low, moderate, high, very high.

IMPORTANT

The examples below are provided to help guide your reasoning. They contain insights and annotations from experts who labeled the dataset. Pay close attention to how emotions and their intensities were derived in these examples, and use this understanding to inform your own analysis.

Format your response EXACTLY as follows:
Explanation: (Your detailed analysis here)

Final Classification:
[emotion1, emotion2, ...]

Here are some similar examples to help guide your analysis:

STFXNLP at SemEval-2025 Task 11 Track A: Neural Network, Schema, and Next Word Prediction-based Approaches to Perceived Emotion Detection

Noah Murrant and Samantha Brooks and Milton King
St. Francis Xavier University
Antigonish, NS, Canada
{x2021gth,x2020ccm,mking}@stfx.ca

1 Abstract

In this work, we discuss our models that were applied to the SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection (Muhammad et al., 2025b). We focused on the English dataset of track A, which involves determining what emotions the reader of a snippet of text is feeling. We applied three different types of models that vary in their approaches and reported our findings on the task's test set. We found that the performance of our models differed from each other, but neither of our models outperformed the task's baseline model.

2 Introduction

Detecting emotion in text is a complex task, as it can be challenging to identify an emotion someone is trying to convey in one snippet. It is essential to accurately identify emotions in a text as it has implications in healthcare, social science, humanities, narrative analysis, and several other fields (Muhammad et al., 2025a). It can be easier to detect emotion when someone explicitly states that they are mad or upset or uses adjectives such as delighted, pleased, or glad. "It broke my heart and nearly ruined me" clearly displays sadness and fear. However, a snippet such as "Colorado, middle of nowhere" can make it difficult to determine how people will perceive the reader's emotions. The task we focused on was Track A: Multi-label Emotion Detection, which involves determining the perceived emotions of a speaker of a snippet of text. For the English dataset, there are five possible emotions a snippet can classify as (anger, fear, joy, sadness, and surprise). This is an any-of classification; therefore, each snippet can be labelled with more than 1 emotion. In our work, we applied three different models to Task A on the dataset containing only English text. We wanted to compare three different models that varied in their approach, which included a standard feed-forward neural network-based model, a model that leveraged the idea of schemas — a key part of how humans detect, classify, and process emotions (Leahy, 2018) — and a model that relied on the next-word prediction of a large language model. Furthermore, each model relied on different types or amounts of data which is discussed in Section 4 and Section 5.

Our models did not perform well, but our best Model_FFNN model scored 82 out of 98 participants for the Task A English dataset. The Model_FFNN performed best with respect to the F1-score on the test set, achieving 64.7% [1]. It performed best on the fear class, with an F1-score of 79.03%. The fear class was the most frequent class in the training set, with 1,611 of 2,768 samples having the fear label. Our Model_FFNN's lowest F1-score was on anger, with only 49.68%. Anger had the lowest number of samples, with only 333 samples of 2768 having the anger label.

3 Background

There were three tracks for this shared task. We focused on Track A: Multi-label Emotion Detection. Within this track, we considered the English dataset. The training set contained 2,768 samples of text snippets taken from Reddit[2], as well as personal narratives, talks, and speeches. Each snippet is made up of 1 to 4 sentences. Snippet length varies between 3 words to 81 words (Muhammad et al., 2025a). The number of samples labelled with each emotion is (Anger: 333, Fear: 1611, Joy: 674, Sadness: 878, Surprise: 839). The number of samples labelled with each emotion for both the training set and test set can be seen in Table 1. Along with the provided dataset, we used WordNet synsets (Miller, 1994). We used the synsets for

[1] There is a discrepancy of approximately 0.1% between our results and those calculated by the Task 11 organizers, which we believe is due to rounding.

[2] https://www.reddit.com

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 651–656

the words anger, fear, joy, sadness, and surprise. Two of our models relied on the ability to generate embeddings. To generate these embeddings, We used BERT-Emotions-Classifier [3]. We adapted code from the Hugging face BERT documentation to create the embeddings [4]. The BERT-Emotions-Classifier was trained for the Semeval 2018 task 1 (Mohammad et al., 2018). It was trained on Tweets [5] with labels: anger, anticipation, disgust, fear, joy, love, optimism, pessimism, sadness, surprise, and trust. BERT-Emotions-Classifier can act as a full pipeline, but we only use the embeddings for our models. We did not perform additional preprocessing steps beyond what is described for each individual model, which are discussed in Section 4. Since BERT focuses on masked language modeling and is not designed for next word prediction, we used gpt-2 (Radford et al., 2019) for our model that uses next word prediction to classify text with their perceived emotions. The next word prediction setup could be viewed as completing a cloze-style (fill-in-the-blank) question, where the blank to be completed is the next word. Schick and Schütze (2021) used cloze-style questions to assist with annotating data that will then be used for training. One of the tasks that they evaluate their model on involves predicting the rating of a review. In one of our models, we compare each snippet to a schema structure. Schema theory is a cognitive psychology theory that outlines a set of learned frameworks that allow us to more quickly understand the world around us, make more accurate predictions, and even influence how we view ourselves. We can extract more information about the observation by comparing things we observe to our schemas. They help us organize and interpret information as a collection of related knowledge about a concept or entity, allowing us to quickly understand and process new information based on our past experiences (Leahy, 2018). In the case of emotion detection, by comparing a snippet to an emotion schema and gauging how similar they are, we attempt to extrapolate whether that snippet exhibits that emotion or not.

Table 1: Number of samples labelled with each emotion in training and test sets. Sad is the sadness class. Surp is the surprise class.

4 System Overview

This section discusses the three different models we applied to the SemEval 2025 Task 11—Track A English dataset.

4.1 Model_FFNN

This model uses five separate feed-forward neural network (FFNN) classifiers. First, the snippets are passed into the BERT-Emotions-Classifier, where the embeddings are generated. The embeddings are then passed into the five separate data loaders, one for each emotion, with their associated label, 1 or 0, that the feed-forward neural networks are trained on. Each feed-forward neural network has an input size of 768, a hidden layer size of 512, a dropout of 0.3, and an output size of one. Each FFNN comprises three fully connected layers, where the first two use a rectified linear unit and dropout, and the final layer uses a sigmoid function to produce a final probability of the associated emotion. The FFNNs do not produce a discrete label for the snippet. They only produce a probability for their corresponding emotion. The probability from each FFNN is put into a single array, where each probability represents the likelihood of anger, fear, joy, sadness, and surprise. There are five separate polynomial SVMs, one for each emotion. Each SVM takes in the array of emotion probabilities and the label corresponding to the emotion the SMV is designated. The idea behind using the SVM is to determine the proper threshold for probability and capture any relation between the probabilities. Due to the nature of the dataset, all emotions are weighted toward the false label, creating a disparity in the data and biasing the FFNNs towards classifying every snippet as having no emotion. A threshold of 50% was used for determining the final classification, but we found that the best threshold was inconsistent across all five emotions, and we began using an SVM. The SVMs capture the best threshold for each emotion's probability. For example, if the threshold for anger is

0.3, the SVM can capture that threshold. By giving the SVM all five probabilities, the SVM can detect relations between the probabilities, where if anger has a high probability, the SVM can more accurately predict whether the snippet should be classified as having the joy label. The final output from each SVM is a 1 or 0, with 1 indicating that the snippet expresses the corresponding emotion and 0 indicating that the snippet does not express the corresponding emotion.

4.2 Model_Cosine

This model uses schemas, a psychological structure used for identifying patterns and extrapolating information. For people, schemas are developed over time and encompass a large variety of information, from facial expressions, tone of voice, keywords, familiarity, and other parameters. In our research, we developed a schema by concatenating all snippets with the same label. Additionally, for every member in each WordNet (Miller, 1994) synset of each emotion, we collected the definition of each member. Senses represent the different meanings a word can exhibit and are captured by synsets. Adding the definitions of the members of the synsets of emotions provides more information to the schema. After snippets of text are concatenated and synset definitions are added, the schemas are passed into the BERT-Emotions-Classifier, and a 768-dimension embedded schema is created for each emotion. Given a snippet text to classify, we make an embedding using the BERT-Emotions-Classifier and then compare it to the five embedded schemas by measuring the cosine similarity. The cosine similarity from each comparison is put into an array and then passed to the five polynomial SVMs along with the corresponding emotions label. This is done for similar reasons it is done for the Model_FFNN. The SVMs can determine the best threshold for accurately classifying the snippet and capturing any relation between the similarities. The final output from each SVM is a 1 or 0, with 1 indicating that the snippet expresses the corresponding emotion and 0 indicating that the snippet does not express the corresponding emotion.

4.3 Model_NWP

This model uses next-word prediction to assist with predicting the perceived emotion in a snippet of text. Given a snippet of text, we strip punctuation at the beginning and end of the text and concatenate the resulting text with the string *"and I was"*. For example, if the original text was "*My stomach was hurting.*", it would become *"My stomach was hurting and I was"*. This concatenated text is then used as input to a large language model, which is used to calculate the probabilities for candidate words to be the next word[6]. We used the gpt-2(Radford et al., 2019) model from Hugging Face[7] for our language model[8]. The candidate next words are then ranked based on their probabilities from highest to lowest. We then check the ranking of words from a predefined list of words associated with the considered emotions for the task. If a word in the list is ranked higher than or equal to some threshold k, then the model predicts the emotion that corresponds with that word. The list of words and their corresponding emotions include (*angry:anger*, *afraid:fear*, *happy:joy*, *sad:sadness*, *surprised:surprise*).

5 Experimental setup

For initial training to gauge the performance of *Model_FFNN* and *Cosine*, these two models were trained on 80% (2214 samples) of the training set, then performance was calculated on the other 20% (554 samples) of the training. PyTorch[9] version 2.5.0+cpu was used for Model_FFNN. SciKit[10] Learn version 1.4.0 was used for the SVM involved with models *Model_FFNN* and *Cosine*. For training the feed-forward neural networks, data was batched into groups of 16 and shuffled. We tuned the dropout rate to 0.3 as it yielded the best F1-score and accuracy results. We found that increasing the size of the hidden layers from 256 to 512 also increased the model's performance. Initially, we used a single feed-forward neural network with an input size of 768 and an output size of 5. However, this performance was low, so we moved to five separate feed-forward neural networks binary probabilistic classifiers. We found we had the best results when using all five outputs provided by the FFNNs to determine the binary classification for each emotion. Both models *Model_FFNN* and *Cosine* were trained on the full training dataset before being submitted on the final test set.

[6] We used the implementation suggested by Ruan at https://stackoverflow.com/questions/76397904/generate-the-probabilities-of-all-the-next-possible-word-for-a-given-text to perform next word prediction.

[7] https://huggingface.co/docs/transformers/en/model_doc/gpt2

[8] We used the AutoModelForCasualLM library.

[9] https://pytorch.org/

[10] https://scikit-learn.org/stable/

Model_NWP uses a threshold k, which determines whether or not an emotion is assigned based on if their corresponding word, such as *afraid* for the fear class, appears in the top k candidate words for next word prediction. To tune our threshold *k*, we observe the performance (F1-score, precision, and recall) of the model on a set of samples that includes samples from the provided training and development set by the task prior to testing with respect to the fear class. Limiting the model to tune *k* to one emotion removes the need to have seen other emotions that might be in the test set and allows it to handle unseen emotions. However, we did observe the performance of the model with different *k* values averaged across all emotions before submitting to the task's test set to check that the model was performing near its potential across all emotions in the set that combines the provided training set and development set. We found that the best *k* value for the fear class was 110, which is true for both the set that combined the provided training and development set and only the training set[11]. 110 was also the best *k* value for the performance averaged across all emotions on both sets of samples. Further analysis showed that the best *k* value differs among different emotions. For this model, we only use a *k* value of 110 when applied to the test set.

6 Results

In this section, we discuss the performance of our models. Table 2 shows the per-emotion performance of our models. Table 3 shows the performance of our models compared against other models applied to the task with respect to the F1-score across the full test set.

Model_FFNN was our best-performing model with respect to the macro F1-score and the per-class performance. The Model_Cosine performed better than Model_FFNN in accuracy on anger and joy and only marginally worse in accuracy on the other emotions. Our models performed worse than the task's baseline model RemBERT (Chung et al., 2021) by 6.22%. The Model_Cosine and Model_FFNN performed poorly on recall except when classifying fear, with Model_Cosine R and Model_FFNN achieving a recall of 77.78% and 81.28&, respectively. Precision and recall for both models were approximately even for fear,

[11]There were some k values near 110 that had the same rounded F1-score.

	Anger	Fear	Joy	Sad	Surp
M_FFNN					
Acc	88.58	75.93	84.10	79.93	78.14
F1	49.68	79.03	65.79	66.14	62.45
R	48.45	81.28	63.13	62.20	62.95
P	50.98	79.03	68.67	70.62	61.95
M_Cosine					
Acc	90.50	74.30	84.86	79.40	73.40
F1	40.36	77.16	60.73	59.8	25.05
R	27.64	77.78	48.36	48.13	15.39
P	74.79	76.55	81.61	78.96	67.21
M_NWP					
Acc	77.05	60.03	39.61	63.57	39.61
F1	28.57	71.81	43.26	43.75	45.73
R	39.44	91.26	95.07	44.49	88.11
P	22.40	59.20	28.00	43.03	30.88

Table 2: Accuracy (ACC), F1-score (F1), Recall (R), and Precision (P) per emotion for each of our models (*Model* in the names has been shortened to M). Sad is the sadness class. Surp is the surprise class.

where fear had the highest number of labelled samples, with 1,611 of 2,768 samples having the fear label. Model_Cosine and Model_FFNN had the worst performance for recall when classifying anger, where achieved a recall of 27.64% and 48.45%, respectively. This reflects the difference in the number of samples between anger and fear. Where predicting each emotion can be viewed as a binary classification, the total number of samples trained for each binary classifier is 2,768. For each emotion, the vast majority of these samples will be considered as the negative class (labelled as not having the emotion). Our model might have been susceptible to this class imbalance in the training set. Fear was the closest to having an even distribution, with 1,611 samples labelled with fear and 1,157 as not fear. Our models achieved their best F1-score with regard to the fear class, which could be due to a more even class distribution or the increase in labelled samples. All of our models performed best when classifying fear. Model_NWP was our worse performing model with respect to the averaged F1-score and per emotion F1-score, except for the surprise class, where it outperformed Model_cosine.

Table 4 shows the co-occurrence between all emotions, meaning if we see one label, there is some probability that we are going to see another label. For example, if we see the anger label, there

Model	F1 Score (%)
Track A Best	**82.30**
Track A Baseline	70.83
Track A Average	70.58
Model_FFNN	64.70
Model_Cosine	52.62
Model_NWP	46.55

Table 3: Macro F1-scores of our models compared to other models applied to the task. There was a discrepancy between our calculated F1-score and the task organizer's F1-score of approximately 0.1%. We report the organizer's F1-score here for all models except Model_Cosine and Model_NWP, since we did not have access to those two models' performances.

	Anger	Fear	Joy	Sad	Surp
Anger	1	0.72	0.02	0.46	0.33
Fear	0.15	1	0.06	0.42	0.36
Joy	0.01	0.15	1	0.07	0.23
Sad	0.18	0.78	0.05	1	0.23
Surp	0.13	0.69	0.19	0.24	1

Table 4: Co-occurrences between each emotion, which is calculate as the P(column class | row class). Sad is the sadness class. Surp is the surprise class.

is a 72% chance we will also see the fear label, but only a 2% chance we will see the joy label. Co-occurrence is calculated by counting the number of times a label appears alongside another label, divided by the count of that label. When looking at anger, which appears 333 times, fear appears 239 times; we divide 239/333, so the co-occurrence between anger and fear is 0.72. Fear appears substantially more than anger, with 1611 samples and its co-occurrence with anger is much lower, only 0.15. Given anger, there is a high chance of seeing fear. Given fear, there is a lower chance of seeing anger. Co-occurrence did not seem to influence the models. One of the reasons for using the SVMs was to attempt to capture the relation in the co-occurrence of the emotions. Anger has a high co-occurrence with fear, being 0.72, but our models performed better on the fear class than in the anger class. The anger class also has the lowest number of positive samples. This may suggest that a higher number of positive samples (samples labelled with the target class of each binary classifier) benefits the model.

7 Conclusion

Our models underperformed compared to the task's baseline model, with our best model placing 82 out of 98 on Track A: Multi-label Emotion Detection. Model_FFNN could have underperformed due to the small number of samples. There were only 333 samples labelled as anger out of a total of 2,768 samples, which could have biased this model towards classifying samples as not anger. There is a similar case for the other emotions. Model_Cosine could have underperformed for a similar reason. Our models recruited the use of three different approaches, which included feed-forward neural networks, schemas, and next-word prediction. Although their performance was relatively poor, it would be interesting to examine the effects of data augmentation to decrease the class imbalances with the binary classification setup in future work. Additional datasets could also be recruited to provide more training data, which could assist with the supervised models Model_FFNN and Model_Cosine. Other embedding models could also be considered for our models. Future experiments could also observe if datasets containing audio can be used to assist with a similar classification task by leveraging tonality and emphases to improve the performance of the schema model.

8 Ethical Consideration

Incorrectly classifying a snippet of text with the wrong perceived emotion could have someone act or react with incorrect information. For example, if a snippet of text was incorrectly labelled with anger, then a person interpreting that could react based on incorrect knowledge, where they would otherwise react in a different manner.

Abstract

This paper tackles SemEval 2025 Task 10, "Multilingual Characterization and Extraction of Narratives from Online News," focusing on the Ukraine-Russia War and Climate Change domains. Our approach covers three subtasks: (1) **Entity Framing**, assigning protagonist-antagonist-innocent roles with a prompt-based Llama 3.1 (8B) method; (2) **Narrative Classification**, a multi-label classification using XLM-RoBERTa-base; and (3) **Narrative Extraction**, generating concise, text-grounded explanations via FLAN-T5. Results show a unified multilingual transformer pipeline, combined with targeted preprocessing and fine-tuning, achieves substantial gains over baselines while effectively capturing complex narrative structures despite data imbalance and varied label distributions.

1 Introduction

This shared task "Multilingual Characterization and Extraction of Narratives from Online News" (Piskorski et al., 2025) tackles the analysis of news articles from the Ukraine-Russia War and Climate Change domains through three subtasks. Subtask 1 - Entity Framing, assigning fine-grained roles (protagonists, antagonists, innocent) to named entities using a prompt-based Llama 3.1 8B model (Meta-AI, 2025); Subtask 2 - Narrative Classification, labeling articles via a multi-label XLM-RoBERTa-base classifier (Facebook-AI, 2019); and Subtask 3 - Narrative Extraction, generating explanations for dominant narratives with Google FLAN-T5 (Google-Research, 2022). These tasks are important for understanding how entities are portrayed and how broader narratives are constructed in multi-domain, multilingual settings.

Our key findings indicate that, while pretrained language models help manage complex label sets in multiple languages, class imbalance and domain variability remain challenging. Notable results include Exact Match Ratios up to 0.33670 (Portuguese) for Subtask 1, F1 (samples) up to 0.16300 (English) for Subtask 2, and macro-F1 scores up to 0.69558 (English) for Subtask 3. The system generally excels at frequent labels yet struggles with rare ones, highlighting the need for more balanced data and refined approaches to boost performance across languages.

2 Background

In the field of natural language processing (NLP), significant progress has been made in three key subtasks of SemEval 2025 Task 10: Entity Framing, Narrative Classification, and Narrative Extraction (Piskorski et al., 2025). These studies have used methodologies such as word embeddings analysis (e.g., Word2Vec and multilingual BERT) to capture semantic similarities across languages, as well as clustering and topic modeling techniques (e.g., LDA) to identify thematic patterns in large text corpora.

For Entity Framing, studies such as Kumar et al. (2013) developed Wikipedia-based systems for entity extraction, classification, and tagging in social media, outperforming traditional approaches. In Narrative Classification, Zhang et al. (2005) demonstrated the importance of narrative classification for effective key phrase extraction in web documents, using machine learning methods. In Narrative Extraction, Keith Norambuena et al. (2023) surveyed event-based techniques for extracting news narratives, highlighting their utility in analyzing evolving information landscapes. In the legal domain, Samy (2021) created a linguistic resource for named entity recognition and classification (NERC) in Spanish legal texts, combining regular expressions, external lists, and trained models. These studies employed tools such as machine learning models, transformers, and hybrid techniques, analyzing diverse texts, from news articles to social

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 657–665

media posts and legal documents.

3 System Overview

3.1 Subtask1 - Entity Framing

To approach the Entity Framing track, the following workflow (Figure 1) was applied uniformly across all languages (English, Bulgarian, Russian, Portuguese, and Hindi) to ensure consistency and reproducibility in the multi-label, multi-class text-span classification task.

Our approach addresses the multi-label, multi-class text-span classification task by dividing it into three sequential stages: context extraction, multi-class and multi-label classification. This approach ensures that both the multi-class and multi-label aspects of the task are effectively handled for each language.

Context Extraction For each entity mentioned in the news articles, we extract its surrounding context by capturing the 18 words to the left and right of the entity. This context is then refined using a prompt-based approach with a large language model (**Llama 3.1 8B** (Meta-AI, 2025)). The prompt includes the full news article and the entity, and the model generates a refined context in English, regardless of the original language of the article. This ensures consistency across languages and improves the quality of the context representation. We gave the prompt shown in Appendix A.1 to the model.

Multi-Class Classification: We first fine-tuned a **roBERTa** (Liu et al., 2019) transformer-based model using a dataset with labels closely related to the main roles in our task (Protagonist, Antagonist, Innocent). Then, we performed a sentiment Augmentation. We enriched the context of each entity by incorporating binary sentiment labels (positive or negative) obtained from a sentiment analysis model. Finally, we performed an additional fine-tuning step on the previously fine-tuned model using the sentiment-augmented dataset for each language in the multi-class classification task.

Multi-Label Classification: We cleaned the data in the previously refined generated dataset. We applied a preprocessing function using `spaCy` to clean the text. The details of this function are described later in the paper. Then, we fine-tuned sentence transformers for each language using preprocessed contexts and added multiple emotion labels per context. For English and Portuguese datasets, we used the **sentence-transformers/all-roberta-large-v1** (Reimers and Gurevych, 2019; Liu et al., 2019) model. For the Russian dataset, we used the **sentence-transformers/all-distilroberta-v1** (Reimers and Gurevych, 2019; Sanh et al., 2020) model. For the Bulgarian and Hindi datasets we used the **sentence-transformers/paraphrase-multilingual-mpnet-base-v2** (Reimers and Gurevych, 2019; Song et al., 2020) model. Finally, for each entity, we added multiple emotion labels to its context and generated embeddings. Using cross-validation, we then trained the classifier K-Nearest Neighbors or Random Forest (depending on the language).

3.1.1 Resources Beyond Training Data

For the Multi-Class Classification, we performed **binary sentiment augmentation** (positive or negative) using a model trained on the **sentiment analysis dataset** presented in (Orbach et al., 2021). This model was fine-tuned to assign binary sentiment labels to an entity based on its context. These sentiment labels were added to the refined contexts. The first fine-tuned model was trained using the HVVMemes dataset—a collection of memes related to US politics and COVID-19 (Sharma et al., 2022). This dataset is annotated with three labels: Villain, Hero, and Victim, which closely align with our classification scheme. Specifically, Villain corresponds to Antagonist, Hero to Protagonist, and Victim to Innocent.

For the Multi-Label Classification, we used the **TweetNLP** model (Camacho-Collados et al., 2022), to further enrich the refined contexts generated by **Llama 3.1 8B** model (Meta-AI, 2025). The sentiment labels provided by were added to the contexts.

3.1.2 Use of Llama 3.1 for entities context improving

Our initial approach employed an 18-word window centered on the target entity for context extraction. This approach lacked narrative coverage and included irrelevant tokens, reducing accuracy, Table 1 shows the results. These shortcomings motivated our adoption of Llama 3.1 for context refinement. An LLM processes discourse-level context, maintaining entity coherence across longer spans while filtering noise, yielding more accurate role classification, particularly for ambiguous cases with poor semantic information. Table 2 shows the improvement; 30% of the training data was used for validation/testing.

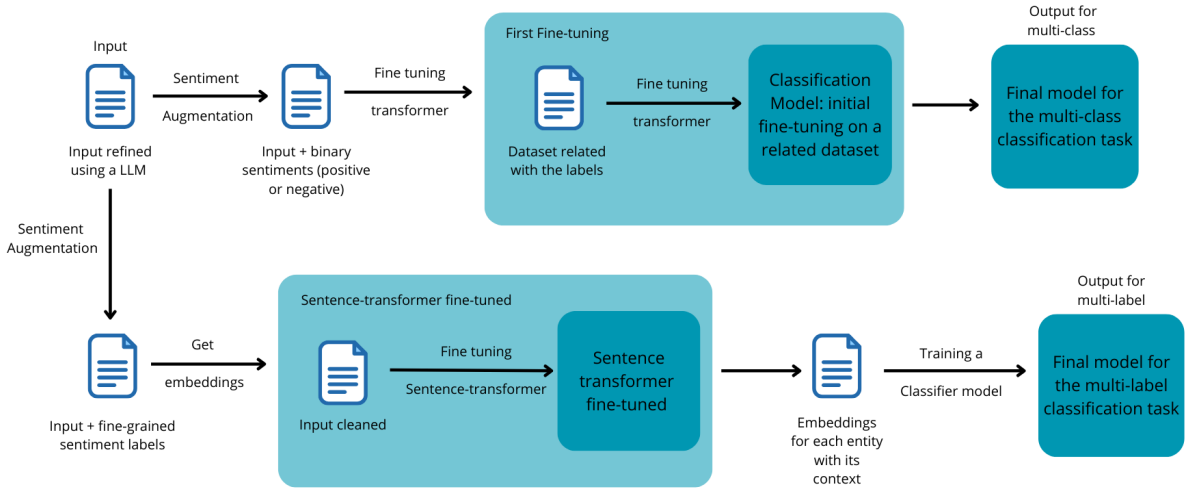

Figure 1: Multi-label classification flow.

	Precision	Recall	F1-score	Support
Antagonist	0.74	1.00	0.85	71
Protagonist	1.00	0.10	0.18	20
Innocent	0.20	0.08	0.12	12
Accuracy	–	–	0.72	103

Table 1: RoBERTa classifier using an 18-word window

	Precision	**Recall**	**F1-score**	**Support**
Antagonist	0.86	0.94	0.90	71
Protagonist	0.65	0.55	0.59	20
Innocent	0.62	0.42	0.50	12
Accuracy	–	–	0.81	103

Table 2: RoBERTa classifier using context generated by Llama 3.1

Llama 3.1 significantly improved the classification of Protagonist and Innocent entities, addressing issues of ambiguity and data scarcity.

3.2 Subtask2 - Narrative Characterization

3.2.1 Key Algorithms and Modeling Decisions

Our approach addresses multi-label multi-class document classification using a two-level taxonomy of narratives (and subnarratives). To effectively capture both levels, we decompose the classification task into three sequential stages (with an adaptation for Russian texts):

1. Binary Classification (Narrative vs. Other): We first distinguish articles that fall under any narrative of interest from those labeled as "Other." This step is omitted in the Russian corpus, as no "Other" category exists there.

2. Multi-Label Multi-Class Classification (Narratives): Once we filter out "Other" articles (or skip directly in Russian), we predict all possible narratives the article may belong to. Each document can have multiple narrative labels.

3. Multi-Label Multi-Class Classification (Subnarratives): For documents assigned one or more narratives in the second stage, we further classify each into their corresponding subnarratives. As before, this is multi-label: an article can contain multiple subnarratives for each of its assigned narratives.

These three stages ensure a clear delineation of responsibilities—separating high-level filtering (stage 1) from more granular classification (stages 2 and 3), as illustrated in Figure 2. We implement all classifiers using XLM-RoBERTa-base, chosen for its multilingual capacity and solid performance across the languages considered in the task.

3.2.2 Model Variants

In our approach, Bulgarian, English, and Hindi employ a three-stage pipeline: (1) a binary classifier distinguishes "Other" from any narrative, (2) multi-label classification identifies possible narratives, and (3) another multi-label classifier targets subnarratives. For Russian, we use a two-stage pipeline by omitting the "Other" label; thus, we directly perform multi-label classification on narratives, followed by subnarratives.

Both variants share the same XLM-RoBERTa backbone (Conneau et al., 2020). Our approach is adapted to varying label distributions across languages using a multilingual transformer model (Wolf et al., 2020).

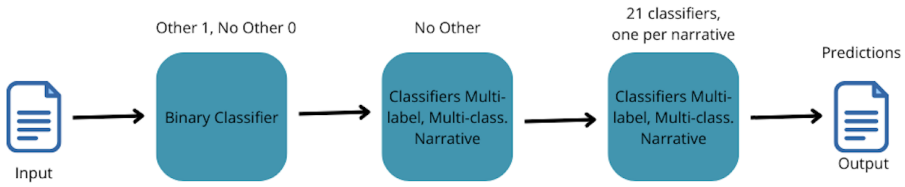

Figure 2: Process diagram for 3 classifiers for Subtask 2

3.3 Subtask 3 - Narrative Extraction

The approach used for this subtask introduces a system based on the fine-tuning of a transformer model for narrative extraction and the generation of an explanation supporting the extracted narrative (Face, 2025). The process is structured into four main stages (illustrated in Figure 3), adapted for four different languages: English, Russian, Bulgarian, and European Portuguese.

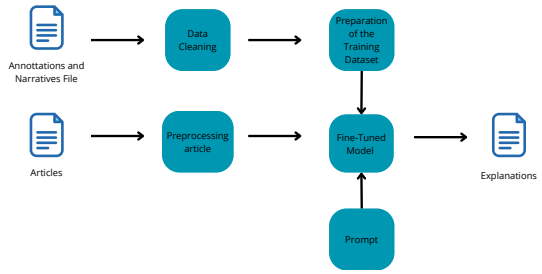

Figure 3: Generate Explanations flow for Subtask 3

3.3.1 Key Algorithms and Modeling Decisions

Data Cleaning: This phase involves two steps. First, cleaning of Annotation and Narrative Files where unwanted prefixes (e.g., "CC:" and "URW:") present in the annotation and narrative files are removed, as these prefixes may be irrelevant and could introduce issues in the generation process. Second, cleaning of articles, where the first two lines of each article are omitted, as they correspond to the title. If a duplicate title is detected, it is also removed. The remaining lines are concatenated to form the complete content of each article.

Preparation of Training Dataset: The system iterates over the annotation rows, and for each row, the corresponding article content is retrieved, and the prompt shown in Appendix A.2 is given.

Then, we fine-tuned the pre-trained Google FLAN-T5 model used for text-to-text generation tasks (Google-Research, 2022). The Hugging Face Trainer API is employed with the hyperparameters as follows: Batch size=4, Epochs=4, Learning rate =3e-5, Save steps= 100 and checkpoint interval=100.

Explanation Generation: The content of all articles is iterated over to generate a structured summary. This summary is derived through the extraction of key sentences using spaCy and NLTK.

Then, we gave a prompt shown in Appendix A.3 is given to the model.

In the postprocessing step, the generated output undergoes refinement that ensures the explanation is adjusted to have a natural opening; overly subjective terms like "obviously" are replaced with more neutral alternatives at the end of the generated text.

4 Experimental Setup

4.1 Subtask1 - Entity Framing

We adopted a stratified split approach to partition the training dataset provided into training, development, and test sets.

For **multi-class classification**, We allocated 90% of the data for training, 5% for development, and 5% for testing. Additionally, for testing purposes, we used the dev dataset provided to simulate a realistic scenario with unseen data.

For **multi-label classification**, We used a 5x2 cross-validation strategy, where the training data was split into 5 parts, with 80% used for training and 20% for testing in each iteration. Again, we used the dev dataset for testing purposes.

4.1.1 Preprocessing and Parameter Tuning

We applied the following preprocessing steps using **spaCy**: First, we removed common stopwords to minimize noise. Next, punctuation marks were eliminated to standardize the text, and extra spaces were reduced to single spaces for consistency. Additionally, we removed numbers and numeric references, as well as special characters, to focus solely on textual content. Finally, lemmatization was applied to reduce words to their base or dictionary

form, ensuring text normalization and improving the quality of the data for subsequent analysis.

About the parameter tuning for **multi-class classification**, the best checkpoint was selected based on the F1-score metric. A softmax function was used to convert raw logits into probabilities.

On the other hand, for **multi-label classification**, using a cross-validation strategy, we were able to obtain the best classifier based on the exact match metric, meaning that the classifier correctly assigns all correct labels to each entity.

The dataset was highly unbalanced, particularly for Innocent entities, as most records were related to Antagonist entities. We did not apply data augmentation or oversampling, as augmenting such data could introduce noise and degrade model performance. To address class imbalance, we first fine-tuned a transformer using the HVVMemes dataset, which was discussed previously.

4.2 Subtask2 - Narrative Characterization

We adopted a stratified split approach to partition our dataset into training and test sets, allocating 80% of the data for training and 20% for testing while maintaining the overall class distribution. Since the dev set presented notable class distribution discrepancies across different languages, we decided to merge the dev set with the training set. Consequently, a combined train+dev set was used for both training and internal validation, and the final test set was solely used to report the official results.

4.2.1 Preprocessing and Parameter Tuning

We used raw text without cleaning—no stopword removal, lemmatization, or stemming—and applied padding and truncation to 128 tokens during tokenization. Fine-tuning was conducted for 3 epochs with a per-device batch size of 8 and a learning rate of 2×10^{-5}; the best checkpoint was selected based on macro-F1 and micro-F1 metrics. No data augmentation was performed. For post-processing, a sigmoid function converts raw logits to probabilities, and labels are assigned when scores exceed a threshold of 0.3, balancing precision and recall (Wolf et al., 2020; Devlin et al., 2018).

Our threshold of 0.3 was chosen based on development set analysis. A standard threshold of 0.5 resulted in too few positive predictions, as the model's outputs rarely exceeded this value, whereas a lower threshold of 0.2 led to many false positives. By evaluating F1 scores, we determined that 0.3 struck the optimal balance, ensuring that texts truly representative of the narrative class surpassed the threshold while minimizing spurious activations.

We did not employ data augmentation or oversampling for classes with very few examples—sometimes as few as 1 to 5—since there were insufficient samples to serve as reliable references. Augmenting such scarce data could have introduced noise and adversely affected the model's performance. Therefore, we aimed to preserve the natural distribution of the narratives.

4.3 Subtask 3 - Narrative Extraction

The training dataset used for the training of the fine-tuned model was divided using an 80/20 split strategy — 80 percent for training and 20 percent for validation. This partitioning was performed using standard functions (such as train test split) to ensure that the validation sample is representative of the entire dataset. The dev set was used for preliminary evaluation of the model, while the test set was exclusively used to report the official results.

5 Results

5.1 Subtask1 - Entity Framing

The model demonstrated strong classification performance across all available languages, consistently ranking within the top 10 positions for each language.

For the **multi-class classification** task the evaluation metric used was **Accuracy**. For the **multi-label classification** task, the **Exact Match Ratio** was the primary metric used to determine the ranking in the competition.

The official results from the leaderboard are presented in the accompanying Table 3.

As can be observed from the results, the performance achieved by the model is highly competitive. The quality of the context surrounding the entities, plays a crucial role in accurately assigning both the main roles and the finer-grained sub-roles. While we utilized **Llama 3.1 8B model** (Meta-AI, 2025) for context refinement, it is possible that more powerful models, such as **DeepSeek R1**, could provide richer and more detailed contexts for the entities.

Finally, an important observation was that the model consistently performed better for languages with Latin-based vocabularies compared to non-Latin languages. This discrepancy could be at-

Language	Exact Match Ratio	micro P	micro R	micro F1	Accuracy for main role	Leaderboard
English	0.3106	0.3671	0.3283	0.3466	0.8383	8
Portuguese	0.3367	0.3872	0.3560	0.3710	0.7172	7
Russian	0.3131	0.3604	0.3524	0.3563	0.6449	10
Hindi	0.2722	0.3711	0.4031	0.3864	0.6361	10

Table 3: Performance scores achieved on the leaderboard for the test set in English, Portuguese, Russia, and Hindi in Subtask 1.

tributed to the limitations of the language model used or the inherent grammatical differences in non-Latin languages, which may make it more challenging to extract meaningful information. Hindi showed strong class imbalance and low performance, partly due to Llama 3.1 generating mixed-language outputs (Hindi and English), which was a problem related to the LLM. This, combined with our limited understanding of Hindi, made it difficult to evaluate and refine the context effectively.

Commonly misclassified labels: Table 4 shows the percentage of misclassifications for each class relative to the other labels in the English Dev dataset. The last column provides examples of entities that were frequently misclassified for each class.

Label	Antag.	Prot.	Inno.	Misclassified samples
Antagonist	95.9%	4.1%	00.0%	climate, sunak, ukraine
Protagonist	44.4%	55.6%	00.0%	russia, conflict, action
Innocent	55.6%	11.1%	33.3%	angeles, conflict, garcetti

Table 4: Misclassified labels on the English Dev dataset by the classifier model.

Ambiguous entities and role confusion often arise with politically charged terms (e.g., "Sunak," "Ukraine") or geopolitical language ("Russia," "conflict"), where context shifts polarity. Negative connotation bias leads to misclassifying Innocent → Antagonist (e.g., "conflict," "action"), as such terms are tied to adversarial contexts. References to places ("Los Angeles") or leaders ("Putin") lack inherent roles but reflect training data biases. Innocent was the most difficult entity type to classify, largely due to the limited number of samples in the dataset, which produces a difficult classification for a multi-label task. Table 5 presents the Exact Match Ratio both overall and broken down by class. It also shows the number of correct predictions relative to the total samples per class, along with the class distribution in the English Dev dataset. This provides a general view of the model's overall performance on the multi-label classification task.

Metric	Overall	Antag.	Prot.	Inno.
Exact Match Ratio	0.32	0.32	0.45	0.00
Correct Predictions	29/91	25/79	4/9	0/3
Class Distribution	100%	86.8%	9.9%	3.3%

Table 5: Fine-grained Role Classification Performance on the English Dev Dataset.

As future work, we propose leveraging verb semantics (e.g., distinguishing between actions such as "negotiate" vs. "attack") to better infer entity roles based on contextual cues. Additionally, incorporating metadata—such as the type of entity (e.g., country vs. individual leader)—could help disambiguate roles and improve classification accuracy. Table 6 presents the results of experiments conducted based on iterative insights. English served as the reference language for approach selection; the methods were first evaluated on the English Dev set, with the best-performing configuration subsequently applied to the remaining languages.

5.2 Subtask2 - Narrative Characterization

We present a multi-stage classification system for English, Bulgarian, and Hindi, targeting both narratives and subnarratives. Our primary evaluation metric is the F1 score at the `narrative_x:subnarrative_x` level, which guided model selection. Overall, our approach outperforms the baseline across all three languages.

In English, binary classification performance is moderate, and multi-label results are strong but affected by class imbalance in the macro-F1. Bulgarian and Hindi achieve high accuracy on the binary task yet show lower F1 for the positive class, also due to imbalance. Across languages, frequent labels are handled effectively, whereas rare labels lower macro-F1.

As shown in Table 7, error analysis indicates frequent misclassifications for labels with minimal training examples, with the system defaulting to more common narratives. This imbalance skews recall toward well-represented classes. Potential improvements include acquiring more diverse data,

Approach	EMR	micro P	micro R	micro F1	Acc. main role
Window-18 words + CountVectorizer	0.04400	0.33330	0.07000	0.11570	0.80220
Llama 3.1 context + CountVectorizer	0.19780	0.23160	0.22000	0.22560	0.86810
Llama 3.1 context + Sentence-Transformer	0.30770	0.31730	0.33000	0.32350	0.86810
Llama 3.1 context + SentenceTransformer + Cross-Validation	0.35160	0.38780	0.38000	0.38380	0.86810

Table 6: Comparison of the performance of different experiments on the English Dev set. The benchmark was established using a RoBERTa multiclass classifier and a KNN multilabel classifier.

oversampling, or using data augmentation to enhance recall for underrepresented narratives.

To validate our approach against a strong general-purpose baseline, we benchmarked it against GPT-3.5 (base). Table 7 shows that our XLM-RoBERTa–based pipeline consistently outperforms GPT-3.5 on binary accuracy and both multi-label micro- and macro-F1 metrics across all languages, demonstrating that specialized fine-tuning yields superior performance compared to off-the-shelf LLM outputs.

Failures centered on underrepresented subnarratives in all three languages,nearly half had fewer than ten examples (many only one), which led to near-zero recall and F1 as the model defaulted to more common labels.

Hindi's poor performance was driven by extreme class imbalance and too few positive examples—causing the binary stage to default to "Other"—while the scarcity of narrative training data hampered reliable learning; translation issues were only a minor factor.

5.3 Subtask 3 - Narrative Extraction

In our latest submission, we integrated data preprocessing, fine-tuned FLAN-T5 model, and employed advanced decoding. Table 8 shows that, despite a robust pipeline, several instances underperformed relative to the baseline.

While the pipeline functioned efficiently across four languages, three evaluations fell below baseline. The model often generated over-simplified outputs, missing key narrative elements, and it struggled with language-specific nuances. These findings suggest the need of more tailored fine-tuning strategies and a richer multilingual training corpus.

6 Conclusions

Our multi-stage architecture—binary filtering followed by multi-label narrative and subnarrative classification demonstrates strong performance on frequent categories and outperforms a baseline system. We evaluated three languages (English, Bulgarian, and Hindi) due to the availability and consistency of data, but the approach generalizes to other languages. Effective capture of major narratives and high micro-F1 suggests robust coverage for well-represented classes. Modular design allows the system to scale and adapt to multilingual contexts with minimal code changes. Reliance on large amounts of representative data for adequate training, classes with fewer than 15 samples defaulted to a single subnarrative, limiting granularity. Finally, we established a pipeline that constructs a model that can both classify and generate narrative explanations. We then fine-tuned a T5-based model for sequence-to-sequence tasks for narrative classification and explanation generation.

A Appendix

A.1 Prompt for subtask 1

Given the following inputs: Full Text: {new text} Entity: {entity} Initial Context: {context}
Refine and enhance the context related to the entity 'entity' to improve text classification for the entity's role. The refined context should:

- Focus specifically on actions, events, or relationships involving the entity that align with one or more of the following roles with its definitions: {descriptions}
- Use the descriptions and examples provided for these roles as a guideline for identifying relevant context.
- Exclude irrelevant or repetitive details, compressing the information into a single concise paragraph.
- Ensure clarity and specificity to support classification, while maintaining alignment with the role definitions.

Provide only the refined context as the output, written as a single paragraph with no introductory phrases or extraneous formatting.

A.2 Constructed Prompt for fine tunning in subtask 3

Input: "Use the following narrative row['dominant narrative'] and the following text to train yourself in order to generate the target explanation. Article-content: row['article content']." **Target**: "Target explanation to generate: row['explanation']".

A.3 Constructed Prompt for explanation generation in subtask 3

Given the dominant narrative row['dominant narrative'], write an explanation of why the following text supports the choice of the narrative. Text: row['processed text']. Use the next template only as a reference to ensure the generated explanation is similar in style row['explanation'].

LATE-GIL-NLP at SemEval-2025 Task 11: Multi-Language Emotion Detection and Intensity Classification Using Transformer Models with Optimized Loss Functions for Imbalanced Data

Abstract

This paper addresses our approach to *Task 11: Bridging the Gap in Text-Based Emotion Detection* at the *SemEval-2025*, which focuses on the challenge of multilingual emotion detection in text, specifically identifying perceived emotions. The task is divided into tracks, we participated in two tracks: Track A, involving multilabel emotion detection, and Track B, which extends this to predicting emotion intensity on an ordinal scale. Addressing the challenges of imbalanced data and linguistic diversity, we propose a robust approach using pre-trained language models, fine-tuned with techniques such as extensive and deep hyperparameter optimization along with loss function combinations to improve performance on imbalanced datasets and underrepresented languages. Our results demonstrate strong performance on Track A, particularly in low-resource languages such as Tigrinya (ranked 2^{nd}), Igbo (ranked 3^{rd}), and Oromo (ranked 4^{th}). This work offers a scalable framework for emotion detection with applications in cross-cultural communication and human-computer interaction.

1 Introduction

Emotions are central to human communication, yet they are inherently complex and often difficult to express or interpret accurately through text, (Mohammad et al., 2018). While we regularly communicate our emotions, the way people perceive emotions in a text can be highly subjective, influenced by individual experiences, cultural backgrounds, and context, (Mohammad and Kiritchenko, 2018).

The *Task 11: Bridging the Gap in Text-Based Emotion Detection*, (Muhammad et al., 2025b), focuses on this challenge, dividing it into two tracks: Track A, which involves multilabel emotion detection, and Track B, which extends this to predicting emotion intensity on an ordinal scale (level 0 to 3). The task is particularly challenging due to imbalanced data and the diversity of languages (28 for Track A and 11 for Track B), each with unique linguistic and cultural nuances, (Muhammad et al., 2025a; Belay et al., 2025a).

This work addresses these challenges by leveraging pre-trained language models from *HuggingFace*, fine-tuned through an extensive search for optimal hyperparameters and custom loss functions tailored to emotion detection. Our approach combines models with advanced techniques such as *Cross Entropy Loss*, *Focal Loss*, and *Label Smoothing*, improving *F1 score* and Pearson correlation metrics, especially for underrepresented languages and imbalanced datasets. Key contributions include:

1. Systematic model selection, hyperparameter tuning, and loss function combination across 28 and 11 languages for Tracks A and B, respectively.

2. Custom loss functions to address the class imbalance and improve performance.

3. Strong results in low-resource languages, such as Tigrinya (ranked 2/35), Igbo (ranked 3/35), and Oromo (ranked 4/37) for Track A.

Our method provides a robust framework for multilingual emotion detection. It has potential applications in cross-cultural communication and human-computer interaction. The main codes used to address this task are available in the *GitHub*[1] repository of our research group.

2 Related Work

Emotion detection and classification have been widely studied in Natural Language Processing (*NLP*), with significant progress driven by deep learning architectures, transfer learning, and

[1]https://github.com/PLN-disca-iimas/Semeval2025-task11

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 666–674

multimodal approaches (Mohammad and Bravo-Marquez, 2017). Early methods relied on lexicon-based techniques and traditional machine learning models, but recent advancements leverage large-scale pre-trained models and hybrid neural architectures to capture complex linguistic patterns more effectively.

The field of emotion detection has evolved from lexicon-based approaches to modern deep-learning models capable of capturing contextual nuances. The adoption of deep learning significantly improved performance by allowing models to learn representations directly from data. Early neural network architectures, particularly recurrent models like Long Short-Term Memory (*LSTM*) networks, enhanced the ability to capture sequential dependencies in text. However, these models required substantial labeled data and computational resources. The introduction of transformer-based models, such as *BERT*, *RoBERTa*, and *XLM-R*, further advanced emotion detection by leveraging self-attention mechanisms to model complex linguistic structures, (Devlin et al., 2018). Pre-trained on large-scale corpora, these models set new benchmarks in emotion detection, outperforming earlier architectures. More recently, *instruction-tuned models*, such as *GPT-4* and *T5*, have shown promise in classifying emotions in ambiguous or contextually complex text, (Longpre et al., 2023). While multimodal approaches integrating textual, auditory, and visual data have gained traction, text-based models remain widely used due to their efficiency and accessibility.

While emotion detection focuses on identifying whether an emotion is present in a given text, an equally important challenge is determining its intensity. Emotion intensity classification has gained increasing attention in *NLP*, with notable advancements in deep-learning architectures and transfer learning. The advent of large-scale pre-trained transformers has further advanced emotion intensity classification. Models such as *BERT* and its derivatives have been fine-tuned on emotion-labeled datasets, achieving state-of-the-art results, (Qin et al., 2023). More recently, frameworks such as *DeepEmotex* have demonstrated the effectiveness of fine-tuned transformer-based models for multi-class emotion classification, significantly outperforming conventional deep learning models, (Hasan et al., 2022).

A major challenge in emotion classification is class imbalance, where certain emotions are significantly underrepresented in datasets. To address the imbalance, recent work has explored hierarchical classification and weighted loss functions to improve model performance in multilingual settings. In the *WASSA 2024* shared task, Vázquez-Osorio et al. (Vázquez-Osorio et al., 2024) proposed a two-stage hierarchical classification approach. The first stage classified tweets into four broad categories, while the second stage further distinguished between underrepresented emotions. Additionally, they employed *FocalLoss* and weighted *CrossEntropyLoss* to emphasize minority classes during training. Their approach, implemented with a fine-tuned *DeBERTa-v3-large* model, resulted in improved performance, ranking among the top 15 submissions. These findings highlight the effectiveness of hierarchical classification and adaptive loss functions in handling imbalanced emotion datasets.

Recent work on multilingual emotion detection (Belay et al., 2025a,b) highlights challenges such as class imbalance and low-resourced languages. Therefore, our approach introduces custom loss functions for imbalanced data, which is critical for some languages with underrepresented data.

3 System Overview

Our system is based on fine-tuning pre-trained transformer models for multilingual emotion recognition and intensity prediction. We designed a two-stage pipeline tailored to the task's requirements of Track A and Track B. In Track A, we focused on detecting the presence of emotions in text through multilabel classification. In Track B, we extended this setup by incorporating an additional step to predict the intensity of each detected emotion. All models were language-specific and selected based on empirical performance.

For Track A, we fine-tuned a multilabel binary classification model for each language to determine whether each emotion was present in the text.

Track B expanded on Track A's process, incorporating a two-step approach to predict emotion intensity. The initial step, the same as in Track A, employed the multilabel classification model to identify emotions. In the next phase, if an emotion was detected (label 1), a separate model estimated its intensity on a scale from 1 to 3.

All our models were based on pre-trained transformer models, which were selected as the most suitable for each language.

3.1 Fine-tuning process

Fine-tuning is the process of adapting the weights of the neural network to optimize the performance for one specific task.

Our approach involved two sequential fine-tuning steps:

1. Binary emotion detection: We first fine-tuned a multilabel classification model to determine whether each emotion was present in a given text. The best-performing model variant for each language was selected based on this step.

2. Emotion intensity classification: Once the best binary classification model was identified, we fine-tuned separate models, one for each emotion intensity prediction. These models classified intensity levels into three categories (1, 2, and 3).

We performed hyperparameter optimization on all fine-tuned models. For Track A, only the first step was necessary. For Track B, both steps were required. Figure 1 shows the workflow of model prediction generation for both tracks.

3.2 Loss Function Optimization

We experimented with multiple loss functions, including standard *Cross Entropy Loss*, *BCE With Logits Loss*, *Focal Loss*, *Label Smoothing Loss*, *MSE Loss*, and a custom loss function that averaged *Focal Loss* with sum reduction, *Weighted Cross Entropy Loss* and *Weighted Smooth Cross Entropy Loss*. This approach has been effective in handling imbalanced datasets, as proposed in (Shi et al., 2024)

To optimize performance in Track A, we experimented with various loss functions and tested a code implementation that combined different previously mentioned losses. The results in Table 4 showed that *BCE With Logits Loss* and *Cross Entropy Loss* were the most frequently selected in the tested combinations, leading to better performance on imbalanced datasets.

For Track B, for each language-emotion combination, we trained models with both *Cross Entropy Loss* and the custom loss function and selected the one that yielded the best performance. As a result, some models used cross-entropy, while others benefited from the custom loss function. In some cases where the training dataset was highly imbalanced, the custom loss function generally provided better results.

4 Experimental Setup

4.1 Data

The dataset provided for all task languages was delivered in separate corpora and divided into three standard splits: *train*, *dev*, and *test*. The *train* and *dev* sets contained golden labels, whereas the *test* set contained no labels. The data were divided as follows:

- Development phase: 80% of the *train* set was used for training the models, and the remaining 20% was reserved for validation during the development phase. This was done for all stages of our solution, i.e., model selection, hyperparameter tuning, and custom loss functions combination. The data split was performed in a stratified way for the emotion classes. The *dev* set was used exclusively for testing the trained models and evaluating their performance, with a particular focus on the macro *F1-score*, which was the primary evaluation metric for Track A.

- Test phase: After finalizing the best-performing model and hyperparameters, the model was retrained using the entire set of *train* and *dev* (combined) to make predictions in the unlabeled test set without an explicit validation stage in the training.

For Track B, the same data split strategy was applied, but the task was extended to predict the intensity of the emotions for each emotion class in the provided languages. In this track, each dataset contains texts annotated with one of six emotions (five for English), with intensity levels ranging from 0 (lower/no emotion detected) to 3 (higher level of intensity). However, a strong class imbalance was observed in all data sets. Most instances were labeled with an intensity of 0, indicating the absence of emotion. A smaller proportion of instances had an intensity of 1, while intensity level 2 was even less frequent. Instances labeled with the highest intensity, 3, were extremely rare and almost nonexistent in some datasets. This imbalance was a consistent pattern across all languages, posing a challenge for model training and evaluation.

4.2 Methods

4.2.1 Preprocessing and Parameter Tuning

The preprocessing and parameter-tuning process involved the following steps:

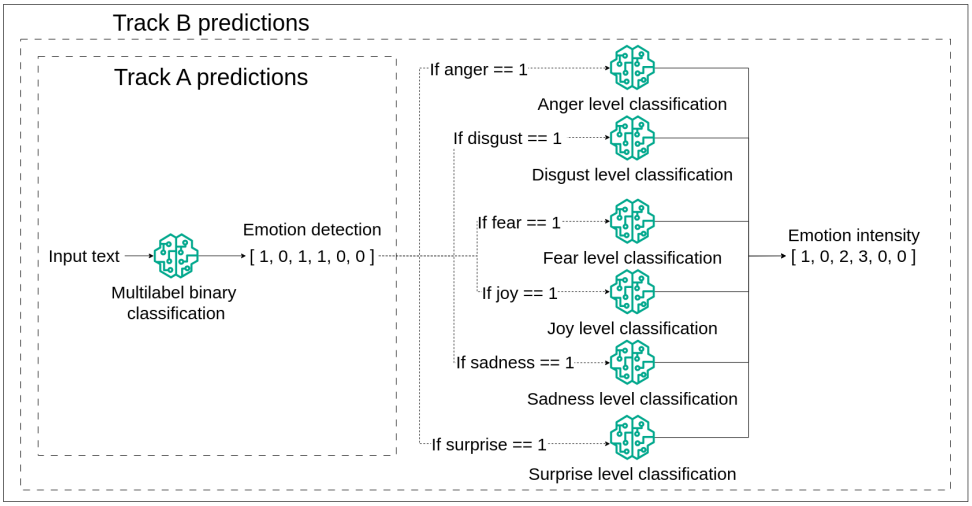

Figure 1: System workflow for predictions

1. **Model selection:** *Python* script was developed to evaluate multiple pre-trained models available on *HuggingFace* that supported the target languages. Models were filtered based on language compatibility, and the top 5 most downloaded models for each language were selected for initial testing. Each model was fine-tuned for 1 epoch on the training set to identify the best-performing model for each language.

2. **Hyperparameter tuning:** A grid search was conducted to optimize hyperparameters using the best-performing model identified in the previous step, all models were trained with the *AdamW*[2] optimizer. The hyperparameters and their respective search ranges were as indicated in Table 1:

Hiperparameter	Proposed values			
Learning rate	$1e^{-5}$	$2e^{-5}$	$3e^{-5}$	$5e^{-5}$
Weight decay	0.001	0.01	0.1	
Dropout prob	0.3		0.5	

Table 1: Proposed hyperparameters for grid search

3. **Custom Loss Functions Combination:** To further improve performance, a customized loss function selection process was applied. The following loss functions were evaluated in all possible combinations: *BCEWithLogitsLoss*, *MSELoss*, *CrossEntropyLoss*, *FocalLoss* with *alpha*=0.25, *gamma*=2.0, *LabelSmoothingLoss* with *smoothing*=0.1.

4. **Final Model Training:** After identifying the best model, hyperparameters, and loss function combination, the final model was trained on the combined *train* and *dev* sets for submission on the *test* set.

4.3 External tools and libraries

The following tools and libraries were used for preprocessing, training, and evaluation:

- *HuggingFace transformers*[3]: For accessing and fine-tuning pre-trained language models.
- *PyTorch*[4]: For implementing custom loss functions and training pipelines.
- *Scikit-learn*[5]: For evaluating model performance using metrics such as macro *F1-score*.
- *Pandas*[6] and *NumPy*[7]: For data manipulation and preprocessing.

4.4 Test Phase Submissions

For the test phase in Track A, three submission attempts were made:

1. **First submission:** Predictions were generated using models trained with the best hyperparameters and custom loss functions.

2. **Second submission:** Predictions were generated using models trained only with the best hyperparameters (without custom loss functions).

[2] https://pytorch.org/docs/stable/generated/torch.optim.AdamW.html

[3] https://huggingface.co/

[4] https://pypi.org/project/torch/

[5] https://pypi.org/project/scikit-learn/

[6] https://pypi.org/project/pandas/

[7] https://pypi.org/project/numpy/

3. **Third submission:** The best-performing predictions from the first two submissions were selected based on their macro *F1 scores* and submitted as the final results.

4.5 Track B Extension

For Track B, the approach was extended to predict the intensity for each emotion class. Separate models were trained for each emotion and language, following the same pipeline as Track A but adapted for the ordinal intensity classification task. However, it is important to mention that, due to a lack of resources and time, we only made one submission in this final/test phase for this track.

5 Results

Macro *F1 score* was the official metric for Track A, and Table 2 shows only the third submission's results with its unofficial ranking. Our best score was 0.8731 in Hindi, ranking 14^{th}, while for Tigrinya, we placed 2^{nd} with a performance of 0.5874.

Language	Ranking	Macro *F1 score*
Afrikaans	31	0.3496
Amharic	22	0.5815
Arabic (Algerian)	30	0.4862
Arabic (Moroccan)	22	0.5132
Chinese (Mandarin)	26	0.5742
Emakhuwa	17	0.1626
English	21	0.7632
German	20	0.6334
Hausa	21	0.6149
Hindi	14	0.8731
Igbo	3	0.5628
Kinyarwanda	9	0.5112
Marathi (English)	30	0.7876
Nigerian Pidgin	23	0.5173
Oromo	4	0.5920
Portuguese (Brazil)	17	0.5470
Portuguese (Mozambique)	12	0.4754
Romanian	25	0.7082
Russian	37	0.7975
Somali	25	0.3692
Spanish	31	0.7517
Sundanese	25	0.4083
Swahili	20	0.2850
Swedish	31	0.4599
Tatar	18	0.6554
Tigrinya	2	0.5874
Ukrainian	31	0.4748
Yoruba	6	0.3754

Table 2: Results for each language in Track A

Table 3 shows the results for every language in Track B. Pearson correlation was used as the official evaluation metric for Track B. It evaluates the degree of linear association between the predicted labels and the gold ones. Our highest score was in Russian with a value of 0.7793.

As we can see, for both tracks, the macro *F1 score* and the Pearson correlation vary significantly across languages. Given that for each language, we fine-tuned a language-specific model, we can observe that the results are highly dependent on the base model. For Hindi, English, Russian, and Spanish, the scores are considerably higher compared to languages like Amharic, Algerian Arabic, or Ukrainian.

Language	Ranking	Pearson correlation
Amharic	15	0.4787
German	23	0.4676
English	23	**0.7228**
Spanish	22	0.6719
Portuguese (Brazil)	16	**0.5079**
Russian	24	0.7793
Arabic (Algerian)	17	**0.3982**
Chinese (Mandarin)	20	**0.4842**
Hausa	11	**0.6360**
Ukrainian	19	**0.4196**
Romanian	15	**0.6053**

Table 3: Result for each language in Track B.
Note: The Pearson correlation results shown in **bold** exceeded the organizers' baseline.

Other factors to take into consideration that can influence the performance of the classification models include the size of the dataset and class imbalance (see Appendix B for details on class distribution for Track A).

Unlike top teams reported in the Task paper (Muhammad et al., 2025b), such as Pai and Chinchunmei, who rely on large LLM ensembles, contrastive learning, and prompt engineering, our approach focuses on robust fine-tuning of pre-trained models using hyperparameter optimization and tailored loss functions for imbalanced and low-resource data. Without external augmentation or instruction tuning, our method achieved competitive results, ranking in the top 10 in multiple languages and significantly outperforming baselines in 17 languages, highlighting the strength of our optimization-based strategy (see Table 4). In addition, our system prioritizes reproducibility, with a simplified architecture and fully documented training settings, making it practical and easy to reproduce with promising results.

6 Ethical Considerations

Predicting perceived emotions and their intensity is inherently subjective and influenced by cultural and individual differences. Biases may arise from the dataset, the annotation process, or the model

itself. As noted in (Muhammad et al., 2025a), the dataset focuses on perceived emotions (what most annotators believe the speaker may have felt and their intensity) rather than determining the true emotional state of the speaker. Therefore, our prediction models should not be used for high-stakes decisions, nor should their outputs be interpreted as definitive assessments of the speaker's actual emotions or intensity. For more ethical considerations and details on the data annotation process, see (Muhammad et al., 2025a).

7 Conclusion

In this paper, we presented our approach to the emotion detection and intensity classification task at *SemEval-2025*. Our approach leveraged fine-tuned models based on pre-trained transformer models. We achieved our best results by incorporating some custom loss functions for certain languages and emotions, demonstrating their effectiveness in handling imbalanced data. However, the performance varied significantly across languages, underscoring the importance of further analyzing and exploring additional techniques and architectures.

A Appendix 1: Experimental Setup Final Training

Table 4 summarizes the configurations and results for the final training of models in Track A, covering all 28 languages. For each language, we report the best configuration of model architecture, learning rate, weight decay, dropout probability, and the combination of custom loss functions, which were used during the training of the final model used in the competition phase. If no loss function is found in the language row, this indicates that the best configuration obtained omits the use of any of the custom loss functions. The custom loss functions are encoded as follows: *BCEWithLogitsLoss* (1), *CrossEntropyLoss* (2), *FocalLoss* (3), and *LabelSmoothingLoss* (4). The table also includes the unofficial ranking achieved by our final submission, with results exceeding the organizers' baseline highlighted in bold. Submissions marked with an asterisk (*) represent the best-performing configuration combining hyperparameters and custom loss functions, while double asterisks (**) indicate submissions using only the best hyperparameters (without custom loss functions). For some languages (marked with ***), the model was trained differently due to the unique structure of the pretrained model used. This table highlights the effectiveness of our systematic approach, particularly in low-resource languages, where our method achieved competitive rankings, such as Tigrinya, Igbo, Nigerian Pidgin, and Yoruba.

B Appendix 2: Heatmap of emotions distribution by language

Figure 2 shows a heatmap of emotion distribution across languages. It can be observed that English (ENG) has a noticeable imbalance in its emotional distribution, with *Fear* making up a large portion at 58.2% and *Sadness* following at 31.7%. Similarly, Chinese (CHN) and Brazilian Portuguese (PTBR) stand out for their unusually high levels of *Anger*, at 44.6% and 32.3%, respectively. The most striking case is Sundanese (SUN), where *Joy* dominates, making up a significant 72.7% of the texts. On the other hand, some languages show a clear lack of certain emotions. For example, Afrikaans (AFR) and Ukrainian (UKR) have surprisingly low levels of *Anger*, at just 3.6% and 4.0%, respectively. Meanwhile, Oromo (ORM) and Yoruba (YOR) fall short in representing *Sadness* (8.7%) and *Joy* (9.1%), respectively.

Language	Pre-trained model	Learning rate	Weight decay	Dropout prob	Custom loss functions used	Unofficial ranking

Abstract

In this paper, the authors address the challenges of multi-label emotion detection in the Algerian dialect by proposing a novel Label-fused Iterative Mask Filling (L-IMF) data augmentation technique combined with a multi-model architecture. The approach leverages DziriBERT, a BERT variant pre-trained on Algerian text, to generate contextually and label-sensitive augmented data, mitigating class imbalance while preserving label consistency. The proposed method uses six independent classifiers, each trained on a balanced dataset for a dedicated label, to improve performance. The results show significant improvement on the multi-label classification task using Deep Learning, with an official Macro F1 score of 48.6% and a best score of 51.2%.The system ranked 28/41 on the Algerian dialect scoreboard, achieving scores more than 7% to 9% higher than the task baseline using RemBERT.

1 Introduction

Dialectical Arabic, like any low-resource language, offers many challenges in the areas of Natural Language Processing. Lack of High-Quality Annotated datasets for tasks makes it particularly difficult to train Machine and Deep Learning models on downstream tasks like sentiment analysis, machine translation, named entity recognition, and emotion detection. Other challenges when dealing with Dialectic Arabic include increased morphological complexity, and variety of dialects,and variation within dialect itself, in a fairly close geographical space, making it considerably harder to develop a generalizable model(Faheem et al., 2024).

Hence, when dealing with a certain Arabic dialect, such as the Algerian dialect, one ought to be resourceful in both data pre-processing and model selection, leveraging any data pre-processing tool that might increase data size without degrading data quality, which could enhance model performance and generalizability. Furthermore, leveraging certain systems and model architecture techniques might alleviate bottlenecks in tasks like multi-label classification(Tarekegn et al., 2024).

The proposed data augmentation strategy, **L**abel-fused **I**terative **M**ask **F**illing (L-IMF), is a resourceful and contextually-based data augmentation technique that uses DziriBERT, a BERT model variant pre-trained on a large Algerian corpus (Abdaoui et al., 2021). Besides the proposed augmentation strategy, the usage of 6 DziriBERTs is also proposed to train on the given task by breaking down the multi-label technique into a set of binary classification tasks, with each DziriBERT dedicated to resolving one. The proposed system architecture addresses common problems associated with deep learning applications in multi-label classification tasks, primarily imbalanced data.

Despite limited time for optimization, the proposed system achieved strong results. This success was driven by a novel data augmentation technique, which expanded the original 901 training instances into over 15,500 samples, and by a model architecture that addressed multi-label classification using a binary relevance problem transformation. Two sampling strategies were applied. In the undersampling approach, a subset of the augmented samples was strategically selected to mitigate the dataset's intrinsic class imbalance, contributing to improved performance. In the oversampling approach, data from the minority class was increased to achieve class balance.

The remainder of this paper is structured as follows: Section 2 provides a background overview of the task and related work. Section 3 describes the proposed system. Section 4 presents the experimental setup, followed by results in Section 5. Section 6 concludes the paper and outlines potential future work. Finally, Section 7 discusses ethical considerations, while Section 8 includes

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 675–683

acknowledgments.

2 Background

The proposed system was designed for Track A: Multi-label Emotion Detection (Muhammad et al., 2025b), which predicts multiple emotions from text snippets. Each input is assigned a binary label (1 or 0) for six emotions; joy, sadness, fear, anger, surprise, and disgust; indicating their presence or absence. The Algerian dialect dataset includes 901 labeled training instances with gold-standard annotations, 100 validation instances, and 902 test instances (Muhammad et al., 2025a).

Multi-label classification extends beyond single-label approaches, allowing multiple classes to be assigned to the same input, sometimes with varying intensity levels (Tarekegn et al., 2024). This approach is widely used across fields, including healthcare, document classification, and emotion recognition.

Various approaches have been proposed to address challenges in multi-label learning. Traditional problem transformation techniques include binary relevance, classifier chain, and label Powerset.

In binary relevance, the multi-label problem is divided into multiple binary classification tasks, where each class is predicted independently and later combined into the final multi-label output. While simple to implement, this method ignores label dependencies, co-occurances, and correlations. Classifier chain addresses these limitations by modeling binary label predictions sequentially, allowing the model to learn relationships from earlier predictions. Label Powerset treats each unique label combination as a distinct class, meaning a six-class binary output results in 64 possible label combinations. However, both classifier chain and label Powerset are computationally expensive and struggle to capture high-order label correlations (Tarekegn et al., 2024).

With the rise of Deep Learning, researchers have explored neural architectures to bypass these traditional transformations. (Yang et al., 2018) used a LSTM layer as a decoder in multi-label document classification tasks where the LSTM layer produces labels sequentially and predicts the upcoming label from previous ones, thus allowing the high order capturing of label relationships. Transformer based model also were used in multi-label classification.

Despite Deep Learning models' ability to overcome the need for traditional problem transformation, many issues have been noticed in the usage of Deep Learning systems in multi-learning classification tasks. One of those limitations include difficulty in capturing high-order label dependencies, where it has been noted that Deep Learning has yet to overcome that inability to effectively address more that two labels simultaneously. There is also an issue with difficulty in addressing class imbalance in multi-label classification tasks. It has been noted that, compared to traditional problem transformations' approaches to resolve class imbalance, Deep Learning approaches are still underdeveloped(Tarekegn et al., 2024).

Several studies have attempted to address these challenges in Arabic multi-label text classification.(Aslam et al., 2024) used three BERT models, MarBERT, AraBERT and ArabicBERT for embedding extraction of a preprocessed arabic 2018 SemEval multi-label dataset where the word embeddings are then concatenated then passed to a meta learner made of a BI-LSTM layer that produces the multi-label outputs. The system was trained using a custom hybrid loss function that leverages label correlation matrix, contrastive learning, and class weighting, the use of three BERT models as extraction embeddings enhanced generalization, and the use of the custom hybrid loss function reduced to the negative effects of class imbalance present in the data along with promoting label dependency and correlation present in the data.

(Taha and Tiun, 2016) have noted the limited attention allocated by researchers towards multi-label classification for Arabic text. Binary classifier, their work proposed a binary relevance model that consists of different traditional machine learning classifiers. They also used multi-label classification for Arabic news articles. This is where each traditional machine learning classifier was trained on a distinct dataset to be able to categorize a news article as belonging to a class or not. They used different combinations of KNN, SVM and NB to be trained on different pre-processed text on different feature selection techniques, they found that a heterogeneous system of the different traditional machine learning model training on text preprocessed on chi-squared as feature selection performed the best results.

Proposed systems for Arabic multi-label classification using Deep Learning include those highlighted by Al-Smadi. (Al-Smadi, 2024) proposed DeBERTa-BiLSTM, which is a DeBERTa model

with a BiLSTM layer that receives the hidden state of the pre-trained DeBERTa model for the purpose of labeling FAQ Covid-19 multi-label dataset released from Arabic digital health platform Altibbi. The author trained the model using a Binary Cross-Entropy with Logits Loss as a loss function, thus treating each label independently as a binary classification problem.

Contrary to the belief that Deep Learning forgoes the need for traditional problem transformation, (Yang and Emmert-Streib, 2024) proposed a Deep Learning system that also successfully integrate traditional problem transformation; Yang and Emmert-Streib developed BR-CNN(Binary-relevance Convolutional neural network) with a custom weight scaling factor in the Binary Cross-Entropy loss function, BR-CNN achieves state-of-the-art performance on AAPD and MIMIC-III datasets, also outperforming models that leverage label dependencies.

While Deep Learning advancements have improved multi-label classification, challenges such as data scarcity and class imbalance persist. To address these issues, data augmentation techniques are employed to synthetically expand datasets, enhancing model performance, generalizability, and robustness while reducing overfitting.

Leveraging pre-trained language models has also been noted to be an effective technique that enhances model performance; Hence, it was successfully used in english classification tasks. One of the successful usages of pre-trained langauge models for english data augmentation is outlined by (Kesgin and Amasyali, 2023). Kesign and Amasyali proposed Iterative Mask Filling, a BERT augmentation technique that iteratively replaces words using masked language modeling to produce a single final augmented sentence for each input sentence. The proposed method outperforms traditional data augmentation approaches like synonym replacement, back-translation, and random modifications in topic classification. By using probabilistic word replacements and confidence based filtering, Iterative Mask Filling significantly improves model robustness. It was noted by the authors that the approach limited effectiveness in sentiment analysis, due to some words being critical in determining sentiment, when masked, allowing for the chance for the filled word to change the entire sentiment of the subsequent fully augmented sentence.

Another english data augmentation technique through language models is sketched by (Wu et al., 2019). Wu et al. proposed Conditional BERT (C-BERT), which is a fine-tuned version of BERT that performs context-aware word filling of randomly masked tokens. C-BERT outperforms other data augmentation techniques mentioned like random synonym replacement from WordNet and Contextual augmentation proposed by (Kobayashi, 2018).

Arabic literature, comparatively, has limitedly explored data augmentation techniques in the field of Arabic text classification. (Sabty et al., 2021) employed methods such as modified Easy Data Augmentation (EDA), back-translation, and word embedding substitution for Arabic Named Entity Recognition (NER) tasks, achieving positive but varying results. Similarly, (Abuzayed and Al-Khalifa, 2021) observed substantial improvements in classification performance through label augmentation.

(Refai et al., 2023) were one of the few researchers to use Transformer-based data augmentation in Arabic text classification, they leveraged AraGPT-2 and AraBERT for generative data augmentation, demonstrating significant performance gains in Arabic sentiment analysis. Additionally, (Carrasco et al., 2021) utilized Generative Adversarial Networks (GANs) to generate dialectal Arabic datasets for sentiment analysis, reporting enhanced model performance when training on the augmented dataset.

3 System overview

3.1 Label-fused iterative mask filling

3.1.1 Augmentation

In low-resource settings, any trained feature space that can be utilized for data augmentation or model enhancement has the potential to significantly improve performance on downstream tasks. The Algerian dialect presents challenges for data augmentation due to limited linguistic resources. For instance, synonym replacement is not a viable augmentation technique, as no comprehensive lexical database comparable to WordNet exists. More advanced techniques, such as back-translation, are also impractical since most Arabic-English translation models are designed for Modern Standard Arabic (MSA) and do not effectively handle dialectal variations.

Techniques leveraging pre-trained language models, such as iterative masking or Conditional BERT, pose additional challenges for multi-label

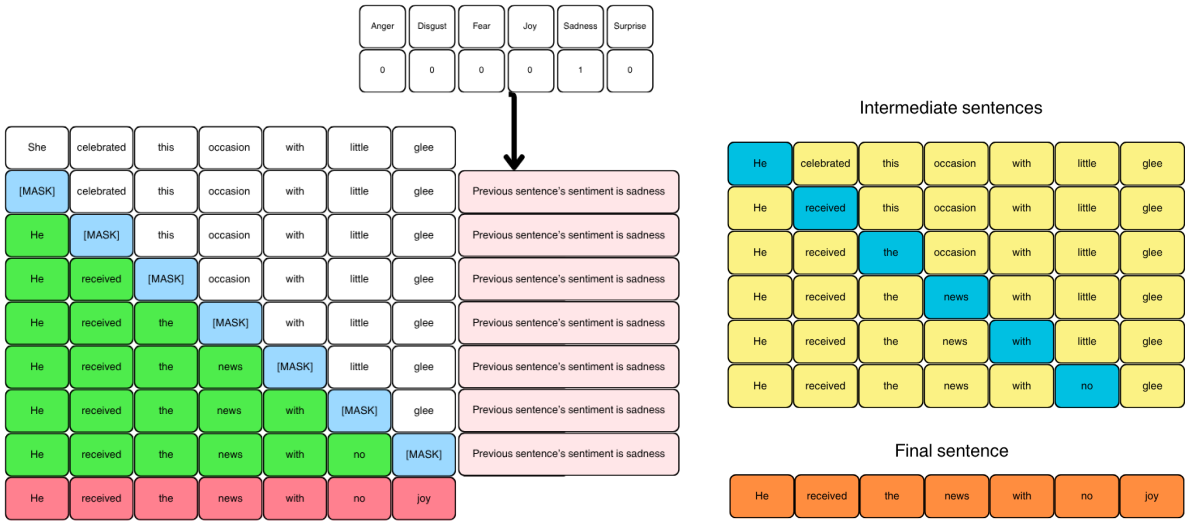

Figure 1: Left figure displays the process Label-fused Iterative Mask Filling . Right figure displays the output of the process.

sentiment-based tasks. Iterative mask filling has a detrimental impact on sentiment-based tasks, while Conditional BERT requires a large dataset for fine-tuning and does not support multiple simultaneous labels.

Data analysis revealed a significant class imbalance in certain instances, with 5 out of 6 emotion labels showing a data imbalance of more than 60% toward one of the labels, with only the sadness label having 44.84% labeled as 1 and 55.16% as 0. More than 57% of instances were annotated with at least two emotions present. The most common co-occurring label pairs were anger and disgust, anger and sadness, fear and surprise, and fear and sadness, with co-occurance percentages of 15.5%, 14.7%, 13.1%, and 12.8%, respectively. A detailed breakdown of label distribution and co-occurance patterns is provided in Appendix A.

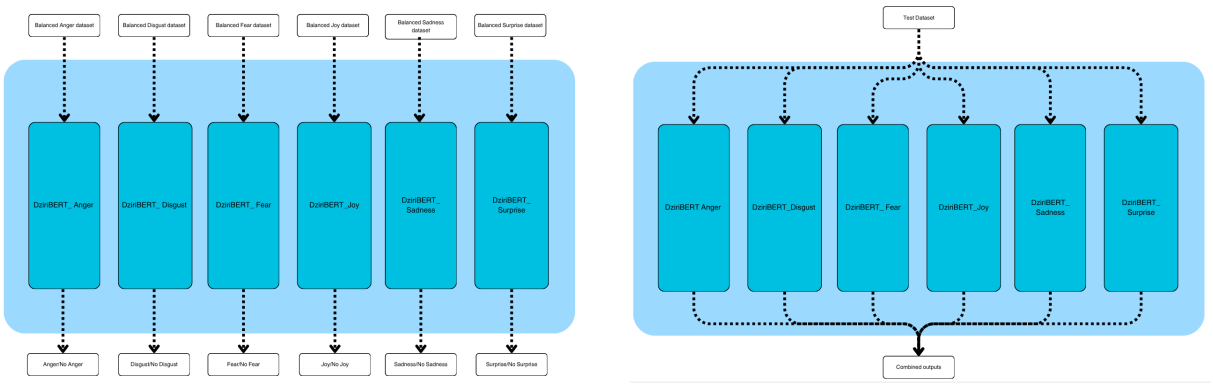
To address this data imbalance, the L-IMF method was proposed, which uses a pre-trained BERT model, or any other language model with Masked Language Modeling (MLM). This approach iteratively masks and replaces words, generating new sentences while also producing intermediate versions. To prevent the model from altering key words that could change the meaning of the sentence, a prompt-like sentence is inserted to guide the model. This prompt helps maintain label-aware token to be predicted. Using this algorithm, shown in Figure 1, around 14,500 intermediate sentences were created, along with 901 fully augmented, or "final", sentences.

Different Label-Fused prompts were tested. The simplest prompt used during augmentation, considered the baseline, involved simply appending the emotion present in the sentence. To minimize confusion, this prompt will be referred to as the *Simple Prompt*. Another prompt involved appending "The previous sentence's sentiment is {emotion(s)}" in Algerian Arabic; This will be referred to as the *Elaborate Prompt*.

To contrast the effectiveness of the proposed L-IMF, simple augmentation techniques were employed namely, random insertion, deletion, and swap. The algorithm that employed these augmentation techniques processed each sentence and randomly selected one of the three. If random insertion was selected, a random word collected from the entire dataset was inserted into the sentence at a random position. If random deletion was chosen, a random word was removed from the sentence. If random swap was selected, two random words within the sentence were swapped.

3.1.2 Sampling strategies

The original training dataset for the task contained 901 sentences, with approximately 15,500 additional sentences generated through L-IMF, resulting in a final training dataset of around 16,400 samples. Despite the increased dataset size, the class distribution exhibited severe imbalance, maintaining proportions comparable to those observed in the original dataset. To address this issue, undersampling and oversampling were performed using the Python-based Scikit-learn library. Each class was processed separately, with an output size



(a) Training process

(b) Inference process

Figure 2: A comparison of training and inference processes.

of 4,000 samples per class for the undersampled dataset and 30,000 samples per class for the oversampled dataset. The resulting balanced datasets were then stored for subsequent training.

With regard to the simple augmentation techniques, namely randomly insertion; deletion; and swap, the final dataset with the original and augmented sentences had a total of 1802 sentences. To avoid discarding any data from the limited dataset size, only oversampling was employed to create 4,000 samples per class for this simple data augmentation technique.

3.2 Model

To mitigate the challenges of class imbalance in multi-label classification with deep learning models, six independent classifiers were trained separately on tailored datasets. Each classifier was responsible for predicting a single class, and their outputs were concatenated only during inference, as illustrated in Figure 2. The model architecture included six pre-trained DziriBERT models, each equipped with a multi-layer perceptron (MLP) head. The MLP consisted of two linear layers with an input size of 768, a hidden size of 768, and an output dimension of 2. A ReLU activation function and dropout layers were applied between each linear layer.

To provide a performance comparison against the proposed model and its problem transformation strategy, a standalone DziriBERT model was evaluated. This model employed an MLP classification head identical to that of the proposed system, with the sole difference being that the output vector dimension is 6 instead of 2. This adjustment effectively transformed the multi-label classification task into a Powerset-based classification problem.

4 Experimental Setup

During training, the proposed model processed six tokenized text inputs, each corresponding to a label from the six datasets. Each submodel employed a separate Cross-Entropy loss function and was optimized using the Adam optimizer. Most layers in the submodels were frozen, except for the pooler layer and the MLP head. Dropout probabilities of 0.1, 0.2, and 0.3, alongside learning rates of 1.5×10^{-5}, 2.5×10^{-5}, and 3.5×10^{-5} were evaluated; however, the batch size was set at 32. Training was conducted for 15 epochs, with performance evaluated on the dedicated test set at the end of each epoch. The epoch with the best Macro F1 score was selected. A Grid Search hyperparameter optimization algorithm was used to tune the hyperparameter for each model. The baseline single DziriBERT model was trained on the original data with no augmentation. Despite almost the same training hyperparameters as the proposed model, the only difference was that Binary Cross Entropy with Logits Loss was set as the loss function. This loss function enables simultaneous prediction of multiple non-mutually exclusive labels by applying a sigmoid activation to each output logit. A detailed breakdown of the computational resources used is provided in Appendix B.

5 Results

The proposed system, combining the model with the L-IMF augmentation technique, achieved its highest performance with a Macro F1 score of 51.2% when trained on an undersampled dataset generated using the L-IMF *Simple Prompt*, while using oversampling on the same L-IMF *Simple Prompt* augmented data achieved 41.6%. Under

alternative settings, training on an undersampled dataset produced via the L-IMF *Elaborate Prompt* resulted in a Macro F1 score of 42.1% For comparison, the task's baseline, RemBERT, attained a Macro F1 score of 41.4%, while the standalone DziriBERT model, that provided a contrast to the proposed problem transformation, achieved only 25.1% under its best hyperparameters. While the proposed problem transformation proved effective, the same could not be said for the L-IMF augmentation technique. When the model was trained on data generated by the simple data augmentation techniques, the model achieved a Macro F1 score of 53.4%. Nonetheless, the proposed system, incorporating the problem transformation and L-IMF, achieved an improvement of nearly 10% over the task's baseline model and over 26% compared to the DziriBERT model. It ranked 28th out of 41 teams on the Algerian dialect task leaderboard with an official score of 48.6%.A more detailed breakdown of the scores along with the tuned hyperparameters for the best performing models is provided in Appendix C.

6 Conclusion

This study introduced the Label-fused Iterative Mask Filling (L-IMF) augmentation technique alongside a multi-model approach for multi-label classification in the Track A: Multi-label Emotion Detection challenge for Algerian dialect. The approach addressed key challenges in multi-label emotion detection, including label dependencies, class imbalance, and limited linguistic resources. By leveraging L-IMF, contextually and label-sensitive augmented data were generated, mitigating class imbalance while maintaining label consistency.

To further tackle the challenges of Deep Learning in multi-label classification, a system of six independent classifiers was implemented, with each DziriBERT-based sub-model specializing in predicting a single emotion. This design allowed the reduction of class imbalance by creating six balanced datasets for model training. Moreover, undersampling and oversampling helped ensure a more equitable distribution of classes, preventing the dominance of majority classes.

Results from the conducted experiments demonstrated the effectiveness of the proposed methodology in enhancing emotion classification performance in low-resource language settings. The integration of a pre-trained Algerian dialect model, L-IMF augmentation, and independent classifiers contributed to strong performance in multi-label emotion detection for dialectal Arabic that more than doubled the Macro F1 score obtained by using a single model via a Powerset problem transformation.

The experimental results indicate that the proposed model and binary problem transformation had the greatest impact on performance. Specifically, using six DziriBERT models as binary classifiers doubled the Macro F1 score compared to a single DziriBERT model with a output vector of dimension 6. In contrast, the L-IMF technique had a slightly negative effect on the model's performance when compared to a simpler augmentation method. However, the authors still argue that L-IMF holds significant potential for future improvements and remains a promising area for further research. Future studies may investigate the effectiveness of the L-IMF technique in augmenting datasets of different types, such as topic-based or sentiment-based datasets. Future work could also explore how the type and positioning of prompts influence performance on downstream tasks.

7 Ethical considerations

As a Pre-trained Language Model was used during both data augmentation and finetuning on downstream tasks, ethical challenges are posed due to the potential reinforcement of cultural bias and stereotypes found in the pre-training data used to train the language model.

A Data analysis and label co-occurance

A.1 Emotion class distribution

Table 1 displays the severe class imbalance that most emotions have, with the most severe class imbalance being present in the joy label. Only around 17% of sentences have a positive joy label.

A.2 Number of labels per data point distribution

Almost 90% of the dataset has been labeled positively with atleast one emotion, with around 10% of the text instances present having no positive labels. The most occuring numbers of labels per text instance is 2 at around 34% of the entire dataset.

Emotion	Count (0)	Count (1)	Ratio (1:0)	% of 1s
Anger	605	296	1:2.04	**32.85%**
Disgust	695	206	1:3.37	**22.86%**
Fear	678	223	1:3.04	**24.75%**
Joy	748	153	1:4.89	**16.98%**
Sadness	497	404	1:1.23	44.84%
Surprise	588	313	1:1.88	**34.74%**

Table 1: Training dataset emotion class distribution, with ratios exceeding a 60/40 split highlighted in bold.

Number of Labels	Count	Percentage
0	91	10.10%
1	294	32.63%
2	303	33.63%
3	160	17.76%
4	50	5.55%
5	3	0.33%

Table 2: Distribution of the number of labels per instance in the training dataset.

Only 3 sentences have been labeled with 5 emotions present. No text instances have been labeled with all 6 emotions, as shown in table 2.

A.3 Co-occurance of emotions

Table 3 shows the co-occurance of emotions with each other. The least co-occurring emotions are joy with disgust, joy with fear, and joy with anger, with co-occurance percentages of 1.11%, 1.33%, and 1.44%, respectively.

B Computational Resources

T4 GPU and TPU v4-8 were used for the set of experiments. TPU v4-8 was used to train models that used either the oversampled data from L-IMF with the *Simple Prompt*, or undersampled data from L-IMF with the *Elaborate Prompt*. The rest of experiments were conducted on a enviroment with T4 GPU as the hardware accelerator.

The T4 GPU environment was configured with PyTorch version 2.5.0 and Transformers version 4.46.2. The TPU v4-8 environment employed PyTorch version 2.6.0, PyTorch XLA version 2.6.0, and Transformers version 4.49.0.

C Results breakdown

Table 4. shows a breakdown of optimal hyperparameters best performing model for each model type, augmentation technique employed and sampling strategy.

	anger	disgust	fear	joy	sadness	surprise
anger	32.85%	15.54%	8.44%	1.44%	14.65%	10.54%
disgust	15.54%	22.86%	4.22%	1.11%	13.32%	5.33%
fear	8.44%	4.22%	24.75%	1.33%	12.76%	13.10%
joy	1.44%	1.11%	1.33%	16.98%	3.55%	6.10%
sadness	14.65%	13.32%	12.76%	3.55%	44.84%	12.09%
surprise	10.54%	5.33%	13.10%	6.10%	12.09%	34.74%

Table 3: Label co-occurance percentage for the multi-label emotion training dataset. Diagonal values represent the individual label's prevalences in the training dataset.

Problem Trans.	**Augmentation**	**Sampling Strat.**	**Dropout**	**Learning Rate**	**Epoch**	**Macro F1**
Binary Relevance	L-IMF simple	Undersample	0.1	3.5×10^{-5}	8	51.2%
Binary Relevance	L-IMF simple	Oversample	0.2	1.5×10^{-5}	4	41.6%
Binary Relevance	L-IMF elaborate	Undersample	0.1	2.5×10^{-5}	11	42.1%
Binary Relevance	Simple augment.	Oversample	0.1	3.5×10^{-5}	10	53.4%
Powerset	None	None	0.2	3.5×10^{-5}	15	25.1%
Powerset - Baseline	None	N/A	N/A	N/A	N/A	41.4%

{m.t.pronk, e.a.kamyshanova, t.w.adam, m.a.x.van.der.maesen.de.sombreff}@student.rug.nl

Abstract

Hallucination in machine-generated text poses big risks in various domains, such as finance, medicine, and engineering. Task 3 of SemEval-2025, Mu-SHROOM, challenges participants to detect hallucinated spans in such text. Our approach uses pre-trained language models and fine-tuning strategies to enhance hallucination span detection, focusing on the English track. Firstly, we applied GPT-4o mini to generate synthetic data by labeling unlabeled data. Then, we employed encoder-only pre-trained language models with a question-answering architecture for hallucination span detection, ultimately choosing XLM-RoBERTa for fine-tuning on multilingual data. This model performed best, ranking 18th in IoU (0.469) and 22nd in Correlation (0.441) on the English track. It achieved promising results across multiple languages, surpassing baseline methods in 11 out of 13 languages, with Hindi having the highest scores of 0.645 intersection-over-union and 0.684 correlation coefficient. Our findings highlight the potential of a QA approach and using synthetic and multilingual data for hallucination span detection.

1 Introduction

Hallucinations can lead to dangerous and misleading information like mathematical inaccuracies in finance, programming errors in autonomous vehicles, and misunderstandings in medical diagnoses (Williamson and Prybutok, 2024). They pose a challenge in the development of AI models. In task 3 of SemEval-2025, called Mu-SHROOM, participants were challenged to create a model that can automatically extract hallucination spans in machine-generated text (Vázquez et al., 2025). This paper contains an overview of our approach for task 3 of SemEval-2025.

The organizers of this shared task define hallucinations as follows: *"Content that contains or describes facts that are not supported by the provided reference"*. (Vázquez et al., 2025)

In other words, hallucinations are cases where the machine-generated text is more specific than it should be or factually incorrect, given the information available in the provided context.

In the task from last year (Mickus et al., 2024), the seemingly best approach was to use pre-trained language models (PLMs) and fine-tuning. Most teams also used unlabeled training data, resulting in promising solutions. For this reason, we have incorporated these ideas. Firstly, we utilized the unlabeled data to fine-tune an open-source PLM to create a model that can effectively detect the spans of hallucinations in a text. We used GPT-4o mini (OpenAI, 2024) with prompt engineering to label the unannotated training data. Then, for our span detection system, we implemented a pre-trained question-answering (QA) architecture, in which we compared RoBERTa (Liu et al., 2019) and DeBERTa (He et al., 2021). In our final system, a multilingual version of RoBERTa, namely XLM-RoBERTa (Conneau et al., 2020), was fine-tuned on the training and validation data. This landed us the 18th and 22nd positions on the English track on the metrics of intersection-over-union and correlation, respectively.

The code is available on our GitHub[1] and the model on Huggingface[2].

2 Background

2.1 Task

This year's task was set up in a multilingual context. It contained fourteen languages: Arabic (Modern standard), Basque, Catalan, Chinese (Mandarin), Czech, English, Farsi, Finnish, French, German,

[1] https://github.com/MichielPronk/bluetoad-semeval-2025-Mu-SHROOM

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 684–694

Hindi, Italian, Spanish, and Swedish. Participants in this task had to predict whether a character in a text generated by a large language model (LLM) is hallucinated. As our team is fluent in English, we mainly experimented with the provided English data in our approach. We also ran our model on the other languages, excluding Catalan, as this data was not properly formatted. The datasets provided by the organizers this year included a manually labeled validation set, an unlabeled training set, and an unlabeled test set, see Table A.1. For English, there were 809 training, 50 validation, and 154 test instances. The labeled data had two categories of labels: soft and hard labels. Both categories labeled text as hallucinations on the character level, with the difference between the soft and hard labels being that soft labels were the probabilities of a character being a hallucination as assigned by human annotators (an example of the data entry is provided in Appendix A.4).

2.2 Related work

This year's task is comparable to Task 6 of SemEval-2024, SHROOM, where participants were challenged to detect hallucinations on the document level instead of the character level (Mickus et al., 2024). An essential part of both of these tasks is handling the data made available by the shared task organizers. Last year, the data consisted of an unlabeled training set and a labeled validation set.

One of the challenges encountered last year was converting the unlabeled data into a useful dataset for experiments. Some of the entries from last year used LLMs to create training data (Das and Srihari, 2024; Bahad et al., 2024; Chen et al., 2024). Das and Srihari (2024) used the Claude 2.1 LLM. However, they found that this model would not always give reliable labels and added a confidence-based measure. Bahad et al. (2024) used Mixtral 8x7B to label the training data and obtained more consistent labels in comparison to Claude 2.1.

What is noticeable in the entries from last year is that some teams used the small validation set and the unlabeled data to create a larger labeled training set. Rösener et al. (2024) did not apply the unlabeled data in their research and focused on the provided labeled validation set. Instead, they used vectors as encoder input to solve the limited data, generating additional contextual information about the features, which helps the algorithm train on the little data more efficiently. In the results from last year (Mickus et al., 2024), it is visible that the teams that used the unlabeled training dataset obtained better results in comparison to the teams that did not, Chen et al. (2024) had the second best-performing model, indicating that good use of the provided unlabeled training data can be very effective towards increasing performance.

The use of ensemble models to classify documents was one of the most popular approaches last year (Das and Srihari, 2024; Chen et al., 2024; Rykov et al., 2024). This worked well in last year's task, but due to the differences in the current task and our time constraints, we have decided not to create an ensemble model. The teams with the highest scores from last year mostly used closed-source LLMs, which were often fine-tuned (Mickus et al., 2024). Other teams that also scored high used open-source LLMs and fine-tuning. Mickus et al. (2024) mentioned that a closed-source model like GPT-3.5 or GPT-4 is not requisite to build a good-working model, as is showcased in the paper by Chen et al. (2024), who used different open-source LLMs in combination with fine-tuning to obtain the second-best results.

Question-answering architecture allows a language model to return the start and end positions of an answer to a question in the given context. In an article by Sadat et al. (2023), QA is used to see whether an answer is grounded, and if it is not grounded, it is predicted to be hallucinated. For this, they use similarity-based testing because they want to detect whether the sentence contains a hallucination. The model obtained an F1-score of 71.1%.

3 System Overview

Our approach to the task consisted of annotating the supplied unlabeled training data and, in turn, using the data to fine-tune a pre-trained large language model for question answering. In both parts, we performed several experiments to find the optimal setup.

3.1 Synthetic Data Generation

A relatively small number of annotated hallucination entries in the English validation data may not provide the system with the necessary insight into the concept of hallucination. Therefore, we automatically converted a sample of provided unlabeled English data into a labeled one. We considered a decoder-only LLM to generate the data due to its strong in-context learning capabilities. This LLM

allows us to control the output by explaining the task to the system with a few-shot prompt. The decoder takes the prompt to generate synthetic data that can contribute to further system training.

3.2 Fine-tuning pre-trained language model

A difficult aspect of the task is to detect the characters that a hallucination consists of. We have boiled this down to extracting hallucination spans, as hallucinations almost always occur on a token level. This is an open exercise without predetermined answer options and number of hallucinations in each output, which poses a great challenge to the whole task.

Model architecture. We propose a pre-trained model with an extractive question answering architecture to tackle the task. This architecture allows a PLM to return an answer's start and end positions to a question in a given context. This approach is similar to the shared task, which aims to extract the hallucination spans from the model output text given an input question. However, a key difference is that in regular question-answering, the model tries to find the best answer to the posed question. In contrast, in our task, the model tries to find information in a context that cannot be inferred from the posed question. We used the `AutoModelForQuestionAnswering` from the transformers library by Huggingface.[3]

Span generation. One challenge encountered with this approach is that extractive question-answering systems are optimized for identifying the single most relevant answer, whereas the task at hand stressed the identification of all potential hallucination spans. The model predicts the probability of each token being the start of an answer span and the probability of it being the end. The start and end positions with the highest logit scores are combined with the answer span. To ensure our algorithm finds multiple spans, it takes the 20 best start and end positions and creates all possible span combinations. It then filters out combinations where the end occurs before the start and which exceed a set length of 30 characters. From the remaining combinations, the start and end logits are added, and this list is sorted descending on logit score. The highest is taken, and a threshold is set at 0.8 of the highest logit score. Every span that exceeds the threshold is seen as a possible hallucination. The maximum character length and logit threshold were determined through experimenting with different values on the validation set.

Fine-tuning. A traditional question-answering architecture takes a question and a context from which to extract the answer as input. In fine-tuning, the answer is given as a single span with the start and end positions corresponding to the context. Our model input is the prompt as question and model output as context. In the dataset, each instance is a model input, output, and a list of hallucination spans. This list of spans did not work well with the chosen architecture. Therefore, we preprocessed the data to create separate instances for each hallucination span, paired with the corresponding model input and output. These were then fed to the model during fine-tuning.

4 Experimental Setup

Synthetic data generation. We selected GPT-4o mini (OpenAI, 2024) as the automatic hallucination detector for its easy-to-access online interface for prompt experimentation, strong instruction-following capabilities, and API availability. Using the various combinations of the entries from the English validation set, we constructed a few-shot prompt for the system (see Appendix A.2). The included examples correspond with the case types the GPT model found the most challenging to predict, mainly involving annotation span nuances. The designed prompt generated a sample of 500 entries with automatically annotated hallucinated text segments (see an example output entry in Appendix A.3). To prevent the system from incorrectly counting the hallucination spans and hallucinating on the numerical probabilities, we instructed the system to provide hallucinations in textual form only, which were then converted to corresponding hard labels using a Python script.

Pre-trained language model experiments. We fine-tuned a RoBERTa (Liu et al., 2019) and DeBERTa (He et al., 2021) model using the same hyperparameters. They were fine-tuned on the synthetically generated data and evaluated on the validation data in English. Our hyperparameter tuning focused on the learning rate, batch size, weight decay, number of epochs, and the logit threshold when selecting hallucination spans. The model was then fine-tuned on the synthetic training and vali-

[3] https://huggingface.co/transformers/v3.0.2/model_doc/auto.html#transformers.AutoModelForQuestionAnswering

dation English data of 550 instances in total. Furthermore, a multilingual model, XLM-RoBERTa (Conneau et al., 2020), was fine-tuned on the synthetic training English data and all validation data (see Table 4), which combined to 1000 instances. This model was also tuned, focusing on the number of epochs and learning rate and using only the training and English validation data. The specific hyperparameters of the final model can be found in Appendix A.5.

Packages. The models were loaded with `huggingface` (Wolf et al., 2020) and fine-tuned using the `transformers` and `datasets` Python libraries.

Metrics. We evaluated the models using the metrics set by the organizers, which are the intersection-over-union (IoU) of the characters marked as hallucinations in the predicted hallucinations and the true hallucinations and correlation (Cor) between the predicted probability of a character being hallucinations and the probability assigned by human annotators. As it seemed more relevant and less ambiguous to find the hallucinations than assigning probabilities to them, we focused on achieving the highest intersection-over-union.

There were three baselines introduced by the organizers of the task: the *mark all*, which predicted every character as hallucination, the *mark none*, which predicted no characters as hallucination, and the *neutral*, which estimates hallucinations based on probability distributions. The *mark all* baseline was in every language the highest scoring baseline.

Model	IoU	Cor
RoBERTa	0.368	0.355
DeBERTa	0.369	0.351

Table 1: Comparison of the RoBERTa and DeBERTa model on the validation set

5 Results and Analysis

5.1 Preliminary Results

We fine-tuned and compared a DeBERTa and RoBERTa model to see their performance using the same hyperparameters on the validation set. During experimentation, we ran each model once. The results can be found in table 1. Since we found that the results were quite close together, we decided to focus on one model only, namely RoBERTa. We experimented with the hyperparameters, including the learning rate, batch size, and weight decay, but found no improvement. We then opted to add the validation data to the training data when fine-tuning. This gave us better scores on the validation but not the test set. The better performance on the validation set could be attributed to overfitting. The score decline on the test set could be due to training and validation data sharing the same inputs, which could also have led to overfitting because more of the same data was added.

Finally, we combined the training and validation data for all languages and fine-tuned an XLM-RoBERTa model. This gave us better scores on the English validation data and higher scores on the English test set. A possible reason is that the multilingual data is more varied and of higher quality, resulting in a better overall performance, topping the performance of the English-specific model. Table 2 shows the results for our iterations of the RoBERTa models on the test set.

Model	Data	IoU	Cor
RoBERTa	Train	0.348	0.334
RoBERTa tuned	Train	0.38	0.347
RoBERTa	Train + EN Val	0.371	0.353
XLM-RoBERTa	-	0.125	0.04
XLM-RoBERTa	Train + all Val	**0.469**	**0.441**

Table 2: Model performance on English test data and what data we used. Also including non fine-tuned XLM-RoBERTa scores. Best results in **bold**.

5.2 Final results

We let the model predict for all the other languages as it is pre-trained on the multilingual data. The results and positions in the competition can be found in table 3. Here, the ranking is based on the IoU scores. We were quite surprised by the performance in the other languages. Our model competed in 13 languages and outperformed the baseline IoU scores in 11 languages, only falling behind in French and Chinese. On Cor we beat every baseline.

In the English task, our model ranked 18th in IoU and 22nd in Cor out of 41 teams and three baselines. Surprisingly, it performed best in Hindi, possibly due to dataset-specific hallucination traits. However, an examination of language represen-

tation within the XLM-RoBERTa model reveals no clear correlation. All languages from the task are in the training corpus of the model, but the languages there seem to have no connection to the performance or the number of tokens in the XLM-RoBERTa training data. Although Swedish and Chinese have lower representation in the data, the model performed well in Swedish and poorly in Chinese. Despite English having the highest data representation, it was not the best-performing language. The varying performance could be attributed to the characteristics of the language, the difference in hallucinations and/or annotations between languages, or the model that produced each output containing hallucinations.

Language	IoU position	Cor position	IoU	Cor
AR	8/29	14/29	0.547	0.506
CS	14/23	14/23	0.351	0.3628

5.3 Error Analysis

We conducted a qualitative analysis of the system's best prediction attempt for the English test set, comparing them with the provided gold standard. One key observation was the variation in spans selected by the system. Since the original QA architecture is designed to identify a single answer, it uses logits to determine the most probable start and end positions. While this approach works for a single span, logits are not intended to link multiple spans or indicate precise hallucination boundaries.

The system provides multiple start and end positions, so we manually combined them into different span variations and assessed their probability of being hallucinations based on their logits. This solution ensured that the picked spans were considered as part of hallucination by the system. Still, it resulted in a lot of noise in the output, consisting of overlapping spans, which negatively reflected on the evaluation scores. Examples of such QA output can be found in Appendix A.6.

These examples also illustrate the system's tendency to pick positions based on the syntactic dependencies within the sentence. This behavior can be linked to the QA system's pre-training to process text at the token level, which ensures accurate span selection. While the current task can benefit from such an approach for a similar reason, the token-based span selection limits the system's ability to detect character-level hallucinations. Since the gold standard hallucination spans were annotated by humans at the character level, some spans appear abrupt and do not always include complete words. As the examples in Appendix A.7 illustrates, our system could not identify these hallucinations with the current fine-tuning and pre-training.

6 Conclusion

In this paper, we presented several contributions to the task of hallucination detection in machine-generated output. We used GPT-4o mini to generate synthetic hallucination span annotations, adapted QA architecture for hallucination span extraction and finetuned an XLM-RoBERTa model to generalize across 13 languages, outperforming the baseline in 11 languages. This approach resulted in the 18th and 22nd position in the English subtask with an intersection-over-union of 0.469 and a correlation of 0.441 respectively.

Further research could focus on trying different large language models. Also, using human-annotated data seemed to give big improvements, so trying to add more quality data could yield better results. Furthermore, we found that our method to synthesize hallucination spans from model predictions could be improved as it can detect the correct spans but assigns a low probability to them, resulting in too many characters being marked as hallucinations. Finally, we used GPT-4o mini, which has the drawbacks of being closed-source and paid. Attempting the automatic annotation process with an open-source model would be preferable.

A Appendix

A.1 Data distribution

	N entries (total)	N entries (EN)	Available for Languages
Train	3351	809	EN, FR, SP, ZH
Validation	500	50	AR, DE, EN, ES, FI, FR, HI, IT, SV, ZH
Test	1902	154	AR, CA, CS, DE, EN, ES, EU, FA, FI, FR, HI, IT, SV, ZH

Table 4: Statistics of the provided unlabeled train, validation, and test sets, showing the number of English entries and data availability across different languages.

A.2 Prompt

You are a model that detects hallucinations in a decoder-generated text. We define a hallucination as "content that contains or describes facts that are not supported by the provided reference". In other words: hallucinations are cases where the answer text is more specific than it should be or factually incorrect, given the information available in the provided context.

You are given a source text represented as a question and an answer to that question. Detect whether the answer contains hallucinations and provide the spans in the answer text that are the source of hallucination. Work per sentence. In each sentence, firstly, detect the word phrases that represent hallucinations. Within each phrase, search for specific words that do not align with the context by introducing a hallucination. Include only these words in the final answer. Below are three examples of correct hallucination detection:

SOURCE TEXT: "What is the population of the Spanish region of Galicia?"
ANSWER: TEXT: "As of 2021, the estimated population in the region is around 1.5 million people."
HALLUCINATION SPANS: "2021", "1.5 million"

SOURCE TEXT: "Do all arthropods have antennae?"
ANSWER TEXT: "Yes, all arachnids have antennas. However, not all of them are visible to the naked eye."
HALLUCINATION SPANS: "Yes", "arachnids", "visible", "naked eye"

SOURCE TEXT: Which country is the World Chess Federation based in?
ANSWER TEXT: The World Chess Federation, also known as FIDE (Fédération Internationale des Échecs), is not based in any one specific country. It is an international organization with its headquarters currently located in Minsk, Belarus. However, it maintains offices in several countries and holds various events around the world.
HALLUCINATION SPANS: 'not based in any one specific country', 'Minsk, Belarus', 'maintains offices', 'several countries'

Follow the examples and provide the hallucination spans for the following text pair:
SOURCE TEXT: <input>
ANSWER TEXT: <input>

A.3 Synthetic Training Data Entry

{"model_input": "Is the Arts and Humanities Citation Index still maintained?", "model_output_text": "As of 2021, the A&HCI is no longer maintained by the U.S. government and is now maintained privately by JSTOR.", "hard_labels": [[6, 10], [53, 68], [104, 109]]}

A.4 Validation and Training Data

Validation data example:

```

"Ġand","Ġticks",")","Ġhave","Ġat","Ġleast","Ġone","Ġantenna",
".","Ċa"]}
```

A.5 XLM-RoBERTa Settings

The hyperparameters used for the best performing XLM-RoBERTa model:

```
max_length=384
stride=128
n_best=20
max_answer_length=30
learning_rate=2e-05
batch_size=16
epochs=4
weight_decay=0.1
```

Here `max_length` corresponds to the maximum input length in the tokenizer. `stride` is the number of overlapping tokens between two successive chunks. `n_best` is the top K of how many start and end span positions to return from the predictions. `max_answer_length` is the maximum span length allowed when creating possible hallucination spans.

A.6 Examples of the Noisy Output by the QA System

The examples below were taken from the English test set. The ROBERTA spans are generated by the best XLM-RoBERTa QA system, while the TRUE spans are the gold standard provided by the organizers. The examples illustrate the large amount of noise the QA system indicates as hallucinations.

Example 1

SOURCE TEXT: "Did Health ever compose videogame soundtracks?"
ANSWER TEXT: " Yes, in 2015, Health composed the soundtrack for "Inside" by Tame Impala."
ROBERTA SPANS: ['2015, Health composed the soundtrack for "Inside', '2015,', '2015, Health composed the soundtrack for "Inside" by Tame Impala', 'Yes, in 2015, Health composed the soundtrack for "Inside', 'Yes, in 2015,', 'Yes, in 2015, Health composed the soundtrack for "Inside" by Tame Impala', 'Yes', 'Inside', 'Inside" by Tame Impala', 'Tame Impala']
TRUE SPANS: ['2015', 'Inside" by Tame Impala']
MATCHES: ['Inside" by Tame Impala']
MISSED SPANS: ['2015']
NOISE: ['2015, Health composed the soundtrack for "Inside', 'Inside', 'Yes, in 2015,', 'Yes', '2015,', 'Tame Impala', '2015, Health composed the soundtrack for "Inside" by Tame Impala', 'Yes, in 2015, Health composed the soundtrack for "Inside', 'Yes, in 2015, Health composed the soundtrack for "Inside" by Tame Impala']

Example 2

SOURCE TEXT: "Who developed International Klein Blue?"
ANSWER TEXT: " The dye was developed by a chemist named Ewald Klein in the 1930s."
ROBERTA SPANS: ['1930s', 'Ewald Klein', 'Ewald Klein in the 1930s', 'chemist named Ewald Klein', 'chemist named Ewald Klein in the 1930s']
TRUE SPANS: ['chemist', 'Ewald', '1930s']
MATCHES: ['1930s']
MISSED SPANS: ['chemist', 'Ewald']
NOISE: ['Ewald Klein', 'chemist named Ewald Klein', 'chemist named Ewald Klein in the 1930s', 'Ewald Klein in the 1930s']

Example 3

SOURCE TEXT: "Is there any year when the BAFTA Award for Best Actor in a Supporting Role hasn't been awarded?"
ANSWER TEXT: " No, there is not."
ROBERTA SPANS: ['No, there is not', 'No', 'there is not']
TRUE SPANS: ['No, there is not']
MATCHES: ['No, there is not']
MISSED SPANS: []
NOISE: ['No', 'there is not']

A.7 Examples of the Challenging Output

The examples below were taken from the English test set. The ROBERTA spans were generated by the best XLM-RoBERTa QA system, while the TRUE spans are the gold standard provided by the organizers. The examples illustrate the challenging cases of gold standard spans the QA system cannot comprehend.

Example 1

```
SOURCE TEXT: "How many martellos are there on Formentera?"
ANSWER TEXT: " There are a total of 4 martello towers on the island of Forments."
ROBERTA SPANS: ['4 martello towers on the island of Forments', '4', 'Forments']
TRUE SPANS: ['s']
MATCHES: []
MISSED SPANS: ['s']
NOISE: ['Forments', '4 martello towers on the island of Forments', '4']
```

Example 2

```
SOURCE TEXT: "is there an airfield in Beauvechain?"
ANSWER TEXT: " no, there is no airport in beauvechains"
ROBERTA SPANS: ['no, there is no airport in beauvechains', 'no, there is no airport',
'no']
TRUE SPANS: ['no', 'e is no airport']
MATCHES: ['no']
MISSED SPANS: ['e is no airport']
NOISE: ['no, there is no airport', 'no, there is no airport in beauvechains']
```

IASBS at SemEval-2025 Task 11: Ensembling Transformers for Bridging the Gap in Text-Based Emotion Detection

Erfan Mohammadzadeh[†], **Aydin Mohandesi**[†], **Mehrzad Tareh**[†], **Ebrahim Ansari**
Institute for Advanced Studies in Basic Sciences (IASBS)
{e.mohammadzadeh, mohandesi, m.tareh, ansari}@iasbs.ac.ir
[†] denotes equal contribution

Abstract

This paper addresses the SemEval 2025 - Task 11 entitled "Bridging the Gap in Text-Based Emotion Detection", with a focus on perceived emotions from short text snippets, as spoken by individuals across various languages. This study involves three tracks: (1) multi-label emotion detection (ED), (2) emotion intensity prediction, and (3) cross-lingual ED. A comprehensive analysis of multiple languages, including Arabic, Amharic, Chinese, English, and other languages, is conducted utilizing a variety of machine and deep learning techniques. For Track A, a hybrid approach using an ensemble of advanced pre-trained transformer models, coupled with majority voting on predictions, yields significant insights. Track B leverages a multilingual transformer model alongside prompt engineering, using Average Ensemble Voting (AEV) for emotion intensity prediction. In Track C, a cross-lingual ED task, a classification of languages based on linguistic families is employed to enhance the performance of multilingual models. The methodologies incorporated, such as model selection, prompt engineering, and voting mechanisms, are evaluated using F1-score and Pearson correlation metrics. This research contributes to the broader field of ED, highlighting the importance of cross-lingual approaches and model optimization for accurate emotion prediction across diverse linguistic landscapes.

1 Introduction

Text-based emotion detection has become a critical task in the field of natural language processing (NLP), enabling systems to understand and respond to human emotions based on written language. The ability to accurately infer the emotions of speakers from their text offers vast potential in applications ranging from customer service automation to mental health monitoring and Sentiment analysis (SA) in social media (Saadati et al., 2024). However, despite significant advancements, this task remains challenging due to the complexity of emotional expressions across cultures, contexts, and languages. The present task (Muhammad et al., 2025b), "Bridging the Gap in Text-Based Emotion Detection", focuses on understanding the perceived emotions of a speaker through short text snippets. Unlike traditional SA, which often centers on the emotional impact on the reader or the identification of the speaker's true emotions—both of which are difficult to ascertain from a limited text—the focus here is on detecting the emotion that is most likely perceived by an average reader or listener. Specifically, the task aims to identify emotions such as joy, sadness, fear, anger, surprise, and disgust from a variety of languages, including widely spoken ones like English, Spanish, and Chinese, as well as lesser-studied languages such as Emakhuwa, Igbo, and Hausa.

The task is organized into three distinct tracks: Track A (Multi-label Emotion Detection), Track B (Emotion Intensity), and Track C (Cross-lingual Emotion Detection). Track A requires systems to predict the presence or absence of specific emotions in text, encompassing the prediction of one or more perceived emotions in a given text snippet. Track B involves determining the intensity of the identified emotions, ranging from no emotion to high degrees of emotion. Track C challenges systems to generalize emotion detection across multiple languages, testing the models' ability to predict emotion labels for unseen languages based on training data.

The challenge further emphasizes the importance of handling multilingual data and the complexities of translating emotional expressions across languages and traditions. With this in mind, various methodologies have been explored, including the use of state-of-the-art models such as Microsoft's DeBERTa (Chehreh et al., 2024), Google's Multilingual DistilBERT (M-DistilBERT) (Sanh et al., 2019), and Google's Gemini (Reid et al., 2024). These models fine-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 695–702

tuned for different tracks, and employ techniques such as translation, prompt engineering, and model ensemble strategies like Majority Voting and AEV, to enhance performance and address the unique challenges presented by the diverse language sets involved.

The paper is organized into seven sections: Section 2 covers the dataset, Section 3 reviews related work, and Section 4 presents the system architecture. Section 5 describes the experimental setup, followed by Section 6, which presents and analyzes the results. Section 7 concludes with key findings and future research directions. This paper aims to present the methodology, evaluation strategies, and results of our approach to tackling the multifaceted problem of text-based emotion detection, while also exploring how advancements in multilingual NLP can bridge the gap in understanding human emotions across different languages.

2 Dataset

The shared task utilizes a comprehensive and multilingual dataset designed to explore how emotions are perceived across different languages. The main objective is to determine which emotion people are most likely to associate with a speaker based on a brief text snippet. Provided by the organizers of SemEval 2025 - Task 11 on Text-Based Emotion Detection, this dataset covers multiple languages and captures a broad range of linguistic and cultural nuances. For all languages except Amharic, Oromo, Somali, and Tigrinya, we have used the dataset referenced in (Muhammad et al., 2025a). However, for any analysis involving one of these four languages, we have used the dataset from (Belay et al., 2025) instead. This distinction ensures that the dataset remains culturally and contextually appropriate for each language. The emotions considered in this study include anger, disgust, fear, joy, sadness, and surprise. In track A, 28 languages are covered. For track B, 11 languages are included. In track C, 32 languages are available. Our output for tracks A and C must be in a binary format (0 or 1), as 1 indicating the presence and 0 indicating the absence of a given emotion in the text. In track B, however, the output must be one of the integers from 0 to 3 for each emotion, representing its intensity level (0: no emotion, 1: low degree of emotion, 2: moderate degree of emotion, and 3: high degree of emotion). The dataset is been pre-processed by the task organizers and is divided into three key subsets: training, validation, and testing.

3 Related Work

Sentiment analysis identifies the overall emotional tone of a text (positive, negative, or neutral), while ED focuses on identifying specific emotions. SA is broader, while ED provides more detailed and intense emotional insights. Emotion detection from text, particularly perceived emotions, is a rich field of research in NLP, playing a crucial role in analyzing human expressions and understanding people's attitudes toward specific subjects. Several studies have focused on detecting emotions based on textual cues, with a variety of approaches ranging from lexicon-based methods to advanced machine and deep learning techniques. However, the challenge of bridging the gap between text and the perception of emotions across different languages, cultures, and contexts remains an open issue. In this section, we review relevant work related to text-based emotion detection, emphasizing approaches related to multi-label emotion detection, emotion intensity prediction, and cross-lingual emotion detection.

3.1 Text-Based Emotion Detection

Early emotion detection methods primarily relied on lexical resources like the Emotion Lexicon (EmoLex), which linked words to specific emotion categories, but these approaches struggled to capture the complexity of mixed emotions or irony (Doan and Luu, 2022). With the rise of deep learning, neural network-based models such as RNNs, CNNs, and Transformer architectures like BERT and its multilingual variants have significantly improved ED by better understanding contextual nuances in the text (Rezapour, 2024). A key challenge in this area is multi-label classification, where texts may convey multiple emotions simultaneously; recent studies (Ameer et al., 2023) have explored frameworks for predicting multiple emotions from a single sentence, showing notable advancements over single-label methods.

3.2 Emotion Intensity Detection

Recent advancements in emotion intensity prediction have gained significant attention in NLP, with datasets like Emotion Intensity (Kajiwara et al., 2021) underscoring its growing importance. This task has become a critical component of emotion recognition, especially in NLP challenges like SemEval. Notably, models like LE-PC-DNN combine convolutional and fully connected layers with

lexicon-based features and transfer learning to predict emotion intensity in tweets, aiming for state-of-the-art performance through deep multi-task learning (Kulshreshtha et al., 2018). Similarly, the CrystalFeel system leverages parts-of-speech, n-grams, word embeddings, and affective lexicons to predict intensity levels for emotions, achieving strong results while revealing insightful word- and message-level associations (Gupta and Yang, 2018). These innovations reflect the increasing sophistication of emotion intensity prediction, combining deep learning and linguistic features for more accurate and efficient emotion analysis in text.

3.3 Cross-Lingual Emotion Detection

Cross-lingual emotion detection is an emerging field within emotion detection, where models are designed to generalize across languages with diverse structures, cultural contexts, and expressions. This contrasts with traditional systems that typically rely on a single language or closely related language sets. Research in this area has investigated the transfer of models across different languages. For example, the work of (Kadiyala, 2024) highlights performance drops when training and testing data originate from different languages. A key approach to improving cross-lingual emotion detection is the use of multilingual models like Google's Multilingual BERT (M-BERT), XLM-RoBERTa (XLM-R), and multilingual T5, which have demonstrated stronger performance in multilingual tasks. For example, (Hassan et al., 2022) adapted M-BERT (Devlin et al., 2018) model for cross-lingual emotion detection, leveraging shared embeddings across languages to achieve competitive results. However, challenges remain, including cultural differences in emotional expression and the need for large, multilingual labeled datasets.

4 System Architecture

The system architecture for multilingual emotion detection uses back translation, multilingual models, transfer learning, LLMs to improve accuracy across languages. Prompt engineering optimizes task processing, ensuring effective and adaptable ED across diverse datasets.

4.1 Back Translation

In our paper for SemEval 2024 - Task 10 (Tareh et al., 2024), we utilized back translation, a widely adopted technique in multilingual NLP, which contributed significantly to achieving the best performance. This method ensures that the meaning of the original text is preserved across languages, particularly in ED tasks. By addressing challenges in handling multilingual data, especially when training models on text from various languages, we were able to improve the model's robustness. The back translation process involves translating the text from the target language to English and then back to the original language, creating a parallel corpus that helps identify any inconsistencies. This technique was crucial in enhancing the accuracy of our ED models, as it helped pinpoint misinterpretations or discrepancies during translation, as detailed in our paper.

For this particular task, back translation was incorporated into the data preprocessing pipeline. Text from various languages was first translated into English using the Llama3.3-70b[1] translation model, which, with its 70 billion parameters, was selected for its effectiveness with a broad range of languages, including those from underrepresented language families. Once the data was in English, it was back-translated to the original language, allowing for a comparison between the original and retranslated texts. This comparison helped detect errors in the translation, ensuring that emotional expressions were accurately preserved and improving the overall quality of the data used for training the ED models (Wendler et al., 2024).

Despite its benefits, back translation has limitations. The quality of the back-translation depends on the initial translation model and the characteristics of the language pairs involved, especially when languages have different sentence structures or cultural contexts. Additionally, the process is computationally expensive and time-consuming, particularly when dealing with large datasets across many languages. However, the advantages of preserving emotional content and reducing translation biases outweighed these challenges, making back translation an essential technique for enhancing multilingual ED models and ensuring more accurate predictions in cross-lingual tasks (Yoon, 2022).

4.2 Multilingual Models and Transfer Learning

In recent years, multilingual transformer models have become the standard for addressing cross-lingual emotion detection. For example, M-BERT and M-DistillBERT have been used for several ED

[1] https://developers.cloudflare.com

tasks, including cross-lingual tasks, due to their ability to handle multiple languages simultaneously and share knowledge across languages. In the context of the present work, models like DeBERTa (Aziz et al., 2023) and Gemini-1.5-flash have been used to tackle the challenges of multi-label classification, emotion intensity, and cross-lingual detection, demonstrating the effectiveness of leveraging pre-trained language models fine-tuned with task-specific datasets. Transfer learning, which involves fine-tuning pre-trained models on task-specific datasets, has also been widely used to bridge the gap between languages. This technique has been especially useful in tackling the challenge of cross-lingual emotion detection, where training data may not be available for all languages. (Mozhdehi and Moghadam, 2023) investigated the impact of transfer learning on cross-lingual performance, demonstrating that fine-tuning multilingual models with domain-specific data enhances their effectiveness.

4.3 Prompt Engineering

Prompt engineering is a key approach for optimizing large language models (LLMs) to perform various tasks effectively. It involves creating well-structured prompts that guide LLMs to generate accurate and relevant responses. This includes clear task descriptions, well-organized input data, and defined output formats. The goal is to enhance the LLM's ability to process and complete tasks, especially through in-context learning, where instructions and examples are provided in natural language (Brown et al., 2020). Effective prompt engineering also requires careful structuring of input data, particularly for specialized formats like knowledge graphs, and ensuring the output format aligns with expectations (Zhang et al., 2023).

As an emerging field, prompt engineering plays a significant role in improving LLM performance across various applications, including vision-language tasks, SA, and academic research. Key prompting techniques, such as few-shot learning, and chain-of-thought, enhance reasoning and task-specific accuracy (Chen et al., 2024). While prompt engineering offers substantial benefits, it also presents challenges, such as ambiguity, bias, and issues of generalizability. As LLMs continue to be integrated into multiple domains, including healthcare and scientific research, mastering prompt engineering has become increasingly important for professionals aiming to leverage AI for enhanced problem-solving and workflow efficiency (Lamba, 2024).

5 Experimental Setup

The experimental setup includes multiple stages aimed at optimizing performance across multilingual tasks, focusing on model transformation, fine-tuning, integration, and strategies like prompt engineering and ensemble learning. Here's an overview of the steps and methods used.

5.1 Text Translation for Multilingual Data

Due to the dataset's diverse linguistic nature, we utilize Llama3.3, a powerful multilingual language model, to translate all text into English. Standardizing the training language enables us to leverage a unified model instead of training separate models for each language, significantly improving efficiency and consistency.

5.2 Model Selection and Fine-Tuning

We carefully select and fine-tune pre-trained transformer models for each track, ensuring they are optimized to meet the specific requirements of the task. Figure 1 shows the architecture.

- **Track A:** Fine-tuned DeBERTa—enhances BERT and RoBERTa with disentangled attention and an improved mask decoder for better efficiency and performance—recognized for its strong emotion classification capabilities.
- **Track B:** Fine-tuned M-DistilBERT—a lightweight yet effective model optimized for multilingual tasks. It is trained on a concatenation of Wikipedia data in 104 languages and features 6 layers, 768 dimensions, and 12 attention heads, totaling 134M parameters.
- **Track C:** Fine-tuned M-BERT and DistilBERT, capable of learning cross-lingual representations.

In tracks A and B, each model is trained on the translated English dataset, with the validation set used for hyperparameter tuning to maximize performance. In track C, We categorize the languages based on linguistic families and their relevance in NLP research. The languages are grouped into seven categories based on linguistic families and their relevance to NLP, as shown in Table 1.

5.3 Prompt Engineering with Gemini

The Gemini family represents a significant advancement in multimodal AI models, offering impressive capabilities across image, audio, video, and text understanding. For our ED task, we deployed Gemini-1.5-flash-002, a more efficient alternative to the computationally intensive Pro version, while still maintaining the 2M+ context length and multimodal capabilities. This transformer decoder model is specifically optimized for tensor processing units (TPUs), featuring parallel computation of attention and feedforward components, online distillation from Gemini-1.5-pro, and training with higher-order preconditioned methods (Reid et al., 2024). We interfaced with the model through its API, which facilitated efficient request handling and response storage. To maximize performance on our emotion tasks, we configured all safety parameters to "*None*", enabling unrestricted access to the model's full potential during inference while balancing performance and cost-effectiveness.

5.4 Ensemble Strategy with Voting Mechanism

To improve robustness and reduce model biases, we leverage ensemble learning techniques:

- **Majority Voting Mechanism for Track A:** DeBERTa, Gemini-1.5, and SVM generate independent predictions, and a majority vote determines the final emotion labels, ensuring balanced and unbiased results. Refer to Equation 1 for the majority voting mechanism formula.
- **AEV Mechanism for Tracks B and C:** Since emotion intensity prediction and cross-lingual detection require nuanced outputs, we apply performance-based weighting, prioritizing predictions from the model with the highest validation accuracy. Refer to Equation 2 for the AEV mechanism formula.

By leveraging transformer models, prompt engineering, and ensemble techniques, our approach ensures accurate, multilingual emotion detection, enhancing both efficiency and generalization across diverse texts.

6 Results

In this section, we present the evaluation results for the three subtasks across multiple languages. The performance of each model is reported using F1-scores and Pearson correlation scores, as appropriate for each subtask. Additionally, we discuss the rankings and highlight key insights drawn from the results.

Track A evaluates the performance of various models, such as DeBERTa, SVM, and Gemini-1.5, and investigates the effectiveness of the majority voting mechanism, which combines multiple strategies, across different languages. The F1-scores for each approach are reported in Table 3.

Track B evaluates the performance of M-DistilBERT, Gemini-1.5, and an AEV strategy using Pearson correlation scores. The results are summarized in Table 4. The AEV strategy yielded the best performance in 7 out of 11 languages, indicating that a hybrid model can enhance generalization.

Track C investigates the ability of models to generalize across languages using DistilBERT, M-BERT, and an AEV strategy. Although the F1-scores of M-BERT and DistilBERT in Table 5 were generally comparable, their predictions showed significant variability in certain cases. M-BERT consistently outperformed DistilBERT in most languages, highlighting its robust performance in cross-lingual tasks. However, there were instances where DistilBERT provided superior results. To leverage the strengths of both models and improve overall performance, we implemented a voting mechanism to combine their predictions.

7 Conclusion

This study addresses the challenges of text-based emotion detection across multiple languages, focusing on multi-label classification, emotion intensity prediction, and cross-lingual detection. By fine-tuning advanced NLP models (Gemini, DeBERTa, M-BERT, M-DistillBERT) and combining them with traditional methods like SVM, strong results were achieved. A voting-based ensemble method enhanced model reliability. The approach demonstrated the effectiveness of multilingual models, especially for low-resource languages, ranking in the top 10 teams of the competition. However, improvements are needed in emotion intensity prediction and for low-resource languages. Future work will refine model architectures, fine-tune LLMs, and explore new techniques like RAG and CAG for further enhancement.

A Language Groups for Track C

The languages are grouped as follows:

Language Groups
Group 1: English, German, Swedish, Afrikaans
Group 2: Spanish, Portuguese, Romanian
Group 3: Russian, Ukrainian
Group 4: Hindi, Marathi
Group 5: Chinese
Group 6: Arabic
Group 7: Hausa

Table 1: Categorization of languages based on linguistic families and NLP relevance

B Majority Voting Formula

The formula calculates the predicted emotion detection $\hat{y}_i^{(e)}$ based on the majority agreement from three models. If at least two models predict 1, the final prediction is 1; otherwise, the prediction is 0.

$$\hat{y}_i^{(e)} = \begin{cases} 1 & \text{if } y_{i,\text{model1}}^{(e)} + y_{i,\text{model2}}^{(e)} + y_{i,\text{model3}}^{(e)} \geq 2 \\ 0 & \text{otherwise} \end{cases} \tag{1}$$

C Average Ensemble Voting Formula

The AEV formula calculates the predicted emotion intensity $\hat{y}_i^{(e)}$ by averaging the outputs from two models and rounding to the nearest integer.

$$\hat{y}_i^{(e)} = \left\lfloor \frac{y_{i,\text{model1}}^{(e)} + y_{i,\text{model2}}^{(e)}}{2} + 0.5 \right\rfloor \tag{2}$$

D Hyperparameters

The hyperparameters for the model were set to optimize performance and training stability, as shown in Table 2.

Hyperparameter	Value
Seed	42
Batch size	16
Weight decay	0.01
Learning rate	2e-5
Warmup ratio	0.06
Warmup steps	500
Max sequence length	128
Number of training epochs	11
temperature	0.1
candidate count	1
max output tokens	500

Table 2: System hyperparameter settings

E Findings

SBU-NLP at SemEval-2025 Task 8: Self-Correction and Collaboration in LLMs for Tabular Question Answering

Rashin Rahnamoun and Mehrnoush Shamsfard
Shahid Beheshti University, Tehran, Iran
rahnamounrashin@gmail.com and m-shams@sbu.ac.ir

Abstract

This paper explains the submission of the SBU-NLP team at SemEval-2025 Task 8: question-answering over tabular data. We present a novel algorithm for this task, aimed at systems capable of interpreting large tables and providing accurate answers to natural language queries. The evaluation uses the DataBench dataset, which covers a wide range of topics and reflects the complexity of real-world tabular data. Our approach incorporates a self-correction mechanism that iteratively refines LLM-generated code to address errors and prevent common mistakes. Additionally, a multi-LLM collaborative strategy is employed to generate answers, where responses from multiple LLMs are compared, and the majority consensus or a valid alternative is selected. The method relies exclusively on open-source, open-weight models, avoiding costly processes like training or fine-tuning. Experimental results demonstrate that combining multiple LLMs with self-correction leads to significant performance improvements. However, challenges arise with list-based answers and responses involving multiple numerical, string, or boolean values, where further refinement is needed. The proposed simple system was among the top performers in both Subtask A and Subtask B among open-source, open-weight models in the competition.

1 Introduction

Task 8(Osés-Grijalba et al., 2025) focuses on question-answering over tabular data. The goal is to evaluate systems that can effectively interpret large tables and provide accurate answers to natural language questions based on the data within those tables. The evaluating dataset, DataBench(Grijalba et al., 2024), is important because many real-world applications rely on tabular data, and everyday datasets can vary significantly in both the subjects they cover and their size. DataBench covers a wide range of topics, making it essential to evaluate systems on diverse data to ensure they can handle a variety of real-world scenarios.

Our system, which we used for this task, employs a novel, simple algorithm based on a self-correction mechanism. In this approach, the large language model (LLM)-generated code from the prompt is iteratively fed back into the LLM to fix errors and avoid common code mistakes. Additionally, we use a multi-LLM collaborative answer generation strategy, where answers from multiple LLMs are compared, and the majority consensus is used. In cases where errors due to code issues prevent the LLM from generating an appropriate answer, alternative answers from other LLMs are utilized. Furthermore, if the generated answers are not in a valid format, a valid answer from another LLM for the same question is adopted. This method uses models that are either open-source or open-weight, avoiding computationally costly procedures like training and fine-tuning.

Participating in this task has led to several key discoveries. The results show that leveraging multiple LLMs and employing a self-correction mechanism significantly improved performance. Additionally, a well-structured Python code generation prompt played a crucial role in obtaining better answers from tables. However, we also discovered that many of the errors in our system were related to cases where the answers were in list format or involved more than one numerical, string, or boolean value. If these specific errors could be better handled, the system's results could be further improved. In terms of ranking, our model performed well among open-source and open-weight models, securing 3rd place out of 37 teams in Subtask B and 6th place out of 37 teams in Subtask A.You can find the code for our system in the fol-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 703–711

lowing GitHub repository[1].

2 Background

Question answering on tabular data is a critical task in natural language processing. Over the years, researchers have developed diverse methodologies to improve the accuracy and efficiency of this process.

The task is about question answering from tabular data. For this goal, a newly introduced benchmark, DataBench(Grijalba et al., 2024), has been used for evaluation, which consists of different large tables that vary in the topics they cover. As input, like the example in Figure 1, a natural language-based question with a table name is given, and the expectation is to find an appropriate answer from the related tables. For the final competition tests, 15 tables were provided. In Subtask A, the tables can be of any size, while in Subtask B, the row count is fewer than 20 due to the context-length limitations for LLMs. We participated in both subtasks with the same system.

2.1 Training and Fine-tuning the Models

To address the challenges of question answering on tabular data, several models have been developed, each leveraging training and fine-tuning strategies. Below, we highlight some of the most notable approaches:

TAPEX: Built on the BART framework, TAPEX(Liu et al.) is tailored for structured tables. It employs a neural SQL executor, pretrained on a synthetic corpus, to interpret and execute queries effectively.

TaPas: TaPas(Herzig et al., 2020) takes a different approach by directly predicting answers through selecting relevant table cells and applying aggregation operations, bypassing the need for intermediate logical forms. Extending BERTs architecture, it encodes tabular structures and is trained end-to-end for seamless performance.

OmniTab: OmniTab(Jiang et al., 2022) enhances table-based question answering by combining natural and synthetic data during pretraining. It aligns questions with corresponding tables.

2.2 Prompting and In-Context Learning

Similar to the approaches used in this task's paper(Grijalba et al., 2024), two key methodologies have been introduced for evaluating the performance of LLMs on the proposed benchmark:

- **In-Context Learning (ICL):** In this approach, examples with corresponding answers are provided to the model within the prompt, enabling it to infer patterns and generate responses accordingly.

- **Code Generation Prompting:** In this method, the model generates code based on the given prompt, executes it, and derives the final answer from the table.

Furthermore, another paper introduces the **Seek-and-Solve pipeline** (Jiang et al., 2024) , a novel framework for enhancing table-based question answering. This approach instructs LLMs to first seek relevant information before solving the given question, integrating these reasoning steps into a structured **Seek-and-Solve Chain of Thought (SS-CoT)** to improve performance.

Additionally, two other papers propose specific methodologies tailored to particular applications that are worth mentioning. One approach employs a relation graph as an encoder and a tree-based decoder to tackle numerical reasoning questions(Lei et al., 2022). Another approach utilizes the **Multi-TabQA** model, (Pal et al., 2023)which is designed to answer questions based on information from multiple tables and is capable of generalizing to generate tabular answers.

3 System Overview

In the question-answering task on tabular data, several challenges may arise. Due to limitations in hardware infrastructure, we employed a prompt-based approach 2.2 to achieve results while avoiding strategies that rely on fine-tuning or training procedures 2.1.

In our experiments, we exclusively used open-source and open-weight models and avoided third-party and commercial models due to their high costs. To generate code, we utilized prompts in LLMs. However, because of context-length limitations, it was not feasible to include tables in the prompt, particularly in Subtask A. Instead, a code-generating prompt was provided to the LLM, and the generated code was subsequently executed.

One of the main challenges encountered was errors in the generated code. To address this,

[1] https://github.com/rarahnamoun/TabularQA/

we implemented iterative prompts for code self-correction. However, not all errors could be resolved through iterative prompting alone. In such cases, we leveraged responses from alternative LLMs to rectify mistakes. Since different LLMs may not exhibit identical errors for a given question, we used responses from other models.

After all, to avoid mistakes due to data types, a post-processing algorithm was run to ensure the correct format of the expected output data. Our framework consists of three main components:

- **Self-Correction:** First, iterative prompts were used to correct errors in the generated code; if self-correction failed to resolve the issue, the next step was to utilize alternative LLM responses.
- **LLM Collaboration:** When self-correction failed, responses from other LLMs were used to improve the results, as not all LLMs generated incorrect code for the same question.
- **Post-Processing:** Finally, a post-processing algorithm was applied to ensure correct formatting and type validation of the results, aligning them with the expected outputs.

3.1 Problem Formulation

Given a dataset D and a natural language question Q, our goal is to find the function $f(D, Q)$ that returns the correct answer A. Formally:

$$A = f(D, Q) = \text{execute}(\mathcal{M}(\mathcal{P}(D, Q))) \quad (1)$$

where $\mathcal{P}$ is the prompt generator, $\mathcal{M}$ is the LLM generating code, and execute runs the code to retrieve A.

3.2 Prompt

The task consists of two subtasks, both following the same approach with one small difference.

For **Subtask A**, the dataset D can be of any size. Given a natural language question Q, the corresponding dataset name D is also provided. The competition includes 15 different datasets spanning multiple subjects and varying in size.

Examples of questions Q and datasets D are given in Figure 1.

Appendix A provides details on the prompt used for code generation in both subtasks. The primary difference between the two subtasks lies in the table information included in the prompt:

Dataset: 066_IBM_HR
Question: Is our average employee older than 35?

Dataset: 077_Gestational
Question: Which number of pregnancies is most common?

Figure 1: Examples of question (Q) and dataset (D).

- In **Subtask A**, due to context-length limitations of LLMs, only the columns and a few initial rows from D are provided in $\mathcal{P}(D, Q)$.
- In **Subtask B**, since only datasets with fewer than 20 rows are considered, the entire table from D is included in $\mathcal{P}(D, Q)$.

This structured approach ensures that the prompt $\mathcal{P}(D, Q)$ effectively guides $\mathcal{M}$ in generating executable code for obtaining A.

4 Self-Correction Mechanism

Let C_t be the generated code at iteration t, and E_t be the error encountered during execution. The LLM refines C_t iteratively:

$$C_{t+1} = \mathcal{M}(\mathcal{P}(D, Q, C_t, E_t)) \quad (2)$$

until execution produces no errors.

The Self-Correction Mechanism involves iterative refinement of a generated code to handle errors encountered during execution. The process starts with an initial code generation, followed by error detection. If an error is detected, the algorithm refines the code using an error-handling prompt in Appendix B. The error-handling prompt is added to the code generation prompt, which is described in Appendix A. This loop continues until the code executes successfully or a specified maximum number of iterations (in our experiments, 5 iterations) is reached. If errors persist after the limit, the algorithm returns a failure. The detailed steps of this mechanism are outlined in Algorithm 1.

4.1 Multi-LLM Collaborative Answer Generation

Our system integrates multiple LLMs, each providing independent responses to a given question based on tabular data. Formally, given a dataset D and a natural language question Q, each LLM M_i, where $i \in \{1, 2, ..., n\}$, receives a prompt $\mathcal{P}_i(D, Q)$ containing relevant table rows, column descriptions.The steps followed in the sections above are carried out separately for each LLM without any changes. The response A_i is given by:

Algorithm 1 Self-Correcting Mechanism

$C_0 \leftarrow \mathcal{M}(\mathcal{P}(D, Q))$ {Initial code generation}
for $t = 1$ to T **do**
  $A_t, E_t \leftarrow$ execute(C_t) {Run code and check errors}
  if $E_t = \emptyset$ **then**
    `Return` A_t {Return final answer}
  end if
  $C_{t+1} \leftarrow \mathcal{M}(\mathcal{P}(D, Q, C_t, E_t))$ {Refine code}
end for
`Return Failure` =0

$$A_i = M_i(\mathcal{P}_i(D, Q)) \tag{3}$$

where A_i represents the answer produced by model M_i for the given input. The system aggregates these answers for further evaluation and refinement.

To derive the final answer A, a consensus function $\mathcal{O}$ is applied over the set of generated answers:

$$A = \mathcal{O}(\{A_1, A_2, ..., A_n\}) \tag{4}$$

where $\mathcal{O}$ ensures that the generated output has a valid format and does not contain any errors.

4.2 Post-Processing

For each subtask, the expected answer must adhere to a predefined format. Given a dataset D and a natural language question Q, each LLM M_k (where $k \in \{1, 2, \ldots, n\}$) produces an answer A_i^k using the prompt $\mathcal{P}_k(D, Q)$. The responses from different LLMs are collected for further validation and selection.

Since some LLM responses may be empty due to iterative self-correction reaching its limit, we prioritize selecting a valid response. The selection process follows these steps:

1. If at least one answer has the correct expected format and size, we choose the valid response with the highest confidence. 2. If multiple LLMs provide valid answers, we apply a consensus function $\mathcal{O}$ based on majority voting where A represents the final selected answer. 3. If the number of valid answers is tied and n is even, a default LLM M_d is chosen as the tiebreaker, as was done in our experiments where $n = 2$.

Each answer must belong to a predefined category, including Boolean (True/False, Y/N), Category (values from dataset cells), Number (numerical/statistical values), List[category] (fixed-length categorical lists), and List[number] (fixed-length numerical lists). The format and constraints depend on the question's wording.

Since the expected answer type is unknown beforehand, the post-processing step ensures that A belongs to one of these categories.

The full post-processing procedure is detailed in Algorithm 2, which formalizes the steps for merging and filtering LLM outputs before selecting the final answer.

Algorithm 2 Post-Processing: Handling n LLM Outputs

$\mathcal{D}_k \leftarrow$ Read file for model M_k, $\forall k \in \{1, 2, \ldots, n\}$ {Load model outputs}
for each $(r_i, q_i, A_i^k) \in \mathcal{D}_k$ **do**
  $q_i \leftarrow g(q_i)$, $A_i^k \leftarrow g(A_i^k)$ {Pre-process questions and answers}
end for
Merge all $\mathcal{D}_k$ on r_i {Align model outputs}
$\mathcal{D} \leftarrow \{e(r_i) \mid r_i \in \mathcal{D}_1 \cup \mathcal{D}_2 \cup \cdots \cup \mathcal{D}_n\}$ {Extract relevant results}
for each $(r_i, q_i, A_1, A_2, \ldots, A_n) \in \mathcal{D}$ **do**
  $A_i^{k'} \leftarrow h(A_i^{k'})$ $\forall k' \in \{1, 2, \ldots, n\}$ {Apply validation and filtering}
  $A \leftarrow \mathcal{O}(\{A_1, A_2, \ldots, A_n\})$ {Select best valid answer}
end for=0

5 Experimental Setup

For generating results, the Together API[2] was used along with two models for experiments.

The models utilized were Llama 3.1 70B[3] (Dubey et al., 2024) and DeepSeek-V3[4] (Liu et al., 2024), The settings for Llama 3.1 70B and DeepSeek-V3 are: Max Tokens = 500 (both), Temperature = 0.7 (both), Top-p = 0.9 (Llama 3.1 70B) and 0.7 (DeepSeek-V3), Stream = False (both).

The evaluation was based on the `databench_eval` Python package introduced by the task organizer in the link[5].

[2] https://www.together.ai/
[3] https://huggingface.co/meta-llama/Llama-3.1-70B
[4] https://huggingface.co/deepseek-ai/DeepSeek-V3
[5] https://github.com/jorses/databench_eval/blob/main/src/databench_eval/eval.py

Metric	Subtask A		Subtask B	
	DeepSeek-V3	Llama 3.1 70B	DeepSeek-V3	Llama 3.1 70B
F1-score	84.9%	80.3%	85.7%	80.7%
Databench_eval	85.6%	80.1%	86.0%	78.9%

Table 1: Performance comparison of DeepSeek-V3 and Llama 3.1 70B on Subtasks A and B.

6 Results

As shown in Table 2, due to higher code errors in Llama 3.1 70B, the improvement percentage after the Self-Correcting step is higher than that of DeepSeek-V3. However, the self-error correction rate ability in DeepSeek-V3 is higher than in Llama 3.1 70B. DeepSeek-V3 outperformed Llama 3.1 70B in the Self-Correcting step across both subtasks. DeepSeek-V3 achieved an error correction rate of 86.67% in Subtask A and 100% in Subtask B, while Llama 3.1 70B showed correction rates of 56.67% and 66.67%, respectively. This demonstrates that DeepSeek-V3 is highly effective in resolving its own code errors. In the Collaborative step, where the outputs of both models were merged to handle cases where one model did not provide an answer, the improvement rates were 5.17% for Subtask A and 4.60% for Subtask B.

The final results in Table 1 also show that although the improvement of each step for Llama 3.1 70B was higher, due to the lack of performance in situations where the Llama 3.1 70B model's answer was accepted as the base model, it performs weaker than DeepSeek-V3.

Step	DeepSeek-V3	Llama 3.1 70B
Subtask A (*Improvement %*)		
Self-Correcting	2.49%	3.25%
Collaborative	5.17%	
Subtask B (*Improvement %*)		
Self-Correcting	1.5%	1.9%
Collaborative	4.60%	

Table 2: The improvement percentages for the Self-Correcting step have been calculated based on the number of corrected code errors relative to the total questions. For the Collaborative step, the percentage represents the number of questions where at least one LLM lacked an answer, and the other LLM's response was used instead, divided by the total number of questions.

As detailed in Appendix C, errors related to list-type outputs (Lists of integers, Lists of strings, and Lists of floats) are the most frequent errors for both DeepSeek-V3 and Llama 3.1 70B across Subtasks A and B. highlighting the difficulty LLMs face when handling structured list-based outputs.

In cases where both LLMs produced error-free answers that differed from each other, one of them was preferred. Because our experiment includes only two LLMs, we simply selected the response from the other LLM. The results are presented in Table 1. DeepSeek-V3 outperforms Llama 3.1 70B across all metrics for both Subtasks A and B. The model achieves higher F1-score and Databench_eval scores, indicating its superior performance in both subtasks.

Table 3 in Appendix D presents the results for open-source, open-weight models category ranking, where TeleAI secured the highest score in both tasks, followed by SRPOL AIS. The SBU-NLP team[6] ranked 6th in Subtask A but improved to 3rd place in Subtask B, demonstrating stronger performance in the second task.[7]

7 Conclusion

This paper presents an innovative algorithm leveraging a self-correction mechanism and a multi-LLM collaborative answer generation approach to address the key challenges in question answering from tabular data. By incorporating iterative error-checking in code generation and utilizing collaborative solutions to ensure valid expected answers, our method significantly reduces errors and inappropriate responses. Our error analysis highlights that most issues arise when the answer is a list rather than a simple data type, such as a number, string, or boolean. Future work will focus on refining the prompting strategies to minimize errors in such scenarios.

A Code Generation Prompt

Prompt for Code Generation

The following table is from the dataset `{{dataset_name}}`. The first few rows are:
`{{sample_rows}}`
Your task is to write Python code that answers the question: "{{question}}"
The code should:

- Load the dataset from the appropriate location. The dataset is in the folder named 'competition' which contains subfolders named after the datasets (e.g., `{{dataset_name}}`).
- Load the dataset file (`sample.parquet`) and perform the necessary operations on the DataFrame.

Please do the following:

- Use `pd.read_parquet` to load the dataset from the full data file (`sample.parquet`).
- Process the DataFrame named 'df' accordingly and print the final result.

Please return only the Python code, without any explanation or extra text, and make sure it selects the correct file using the `dataset_name` from the 'competition' folder.
The file path for the full dataset is: `competition/{{dataset_name}}/sample.parquet`
Important Rules:

- Do not include explanations, comments, or code block markers (e.g., `python`).
- If there are multiple answers, format the output as: `['United Kingdom', 'Germany', 'France']`.
- Each code print must be in a single line (no line breaks).
- If the question answer is binary (`True`, `False`), do not include the count.

Types of Answers Expected:
According to the expected answer types:

- **Boolean:** Valid answers include `True/False`, `Y/N`, `Yes/No` (case insensitive).
- **Category:** A value from a cell (or a substring of a cell) in the dataset.
- **Number:** A numerical value from a cell in the dataset, which may represent a computed statistic (e.g., average, maximum, minimum).
- **List[category]:** A list containing a fixed number of categories. The expected format is: `['cat', 'dog']`. Pay attention to the wording of the question to determine if uniqueness is required or if repeated values are allowed.
- **List[number]:** Similar to List[category], but with numbers as its elements.

Prompt for Code Generation

Additional Notes:
Also, import all needed packages.
You will not know the specific type of answer expected, but you can be assured that it will be one of these types.
For the competition, the order of the elements within the list answers will not be taken into account.
The printed output in the code must be one of the above answer types.

B Error Correction Prompt

The code with errors, along with the error information, is sent to the LLM to attempt generating a corrected version. If a previous attempt resulted in an error, the following additional prompt is used to refine the code.

Error Handling Prompt

The previous attempt resulted in an error: `{{previous_error}}`

The previous code was: `{{previous_code}}`

Instructions: Correct the error and return **only** the fixed Python code.

C Error Analysis

As shown in Figures 2, 3, 4, and 5, errors related to list-type outputs (Lists of integers, Lists of strings, and Lists of floats) consistently account for the largest proportion of mistakes across both models and subtasks. . Additionally, numerical errors are notably frequent.

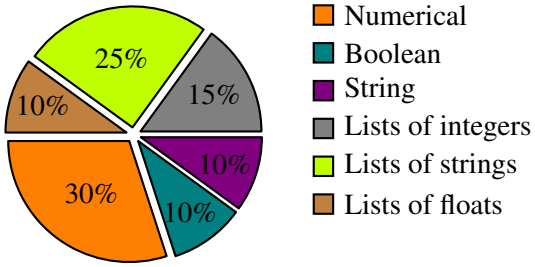

Figure 2: Error Breakdown for DeepSeek-V3 Subtask A

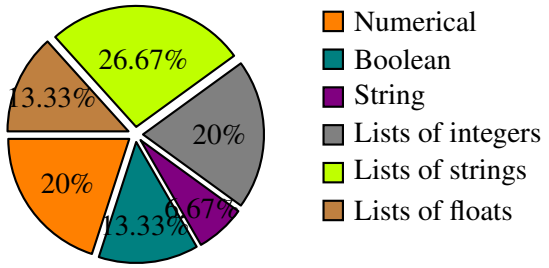

Figure 3: Error Breakdown for DeepSeek-V3 Subtask B

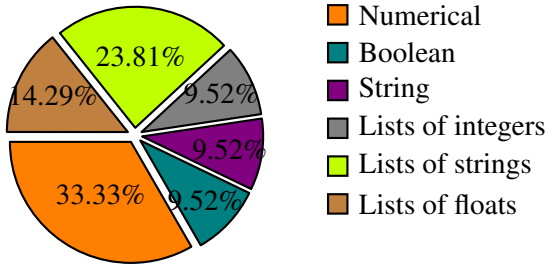

Figure 4: Error Breakdown for Llama 3.1 70B Subtask A

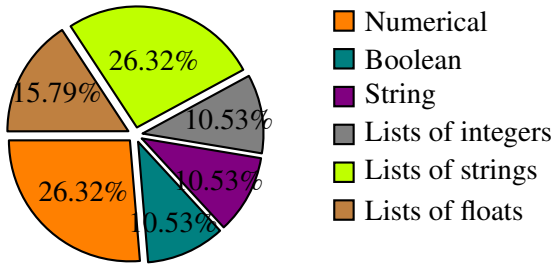

Figure 5: Error Breakdown for Llama 3.1 70B Subtask B

D SemEval Databench 2025 ranking

Subtask A			Subtask B		
Rank	**Team**	**Score (%)**	**Rank**	**Team**	**Score (%)**
1	TeleAI	95.02	1	TeleAI	92.91
2	SRPOL AIS	89.66	2	SRPOL AIS	86.59
6	**SBU-NLP**	85.63	3	**SBU-NLP**	86.02

Table 3: Performance comparison for Subtask A and Subtask B. Among the 37 teams using only open-source or open-weight models, the ranking is in a separate category. The table presents the top 2 rankings along with the result and ranking of SBU-NLP in both subtasks.

Duluth at SemEval-2025 Task 7: TF-IDF with Optimized Vector Dimensions for Multilingual Fact-Checked Claim Retrieval

Shujauddin Syed & Ted Pedersen
Department of Computer Science
University of Minnesota
Duluth, MN 55812 USA
{syed0093, tpederse}@d.umn.edu

Abstract

This paper presents the Duluth approach to the SemEval-2025 Task 7 on Multilingual and Crosslingual Fact-Checked Claim Retrieval. We implemented a TF-IDF-based retrieval system with experimentation on vector dimensions and tokenization strategies. Our best-performing configuration used word-level tokenization with a vocabulary size of 15,000 features, achieving an average success@10 score of 0.78 on the development set and 0.69 on the test set across ten languages. Our system showed stronger performance on higher-resource languages but still lagged significantly behind the top-ranked system, which achieved 0.96 average success@10. Our findings suggest that though advanced neural architectures are increasingly dominant in multilingual retrieval tasks, properly optimized traditional methods like TF-IDF remain competitive baselines, especially in limited compute resource scenarios.

1 Introduction

The SemEval-2025 Task 7 on Multilingual and Crosslingual Fact-Checked Claim Retrieval addresses the challenge of identifying previously fact-checked claims across multiple languages (Peng et al., 2025). This task is important because the global spread of misinformation makes it difficult for professional fact-checkers to manually identify existing fact-checks, as false narratives frequently cross linguistic boundaries. The task covers a diverse set of languages including English, Spanish, German, Portuguese, French, Arabic, Malay, Thai, and two surprise languages (Polish and Turkish) in the test phase, creating a broad evaluation framework for multilingual information retrieval systems in the fact-checking domain.

Our approach uses a TF-IDF[1] (Sparck Jones, 1972) based retrieval system with optimization of key parameters. We experimented with different vector dimension settings and tokenization to identify an optimal configuration for multilingual retrieval. After testing, we found that a word-level tokenization approach with a vocabulary size of 15,000 features provided the best performance across all languages. Our pipeline[2] includes data cleaning, text preprocessing, vector embedding generation, similarity computation, and ranked retrieval of the most relevant fact-checked claims for each social media post.

The optimized TF-IDF system achieved an average success@10 score of 0.78 on the development set and 0.69 on the test set, ranking 23rd out of 28 participating teams. The top-performing system outperformed our approach with an average score of 0.96, showing the performance gap between traditional statistical methods and modern neural approaches. Our system performed better on languages such as French: 0.814 and Arabic: 0.820, but struggled with others such as English: 0.452 and Spanish: 0.546. These results suggest that though TF-IDF can serve as a reasonable baseline, significant improvements in multilingual retrieval tasks require advanced contextual embedding techniques and language-specific optimizations.

2 Task Description

The SemEval-2025 Task 7 organizers offer the **MultiClaim** dataset, an augmented and modified version of the original MultiClaim corpus (Pikuliak et al., 2023). This dataset collects social media posts containing potential misinformation, previously fact-checked claims, and various related information. The following information in the dataset is used in this task:

- `post/query`: The social media post containing a potential misinformation

[1] https://scikit-learn.org/stable/modules/generated/sklearn.feature_extraction.text.TfidfVectorizer.html.

[2] Our code is publicly available at https://github.com/syed0093-umn/SemEval_Task7.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 712–717

claim, for example : *"[(1525826671.0, 'fb')]","[(""fb/david avocado wolfe Flip the bell peppers over to check their gender. The ones with four bumps are female and those with three bumps are male. The female peppers are full of seeds, but sweeter and better for eating raw and the males are better for cooking. I didn't know this!"", ""fb/david avocado wolfe Flip the bell peppers over to check their gender. The ones with four bumps are female and those with three bumps are male. The female peppers are full of seeds, but sweeter and better for eating raw and the males are better for cooking. I didn't know this!"", [('eng', 1.0)])]",['False information'],"*

- `fact check`: A collection of previously fact-checked claims from verified fact-checking organizations, for example : *"(' Are avocados good for you?', ' Are avocados good for you?', [('eng', 1.0)])","[(1525653998.0, 'https://metafact.io/factchecks/175-are-avocados-good-for-you')]",*
- `pair`: The mapping between fact check ids and post ids.
- `claim metadata`: Additional information about each fact-checked claim, including source, publication date, and veracity rating.
- `relevant claims`: Human-identified relevant fact-checked claims that match the query, serving as gold standard matches.

The task is to retrieve relevant fact-checked claims from the `fact_check` collection that match the given post. Retrieved claims are classified into the following two tracks based on language:

- `monolingual`: Retrieving relevant fact-checked claims in the same language as the query.
- `crosslingual`: Retrieving relevant fact-checked claims across different languages.

The provided training data consists of 153,743 samples in the `fact_checks.csv`. The distribution across languages is: English: 85,734 (55.76%), Portuguese: 21,569 (14.03%), Arabic: 14,201 (9.24%), Spanish: 14,082 (9.16%), Malay: 8,424 (5.48%), German: 4,996 (3.25%), French: 4,355 (2.83%), and Thai: 382 (0.25%).

The test phase introduced two surprise languages: Turkish and Polish.

The agreement between the model's predictions and the ground truths is evaluated based on **success-at-10 (S@10)**, which measures if at least one relevant fact-checked claim appears among the top 10 retrieved results. Participants may choose to participate in either one or both tracks when making submissions, with a maximum of 5 submissions allowed during the test phase, where only the last submission will be counted for the final leaderboard. In our submission, we participated only in the `monolingual` track.

3 Related Work

Fact-checked claim retrieval has seen various approaches over the past few years. Early work by (Shaar et al., 2020) and later, the extensive MultiClaim study by (Pikuliak et al., 2023), provided a broad multilingual dataset that expanded the task past English and monolingual settings. Their work highlighted the challenges in retrieving fact-checked claims across many languages.

Parallel to the fact-check retrieval, the development of Multilingual Language Models (MLLMs) is explained in (Doddapaneni et al., 2021)'s primer. MLLMs like mBERT and XLM-R have shown impressive zero-shot transfer capabilities in a wide range of tasks. These models are designed to learn shared representations across languages, using large-scale multilingual pre-training to enable cross-lingual transfer.

4 System Overview

The section presents a detailed view of our proposed system which generates the monolingual predictions for the given fact checks and posts; based on the given tasks file.

4.1 Data Cleaning

We decided to implement the data loading procedure given to us in the task, which utilized the `load.py` script. This script loads and preprocesses `posts.csv`, `fact_checks.csv`, and `pairs.csv`. It checks if the files exist, and then handles newline characters in text fields by replacing `"\n"` with escaped `"\\n"` before using `ast.literal_eval` to parse string representations of lists or dictionaries. The script loaded `fact_checks.csv` and `posts.csv` into Pandas DataFrames, filling missing values with empty strings and setting specific

columns to be processed with the `parse_col` function. The use of this script led us to having clean data with defined columns.

4.2 Model Discussion

The exploration of models was twofold; we first wanted to see the model performance on the dev set and then proceeded further to tune the model whose performance was found to be suitable.

We used the TF-IDF (Term Frequency-Inverse Document Frequency) model, implemented using scikit-learn's `TfidfVectorizer`[3]. It is a statistical method used to convert text into numerical features by evaluating the importance of words in a document relative to a collection of documents. We used the TF-IDF model with modifications to the 'max_features' (vector_size) and 'analyzer' parameters. For the final system, only `task.json`, which is a task configuration file was used to ensure that the test data remained unseen.

We lay out a standard procedure and follow that for every model. Our procedure included the following steps: 1) We start with parsing the tuple string format of the fact check data; and then proceed towards parsing the instances string to extract the URLs and timestamps. And to preprocess the post, we combine all the relevant text fields from a post. 2) The `create_retrieval_system` function takes in the fact checks, task configuration file, and posts to create vector embeddings for the specific model. And then returns the retrieval model, fact check vectors, and fact check IDs for further retrieval tasks. 3) The `retrieve_fact_checks` function takes an individual post's data, the model retriever (which calls the model), vector embeddings, fact check ids and the number of required results dictated by the organizers as input (10). The post's text data is converted into vector representations and similarities are computed between the query and the fact check. The fact checks are then ranked by similarity score and the list of top 10 fact check ids is returned by the function. 4) The `generate_predictions` function handles multiple posts at once. It processes each post by first extracting relevant text data, converting it into vector representations, and then using the retrieval model from `retrieve_fact_checks` to find the most similar fact checks. The function generates predictions by mapping each post to the corresponding top-ranked fact check IDs based on similarity scores. The output is returned in a JSON-like structure that maps multiple post IDs to all of their corresponding fact check IDs. 5) In our pipeline the main function is responsible for loading the input data, processing each language individually, and generating predictions for each post. The processing includes parsing the posts' content, applying the retrieval system, and selecting relevant fact checks. The function then saves the predictions in a standard `monolingual_predictions.json` file, which is used for evaluation on the task organizers' platform, CodaBench.

5 Experiment

We stuck to TF-IDF because it gave us the best results. However, there were several models that we wanted to experiment with before finalizing TF-IDF:

TF-IDF – Within TF-IDF, we experimented with different vector sizes and with the analyzer parameter having values: 'word', 'char', 'charwb'.

XLM-RoBERTa (Conneau et al., 2020) – We tried two approaches for XLM-RoBERTa[4], the first approach used mean pooling over token embeddings weighted by attention masks, capturing richer contextual information, whereas the second approach relied on the CLS token embedding. The first approach processed texts one at a time, making it slower, while the second implemented batch processing (batch size = 8), which aimed to improve efficiency.

Multilingual E5 Large (Wang et al., 2024) – We use the E5 Retriever, a transformer-based embedding model[5]. Our retriever encodes text using an average pooling strategy over token embeddings, followed by L2 normalization for better similarity computation. We generated dense embeddings in batches.

FastText (Joulin et al., 2016) – Fasttext uses pre-trained word vectors for 157 languages (Grave et al., 2018) (`cc.en.300.bin`)[6]. Our FastTextRetriever preprocesses text by removing special characters and normalizing case before generating sentence embeddings. We compute dense representations for fact-check claims and social media posts,

storing fact-check embeddings in batches.

T5-Model (Ni et al., 2021) – The `sentence-transformers/gtr-t5-large`[7] was used to generate dense text embeddings. Our GTR Retriever preprocesses text by removing special characters and normalizing case before encoding claims and social media posts into 768-dimensional vectors.

distilBERT (Sanh et al., 2020) – We utilize `distilbert-base-nli-stsb-mean-tokens`[8] to generate dense text embeddings. Our DistilBERTRetriever preprocesses text by removing special characters and normalizing case before encoding claims and social media posts into contextualized vector representations.

5.1 Experimentation with TF-IDF

When we finalized our model, we wanted to improve performance and thought the best way to do so would be to tinker with model parameters such as `max_features` and `analyzer`.

The `max_features` parameter controls the vector size by limiting the number of unique terms in the vocabulary. It retains only the topmost important words based on term frequency. Hence, the TF-IDF matrix will have at most that many columns, where each column represents a term.

The `analyzer` parameter controls how the input text is processed before applying the TF-IDF transformation. The default setting, `word`, tokenizes the text into individual words, allowing the model to capture word-level features. Other options, such as `char` and `char_wb`, allowed for character-level tokenization or character n-grams.

The reason why we chose the default `word`, was to ensure that the most relevant features are captured at the word level, and because of all permutations and combinations of both model parameters, we were getting the best model performance and **success@10** by utilizing the default analyzer parameter.

6 Experimental Results and Discussion

The default parameter 'word' along with a vector size of 15,000 gave us the best **success@K** score of 0.78 (avg) on the dev set and 0.69 (avg) on the test set.

The Duluth system achieved the highest success@K score of 0.78 (dev set) and 0.69 (test set) with the TF-IDF 15K configuration, which outperformed all other methods.

The TF-IDF 15K configuration showed consistent high performance across all languages, and improved over the TF-IDF 10K model (0.7757 vs. 0.7630 avg). TF-IDF performed well on English (0.6130) and Spanish (0.8358), which indicated that increasing the vocabulary size improved re-

[7] https://huggingface.co/sentence-transformers/gtr-t5-large.

Table 3: Unseen Test Set Scores: Comparison between Duluth and the Top Ranked System

Sys.	pol	eng	msa	por	deu	ara	spa	fra	tha	tur	avg
DLH	0.626	0.452	0.8495	0.558	0.690	0.820	0.546	0.814	0.8415	0.686	**0.6883**
Top	0.926	0.916	1.000	0.926	0.958	0.986	0.974	0.972	0.9945	0.948	0.9601

trieval performance. However, character-based TF-IDF approaches underperformed, such as TF-IDF 15K (Char WB Analyzer) with an average score of 0.4528, which suggests that word-based tokenization was more effective than character-based representations.

From the neural methods, E5 Large achieved an average score of 0.6494 and T5 Model closely followed at 0.6360. XLM-RoBERTa and DistilBERT performed poorly, with XLM-RoBERTa averaging only 0.0984 and DistilBERT at 0.3212.

TF-IDF was pretty standard across languages, but minor performance drops were observed for German (DEU) and Thai (THA). Character-based analyzers underperformed, more so in German and Arabic, mainly due to their complex word forms and stuck together structures.

E5 Large and T5 Model had strong performance, but they had more errors in lower-resource languages (e.g., Malay and Thai), this could be due to pretraining biases as these models have largely been trained on other languages.

BERT-based models had very low performance, especially on Arabic (ARA), Malay (MSA), and Thai (THA), which suggested poor generalization in non-Latin scripts.

7 Future Work and Conclusions

Potential modifications to improve the performance of T5 Model and E5 Large could be fine-tuning these models on a more extensive and diverse set of fact-checking data to help them better capture domain-specific features.

Models could be generalized more by augmenting and balancing the training data, resulting in a reduced bias observed in pretraining. Experimenting with language-specific tokenizers could address difficulty with non-Latin scripts and complex word forms.

We presented an optimized TF-IDF retrieval system for multilingual fact-checked claim retrieval. By fine-tuning vector dimensions and using word-level tokenization with a 15,000-feature vocabulary, our approach achieved robust performance—0.78 success@10 on the development set and 0.69 on the test set. These results highlight that, with careful tuning, traditional methods can be competitive even against advanced neural models, especially in high-resource settings.

We plan to investigate why our neural methods did not reach the level of TF-IDF by doing a case-by-case error analysis of where TF-IDF was performant and where it failed, to see if there exist any patterns to discover.

Future work could incorporate the reviewers' recommendation of a hybrid approach, combining TF-IDF and neural embeddings, to better support lower-resource languages and enhance retrieval effectiveness.

8 Acknowledgments

The authors would like to thank the organizers for the opportunity to participate in SemEval-2025 Task 7 and the Department of Computer Science, University of Minnesota Duluth, for helping us with all resources needed to participate in this task. We also appreciate the valuable input and guidance provided by the reviewers.

Abstract

Automatic and early detection of foodborne hazards is crucial for preventing foodborne outbreaks. Existing AI-based solutions often cannot handle complexity and noise in food recall reports and they struggle to overcome the dependency between product and hazard labels. We introduce a methodology for classifying reports on food-related incidents that addresses these challenges. Our approach leverages LLM-based information extraction, to minimize report variability, along with a two-stage classification pipeline. The first model assigns coarse-grained labels that narrow the space of eligible fine-grained labels for the second model. This sequential process allows us to capture hierarchical label dependencies between products and hazards and between their respective categories. Additionally, we designed each model with two classification heads that rely on the inherent relations between food products and associated hazards. We validate our approach on two multi-label classification sub-tasks. Experimental results demonstrate the effectiveness of our approach, which achieves an improvement of +30% and +40% in classification performance compared to the baseline.

1 Introduction

Food hazard detection — identifying potential risks associated with food products — is pivotal for public health. In this context, researchers have started exploring solutions based on traditional machine learning (ML) and deep learning (DL) techniques to automate food hazard detection tasks. This can help mitigate foodborne outbreaks and improve food safety measures (Zhou et al., 2019; Qian et al., 2023).

Albeit promising, such approaches leverage structured data extracted from incomplete or misleading information collected from social media (Maharana et al., 2019; Tao et al., 2023). More interestingly, natural language processing (NLP) techniques powered by large language models (LLMs) have unlocked new possibilities—especially in scenarios with limited labeled data (such as low-resource languages (Perak et al., 2024; Koudounas et al., 2023) or specific context (Pal et al., 2024; Benedetto et al., 2023)).

They enable the extraction of more robust and context-enhanced information from unstructured data when it relies on authoritative sources such as public reports from government agencies (Özen et al., 2025). This allows for more reliable and comprehensive analysis of food hazard trends and their potential impact.

Among others, Randl et al. (2024) have introduced a dataset of publicly available food recall announcements, annotated at two hierarchical levels — i.e., high-level categories and fine-grained labels for both food products and associated hazards. The authors use this dataset to benchmark a food hazard detection methodology for addressing a multi-label report classification task. While the reports included in the dataset provide authoritative insights, they inherently present noise and span thousands of classes, which poses significant analytical challenges.

Relying on the work of Randl et al. (2024), we hypothesize that information about hierarchical structure can enhance a model's classification performance. Specifically, classifying broader product categories first can facilitate subsequent identification of specific food items, and the same applies to hazard classification. Moreover, while the relationship between food products and associated hazards is highly correlated, existing approaches fail to explicitly model these dependencies (Randl et al., 2024).

In this paper, we address the report classification task in a multitask fashion. We propose a novel approach based on sequential multi-head classification. We present three key advances in multi-label food hazard detection:

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 718–725

1. *Multi-Head Architecture:* We decouple product and hazard prediction by leveraging two classification heads, which enables specialized feature learning for each label type.

2. *Hierarchical Constraint Mechanism:* We first predict macro-categories to dynamically restrict fine-grained class probabilities, leveraging label hierarchy to improve accuracy.

3. *LLM-Driven Corpus Normalization:* We apply LLM information extraction to standardize report texts, thus reducing variability and noise prior to classification.

The classification results on The Food Hazard Detection Challenge (Randl et al., 2025) dataset validate the effectiveness of our approach. Our pipeline achieves an F-score of 0.80 for product classification and an F-score of 0.47 for hazard classification. The Multi-Head approach accounts for the largest improvement in performance, adding an absolute F1 of +0.30 on product classification and an absolute F1 of +0.46 on hazard classification to the single-head baselines. Corpus normalization contributes an additional +0.01 F1 improvement by reducing text variability. Enforcing the hierarchical constraints at the Sequential Classification stage yields a marginal +0.005 F1 gain. Additionally, our approach ranks in the top 15 of the public leaderboard ("title and text" tracks), reaching 6th place in ST1 and 13th place in ST2[1].

2 Background

In the last decade, researchers have focused their efforts on exploring AI-based solutions for food hazard detection (Zhou et al., 2019; Qian et al., 2023). Most of the existing research rely on traditional ML (Kumar et al., 2024) and DL techniques (Xiong et al., 2023), from the detection of zoonotic disease sources (Lupolova et al., 2017) to microbial risk assessment (Njage et al., 2019), to name but a few. Nevertheless, the recent development of LLMs and the advancement of NLP techniques (Zhao et al., 2024) have pushed the boundaries towards more sophisticated approaches (Özen et al., 2025; Prabhune et al., 2025; Randl et al., 2024).

Although recent studies have started leveraging insights from the scientific literature (Xiong et al., 2023; Özen et al., 2025), the majority of food risk detection approaches rely on corpora consisting of news or social media posts (Tao et al., 2023; Maharana et al., 2019). Such sources often provide incomplete information and lack precision from both a taxonomical and scientific perspective, making it challenging to extract structured and reliable data for AI-driven food risk assessment (Randl et al., 2024).

The majority of existing approaches frame the problem as a binary classification task where the goal is to detect the presence of an incident from tabular or image data (Wang et al., 2022). Such approaches are promising but are often too simplistic for real-world scenarios (Hu et al., 2022) where food risk assessment requires complete interpretation of textual data, consideration of context, and distinguishing between different levels of risk severity (Danezis et al., 2016; Prache et al., 2022).

To overcome these issues, Randl et al. (2024) created a new dataset of $>$ 6000 food recall announcements from 24 public food safety authority websites spanning 28 years from 1994 to 2022. They formulated the food hazard detection problem as two supervised multi-label classification tasks and organized the collected reports accordingly: (i) the aim of subtask ST_1 is the classification of each report into macro categories of food products (22 labels) and related hazards (10 labels); (ii) the aim of subtask ST_2 is identification of the specific products (1 142 labels) and hazards (128 labels) mentioned in the reports.

Randl et al. (2024) relied on that dataset to validate a methodology based on LLMs and conformal prediction (Vovk et al., 2022). They addressed the two classification subtasks separately by training two different classifiers, each designed with a single classification head that simultaneously processed products and their associated hazards. While promising, this design may limit the model's ability to distinguish between the different aspects of each target.

In contrast, we propose a modification to this architecture by splitting the classification head into two distinct heads, which allows the model to better capture the relationship between food products and potential hazards.

Moreover, while Randl et al. (2024) addressed the two subtasks independently, we introduce a sequential classification approach (see Section 3), where we constrain the classification probabilities of the detailed labels (i.e., subtask ST_2) to the probabilities of the category labels (i.e., subtask ST_1).

[1]Code available at https://github.com/auro736/BitsAndBites_SemEval2025_Task9.

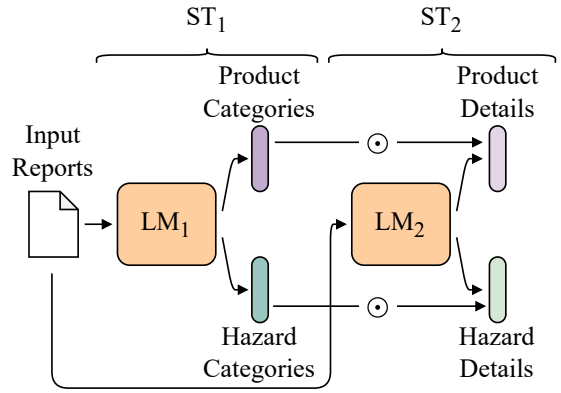

Figure 1: Overview of the adopted methodology. For each subtask (ST_1 and ST_2), we train one classification model with two classification heads: one for classifying the product labels, and one for classifying the food hazard. Then, we constrain the probabilities of the ST_2 detailed labels based on the probabilities of the ST_1 generic categories.

This enables the model to refine its predictions by leveraging the hierarchical dependency between the two tasks, ultimately improving both the accuracy and robustness of food hazard detection.

3 Methodology

In this section, we present our food hazard detection methodology. In Section 3.1, we address the overall problem by relying on a multi-head architecture. This results in two models — one for high-level categories (ST_1) and one for fine-grained labels (ST_2). Then, in Section 3.2, we introduce the sequential classification approach, where fine-grained predictions are guided and constrained by the predictions of the broader categories. Finally, in Section 3.3, we describe how we leverage LLMs to normalize the noisy, unstructured reports through summarization and information extraction, which also enhances classification performance.

3.1 Multi-Head Architecture (MH)

Given the possible correlations between food products and their associated hazards (Randl et al., 2024), we have opted for a double classification head approach.

For each subtask, we split the classification layer of the LM into two classification heads. This way, part of the model parameters are shared across the two subtasks while each classification head is specialized in a different classification subtask (see the green and purple blocks of Figure 1).

As a consequence, for a single subtask we obtain two loss functions, i.e., L_P for the product classification head and L_H for the hazard classification head. We jointly train the two classification heads with a linear combination of the two loss functions. The resulting loss function is $L = \lambda_P \cdot L_P + \lambda_H \cdot L_H$, where $\lambda_P, \lambda_H \in \mathbb{R}$ are multiplicative coefficients to balance the contributions of the head-specific losses.

3.2 Sequential Classification (SC)

We define the set of hazard/product categories $\mathcal{C} = \{c_1, \ldots, c_C\}$ from ST_1 and the set of detailed hazards/products as $\mathcal{D} = \{d_1, \ldots, d_D\}$ from ST_2. As mentioned in Section 2, the dataset exhibits a hierarchical structure between ST_1 and ST_2, i.e., given a hazard/product category $c_i \in \mathcal{C}$, there exists a subset of details $\mathcal{D}_i \in \mathcal{D}$ associated with c_i.

We train two classifiers independently, each tailored to their respective subtask — i.e., LM_1 for ST_1 and LM_2 for ST_2, as highlighted in Figure 1.

First, in ST_1 we leverage LM_1 to predict the probabilities of all the hazard/product categories of an input report. Hence, we assign the report to the hazard/product category with the highest probability, formally $\arg\max_{c_i \in \mathcal{C}} p_{c_i}$, where p_{c_i} is the probability of category c_i.

Then, in ST_2, we exploit the hierarchical relationship between categories and their associated details by weighting the probability of each detail (p_{d_j}) by the probability of its corresponding category (p_{c_i}). Rather than considering a single category, we propagate all probabilities from ST_1 into their corresponding detailed hazard/product probabilities in ST_2:

$$\hat{p}_{d_j} = p_{d_j} \cdot p_{c_i}, \ \forall d_j \in \mathcal{D}_i \ , \ \forall c_i \in \mathcal{C}$$

Hence, we consider the final detailed prediction with the maximum probability, formally $\arg\max_{d_j \in \mathcal{D}} \hat{p}_{d_j}$.

This ensures that the predictions for detailed hazards/products are influenced by the category-level classification, thus maintaining hierarchical consistency between ST_1 and ST_2. As a result, this sequential classification approach should enhance the accuracy and consistency of predictions by restricting LM_2 to only relevant details.

3.3 Corpus Normalization (CN)

The texts included in the dataset follow different formats and structures depending on the type of

	ST_1		ST_2	
	Validation	**Test**	**Validation**	**Test**
Baseline	0.4932	0.4722	0.0031	0.0037
MH	0.7893	**0.7998**	0.4777	0.4644
MH + SC	–	–	**0.4825**	0.4693
MH + CN	**0.8020**	0.7817	0.4813	**0.4700**
MH + CN + SC	–	–	0.4802	0.4681

Table 1: Comparison of classification results across the proposed approaches: sequential classification (SC) and corpus normalization (CN). The experiments are conducted using RoBERTa-large, identified as the best-performing model. The best results are highlighted in **boldface**.

report, the country, the government agency, or the website from which they were extracted. This poses significant challenges for a classifier based on an LM.

To address this issue, we reduce the reports' variability and noise by leveraging another LLM in a zero-shot setting to extract specific information in a uniform and fixed format. Hence, we obtain the final report by prepending the extracted text to the original report.

Below, we provide the prompt template we used to normalize the report:

```
You are an expert in analyzing food-related incident
reports. For the given text, identify the recalled food
product and the motivation for the recall. Add also the
categories that you can infer of the food product and the
motivation.
Provide the output in the following format:
PRODUCT: <food product and its category extracted>
HAZARD: <motivation and its category extracted>
Do not include any additional explanation or output. Follow
the format strictly.
```

4 Experimental Setup

When not explicitly stated, we ran our experiments on the training, validation and test datasets[2] released by the "Food Hazard Detection Challenge" (Randl et al., 2025).

We used RoBERTa-large as the best model among BERT-uncased-large, DeBERTa-v3-large and ModernBERT-large evaluated during a model selection stage (see Appendix A). We used sequence cross-entropy as the loss function as well as the AdamW optimizer (Loshchilov and Hutter, 2017) with a weight decay of 0.01 and a learning rate of 10^{-5}. To prevent overfitting, we remove connections in the last classification layer with a probability of 0.1.

After a hyperparameters tuning stage, we set the coefficients of the multi-head architecture to $\lambda_P = 0.5$ and $\lambda_H = 0.5$ for subtask ST_1, whereas we set $\lambda_P = 1.0$ and $\lambda_H = 1.5$ for subtask ST_2 (please refer to Appendix B for further details on loss coefficient tuning). We extracted the structured information from the reports (CN) with Meta-Llama-3.1-8B-Instruct in zero-shot fashion. We ran all the experiments on a Ubuntu 22.04 Long Term Support (LTS) machine equipped with Intel® Xeon™ Gold 6126 CPU, 1 × Nvidia® RTX 6000 graphics processing unit (GPU), 24 gigabyte (GB) of random access memory (RAM).

Evaluation Metric We evaluated our approach through the *task F1-score* evaluation metric proposed by the organizers of the "SemEval" challenge (Randl et al., 2025). This metric is a customized version of the traditional F1-score accounting for the relation between food products and associated hazards. We provide its implementation in the following code snippet in Python:

```python
from sklearn.metrics import f1_score

def task_f1_score(H_true, P_true, H_pred, P_pred):
  # Compute F1 for hazards:
  H_f1 = f1_score(H_true, H_pred, average='macro')
  # Constraint the products on the predicted hazards
  P_true = P_true[H_pred == H_true]
  P_pred = P_pred[H_pred == H_true]
  # Compute F1 for products:
  P_f1 = f1_score(P_true, P_pred, average='macro')
  # Compute the final task F1-score
  return (H_f1 + P_f1) / 2
```

In a nutshell, we first evaluated the F1-score of the predicted hazards with macro averaging to account for labeling unbalances. Then, we constrained the evaluation to only those instances where the predicted and ground truth hazards align. Within this subset, we then computed the macro average F1-score for the associated food products. Finally, we computed the final task F1-score by averaging the product and hazard scores. This ensures that both hazard detection and product association are jointly considered in the evaluation.

[2]We use the *title* and *text* features from the datasets to create a single concatenated text.

5 Experimental Results

In Table 1, we provide the task F1-scores for the two classification tasks obtained with our approach[3].

We use as baseline a standard classification model based on RoBERTa-large and a single classification head for each task — i.e., ST_1 and ST_2.

Firstly, using a single classification head limits the baseline performance, with a task F1-score of $< 50\%$ in ST_1. This limitation is even more evident in ST_2, where the task F1-score is $< 1\%$. Here, further analysis reveals that merging the product and hazard labels in a unique classification head leads to a strong bias for the predominant class — i.e., the products. As a consequence, 89% of the hazards are misclassified as products.

The multi-head (MH) classification brings a substantial improvement over the baseline in both ST_1 and ST_2, with improvements in the task F1-scores of $> 39\%$ and $> 46\%$ respectively. The classification results confirm our assumption that splitting the hazard and product classification heads allows the classifier to achieve high specialization while accounting for label unbalancing.

Overall, corpus normalization (CN) applied along with MH leads to a performance comparable to simple MH, except for a slight decrease in the test task F1-score of $\sim 2\%$ for ST_1. Apart from this specific case, the information extracted by the LLM follows a uniform and fixed structure, effectively reducing the reports' variability and facilitating the classifier's handling of heterogeneous data. As a result, with CN the classifiers can correctly assign over 100 more reports to the correct products and hazards compared to using the MH alone.

Leveraging the hierarchical structure of labels (i.e., categories and details) through sequential classification (SC) applied alongside simple MH pays off, resulting in a slight task F1-score improvement of $\sim 0.5\%$. On the other hand, SC seems to slightly limit the improvement of the CN approach. Despite the classifier performing comparably with a task F1-score of around 48%, combining the three approaches leads to a slight decrease in performance of $\sim 0.1\%$.

[3]Note that the results presented in this table differ from those in the public competition leaderboard. Here, we have revised and refined the methodology to achieve greater stability and robustness across different model configurations.

6 Conclusions

In this paper, we proposed a novel sequential multi-head classification approach to classify food-related incident reports. We introduced a classification pipeline that integrates (i) multi-head classifiers to split food products and associated hazard labels, (ii) a sequential classification strategy leveraging hierarchical labels, and (iii) LLM information extraction for normalizing reports that exhibit high variability.

Experimental results demonstrate the efficacy of our approach, which yields significant performance improvements over the baseline single-head classifier. The multi-head approach substantially enhances the classifier's performance, mitigating the biases caused by labeling imbalances observed in the baseline model. Corpus normalization reduces report variability and provides a common structure to the texts, thereby slightly improving the classification performance. Finally, sequential classification marginally boosts performance by constraining predictions based on hierarchical label dependencies.

Future work could explore alternative approaches to hierarchical classification constraints, further optimizing the balance between interpretability and performance. Additionally, integrating external knowledge could enhance model robustness and generalization across different food safety scenarios. We also plan to evaluate the use of the embeddings produced by our multi-head, hierarchy-based approach to index incident reports in a retrieval-augmented generation (RAG) framework to enable more efficient retrieval and richer contextualization of historical cases.

Limitations and Ethical Statement

The dataset used in this study, to the best of our knowledge, does not contain any personal information. However, it may include potentially harmful or inappropriate content. This consideration also extends to the model employed, which may generate incorrect responses. The use of this particular dataset and models is subject to the limitations outlined in their respective technical reports and licenses.

Our approach depends on the quality and comprehensiveness of the dataset used. Although it consists of authoritative food recall reports, the dataset may still contain inconsistencies or outdated information, and the performance of the model may vary

due to the presence of other kinds of data. As such, the generalizability of our approach to other food safety datasets or real-world scenarios remains an open question requiring further validation on different food safety records.

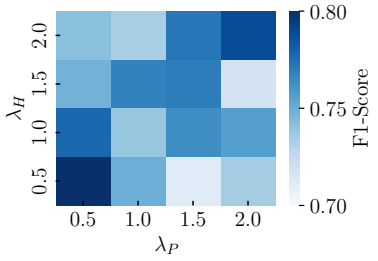
A Model Selection

Here, we complement our experimental results by reporting the model selection task F1-Scores. We organize our dataset relying only on the challenge training data, properly split into training (70%), validation (15%) and test sets (15%).

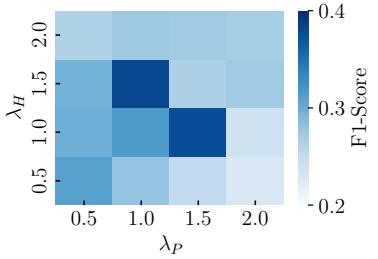
We choose the best model among BERT-uncased-large, RoBERTa-large, DeBERTa-v3-large, ModernBERT-large. We train each model for a maximum of 10 epochs with early stopping and the same experimental settings of Section 4. Appendix A showcases the classification results.

	Task ST_1		Task ST_2	
	Validation	**Test**	**Validation**	**Test**
ModernBERT	0.6379	0.6591	0.2368	0.2223
BERT-uncased	0.6735	0.6866	0.2634	0.2472
DeBERTa-v3	0.7393	0.6741	0.2291	0.2022
RoBERTa	**0.7487**	**0.7394**	**0.3315**	**0.3175**

Table 2: Model selection classification scores for the two subtasks ST_1, ST_2 with sampled data. Best results are in **bold**.



(a) Task ST_1: Classification of categories



(b) Task ST_2: Classification of details

Figure 2: Task F1-Scores with different values of λ_P and λ_H.

.

B Choice of λ_P and λ_H

Here, we complement our experimental results by reporting the results of the hyperparameter tuning stage for λ_P and λ_H introduced in Section 3.1. As for the model selection, we organize our dataset relying only on the challenge training data, properly split into training (70%), validation (15%) and test sets (15%).

We use RoBERTa-large as the best model resulting from the model selection stage and train it for a maximum of 10 epochs with early stopping. We test λ_P and λ_H values in the range from 0.5 to 2.0 and report in Figure 2 the task F1-Scores.

G-MACT at SemEval-2025 Task 8: Exploring Planning and Tool Use in Question Answering over Tabular Data

Abstract

This paper describes our system submitted to SemEval-2025 Task 8 "Question Answering over Tabular Data." The shared task focuses on tackling real-life table question answering (TQA) involving extremely large tables with the additional challenges of interpreting complex questions. To address these issues, we leverage a framework of Multi-Agent Collaboration with Tool use (MACT), a method that combines planning and tool use. The planning module breaks down a complex question by designing a step-by-step plan. This plan is translated into Python code by a coding model, and a Python interpreter executes the code to generate an answer. Our system demonstrates competitive performance in the shared task and is ranked 5th out of 38 in the open-source model category. We provide a detailed analysis of our model, evaluating the effectiveness and the efficiency of each component, and identify common error patterns. Our paper offers essential insights and recommendations for future advancements in developing TQA systems.

1 Introduction

Table question answering (TQA) focuses on addressing questions related to tables. It has been widely studied across domains (Zhu et al., 2021; Lu et al., 2023; Katsis et al., 2022) and languages (Zheng et al., 2023; Pal et al., 2024; Jun et al., 2022). Current TQA datasets predominantly feature tables from Wikipedia (Pasupat and Liang, 2015; Zhang et al., 2023), resulting in an oversimplified task setup characterized by small, clean tables with limited diversity in data types. To promote studies in real-life TQA, Osés-Grijalba et al. (2025) propose DataBench, an English TQA dataset consisting of 65 tables and around 1300 manually created questions spanning various domains. Based on this dataset, the SemEval-2025 Task 8 "Question Answering over Tabular Data" encourages TQA modeling in a more realistic and challenging setup. It consists of two subtasks: ALL, where original long tables are used and LITE, in which only the first 20 rows of a table are used.

There are two main challenges in the task: (1) the **large table size** makes direct inference using large language models (LLMs) difficult due to their limited input lengths and problems of being *lost in the middle* (Liu et al., 2024). (2) The **complexity of questions** requires multiple steps to be solved. For instance, to answer the question in Figure 1, a system should first filter for employees who are working in sales and then calculate the average of working years among those employees.

To address these challenges, we propose G-MACT, a method combining Global planning with Multi-Agent Collaboration with Tool use (Zhou et al., 2025). G-MACT comprises two modules: a global and an iterative planning module. The global planning module takes in the first several rows of a table alongside a question, and generates a step-by-step plan. By doing this, we break down a complex question into easier sub-steps. A coding agent translates this plan into pandas-based Python code,[1] which is executed using a Python interpreter to derive an answer.

Despite being efficient, the global planning module may encounter difficulties in formulating an optimal plan when it relies solely on a partial table and a question. To enhance the robustness of plan generation by conditioning it also on past observations, we apply the iterative planning framework MACT whenever the global planning module does not yield an answer. The framework generates one step of a plan in each iteration, considering past steps and observations. We ensemble results from four models for our final submission. Our method ranks 5th among 38 open-weight systems in the challenging ALL setup.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 726–742

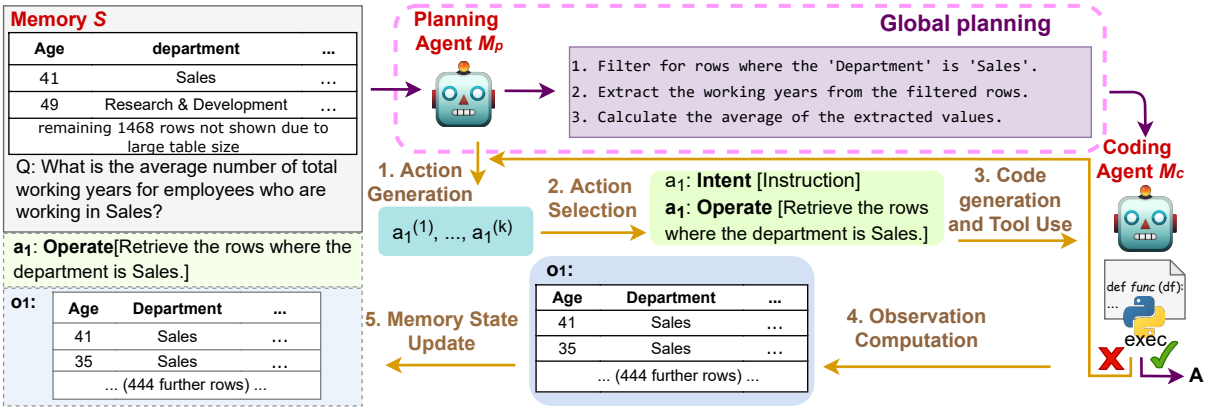

Figure 1: G-MACT illustration. It leverages both global planning (shown in purple) and iterative planning (shown in orange).Iterative planning is applied if Python fails to compile and no answer is obtained.

We thoroughly analyze G-MACT from three perspectives: effectiveness of the global and iterative planning modules, efficiency, as well as error patterns. We find that most instances in DataBench can be solved by global planning and tool use alone. However, the iterative planning module proves essential for instances where global planning fails to yield an answer. Additionally, our findings underscore the significance of selecting an optimal ensemble method. We observe for around 91% of the cases, at least one model predicted the correct answer, while the ensemble method used in our approach only achieves around 86% of exact match (EM) accuracy. This discrepancy highlights a clear need for exploring more sophisticated ensembling techniques. Lastly, through an error analysis, we find that developing a good planning agent that can understand table semantics and has access to factual and domain-specific knowledge is of vital importance for further enhancing a model's performance. We make our system publicly available.[2]

2 Related Work

The main methodologies used by G-MACT are planning and tool use. Both have been employed in TQA to facilitate more fine-grained problem solving, thus improving model performance (Zhao et al., 2024; Wu and Feng, 2024; Zhou et al., 2025; Wang et al., 2024). Current research either utilizes global planning (Zhao et al., 2024) or iterative planning (Wang et al., 2024; Zhou et al., 2025). Global planning involves generating a plan consisting of multiple steps in a single iteration, conditioned solely on a question and a table. Iterative planning conditions the generation of the next step of a plan on previous observations and steps. While global planning tends to be more efficient, iterative planning offers more fine-grained plan generation. In G-MACT, we integrate both planning methods.

3 System Overview

Given a table T and a question Q, a TQA system aims to address Q and return an answer A. Our proposed system G-MACT combines global planning with the iterative approach of multi-agent collaboration with tool use (Zhou et al., 2025) in a pipeline manner as illustrated in Figure 1. In this section, we introduce the global planning module, the iterative planning module, and the ensemble method used to create the submission results.

3.1 Global Planning

Our global planning module comprises a planning agent M_p and a coding agent M_c with a Python interpreter. As shown in Figure 1, M_p takes in the first two rows of a table and a question, then generates a step-by-step plan. This can be represented as: $P \sim M_p(P|Q, T', \phi_p, \tau_p)$, where T' is a subpart of a table. ϕ_p and τ_p are the prompt (provided in A.1) and the temperature of the LLM used for M_p, respectively. We pass only the first two rows of a table because (1) LLMs have been shown to struggle with long tables (Zhou et al., 2024) and (2) plan generation requires mainly information about the table columns and data types, which can be derived from the columns and first two rows of the table. We utilize in-context learning to prompt M_p to generate a step-by-step plan, providing instructions to solve a question, without intermediate results. An example is shown in the purple box of Figure 1. Given a plan P, a cod-

[2] https://github.com/boschresearch/MACT

ing agent M_c generates Python code using pandas: $c_i \sim M_c(c_i|P, T', Q, \phi_c, \tau_c)$. We sample k times from M_c to increase the robustness of the system against generated syntax errors, resulting in a set of code snippets $C = \{c_i^n\}_{n \leq k}$. A Python interpreter is run on each c_i, creating a set of executed solutions $\hat{A} = \{\hat{a}_i^n\}_{n \leq k}$. The final answer A is the most frequent answer in $\hat{A}$.

3.2 Iterative Planning

The global planning module can be very efficient since each question requires only one LLM call to generate a plan. However, it is still possible that no prediction is given by the module, namely if no code generated from M_c is successfully executed. To mitigate the impact of failed execution, we resort to an iterative planning module if no answer is given by the global planning module. The design of the module is based on MACT (Zhou et al., 2025). The framework takes in a TQA problem, i.e., a full table and a question, and returns a prediction. This is achieved by breaking down a complex problem into fine-grained steps and addressing each step with two agents (a planning M_p, a coding agent M_c) and a toolset. Zhou et al. (2025) define each step as an intent and an instruction. An intent encodes the purpose of a step and the instruction provides detailed specifications of the intent. For addressing each step, M_p and M_c perform two layers of collaboration: (1) M_c takes in instructions given by M_p for code generation. (2) The final step solution is determined as the most frequent result from $\{\hat{o}_i^n\}_{n \leq k} \cup \hat{C}$, where $\{\hat{o}_i^n\}_{n \leq k}$ are step solutions generated by M_p and $\hat{C}$ is based on executing Python code generated by M_c. Note that in MACT, the generation of a next step depends on previous steps, thus being iterative and more computationally expensive. To boost efficiency, MACT features an efficiency optimization module, where simple questions are directly answered by M_p without going into the iterative loop. Zhou et al. (2025) approximate question complexity by the confidence of M_p in directly solving a TQA problem: a confident model will output more agreed predictions and this suggests the problem is less complex.

We adapt MACT for the shared task as follows: (1) MACT requires a whole table as input. As this is not possible with large tables, we only pass the first two rows for each step and code generation. Accordingly, we adapt the prompts for M_p and M_c used in the iterative planning module. These are presented in Appendix A.1. (2) We remove the efficiency module in MACT. This module requires a full table to generate the final answer. In our case, since only the first two table rows are passed to the system, the answer predicted by the efficiency module cannot be trusted. (3) We remove the layer of collaboration where step solutions are determined by both M_p and M_c and select the most frequent observation from $\hat{C}$, as step solutions generated by M_p might not be correct given only two table rows. (4) We merge the intent *Retrieve* and *Calculate* into *Operate* to increase efficiency since both use Python and M_c in this case. We remove intents *Search* and *Read* where Wikipedia search and LLM extraction over texts happen, as DataBench does not have additional text input and does not feature open-domain TQA. If no answer is obtained from the iterative planning module, we return *none* as the final answer.

3.3 Ensemble Method

For our submissions, we ensemble results from four different M_p and one M_c. Since each M_p and M_c combination yields an answer A for a TQA instance, we have four predictions for an instance. We design our ensemble method as a combination of self-consistency (sc)(Wang et al., 2023) and LLM-as-judge (Yao et al., 2023): If more than 60% of the predicted answers are the same, we use the most agreed answer as the final answer (sc). If less than 60% of the predicted answers are the same, we prompt an LLM to select the most reasonable plan. Prompts can be found in Appendix A.1. The corresponding answer obtained by executing the selected plan is chosen as the final answer.

4 Experimental Setup

We present details on our experimental setup.

Data and Evaluation. DataBench (Osés-Grijalba et al., 2025) includes 65 English tables from diverse domains, with an average of over 3,200 rows and 1,600 columns. Each table is accompanied by more than 20 manually created questions, resulting in approximately 1,300 questions in total. The questions vary in terms of answer types including boolean, category, number, list[category], and list[number]. We use only the test set of DataBench, which contains 15 tables and 522 questions. Detailed statistics are presented in Appendix A.2. We use exact match (EM) as evaluation metric, which counts the percentages of

Models	ALL						LITE					
	Avg	Bool	Ctg	Num	[ctg]	[num]	Avg	Bool	Ctg	Num	[ctg]	[num]
	522	129	74	156	72	91	522	129	74	156	72	91
Qwen-2 (72B)	80.1	89.1	75.7	81.4	69.4	76.9	78.5	89.1	77.0	78.8	66.7	73.6
Deepseek (14B)	81.6	88.4	81.1	85.3	69.4	75.8	81.8	86.8	79.7	84.6	72.2	79.1
Mistral (13B)	75.5	89.1	70.3	77.6	56.9	71.4	78.0	87.6	73.0	81.4	69.4	69.2
LlaMA-3 (8B)	70.1	89.1	66.2	67.3	59.7	59.3	74.7	90.7	74.3	76.3	61.1	60.4
Ensemble	**86.0**	91.5	82.4	78.2	73.6	80.2	**84.5**	89.1	86.5	85.9	73.6	82.4

Table 1: Exact Match of G-MACT using different models as the planning agent in terms of answer category. Ctg and Num stand for category and number, respectively. [x] refers to a list with items of type x. We report the instance number of each answer type at the top part of the table.

predicted and reference answers that match exactly. We use the official evaluation scripts provided by Osés-Grijalba et al. (2025).

Models and Parameters. We use four different LLMs as planning agents: Qwen-2-int4 (72B) (Yang et al., 2024a), Mistral Nemo (13B),[3] Deepseek-R1-distill-Qwen (14B) (DeepSeek-AI et al., 2025), and LlaMA 3 (8B) (Dubey et al., 2024). As coding agent, we use Qwen-2.5-coder (32B) (Yang et al., 2024b). This results in four possible pairs of planning and coding agents. We set the sampling number k to 5. The temperature is set to 0.6. To speed up inference, we use vllm[4] to run M_p. M_c is deployed with SGLang.[5] We use Deepseek-R1-distll-Qwen (32B) (Yang et al., 2024b) as the judge to choose the best plan in the ensemble method.

Baselines. We compare G-MACT with top four systems in the open-weight model category in SemEval-2024 Task 8, with a focus on the more challenging ALL setup. In addition, we compare our method with the baseline reported by Osés-Grijalba et al. (2025), where stable-code[6] is used to generate code and a Python interpreter executes the code to obtain an answer.

5 Results

Figure 2 shows the performance of G-MACT compared with top four systems and the baseline reported in Osés-Grijalba et al. (2025) for the more challenging ALL setup. Our ensemble model outperforms the baseline method by a large margin. However, there is still a gap between our method and the best-performing system in the shared task.

[6] https://huggingface.co/TheBloke/stable-code-3b-GGUF

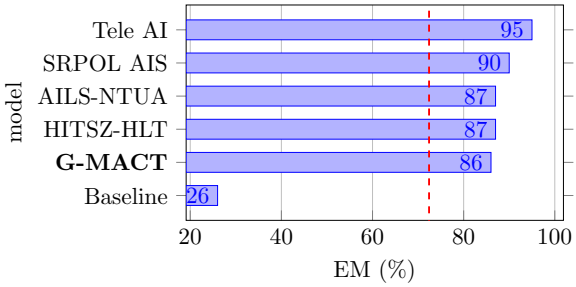

Figure 2: Comparing G-MACT with top four systems in the open-weight model category in the ALL setup. We also report baselines (ranked 33) provided by Osés-Grijalba et al. (2025). The red dotted line (72.4) indicates the median performance.

Table 1 shows results using different planning models in ALL and LITE settings (see columns title **Avg**). We find: (1) Ensemble results from different models improve overall performances. (2) Using Deepseek-Distill-Qwen (14B) as planning agent leads to the best results among individual planning-coding agent pairs. This might be attributed to the model's recency, its training mechanism, and its pretraining data (DeepSeek-AI et al., 2025). When looking at break-down results in terms of answer categories, we find that for almost all models and settings, questions that require a list of categorical values as answers pose the biggest challenges. This is followed by questions that ask for a list of numbers as answers. In contrast, questions with boolean answers are the easiest. Osés-Grijalba et al. (2025) report similar observations. This suggests that multi-value prediction poses unique challenges to current TQA systems.

6 Analysis and Discussion

We analyze G-MACT in terms of planning, ensembling, efficiency, and errors, and summarize key insights for future studies.

	ALL		LITE	
	EM	Global%	EM	Global%
Global	76.4	100	77.8	100
Iterative	64.2	0	63.4	0
Both	**81.6**	91.0	**81.8**	92.0

Table 2: Exact Match (EM) of each single module and combined, as well as the percentages of instances addressed by using the global planning module with Deepseek-Distill-Qwen (14B) as the planning agent.

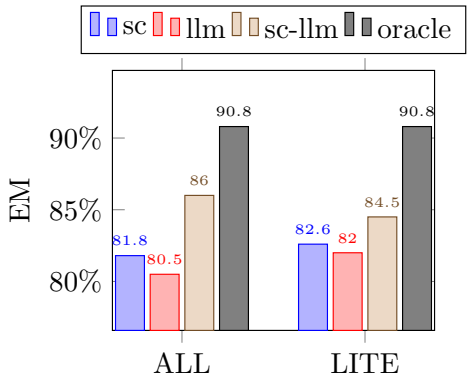

Figure 3: Exact Match (EM) of using different ensemble methods. sc=self-consistency. llm=LLM-as-a-judge. oracle=an ensemble method that always selects correct answers as final predictions if there are any.

Effectiveness of Global/Iterative Planning. To assess the effectiveness of the global/iterative planning modules, we experiment with using each module independently. We also calculate the proportion of instances that are successfully addressed by only applying the global planning module. These are shown in Table 2. Results are obtained using Deepseek-Distill-Qwen (14B) model, as it demonstrates the best overall performances in both ALL and LITE settings among investigated planning models. We find that most instances can be addressed using only the global planning module. However, incorporating the iterative module significantly enhances performance by 9.6% and 6.7% in the ALL and LITE settings, respectively. This proves the effectiveness of combining both modules. Despite these gains, we observe that the iterative planning module alone results in lower performances compared to the global planning approach.

Ensemble Methods. We report EM achieved by our ensemble method combining sc and LLM-as-judge, as well as each individual method in Figure 3. We present an EM upper bound of ensembling the four models, which is calculated as the percentage of correct answers in any of the four models' predictions. We find that combining both sc and LLM-as-judge leads to better results than using them alone. However, there is still a gap between our ensemble method and the potential best ensemble approach (oracle), indicating that a better confidence estimation for the answers provided by each individual component of the ensemble could lead to considerable improvements.

Efficiency Analysis. The global planning module requires six LLM calls (one for planning and five for code generation) for each instance. As shown in Table 2, most instances can be addressed by applying global planning alone. For those requiring additional iterative planning, we observe that most instances can be addressed within two iterations. This is shown in Appendix A.3). This means most instances only require 15 LLM calls.[7]

Error Analysis. We manually analyze and summarize error types among instances whose predicted answers are wrong by all four models in both settings. This results in 96 instances in total. Around 50% of errors are caused by **wrong plan generation**, which includes incorrect question interpretation (e.g., selecting wrong features for computing), failure to understand table semantics (e.g., the column *Tier 1* is the parent node of the column *Tier 2*), and incorporating factual or domain-specific knowledge (e.g., in basketball, *OREB* stands for offensive rebounds, where the ball is recovered by the offensive side and does not change possession). Another 20% of the errors can be attributed to **incorrect semantic matching between questions and tables**, e.g., the entities mentioned in the question might not exactly match the entities in the tables. Using only the first two rows of a table can exacerbate the problem of matching semantically similar entities in a question and a table, e.g., "books about computer science" in the question and "Computer Science & Engineering" in the table. The challenge can be addressed by utilizing more flexible row selection methods. For instance, instead of passing the first two rows where no category name of computer science is shown, one can use semantic matching between a question and rows to select the most relevant rows that contain "Computer Science & Engineering".

[7] 5*2=10 LLM calls for iterative planning. For code generation, only 5 LLM calls are needed since the last iteration does not require tool calling and only returns a final answer.

By doing this, the coding model is more likely to generate correct filtering conditions. Similar ideas have been explored in Chen et al. (2024). Due to limited time, we leave this for future exploration. Interestingly, fewer errors are caused by **code generation and execution** (10%) and most of them can be solved by data cleaning beforehand, e.g., aligning the categories encoded in a categorical header with the values in the column. This might be because code about common table operations, e.g., filtering, is easy to generate given clear textual instructions. Lastly, around 20% of the errors come from **question ambiguity**. We provide error examples for each category in Appendix A.4.

Takeaway Messages. Combining global and iterative planning in TQA is effective and worth exploring. Designing a good planner that understands table semantics and has access to factual and domain-specific knowledge is crucial. Ensembling different models increases overall performance. Moreover, how to select the best model/plans is decisive for improving ensemble results.

7 Conclusion

In this paper, we introduce G-MACT, a pipeline framework combining planning and tool use, developed for the SemEval-2025 Task 8. Our method ranks 5th among all approaches using open-weight models, with no training involved. We carefully analyze our system in terms of the effectiveness of each module, efficiency, and error patterns. We provide key insights for future work to address real-life table question answering.

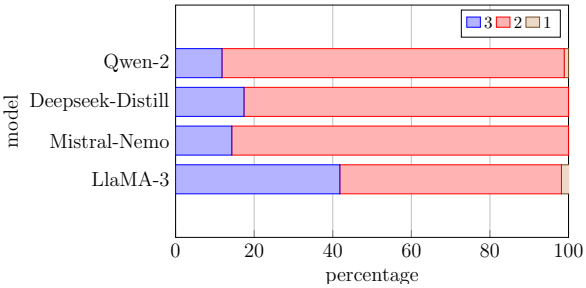

Figure 4: Average iteration distribution over settings.

A Appendix

A.1 Prompts

We show prompts used for a planning agent in the global and iterative planning modules in Figure 5 and Figure 6, respectively. We show prompts used for a coding agent in the global and iterative planning modules in Figure 7 and Figure 8, respectively. Lastly, we show the prompt used to select the best plan in our ensemble method in Figure 9.

A.2 Data Statistics

Table 3 shows statistics about the test set of DataBench.

A.3 Efficiency Analysis

We plot the number of steps required in the iterative planning module to solve a question, averaging over two settings in Figure 4.

A.4 Error Examples

We show four concrete examples of errors made using G-MACT in Figure 10, 11, 12 and 13, with each mapping an aforementioned category.

You are an expert in analyzing table data and generate step-by-step plans to solve any questions related to long tables.
The following table only shows the first three rows of the table due to its large size.
Please generate a step-by-step plan to address the question, following the below requirement:
1. A plan should contain no more than 4 steps.
2. Each step should be in one line.
3. Return only the step-wise plan and nothing else.
4. No repetition of the plan.
Please return only a plan and nothing else.
Following are three examples:
Table:
| rank | personName | age | finalWorth | category | source | country |…
| 1 | Elon Musk | 50.0 | 219000 | Automotive | Tesla, SpaceX | United States |…
| 2 | Jeff Bezos | 58.0 | 171000 | Technology | Amazon | United States ...
…[remaining 2665 rows unshown due to large table size]...
Context: Table caption: Forbes Billionaires 2022.
Question: How many billionaires are there from the 'Technology' category?
Plan: 1. I need to filter the table to get all billionaires from the 'Technology' category.
2: Then I need to count the number of retrieved entries.
3. The answer to the question is the number of retrieved entries in the second step, and I will return this value as the final answer.

Table:
| segmentation_1 | descriptor | complaint_type | created_date |…
| [] | Business not in compliance | NonCompliance with Phased Reopening | 2020-10-02 11:50:27+00:00 |…
| [] | ENTIRE BUILDING | HEAT/HOT WATER | 2021-11-03 06:48:49+00:00 |…
...[remaining 99997 rows unshown due to large table size]...
Context: Table caption: NYC 311 Calls
Question: Mention the 2 most common weekdays for complaints.
Plan: 1. I need to count the frequency of each unique weekday in the column 'weekday_name'.
2. I will create an additional dataframe with two columns to store the results from the first step, with one column being the name of the weekday, and one being the frequency of that weekday.
3. I will sort the dataframe I made in step 2 in descending order.
4. The question asks 2 most common weekdays, this corresponds to the weekday values of the top two rows. I will retrieve the weekday values of the top two rows, store them in a list and return the list as the answer.

Table:
| segmentation_1 | descriptor | complaint_type | created_date |…
| [] | Business not in compliance | NonCompliance with Phased Reopening | 2020-10-02 11:50:27+00:00 |…
| [] | ENTIRE BUILDING | HEAT/HOT WATER | 2021-11-03 06:48:49+00:00 |…
...[remaining 99997 rows unshown due to large table size]...

Context: Table caption: NYC Taxi Trips.
Question: Are there any trips with a total distance greater than 30 miles?
Plan: 1. I need to count the number of entries whose 'trip_distance' is larger than 30.
2. If the value from step 1 is larger than 0, then the answer is 'True', otherwise, it is 'False'.
3. I will create a variable name after 'final_result' to store the boolean answer and return the variable as final answer.

Now generate a plan for to address the following question and table. The plan should contain maximum 4 steps, with each step one line.
Table: {table}
Context: {context}
Question: {question}

Figure 5: A prompt for a planning agent in the global planning module.Caption

Solve a table question answering task with interleaving Thought, Action, Observation steps. Thought can reason about the current situation, and Action can be two types:
(1) Operate[instruction], which carries out operations such as information retrieval or calculations based on the instruction and returns the retrieved or calculated results.
(2) Finish[answer], which returns the answer and finishes the task.
You may take as many steps as necessary.
Here are some examples:
Table:
| rank | personName | age | finalWorth | category | source | country |…
| 1 | Elon Musk | 50.0 | 219000 | Automotive | Tesla, SpaceX | United States |…
| 2 | Jeff Bezos | 58.0 | 171000 | Technology | Amazon | United States |...
…[remaining 2665 rows unshown due to large table size]...
Context: Table caption: Forbes Billionaires 2022.
Question: How many billionaires are there from the 'Technology' category?
Thought 1: I need to count the number of billionaires from the 'Technology' category.
Action 1: Operate[count the number of entries whose category is Technology]
Observation 1: 343
Thought 2: In observation 1, 343 billionaires are from the 'Technology' category, therefore, the answer is 343.
Action 2: Finish[343]

Table:
| segmentation_1 | descriptor | complaint_type | created_date |…
| [] | Business not in compliance | NonCompliance with Phased Reopening | 2020-10-02 11:50:27+00:00 |…
| [] | ENTIRE BUILDING | HEAT/HOT WATER | 2021-11-03 06:48:49+00:00 |…
...[remaining 99997 rows unshown due to large table size]...
Context: Table caption: NYC Taxi Trips.
Question: Are there any trips with a total distance greater than 30 miles?
Thought 1: I need to count the number of entries whose 'trip_distance' is larger than 30.
Action 1: Operate[count the number of entries whose 'trip_distance' is larger than 30.]
Observation 1: 0
Thought 2: In observation 1, there is 0 entry whose trip distance is larger than 30. Therefore, the answer is False.
Action 2: Finish[False]

Table:
| segmentation_1 | descriptor | complaint_type | created_date |…
| [] | Business not in compliance | NonCompliance with Phased Reopening | 2020-10-02 11:50:27+00:00 |…
| [] | ENTIRE BUILDING | HEAT/HOT WATER | 2021-11-03 06:48:49+00:00 |…
...[remaining 99997 rows unshown due to large table size]...
Context: Table caption: NYC 311 Calls
Question: Mention the 2 most common weekdays for complaints.
Thought 1: I need to count the frequency of each unique weekday in the column 'weekday_name'.
Action 1: Operate[count the frequency of each unique weekday in the column 'weekday_name'.]
Observation 1: {'Tuesday': 15847, 'Monday': 15816, 'Wednesday': 15445, 'Thursday': 14978, 'Friday': 14707, 'Saturday': 11781, 'Sunday': 11426}
Thought 2: The question ask for 2 most common weekdays. From observation 1, we find Tuesday and Monday have the largest frequencies and they are weekdays. Therefore, the answer is ["Tuesday", "Monday"]
Action 2: Finish[["Tuesday", "Monday"]]
(END OF EXAMPLES)
Now generating the Thought, Action, Observation for the following instance:
Table:
{table}
Context: {context}
{question}
{scratchpad}"""

Figure 6: A prompt for a planning agent in the iterative planning module.

You are an expert in python code generation.
Write a python function named 'target_function' according to the given plan using pandas dataframe.
The given dataframe shows only two records of the original data due to its large size. The main goal of showing the dataframe is to show the data type associated to each column.
However, you should not operate any code based on the given dataframe, since it does not contain all information about the table.
Below are two examples
Plan: 1. I need to filter the table to get all billionaires from the 'Technology' category.
2: Then I need to count the number of retrieved entries.
3. The answer to the question is the number of retrieved entries in the second step, and I will return this value as the final answer.
Dataframe code for the first two records: import pandas as pd
data={'rank':[1.0, 2.0],'personName':['Elon Musk', 'Jeff Bezos'],'age':[50.0, 58.0],'finalWorth':[219000.0, 171000.0],'category':['Automotive', 'Technology'],'source':['Tesla, SpaceX', 'Amazon'],'country':['United States', 'United States'],…}
df=pd.DataFrame(data)
Code: ```Python
def target_function(dataframe):
  # filter the table for 'Technology' as the category and count the number of the entries
  technology_entries_count = len(dataframe[dataframe['category'] == 'Technology])
  # return the result as final answer
  return technology_entries_count
```

Plan: 1. I need to retrieve the first five values from the 'Gold' columns.
2. To calculate the average number, I will sum the retrieved values and divide the sum by 5.
3. The answer to the question is the result from step 2. I will return that value as the final answer.
Dataframe code for the first two records: import pandas as pd
data={"Rank": ["1", "2"], "Nation": ["United States", "Jamaica"], "Gold": ["5", "4"], "Silver": ["6", "1"], "Bronze": ["5", "1"], "Total": ["16", "6"]}
df=pd.DataFrame(data)
Code: ```Python
def target_function(dataframe):
  # retrieve the top 5 gold medals values from the table
  top_5_medals = dataframe["Gold"].astype(int).tolist()[:5]
  # get the average number of the gold medal
  final_result = sum(top_5_medals) / 5
  # return the result
  return final_result
```
Now generate the python function according to the given plan.
Plan: {instruction}
Dataframe code for the first two records: {table_df}
Code:

Figure 7: A prompt for a coding agent in the global planning module.

According to the instruction, write a function named after 'target_function' in one python code block to perform calculations on a dataframe object. The given dataframe shows only two records of the original data due to its large size. However, you should be able to infer the data type based on the given dataframe. Return only the python function without any execution and do not use print statement in the code block.
Below are two examples:
Instruction: count the number of entries whose category is Technology
Dataframe code for the first two records: import pandas as pd
data={'rank':[1.0, 2.0],'personName':['Elon Musk', 'Jeff Bezos'],'age':[50.0, 58.0],'finalWorth':[219000.0, 171000.0],'category':['Automotive', 'Technology'],'source':['Tesla, SpaceX', 'Amazon'],'country':['United States', 'United States'],…]}
df=pd.DataFrame(data)
Code: ```Python
# Define the function to count entries with category "Technology"
def target_function(dataframe):
  technology_entries_count = len(dataframe[dataframe['category'] == 'Technology])
  return technology_entries_count
```

Instruction: calculate the average of gold medals for the top 5 nations.
Dataframe code for the first two records: import pandas as pd
data={"Rank": ["1", "2"], "Nation": ["United States", "Jamaica"], "Gold": ["5", "4"], "Silver": ["6", "1"], "Bronze": ["5", "1"], "Total": ["16", "6"]}
df=pd.DataFrame(data)
Code: ```Python
# average number of gold medals for the top 5 nations in the dataframe
def target_function(dataframe):
  top_5_medals = dataframe["Gold"].astype(int).tolist()[:5]

UMUTeam at SemEval-2025 Task 1: Leveraging Multimodal and Large Language Model for Identifying and Ranking Idiomatic Expressions

Ronghao Pan, Tomás Bernal-Beltrán, José Antonio García-Díaz, Rafael Valencia-García
Facultad de Informática, Universidad de Murcia, Campus de Espinardo, 30100 Murcia, Spain
{ronghao.pan, tomas.bernalb, joseantonio.garcia8, valencia}@um.es

Abstract

Idioms are non-compositional linguistic expressions whose meanings cannot be directly inferred from the individual words that compose them, posing significant challenges for natural language processing systems. This paper describes the participation of the UMUTeam in Subtask A of the AdMIRe shared task (SemEval 2025), which focuses on understanding idiomatic expressions through visual and contextual representations in English and Portuguese. Specifically, the task involves ranking a set of images according to how well they represent the sense of a potentially idiomatic nominal compound within a given contextual sentence. To address this challenge, we adopted a multimodal approach that combines textual and visual features using pre-trained language models, such as BERT and XLM-RoBERTa, along with Vision Transformers. Additionally, we explored the in-context learning capabilities of Large Language Models (LLMs), particularly Llama-3.1-8B, for image classification. These models are trained using a regression approach to rank images according to their semantic alignment with the contextual meaning of idioms. The results show that the Llama-3.1-8B model performs best for English, ranking 17th in the test set and 12th in the extended evaluation set, while the XLM + ViT model is more effective for Portuguese, ranking 9th in the test set and 8th in the extended evaluation set.

1 Introduction

An idiom is a linguistic expression or construction whose meaning cannot be derived directly and literally from the words that make it up (Bobrow and Bell, 1973). Idioms are fixed phrases or sayings that use a figurative sense to convey ideas, emotions, or situations in a particular language, and they can be difficult to translate into another language without losing their intended meaning. An extensive review of figurative language and idioms has been carried out in (del Pilar Salas-Zárate et al., 2020).

Idioms are common to all languages and are based on the culture, history and traditions of each society, reflecting the unique cultural and linguistic aspects of that society. This means that a literal interpretation of them results in the loss of essential cultural and contextual nuances, preventing their original meaning from being accurately conveyed in another language (Lakoff and Johnson, 1980). For example, the expression "when pigs fly" is an excellent example of non-literal language. Even when people are not explicitly familiar with the expression, human cognition is able to infer its meaning from the images it evokes. The impossibility of pigs flying intuitively suggests an event of extreme improbability or outright impossibility. This phenomenon highlights the sophisticated way in which humans process language. Rather than relying solely on literal definitions, humans integrate contextual cues, cultural knowledge, and metaphor to construct meaning.

Large Language Models (LLMs) have proven to be efficient in various natural language processing tasks such as hate speech detection (García-Díaz et al., 2023; Pan et al., 2024), emotion identification (Salmerón-Ríos et al., 2024), hope speech (García-Baena et al., 2023), or translation among others. However, they often misinterpret or mistranslate idiomatic expressions because they tend to process idioms as if they were compound expressions, producing literal translation errors, in which the figurative meaning is lost and the intended message is inappropriately conveyed (Li et al., 2024) (Tayyar Madabushi et al., 2021). Their reliance on such correlations, without a real conceptual understanding of non-compositional language, remains a fundamental limitation in dealing with idioms (Phelps et al., 2024).

Accurate interpretation of idioms is essential for applications such as sentiment analysis, ma-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 743–749

chine translation and natural language understanding (Salehi et al., 2015) (Reddy et al., 2011). As these fields require a more sophisticated understanding of language, improving models' ability to interpret idioms could lead to significant improvements in their overall performance.

The AdMIRe shared task (SemEval 2025) (He et al., 2025) focuses on the discovery and understanding of idioms. However, this task is not about binary classification of idioms, but about understanding and correctly associating their meaning through visual and visual-temporal representations, in two languages: English and Portuguese. It is divided into two subtasks: (1) **Subtask A: Static Images**. Given a set of 5 images and a context sentence in which a given potentially idiomatic nominal compound (NC) appears, the goal is to rank the images according to how well they represent the sense in which the NC is used in the given context sentence; and (2) **Subtask B: Next Image Prediction**. Given a target expression and an image sequence from which the last of 3 images has been removed, the goal is to select the best fill from a set of candidate images.

Vision transformers have proven effective in correctly identifying and understanding objects, patterns, and contexts in complex images, facilitating advances in classification, detection, and segmentation in computer vision applications (Lu et al., 2019). This makes them efficient in the task of correctly identifying, understanding and graphically representing idioms present in an image. Moreover, thanks to the combined use of these models with a large language model, it is possible to identify the idioms present in the text while describing the images, which allows to find out which image best represents each idiom. Therefore, in this study, two different approaches have been tested to discover and understand idiomatic expressions using visual and visual-temporal representations in two languages, English and Portuguese. The first approach involves a multimodal model that uses the correlation between images and textual descriptions to capture the contextual meaning of idiomatic expressions. The second approach exploits the in-context learning capability of LLMs, such as Llama-3.1-8B (Dubey et al., 2024), to classify images based on their descriptions using prompt engineering techniques such as zero-shot learning.

We participated in Subtask A and used a multimodal approach combining textual (image caption) and visual representations. Based on pretrained language models such as BERT and XLM-RoBERTa, and vision models such as Vision Transformers (ViT), we have adopted an approach that fuses textual embeddings and images to improve the semantic understanding of idioms in context. In addition, the models have been trained using a regression approach with the aim of learning to assign scores to images according to their correspondence with the contextual meaning of an idiom in a sentence. In addition, we tested the in-context learning capability of LLMs, such as Llama-3.1-8B, for image classification by utilizing image descriptions.

2 Background

At the computational level, one of the first approaches to deal with idiomatic expressions was the use of supervised binary classification models to distinguish between literal and figurative uses, as seen in the work of (Fazly et al., 2009), who proposed an unsupervised method to identify idiomatic types and occurrences from syntactic patterns and lexical co-occurrences.

Subsequently, with the rise of models of distributional representations, research such as (Salehi et al., 2015) explored the use of word embeddings to predict the compositionality of complex expressions. While useful, these approaches do not adequately capture deep idiomatic meaning, especially in ambiguous contexts.

More recently, with the development of pretrained language models such as BERT, RoBERTa, T5, among others, considerable improvement has been achieved in detecting idioms using context. However, these models still face difficulties when attempting to represent the full semantic meaning of idioms, especially outside their immediate context.

Moreover, in terms of evaluation, tasks such as SemEval-2022 Task 2: Multilingual Idiomaticity Detection and Sentence Embedding (Tayyar Madabushi et al., 2022) have proposed multilingual benchmarks. However, as highlighted by (Boisson et al., 2023), certain artifacts in these datasets may bias the results, allowing models to detect idiomatic expressions without true semantic understanding.

In the face of these limitations, there has been a growing interest in multimodal approaches that integrate text with images or visual descriptions. To this end, the AdMIRe task has emerged, which seeks to assess idiomatic comprehension through

```
**Instructions for the model:**
1. Identify the nominal compound (NC) in the provided context sentence.
2. Interpret the specific meaning of the NC **within the given context**
(considering both literal and idiomatic meanings).
3. Analyze the five provided image captions.
4. Compare each image caption against the meaning of the NC in context,
assessing **how well it represents the intended sense**.
5. Assign a **similarity score (1.000 - 10.000)** for each image, where:
   - **1.000** means the image is completely unrelated.
   - **10.000** means the image perfectly represents the meaning.
6. Output the similarity scores in the following format:
   ```
   Image_1: 3.245, Image_2: 7.530, Image_3: 9.870, Image_4: 5.610, Image_5: 2.490
   ```
7. Do **not** provide any explanations for the scores.
8. Ensure consistency in scoring across different instances.

Context: {sentence}
NC: {compound}
Image_1 caption: {image_caption_1}
Image_2 caption: {image_caption_2}
Image_3 caption: {image_caption_3}
Image_4 caption: {image_caption_4}
Image_5 caption: {image_caption_5}

**Output the similarity scores in the following format:**
```
Image_1: 3.245, Image_2: 7.530, Image_3: 9.870, Image_4: 5.610, Image_5: 2.490
```

Answer:
```

Listing 1: Structure of the prompt

multimodal representations in English and Portuguese.

3 System overview

Figure 1 shows the architecture of the first approach, which consists of training a multimodal model that combines visual and textual features to understand idiomatic expressions. Unlike classifying images in a binary problem using an input sentence (e.g., as literal or figurative), the goal of this approach is to correctly associate their meaning by using images and contextual textual descriptions.

The process begins with preprocessing the training set. In this case, we have linearly ranked the 5 images associated with each `sentence`, assigning them a relevance score based on their position in the expected order. This score is calculated in a normalized way, where the most relevant image receives the highest value and the least relevant the lowest. The ranking is based on the `expected_order` list, which indicates the expected sequence of relevance of the images for each idiomatic expression. For example, the first image will be assigned a score of 1.0, the second 0.8, the third 0.6, the fourth 0.4, and the fifth 0.2, with a consistent difference of 0.2 between each ranking position.

Next, visual feature extraction is carried out using a ViT model. Each image is divided into small patches, which are then enriched with positional encodings to preserve the spatial layout of the original image. These position-aware patches are passed through a transformer encoder, producing an embedding that captures both global and local visual information.

In parallel, textual encoding is performed for both the image descriptions and the main `sentence` using pretrained language models such as BERT or RoBERTa. These models convert the input text—whether in English or Portuguese—into contextual embeddings that capture semantic nuances, including idiomatic meanings.

To integrate the visual and textual modalities, a Cross-Attention module is applied. This module allows the text embeddings to attend to relevant regions of the image embedding, effectively aligning the linguistic and visual representations. This multimodal fusion is crucial for understanding idiomatic expressions, as these often involve metaphorical or symbolic visual cues that need to be associated with their corresponding textual interpretations. In

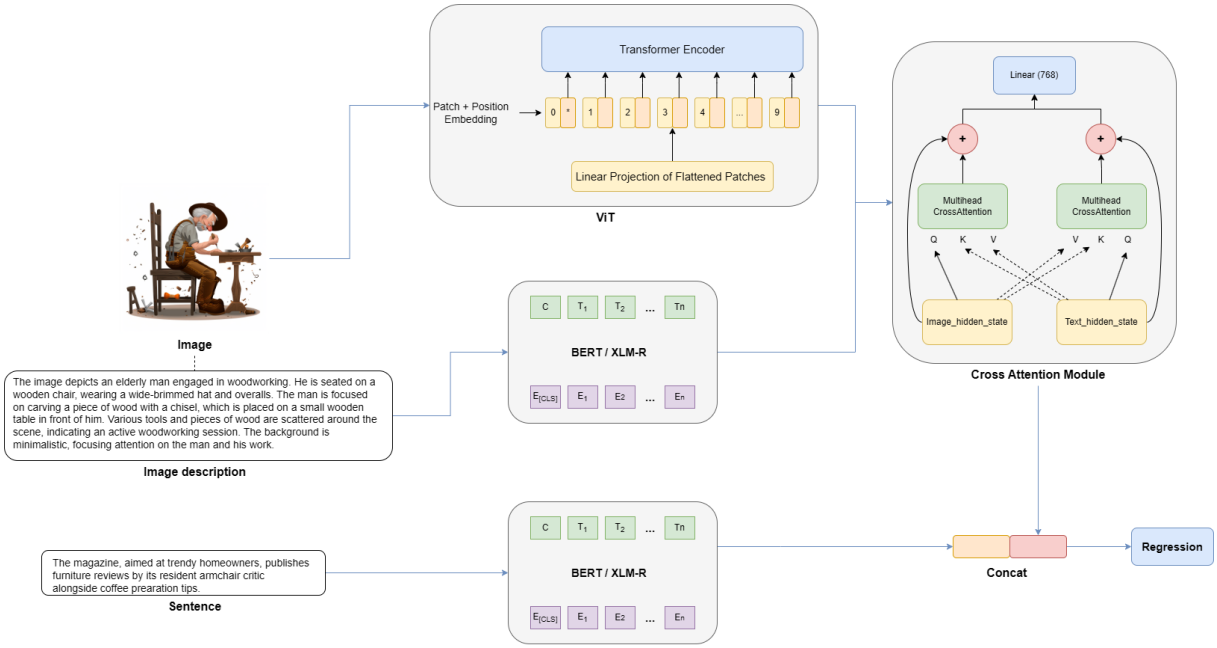

Figure 1: System architecture pipeline.

this case, we used a gated fusion mechanism based on multi-head attention with 8 heads and hidden dimensionality distributed across the heads. This mechanism dynamically balances the contribution of each modality, resulting in a unified multimodal representation that combines visual and textual context.

The resulting fused representation is then concatenated with the sentence embedding, producing a joint vector that encodes both visual and textual context. This combined representation is subsequently passed through a regression layer, which predicts a relevance score for each image in relation to the idiomatic meaning of the sentence. To evaluate the model's performance, we use Root Mean Square Error (RMSE) as the reference metric, as it effectively captures the deviation between the predicted and expected relevance scores.

The second approach is based on specific LLMs such as Llama-3.1-8B-Instruct (Dubey et al., 2024), taking advantage of their In-context learning capability and prompt engineering techniques such as zero-shot learning, to classify images according to their relevance in relation to idiomatic expressions. First, the model is prepared and a prompt (as shown in Listing 1) is generated with the sentence context and image descriptions. Then, the model evaluates each image and generates a similarity score, which indicates how relevant each image is to the meaning of the idiomatic expression. Finally, the images are sorted according to the score obtained and the results are saved in a file.

4 Experimental setup

For Subtask A, we have used only the training set provided by the organizers, which, after our preprocessing, is left with a total of 350 examples (of which, for each sentence, we have 5 related images).

For the first approach, different pre-trained language models have been tested, both multilingual and monolingual, such as BERT-base for English, BERTimbau-base (Souza et al., 2020) for Portuguese and, finally, XLM-RoBERTa for English and Portuguese. As for the ViT models, the "vit-base-patch16-224-in21k" (Wu et al., 2020) (Deng et al., 2009) model has been tested. The models are trained with 4 layers and 8 attention heads (num_heads) for the multimodal module, using a learning rate of `2e-5`, 20 epochs, and the RMSE metric as reference.

For the second approach, we use Llama-3.1-8B-Instruct. The parameters set for inference are: `do_sample=False`, which disables random sampling, ensuring reproducibility without the need to set the parameters `temperature`, `top_p` and `top_k`. In addition, a limit of `max_new_tokens=256` is set, ensuring that text generation does not exceed 256 tokens, optimizing model consistency and relevance in the image classification task.

5 Results

Table 1 presents the results obtained using three different approaches for the classification of images associated with idiomatic expressions: the BERT + ViT model, the XLM-RoBERTa + ViT model and the Llama-3.1-8B-Instruct model. The results were evaluated on two datasets: the Test set and the Extended eval set, both in English and Portuguese. The metrics used for the evaluation were Accuracy and Discounted Cumulative Gain (DCG) score.

In the test set, the approach of using Llama-3.1-8B as the classification model achieved the best results in terms of accuracy (0.4) and DCG score (2.677), standing out as the most effective approach. In comparison, the BERT + ViT model achieved an accuracy of 0.266 and a DCG score of 2.337, while the XLM + ViT model achieved an accuracy of 0.133 and a DCG score of 2.232. For the extended evaluation set, the results were similar. The LLM approach achieved an accuracy of 0.24 and a DCG score of 2.520, again standing out for its superior performance. The BERT + ViT model had an accuracy of 0.21 and a DCG score of 2.348, while the XLM + ViT model achieved an accuracy of 0.24 and a DCG score of 2.372.

In the Portuguese test set, the XLM + ViT model outperformed, achieving the highest accuracy (0.384) and the best DCG score (2.572). In comparison, the BERT + ViT model achieved an accuracy of 0.308 and a DCG score of 2.475, while the Llama model had an accuracy of 0.231 and a DCG score of 2.444. In the extended evaluation set in Portuguese, the BERT + ViT model was the best in terms of accuracy (0.236) and DCG score (2.387), while the LLM approach achieved an accuracy of 0.181 and a DCG score of 2.362. The XLM + ViT model, although obtaining a lower accuracy (0.182), achieved a DCG score of 2.331.

The results obtained show that the Llama model proved to be the most robust approach in English, achieving the best performance in terms of accuracy and DCG score in the test set. However, in Portuguese, the XLM + ViT model excelled in accuracy and DCG score in the test set, while the BERT + ViT model led the extended evaluation set.

Table 2 shows the results obtained using the Llama-3.1-8B approach developed by *UMUTeam*, as well as our position in the official Subtask A ranking.

On the English test set, the *PALI-NLP* team achieved first place with an accuracy of 0.933 and a DCG score of 3.581, followed by *dutir914* in second place with similar results. In this case, our approach based on Llama-3.1-8B achieved an accuracy of 0.4 and a DCG score of 2.677, placing us 17th in the test dataset ranking and 12th in the extended eval set. As for the Portuguese test set, the results were significantly different. The *HiTZ-Ixa* team led with a perfect precision of 1 and a DCG score of 3.505, followed by *dutir914* and *Zhoumou*. Using the XLM + ViT model, we achieved an accuracy of 0.384 and a DCG score of 2.572, which allowed us to reach 9th place in the test set and 8th place in the extended eval set.

It is important to note that the official evaluation system used by the organizers prioritized the model that showed the best performance in English, which resulted in a relatively low position for UMUTeam in the Portuguese ranking with the Llama-3.1-8B model. However, if we had employed the XLM + ViT model as the main approach for Portuguese, the results would have been considerably better, significantly improving our position in the Portuguese ranking.

Table 1: Results of different approaches: BERT + ViT (Approach 1), XLM + ViT (approach 2), and Llama-3.18b (Approach 3). Accuracy (ACC) and Discounted Cumulative Gain (DCG) scores are reported for the test (T) and the extended eval dataset (E)

#	ACC-T	DCG-T	ACC-E	DCG-E

6 Conclusion

Our participation in Subtask A of the AdMIRe shared task (SemEval 2025) focused on the complex challenge of interpreting idiomatic expressions using visual and contextual clues. We explored two distinct approaches: a multimodal model that fuses textual embeddings from BERT and XLM-RoBERTa with visual features from Vision Transformers, and an in-context learning ap-

proach utilizing the Llama-3.1-8B model for image classification.

Our experimental results reveal that while Llama-3.1-8B outperforms other models in English, the XLM + ViT model demonstrates superior accuracy and DCG scores in Portuguese. This highlights the importance of language-specific strategies for idiom interpretation. Furthermore, the success of the multimodal approach underscores the value of integrating visual and contextual information to better capture the figurative meanings of idiomatic expressions.

These findings contribute to the broader field of natural language understanding, particularly in enhancing machine comprehension of non-literal language. Future work will explore more advanced fusion techniques and investigate the role of cultural context in idiom interpretation to further improve model performance across languages.

Abstract

Large Language Models like GPT-4, LLaMa, Mistral, and Gemma have revolutionized Natural Language Processing, advancing language comprehension, generation, and reasoning. However, they also present challenges, particularly the tendency to hallucinate—that is, to produce false or fabricated information. This paper presents our participation in Task 3 MuSHROOM of SemEval 2025, which focuses on detecting hallucinations in multilingual contexts. Specifically, the task requires identifying text segments generated by LLMs that correspond to hallucinations and calculating the hallucination probability for each character in the text. To address this challenge, we adopted a token classification approach using the pre-trained XLM-RoBERTa-large model, fine-tuned on the provided training set. Additionally, we integrated context from Llama-3.1-70B to enhance hallucination detection by leveraging its broader and more up-to-date knowledge base. Our approach combines the multilingual capability of XLM-RoBERTa with the contextual understanding of Llama-3.1-70B, producing a detailed hallucination probability for each character in the text. The results demonstrate that our approach consistently outperforms baseline methods across multiple languages, particularly in detecting token-level hallucinations.

1 Introduction

Large Language Models (LLMs) such as GPT-4, LLaMa, Mistral, Gemma, and others, have marked a significant paradigm change in Natural Language Processing (NLP), achieving significant advances in language compression, generation, and reasoning (Brown et al., 2020). These models have overcome many limitations of previous models, enabling more robust and sophisticated applications in areas such as machine translation, virtual assistance, visual content generation, sentiment analysis, etc (Das et al., 2025).

One of the key factors of their success has been the massive scaling of parameters and training data, which has allowed them to capture linguistic nuances and broad domain knowledge. In addition, the development of more efficient and optimized architectures has improved their reasoning capabilities, allowing them to perform complex logic and analysis tasks.

Another revolutionary aspect has been the ability of LLMs to perform few-shot learning and even zero-shot learning, adapting to new tasks with few or no specific examples, expanding their versatility and applicability in dynamic environments. This has opened up new possibilities in areas such as customer service (Xiaoliang et al., 2024), personalized education (Wen et al., 2024), and AI-powered scientific research.

However, along with these remarkable advances, concerns have arisen about the tendency of LLMs to hallucinate, i.e., to produce false or fictitious information with high confidence and apparent consistency. These hallucinations can range from factually incorrect data to fabricated quotes or specific details that do not correspond to reality, posing significant risks in critical applications such as medicine, legal advice, or news broadcasting (Huang et al., 2025).

The root of the problem lies in the way LLMs generate text: based on statistical patterns learned from large amounts of data. While this allows them to produce fluid, contextually relevant responses, it also means that they have no real understanding of the world and no internal fact-checking (Guerreiro et al., 2023). As a result, they may combine information plausibly but incorrectly, leading to hallucinations. This complicates the practical implementation of LLMs, especially in real-world information retrieval systems that have become integrated into our daily lives, such as chatbots (Aljamaan et al., 2024), search engines (Shi et al., 2025), or content moderation (Pan et al., 2025, 2024; García-Díaz

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 750–756

et al., 2023).

It is important to note that hallucinations in conventional natural language generation (NLG) tasks have been extensively studied, and are defined as generated content that is illogical or not faithful to the provided source content. Moreover, in recent years, several tasks have been developed to detect hallucinations in LLMs, such as Shroom 2024 (Mickus et al., 2024), etc.

For this reason, Task 3 Mu-SHROOM of SemEval 2025 (Vázquez et al., 2025) was also released with the aim of detecting the parts of texts that correspond to hallucinations. The main goal of this task is therefore for participants to determine which parts of a text produced by LLM represent hallucinations. The task is organized in several languages and is performed in a multilingual context with different LLM. For each text, the probability that it is a hallucination must be generated for each character in the text.

To solve this task, we have adopted a token classification approach based on a pre-trained language model, specifically XLM-RoBERTa-large (Conneau et al., 2019), which is fine-tuned with the training set. However, in this case, for hallucination detection, the context, or response generated by an LLM, such as Llama-3.1-70B (Dubey et al., 2024), is added, as this model has broader knowledge. This improves hallucination detection by providing additional information that helps the model to distinguish between correct and hallucinatory content. Furthermore, the combination of XLM-RoBERTa-large with Llama-3.1-70B exploits the strengths of both models: the multilingual capability and robustness of XLM-RoBERTa, together with the up-to-date and contextual knowledge of Llama-3.1-70B. The fitted model generates the hallucination probability for each character in the text, providing a detailed and accurate analysis. This approach proves effective in a multilingual context and with different LLMs, optimizing hallucination detection in different scenarios.

2 Background

LLMs are large-scale language models designed to understand and process human language by learning contextual patterns and relationships in large volumes of textual data. These models have a large number of parameters and use advanced pre-training techniques, such as Masked Language Modeling (MLM) and autoregressive prediction, allowing them to accurately model probabilities and contextualized semantics of text (Huang et al., 2025).

In recent years, several high-profile LLMs have been developed, including OpenAI's GPT-4, Meta AI's Llama, Google's Gemma, Mixtral and Mistral. These models have demonstrated their versatility in a wide range of applications, from search engines and customer support to code generation, education, healthcare and financial analysis.

Despite their remarkable advances and versatility in multiple domains, LLMs present several limitations that affect their reliability and applicability in real environments, such as the generation of hallucinations, lack of fact and reasoning verification, context sensitivity, as well as biases and limitations in complex reasoning and specialized tasks. Therefore, there is a need for new approaches and more robust strategies to solve these problems and, thus, optimize resources in the future development of LLMs (Huang et al., 2025).

Thus, different techniques and approaches have emerged for detecting hallucinations in LLMs, such as fact-checking, which verifies the accuracy of generated content by cross-referencing it with reliable external sources (Min et al., 2023). Additionally, frameworks that utilize evidence gathering and internal verification tools leverage the knowledge stored within the LLMs themselves, using techniques like Chain-of-Thought (CoT) (Dhuliawala et al., 2024). However, these methods are limited, as LLMs are not always reliable data sources.

Several approaches attempt to detect hallucinations without relying on sources external to the LLMs themselves. These include analyzing internal signals such as token-level confidence scores or entropy measures (Varshney et al., 2023; Luo et al., 2024), as well as evaluating model behavior through consistency checks, for example by comparing multiple generations or using multi-agent discussion frameworks (Agrawal et al., 2024).

In our approach, we use a multilingual token classification model based on XLM-RoBERTa to identify hallucinated segments in text generated by LLMs. Instead of relying on external knowledge bases, we incorporate a reference response generated by Llama-3.1-70B as additional context. This setup allows the model to compare the original output with a high-quality alternative and detect inconsistencies at the token level. Our method uses internal information from the LLMs' outputs and comparison signals between model generations to

improve hallucination detection.

Specifically, XLM-RoBERTa is used as a token classification model to identify hallucinations generated by LLMs, incorporating the response generated by Llama-3.1-70B as context into the token classification input to improve detection accuracy. This integration allows the XLM-RoBERTa model to benefit from the enhanced generation and understanding capabilities of Llama-3.1-70B, increasing its effectiveness in identifying inconsistencies and errors in the output generated by other LLMs.

3 System overview

Figure 1 shows the system architecture, where the XLM-RoBERTa-Large model is used as the basis for performing fine-tuning in a token classification task. In this approach, each token in the text is classified with a value of 1 or 0, indicating whether that token corresponds to a hallucination (1) or not (0).

XLM-RoBERTa-Large is a multilingual version of RoBERTa, trained on 2.5 TB of CommonCrawl filtered data spanning 100 languages. This model was pre-trained using the Masked Language Modeling (MLM) objective, in which 15% of the words in the input are randomly masked, and the model must predict the masked words using the surrounding context.

Unlike traditional recurrent neural network models (RNNs), which process words sequentially, or autoregressive models such as GPT, which mask future tokens, XLM-RoBERTa leverages a bidirectional representation of the sentence. This allows it to learn an internal representation of 100 languages, which is essential for multilingual tasks.

To provide the model with a broader context or a pre-answer to the question, an LLM such as Llama-3.1-70B has been used. Since this model has been trained with a larger amount of data, it offers superior performance compared to the LLMs used to generate the dataset answers. To incorporate the response or context generated by Llama-3.1-70B, a `text_pair` configuration has been employed, in which the text generated by the model (`model_output_text`) and the context or response of the larger model (teacher model) are entered together.

This configuration allows XLM-RoBERTa-Large to consider not only the text itself, but also its context, which can help the model better distinguish between factual and hallucinated content.

During tokenization, labels are assigned to the tokens using the offset mappings generated by the tokenizer, which indicate the start and end positions of each token in the original text. Those tokens whose ranges match the positions specified in the hard labels, which mark the hallucinations in the text, are labeled as 1. All other tokens receive a label of 0.

This granular approach at the token level enables accurate and detailed detection of hallucinations, helping to identify exactly where in the text the hallucination occurs. In addition, by using XLM-RoBERTa-Large with text pairs (`text_pair`), a more robust and effective contextual analysis is achieved, maximizing model performance in a multilingual environment.

We used the HuggingFace transformers library with the XLM Roberta large model and its associated tokenizer. Each input sample was encoded using the `text_pair` format, where the first segment corresponds to the model-generated output (`model_output_text`) and the second segment corresponds to the context provided by Llama-3.1-70B model.

A token classification head with a single linear layer and softmax activation was added on top of the encoder. Although the output logits consist of three values per token (due to padding and special tokens), only two labels are used during training: 1 for hallucinated tokens and 0 for the rest. Tokens not aligned with any character (e.g., special tokens) were assigned a label of -100 to be ignored by the loss function.

The model was trained using the cross-entropy loss function, which is standard for token classification tasks. Offset mappings were used to align character-level annotations with token-level labels.

4 Experimental setup

For the experiment, the labeled training set provided by the organizers has been used with 50 examples are kept for each language, except for SV which has 49 examples.

In Figure 2, the length distribution of the input, the response generated by the LLM and the response generated by the LLM teacher (Llama-3.1-70B) is shown. It can be seen that the maximum length of the response generated by the LLM teacher is around 100 tokens, while the length of the responses generated by the LLM can reach up to about 500 tokens. This difference could be

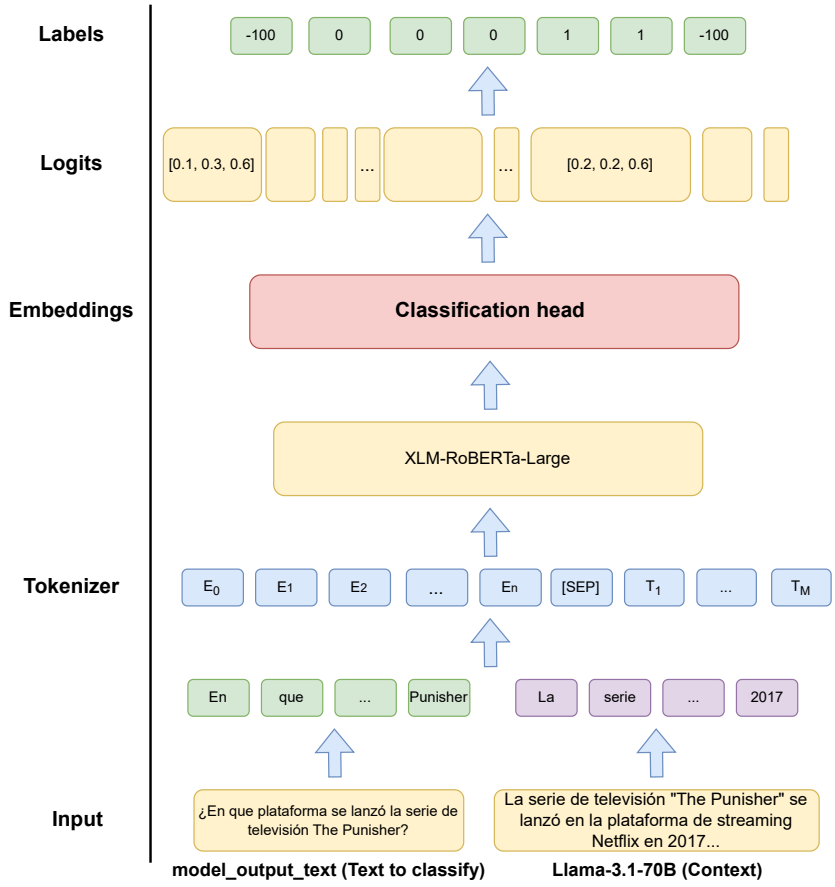

Figure 1: System architecture. Inputs are encoded using text_pair format: the first segment is the model output to classify (model_output_text), and the second is a hallucination-free reference generated by Llama-3.1-70B.

related to the tendency of the LLM to generate longer responses, which could be an indication that the model is generating hallucinations. Longer responses may be associated with a higher probability of producing unrelated or incorrect information, whereas the LLM teacher, being more oriented to provide precise and concise responses, has a more controlled response length.

For model training, the dataset has been divided into 80% for training and 20% for validation, in order to evaluate the model performance on an unseen dataset. As for the training parameters, a batch size of 16 tokens per device is used, with a total of 10 training epochs and a learning rate of 2e-5. Model evaluation is performed at the end of each epoch, and the model is saved after each evaluation.

To generate the answers with Llama-3.1-70B, the "meta-llama/Llama-3.1-70B-Instruct" template loaded in 4-bit format using the BitsAndBytes configuration was used to optimize memory usage on

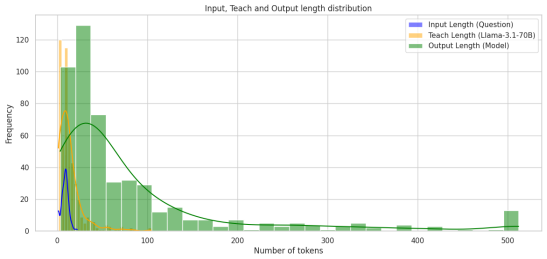

Figure 2: Input, Teach and Output length distribution.

GPUs.

The prompt used follows a consistent template specifying that the wizard must answer in the same language as the question, ensuring a clear, precise and concise answer. The prompt template is described in Listing 1.

For text generation, the following decoding parameters were used: a limit of 4096 tokens for the maximum length of the generated response, a top_p value of 0.95 to apply nucleus sampling and keep diversity controlled in the generation, and a top_k

```
You are an advanced multilingual assistant.

of 10 to restrict the selection to the 10 most likely tokens. In addition, a temperature of 0.7 was used to balance creativity and consistency of responses, along with a num_beams value of 1 to generate responses efficiently without beam search.

5 Results

Table 1 presents the official results of our approach compared to the baselines (mark all, mark none, and mark neutral) in terms of the IoU and Cor metrics. Performance was evaluated in fourteen languages, allowing for a comprehensive analysis of the effectiveness of our approach in a multilingual context.

Overall, our approach consistently outperforms the baselines in both metrics, indicating its ability to effectively detect LLM model-generated hallucinations in multiple languages. For example, in ES and EN, our model obtained an IoU of 0.2980 and 0.3667, respectively, and a Cor of 0.4152 and 0.4966. These results reflect a considerable improvement compared to the baselines, especially in the Cor metric, suggesting a higher accuracy in detecting token-level hallucinations.

It is observed that languages with more complex grammatical structures or less represented in the model pre-training, such as AR, FA and FI, show slightly lower performance. This behavior can be attributed to the lower availability of data in these languages, which affects the model's ability to generalize correctly. Moreover, only the "mark everything as hallucination" baseline outperforms our approach in some cases.

Notably, in languages such as SV and ZH, the model achieved an IoU of 0.4393 and 0.3875, respectively, with Cor values of 0.3936 and 0.4916. Although our approach presents a lower IoU than the baseline (mark all) in these languages, the model maintains a robust correlation, indicating its ability to capture consistent patterns in hallucination generation.

In terms of ranking, our approach demonstrates competitive performance, consistently ranking high for most of the languages evaluated. For example, it was ranked 13th in FA and 16th in IT, reflecting its effectiveness in languages with different linguistic backgrounds.

In conclusion, the results demonstrate the effectiveness and robustness of our approach for hallucination detection in multiple languages, significantly outperforming the baselines and maintaining a robust correlation. This confirms its generalizability in multilingual contexts and its potential application in language model-generated text evaluation tasks.

6 Conclusion

Our participation in Task 3 Mu-SHROOM of SemEval 2025 focused on the detection of hallucinations in texts generated by LLMs, a critical challenge as these systems are increasingly integrated into real-world applications. We adopted a token classification approach using the pre-trained multilingual XLM-RoBERTa-large model, augmented with contextual information from Llama-3.1-70B. By comparing the model-generated output with a hallucination-free reference, our system produces token-level hallucination probabilities, allowing for fine-grained analysis. Experimental results show that our approach consistently outperforms baseline methods in several languages, with particularly strong performance in English and Spanish. However, results in languages with complex grammar or fewer pre-training representations, such as Arabic and Finnish, highlight the need for language-specific strategies to improve generalization. These results highlight the benefits of combining multilingual modeling with LLM-generated context. Future work will explore more advanced fusion techniques, cultural and linguistic factors influencing hallucination generation, dataset expansion, and the use of reinforcement learning to further improve performance.

Future work will explore fine-tuning strategies such as cross-lingual transfer learning or data augmentation to mitigate the performance gap observed in low-resource languages. In addition, while Llama-3.1-70B provides strong contextual guidance, its size may hinder real-time deployment. Exploring more lightweight alternatives, such as distilled models or hybrid architectures, remains a promising direction. Although we did not perform

Table 1: Official results for each language (L), reporting the rank (#), Cor of baseline (mark all, mark none, and mark neutral), IoU and Cor.

L	#	IoU Bas.	IoU Bas.	IoU Bas.	IoU	Cor
		mark all	mark none	mark neutral

Abstract

In today's digital age, the rapid dissemination of information through social networks poses significant challenges in verifying the veracity of shared content. The proliferation of misinformation can have serious consequences, influencing public opinion, policy decisions, and social dynamics. Fact-checking plays a critical role in countering misinformation; however, the manual verification process is time-consuming, especially in multilingual contexts. This paper presents our participation in the Multilingual and Crosslingual Fact-Checked Claim Retrieval task (SemEval 2025), which aims to identify previously fact-checked claims relevant to social media posts. We propose a retrieval approach based on XLM-RoBERTa, a multilingual Transformer model, combined with metric learning, hard negative mining, and a Multi-Similarity Loss function to optimize cross-lingual semantic representations. Our system uses a single multilingual encoder to handle all languages, offering a scalable and efficient solution without requiring language-specific adaptations. Although our final ranking (25th place) reflects modest performance compared to top systems, our model achieved consistent results across languages, with over 50% hit rate in most cases. These results highlight both the potential and current limitations of general-purpose multilingual models for fact-checking retrieval.

1 Introduction

The massive and continuous dissemination of information on social networks makes it increasingly difficult to distinguish between accurate content and misinformation (Bartolomé, 2021). This challenge is exacerbated by the fact that fake news can spread rapidly and influence public opinion, social behavior, and even political processes. Ensuring the veracity of online content is therefore critical to safeguarding societal well-being.

Manual fact-checking is a slow and resource-intensive task, especially in a multilingual context where claims and their verifications may appear in different languages. To address this challenge, recent research has proposed decomposing the process into subtasks that can be partially automated using Natural Language Processing (NLP), such as identifying check-worthy claims, retrieving relevant evidence, and assessing veracity (Guo et al., 2022; Pikuliak et al., 2023). Despite progress, automated fact-checking remains difficult due to linguistic ambiguity, implicit or biased wording, and the challenge of assessing the reliability of sources. Nevertheless, automating this process is essential to combat misinformation at scale and support a more informed and resilient society.

The Multilingual and Crosslingual Fact-Checked Claim Retrieval shared task (SemEval 2025) (Peng et al., 2025) focuses on the efficient identification of claims that have already been fact-checked in a multilingual and cross-lingual context. Given a social media post, the goal is to determine the most relevant corresponding to fact-check for the post. It is divided into two "subtasks", that is, the task could be done following two different setups: (1) **Setup A: Monolingual**. In which both posts and fact-checks are in the same language; and (2) **Setup B: Crosslingual**. In which posts and fact-checks may be in the same language or in different languages.

For this task, we propose an approach based on XLM-RoBERTa, a multilingual Transformer-based model, to generate contextual embeddings for both social media posts and fact-checked claims, enabling semantic comparisons across languages. Our approach employs a metric learning pipeline where the model is trained to optimize the cosine similarity between embeddings of relevant claim-post pairs, facilitating effective cross-lingual retrieval. To improve the model's discriminative ability, we incorporate a hard negative mining strategy

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 757–762

that dynamically selects challenging pairs that are semantically similar but do not correspond to the same fact-checked claim. This forces the model to learn more refined feature representations, improving its ability to distinguish between highly related but distinct claims. By leveraging this multilingual embedding space and fine-tuning it with task-specific constraints, our approach efficiently retrieves fact-checked claims, addressing the challenge of misinformation detection in a multilingual and cross-lingual setting.

2 Background

An automated fact-checking chain typically consists of several modules, each one in charge of performing one of the subtasks that make up the automation of the fact-checking process (Guo et al., 2022). Generally speaking, this process begins with the detection of whether a fact should be verified or not and ends, after identifying which facts can be verified with the same information, with the extraction, from some data source, of the original source or set of evidences that supports or refutes the fact.

Specifically, this task focuses on previously fact-checked claim retrieval (PFCR) (Shaar et al., 2022): that is, given a text making a claim and a set of claims that have already been verified, the objective is to rank the fact-checked claims so that those that are the most relevant with reference to the given claim. Following the process described above, this task would correspond to the last step of the automated fact-checking process.

Fact-checked claim retrieval has become an important research topic, mainly due to its potential applications in many challenging tasks such as the detection and correction of fake news and misinformation on digital platforms. This would allow to quickly identify this incorrect information, contrast it in real time, and improvements in search and recommendation systems by integrating mechanisms that prioritize verified and high quality information. Since automated systems can continuously crawl and monitor news websites, social networks and other online sources, they are capable of identify new claims and information as they emerge. Additionally, fact-checking requires prioritizing which claims should be checked. Advanced algorithms make these decisions based on factors such as virality, potential impact and source credibility (Nakov et al., 2021).

Once the information to be verified has been identified, machine learning models use historical data to pinpoint statements that may verify or contradict the fact being verified. This process consists of evaluating the similarity between each fact and previously verified facts, and assigning similarity scores to them, which significantly speeds up the extraction of verifying or contradicting statements. Moreover, rapid advancements in NLP in recent years have led to the emergence of many pre-trained Transformer-based models. These models are trained on vast corpora of unlabeled text and, thanks to their transfer learning capabilities, they can be adapted to various tasks, which makes them an interesting option for this task. They have been shown to be effective in extracting verifications and identifying contradictions for a given fact (Ünver, 2023).

Furthermore, pre-trained multilingual models based on Transformers, such as mBERT and XLM-RoBERTa, have proven to be effective in the task of crosslingual fact-checking (Kazemi et al., 2022). Trained on a large multilingual corpora, they are capable of handling multiple languages, making them capable of performing the extraction of information that verifies or contradict a fact even when the texts are in different languages.

Therefore, in this study, we tested a self-alignment pretraining strategy based on XLM-RoBERTa and metric learning. Our approach involves training a multilingual language model to match social media posts with relevant fact-checks by leveraging semantic representations. Using hard pair mining and optimization with a multi-similarity loss function, the model learns to identify difficult to distinguish examples, improving the matching accuracy between posts and claims. We fine-tuned the model on a shared embedding space and used MultiSimilarityLoss (Wang et al., 2019) to refine similarity and dissimilarity relationships.

3 System overview

Figure 1 illustrates the architecture of our system for claim identification in fact-checking publications. Our approach is based on a self-alignment pretraining method similar to SapBERT (Liu et al., 2021), which involves training a multilingual language model, such as XLM-RoBERTa (Conneau et al., 2019), through metric learning to match social media posts with relevant fact-checks. In this way, the trained model is able to identify seman-

tic representations through a process of hard pair mining and optimization using a multiple similarity loss function.

Specifically, the pipeline of our system is organized into several stages, as shown in Figure 1. First, data loading and processing are performed. For this, we use the three datasets provided by the organizers: `posts.csv`, which contains texts of social media posts, including OCR of each post; `fact_check.csv`, which gathers verified facts (claims); and `pairs.csv`, which links posts to relevant claims. Text encoding is then carried out using XLM-RoBERTa, which generates embeddings for both posts and claims. These embeddings capture the semantic meaning of the texts in a shared vector space, facilitating similarity matching.

The next step involves hard pair mining, using the MultiSimilarityMiner library to identify examples that present high similarity in the embedding space and are therefore more difficult to distinguish, as they are not present in the `pairs.csv` file. Once the pairs and hard pairs are identified, the model is trained using MultiSimilarityLoss as the loss function, which adjusts the similarity and dissimilarity relationships between pairs of embeddings. Additionally, AdamW is employed as an optimizer to efficiently update the model parameters.

Figure 2 shows the pipeline used for the evaluation of the model. A previously trained model was used to identify the most relevant claims related to social media posts. In order to speed up the search time, a dictionary of embeddings of the facts was created. These claims are tokenized and passed through the trained model to obtain their representations in the form of embeddings. These representations are stored in a list and concatenated with their corresponding `fact_id`. Once this fact dictionary is available, to extract the top 10 most related claims to an input post, the embedding of the post is obtained using the trained model and the distance between the embedding of the post and the pre-generated embeddings of the claims is calculated. From the distance matrix, the indices of the closest (i.e., most similar) facts are selected and the first 10 results are returned.

4 Experimental setup

For experimentation, the datasets provided by the organizers were used for both training and testing. In the training process, a set of 153,742 facts, 24,431 posts, and 25,742 pairings were available, as shown in Table 1. For the testing phase, the facts set consists of 272,446 examples, and the goal is to find the 10 most related facts for each post (with a total of 8,275 posts in the test set).

It is important to note that the facts set is considerably large, with 272,446 examples. However, with our model and approach, the search time is significantly reduced, as it is only necessary to extract the 10 embeddings of facts most related to the embedding of the input post. In contrast, many other current approaches would require a sequential search through the entire set of facts for each post, which is much less efficient.

For training, XLM-RoBERTa was used as the base model, together with MultiSimilarityLoss as the loss function and MultiSimilarityMiner for hard pair generation. In addition, AdamW was used as optimizer, with a learning rate of 2e-5 and a weight decay of 0.01. The model was trained for a total of 20 epochs.

Table 1: Dataset distribution

Type	Number
Train	
Pairs	25.742
Facts	153.742
Posts	24.431
Test	
Facts	272.446
Posts	8.275

5 Results

In this task of identifying the most relevant facts related to the posts, S@10 was used as the reference metric to evaluate the performance of the models. S@10 measures the proportion of posts for which at least one of the ten retrieved facts is relevant.

The detailed analysis of the results, presented in Table 2, reveals crucial information about the performance of the top three teams and our team in this task, including the official ranking in several languages. Overall, PINGAN AI leads the ranking with an S@10 (avg) of 0.96, standing out as the most effective model. It is followed by PALI and TIFIN India, with average scores of 0.9472 and 0.938 respectively, demonstrating their high accuracy in fact retrieval. In contrast, UMUTeam

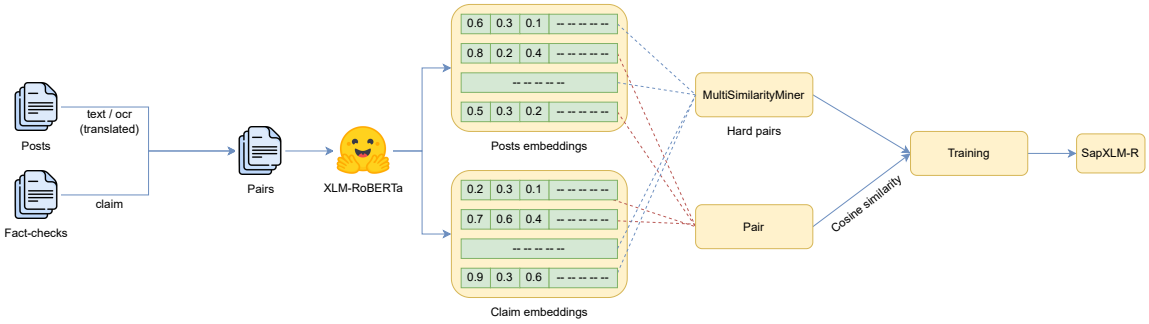

Figure 1: System architecture pipeline.

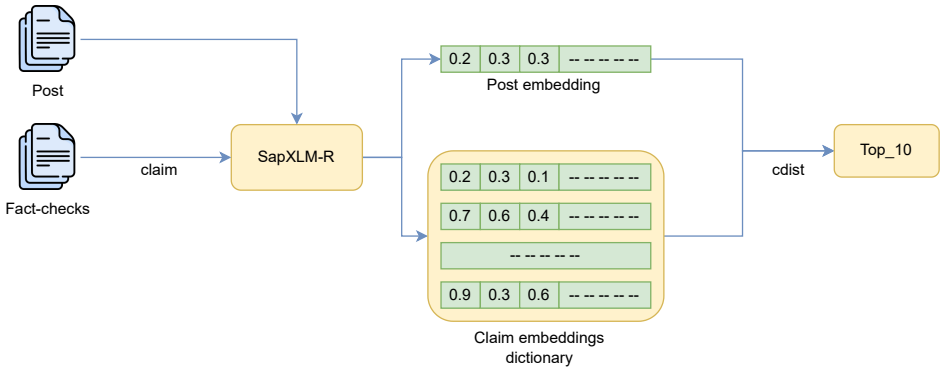

Figure 2: Evaluation approach pipeline.

ranks 25th with an S@10 (avg) of 0.544, reflecting a much lower performance compared to the leaders.

Analyzing the performance by language, it can be seen that in ENG, the top three teams show solid results, especially PINGAN AI (0.916) and PALI (0.904), while UMUTeam achieves only 0.414, indicating significant difficulties in this language. In SPA, PINGAN AI and PALI perform excellently (0.974 and 0.97, respectively), while UMUTeam scores only 0.42, suggesting considerable room for improvement. In THA and MSA, PINGAN AI, PALI and TIFIN India achieve perfect or near perfect scores, demonstrating exceptional performance. However, although UMUTeam shows relatively better performance in these languages (0.786 and 0.688 respectively), it still lags behind the leading teams. The lowest overall performance is observed in POL. While PINGAN AI and PALI score 0.926 and 0.888, respectively, UMUTeam scores only 0.464, which is its lowest score in this language assessment.

Analysis of these results shows that language diversity significantly affects model performance, with generally higher scores observed for THA and MSA, in contrast to ENG and POL. This variability suggests that the models used may not be equally optimized for all languages. Although our team (UMUTeam) did not achieve a high score in the ranking, our approach has notable advantages. Unlike other approaches that may require separate models or language-specific settings, our approach uses a single model for all languages and achieves a hit rate above 50% for most languages. It also has a relatively short search time, making it a more efficient and scalable solution.

6 Conclusion

Our participation in the Multilingual and Crosslingual Fact-Checked Claim Retrieval task (SemEval 2025) addressed the challenge of identifying relevant fact-checked claims for social media posts across multiple languages. We proposed a solution based on XLM-RoBERTa, leveraging its multilingual capabilities to generate contextual embeddings that enable semantic comparisons between posts and fact-checks. By incorporating a metric learning pipeline with hard negative mining, our approach effectively distinguished between highly related but distinct claims, improving cross-lingual retrieval accuracy.

Table 2: Official ranking reported by language and final average

Language	#1 PINGAN AI	#2 PALI	#3 TIFIN India	...	#25 UMUTeam
English	0.916	0.904	0.88	...	0.414
French	0.972	0.954	0.954	...	0.564
German	0.958	0.936	0.936	...	0.384
Portuguese	0.926	0.908	0.902	...	0.47
Spanish	0.974	0.97	0.96	...	0.42
Thai	0.9945	1.000	0.9945	...	0.7869
Malay	1.000	1.000	1.000	...	0.6882
Arabic	0.986	0.982	0.966	...	0.716
Turkish	0.948	0.93	0.904	...	0.538
Polish	0.926	0.888	0.886	...	0.464
Average	0.96	0.9472	0.938	...	0.544

The experimental results demonstrated that our system efficiently retrieved relevant claims across various languages, achieving a hit rate above 50% for most of them. Notably, the model showed competitive performance in Thai and Malay, highlighting its effectiveness in languages with simpler grammatical structures. However, the system's performance was lower in English and Polish, indicating challenges in processing complex linguistic nuances. These results underscore the impact of language diversity on model performance, suggesting the need for language-specific optimizations.

Despite not achieving top ranks, our unified model approach proved to be efficient and scalable, offering a significant advantage over language-specific solutions. The system's rapid search time and ability to handle multilingual input with a single model demonstrate its potential for real-world misinformation detection applications.

It is worth noting that we trained the model using the full training set provided by the organizers, without holding out a separate validation set. This decision was motivated by the retrieval nature of the task, where the goal was to optimize a embedding space to compare posts and fact-checked claims efficiently. While this choice allowed us to leverage all available data for training robust representations, it also limited our ability to perform detailed hyperparameter tuning and ablation studies. We acknowledge this limitation and consider incorporating a validation split and more granular experiments in future work. Besides, we will explore domain adaptation, cross-lingual transfer learning techniques, and addressing the challenges posed by languages with complex grammatical structures.

Finally, we aim to apply our fact-checked claim retrieval system to domains involving political discourse (Garcia-Díaz et al., 2023) and harmful or emotionally charged narratives, such as hate speech and hope speech (Pan et al., 2025a,b). In this sense, integrating multilingual claim retrieval into these pipelines could help validate or challenge politically biased or manipulative statements, especially in settings where real-time verification is critical. In future work, we plan to explore domain adaptation strategies and joint modeling approaches that combine claim verification with stance and intention detection, allowing for a more comprehensive analysis of ideological and affective discourse.

Abstract

Multi-label emotion classification in low-resource languages remains challenging due to limited annotated data and model adaptability. To address this, we fine-tune large language models (LLMs) using a sentence-label pairing approach, optimizing efficiency while improving classification performance. Evaluating on Sundanese, Indonesian, and Javanese, our method outperforms conventional classifier-based fine-tuning and achieves strong zero-shot cross-lingual transfer. Notably, our approach ranks first in the Sundanese subset of SemEval-2025 Task 11 Track A. Our findings demonstrate the effectiveness of LLM fine-tuning for low-resource emotion classification, underscoring the importance of tailoring adaptation strategies to specific language families in multilingual contexts. Our source code is available at: https://github.com/LazarusNLP/SemEval2025-Emotion-Analysis.

1 Introduction

Emotion recognition is a challenging and multifaceted task that plays a crucial role in natural language processing (NLP) applications, including consumer sentiment analysis (Herzig et al., 2016), healthcare (Saffar et al., 2023), and human-computer interaction (Singla et al., 2024). Despite advancements in large language models (LLMs), accurately classifying nuanced emotional expressions across diverse languages remains a significant challenge, particularly for low-resource languages. SemEval-2025 Task 11 (Muhammad et al., 2025b) addresses this challenge by providing a multilingual dataset BRIGHTER (Muhammad et al., 2025a) for three distinct sub-tasks: (A) Multi-label Emotion Detection, (B) Emotion Intensity Prediction and (C) Cross-lingual Emotion Detection. This task aims to evaluate the ability of models to identify perceived emotions in text across 28 languages, including several underrepresented ones.

In this paper, we tackled Track A (supervised multi-label emotion detection) and C (cross-lingual emotion detection). Our approach focuses on fine-tuning large language models using a novel sentence-label pairing strategy to enhance performance across both monolingual and cross-lingual tasks. We specifically target three languages spoken in Indonesia: Indonesian (`ind`), Javanese (`jav`), and Sundanese (`sun`). Track A involves assigning binary labels (0 or 1) to perceived emotions, while Track C evaluates a model's ability to transfer knowledge from one language to another without access to in-language training data.

Our methodology highlights three key contributions. First, we reformulate the multi-label classification task as a series of binary classification problems, pairing each sentence with its corresponding emotion labels. This simplifies the task into multiple single-label classifications and increases the number of training samples. Second, we leverage multilingual pre-trained LLMs to transfer cross-lingual knowledge from Sundanese (supervised training set available in Track A) to Indonesian and Javanese (test sets available in Track C), taking advantage of their linguistic similarities within the same language family. Finally, instead of using a conventional binary cross-entropy (BCE) loss with a linear classifier head, we frame the task as text generation, training the model to output "yes" or "no" as predicted labels for each emotion. Our experiments reveal the effectiveness of these strategies in improving model performance across both monolingual and cross-lingual scenarios, providing insights into addressing linguistic gaps in emotion detection tasks.

2 Related Works

Emotion Classification Approaches Early emotion classification systems primarily relied on lexicon-based approaches, which mapped words

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 763–772

to predefined emotional categories (Mohammad, 2023). While effective to some extent, these methods lacked deeper semantic understanding and were purely syntactic. As a result, machine learning models and neural networks (e.g. language models) eventually replaced rule-based systems, enabling more context-aware and flexible emotion classification.

Traditionally, multi-label emotion classification has been approached as a conventional classification problem, where a pre-trained encoder-based language model is augmented with a linear classifier and trained using BCE loss. More recent innovations have explored alternative formulations. SpanEmo (Alhuzali and Ananiadou, 2021) introduced span prediction, where models learn direct associations between text spans and emotion labels, reducing ambiguity and improving classification performance on SemEval benchmarks. Meanwhile, T5 (Raffel et al., 2020) reframed downstream tasks (e.g. classification) within a text-to-text framework, which was later extended and scaled up by FLAN (Wei et al., 2022; Chung et al., 2024) to instruction tuning, improving zero-shot generalization.

Emotion Classification in Indonesian Languages The first major benchmark for Indonesian emotion classification was the EmoT dataset (Saputri et al., 2018), later standardized in IndoNLU (Wilie et al., 2020), where IndoBERT achieved state-of-the-art performance. However, most studies have focused on Indonesian, with limited work on regional languages. For Sundanese, Putra et al. (2020) employed traditional machine learning algorithms, while Wongso et al. (2022) benchmarked Sundanese BERT models on the former's dataset. NusaWrites (Cahyawijaya et al., 2023) later expanded the EmoT dataset by translating it into various regional languages, broadening multilingual evaluation.

Language Models for Languages of Indonesia Indonesian, Javanese, and Sundanese are among the most widely available language datasets from Indonesia (Aji et al., 2022) and have been integrated into various pre-trained language models. IndoBERT (Wilie et al., 2020) was specifically designed for Indonesian, while IndoBART (Cahyawijaya et al., 2021) extended support to Javanese and Sundanese. Additionally, multilingual models such as XLM-R (Conneau et al., 2020) and mBERT (Devlin et al., 2019) have incorporated these languages into their training corpora. More recently, large language models (LLMs) such as Cendol (Cahyawijaya et al., 2024), SEA-LION (Singapore, 2024), and Sahabat-AI[1] have further expanded coverage of these languages in their pre-training.

Building on these advancements, our approach extends the emerging trend of treating classification as an instruction-tuning task. By reformulating multi-label emotion classification as a text generation problem, we leverage the capabilities of modern Indonesian LLMs for cross-lingual transfer and improve generalization across low-resource languages.

3 Multi-label Emotion Classification

Muhammad et al. (2025a) introduced BRIGHTER, an emotion recognition dataset covering 28 languages, including several low-resource ones. In this study, we focused on languages spoken in Indonesia: Indonesian, Javanese, and Sundanese, and participated in tracks that included these languages.

Briefly, Track A is a supervised multi-label emotion detection task, where given a text snippet, the goal is to predict the speaker's perceived emotions by assigning a binary label to each (0 or 1). Track B focuses on emotion intensity prediction, requiring models to predict the intensity of a given emotion on a four-level ordinal scale. However, since none of the Indonesian languages were included in Track B, we did not participate. Track C is a cross-lingual emotion detection task, where models must predict emotions in a target language without access to a corresponding training set, relying instead on labeled data from another language. We present sample instances from the dataset in Appendix A.

Since Track A includes Sundanese, we trained on its subset and applied cross-lingual transfer to Indonesian and Javanese for Track C. This approach is feasible because all three languages share the same six emotion labels (anger, disgust, fear, joy, sadness, and surprise), eliminating the need to handle unseen emotions separately. Details of each language's subset are provided in Appendix A. Moreover, these three languages share a common origin within the Malayo-Polynesian language family. Previous studies (Winata et al., 2023; Cahyawijaya et al., 2021) suggest strong cross-lingual transfer among them, which leads us to hypothesize that our approach will be effective—especially if the pre-trained language model has been exposed to these languages during pre-training.

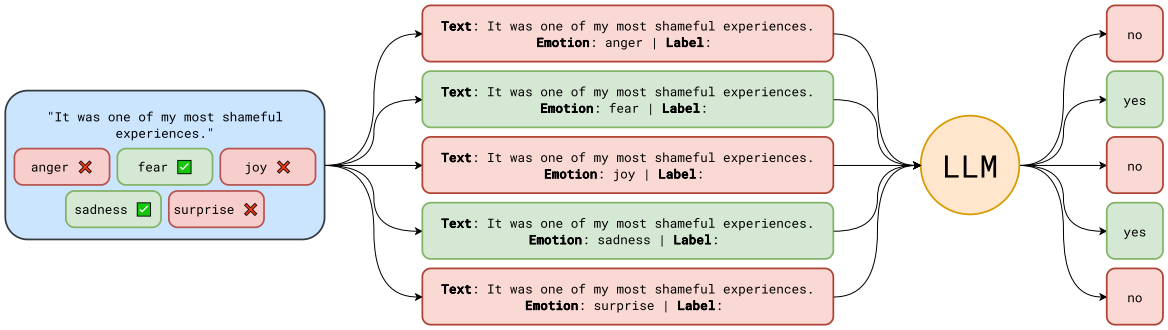

Figure 1: Our proposed LLM fine-tuning methodology for multi-label classification via sentence-label pairing.

4 System Overview

Based on our findings and problem formulation, we propose the methodology illustrated in Fig. 1. The subsequent paragraphs provide a detailed explanation of our pipeline, including data preparation, training, and inference.

4.1 Multi-Label Emotion Classification via Sentence-Label Pairing

Conventionally, with encoder-based language models such as BERT (Devlin et al., 2019), emotion classification is performed by leveraging the model's pre-trained encoder backbone and adding a linear classifier head. The model is then trained using BCE loss. The same approach can be applied to autoregressive language models, which are now commonly associated with LLM architectures. However, prior works (Radford et al., 2019; Brown et al., 2020) have demonstrated that framing tasks as text generation problems allows better utilization of an LLM's pre-trained capabilities. Building on this insight, we designed a method to adapt multi-label classification to a text generation framework.

A straightforward approach would be to concatenate the binary emotion labels into a delimited string and train the model to generate this sequence. However, we opted for a more effective strategy by reformulating the task into multiple single-label classification instances. This not only simplifies the learning process but also increases the number of training samples, which is particularly beneficial given the relatively small dataset size.

Specifically, for each text sample, we created a separate instance for each emotion label. The binary labels were then converted into natural language responses: 1 was replaced with "yes", and 0 with "no". Additional prompts (shown in Appendix B) were included to provide clearer task instructions.

4.2 Parameter-efficient LLM Supervised Fine-tuning

With the setup outlined above, we can train LLMs autoregressively for emotion classification, leveraging their natural language generation capabilities and specializing them for emotion classification through supervised fine-tuning (SFT). However, training such LLMs is computationally expensive and impractical in our resource-constrained environment.

To address these challenges and optimize both computational and time efficiency, we applied Low-Rank Adaptation (LoRA) (Hu et al., 2022), which targets only the attention layers using rank-8 matrices. We also employed QLoRA (Dettmers et al., 2023), a memory-efficient approach that quantizes model weights to 4-bit NormalFloat precision while maintaining all forward and backward passes in bfloat16, significantly reducing memory overhead. Additionally, Liger Kernels (Hsu et al., 2024) were used to further accelerate training efficiency.

4.3 Causal Inference

After SFT, we follow a standard procedure for causal inference as outlined in (Hendrycks et al., 2021). The input prompt, consisting of the text and the target emotion (e.g., happy), is passed to the LLM to generate logits. We then compare the logits for the "yes" and "no" labels, indexed by their respective token IDs. The final prediction for each emotion is the label with the higher logit score. This process is repeated for all six emotion categories.

5 Experiments

5.1 Models and Datasets

We applied our proposed methodology to two related families of LLMs: SEA-LION (Singa-

pore, 2024) and Sahabat-AI. To begin, we selected **Gemma2 9B CPT SEA-LIONv3 Base**[2] as our pre-trained LLM, which included Indonesian as part of its continued pre-training (CPT) corpus built on top of Gemma 2 (Team et al., 2024). In addition, we experimented with **Gemma2 9B CPT Sahabat-AI v1**[3], which extended SEA-LION-v3 by conducting additional CPT on English, Indonesian, Javanese, and Sundanese. Given this added exposure to the target languages, we anticipated that Sahabat-AI would deliver superior performance.

As mentioned in §3, we exclusively used Track A's Sundanese subset as our SFT dataset. Using our unpivoting method, we transformed the dataset into $924 \times 6 = 5,544$ training samples, enabling the model to learn each emotion label independently. We monitored the evaluation loss on the development subset to assess model performance during training. During inference, we applied the causal inference method to the Sundanese Track A test set, as well as the Indonesian and Javanese Track C test sets. The latter was conducted in a zero-shot and cross-lingual setting, with no additional change of prompts or modifications applied.

5.2 Implementation

The model was fine-tuned for 5 epochs with a learning rate of 2e-4 and a batch size of 32, training only the LoRA matrices. We implemented our methodology using Hugging Face Transformers (Wolf et al., 2020) and TRL (von Werra et al., 2020). All experiments were conducted on an NVIDIA L40S GPU.

5.3 Baseline

For comparison, we used NusaBERT (Wongso et al., 2025) as baseline, following the conventional approach for multi-label emotion classification explained in §4.1. A full fine-tuning was conducted with a learning rate of 1e-5, 100 epochs, early stopping with patience of 10, and a batch size of 8.

6 Results

6.1 Subtask A: Supervised Fine-tuning

We evaluated the development set results for SEA-LION-v3, Sahabat-AI, and NusaBERT fine-tuned on the Sundanese subset, with the results presented in Table 1. NusaBERT provided a solid baseline, achieving a macro F1-score of 52%. SEA-LION-v3, as expected, outperformed the conventional approach, reaching 57%. This improvement is likely due to its larger model size and enhanced capabilities, despite not being trained on Sundanese during pre-training. Nonetheless, this demonstrated the effectiveness of our proposed approach. Sahabat-AI further improved the score to 61%, which we attribute to its inclusion of Sundanese in its CPT corpus. Given its highest development score, Sahabat-AI was selected for the final testing phase on Track A and C.

Classifier	Model	Dev Score
Linear	NusaBERT Large	52%
Generative	Gemma2 9B CPT SEA-LIONv3	57%
	Gemma2 9B CPT Sahabat-AI v1	**61%**

Table 1: Macro F1-scores on the Sundanese development set for different models and training methods.

Team	Test Score (%)
SemEval Baseline (RemBERT)	37.31
PA-oneteam-1	50.72
TREDENCE AICOE	51.34
Lev Morozov	52.94
PAI	54.14
Lazarus NLP (ours)	**54.97**

Table 2: Test set macro F1-scores for Sundanese Track A, comparing our model with the top-5 leaderboard entries and the official baseline.

The test set results[4] for Sundanese Track A are shown in Table 2. Our team secured first place in the Sundanese subset, out of 38 teams on the leaderboard. However, our model's test score dropped to 54.97%, which is expected given the relatively small size of the training and development sets. Notably, most participants significantly outperformed the official baseline score of 37.31% (Muhammad et al., 2025a), where RemBERT (Chung et al., 2021) was found to be their best model under the same monolingual SFT setting.

6.2 Subtask C: Cross-lingual Transfer

We then used Track A's fine-tuned Sahabat-AI model and performed zero-shot cross-lingual transfer on the Indonesian and Javanese test sets from Track C. The results are shown in Table 3 and Table 4, respectively. Our method secured second place

Heimerdinger	43.86

Table 4: Test set macro F1-scores for Javanese Track C, comparing our model with the top-5 leaderboard entries and the official baselines.

for the Indonesian subset (out of 18) and third place for the Javanese subset (out of 14).

Interestingly, our model achieved a higher score on Indonesian than Sundanese, despite the former being evaluated in a zero-shot, cross-lingual manner. We hypothesize that this may be due to the base model's stronger understanding of Indonesian, stemming from its extensive continued pre-training on a larger Indonesian corpus.

Compared to the baseline RemBERT approach provided by the organizers, our method resulted in a +26.48% improvement, further demonstrating its effectiveness. Muhammad et al. (2025a) also provided a baseline score for cross-lingual multi-label classification, where they trained on languages from the same language family–excluding the target language–and performed a cross-lingual transfer[5], reaching 47.50% with LaBSE (Feng et al., 2022). Additionally, they conducted few-shot multi-label classification, achieving 57.29% using Qwen2.5-72B (Qwen et al., 2025). Both our method and the first-place solution outperformed these approaches.

[5]In this case, training on Javanese and Sundanese (the only other two Austronesian languages), and doing a cross-lingual transfer to Indonesian.

Lang	Test Score (%)						
	Anger	Disgust	Fear	Joy	Sadness	Surprise	Overall
Zero-shot							
ind	44.55	44.56	49.24	61.33	42.44	45.29	13.51
jav	43.79	47.33	46.76	49.47	41.86	44.88	11.79
sun	47.33	48.12	48.53	53.57	43.36	48.63	14.49

jav	60.13	60.86	55.12	64.67	80.43	60.67	43.77
sun	72.02	69.75	62.07	81.80	85.41	62.71	54.97

Table 5: Test set macro F1-scores for individual emotions and overall score.

Conversely, on the Javanese subset, the organizers achieved the highest score among all participants. Qwen2.5-72B reached the top score of 50.47% via few-shot classification, outperforming our approach by +6.7%. Although not disclosed, Qwen2.5 appears to have a strong understanding of Javanese, as demonstrated by their result.

6.3 Error Analyses

Firstly, we evaluated the impact of fine-tuning by comparing the fine-tuned model with the base model under the same evaluation procedure, with results shown in Table 5. In the zero-shot setting, the Sahabat-AI model performed worst on Javanese (11.79%) and best on Sundanese (14.49%). After fine-tuning, however, the model achieved its highest F1 score on Indonesian, showing the most improvement, while Javanese performance remained the lowest. This contrasts with the pre-trained Sahabat-AI results on the SEA-HELM benchmark (Susanto et al., 2025), where the model performed best on Javanese and worst on Indonesian[6]. This suggests that the observed improvements are due not just to pre-training biases, but also to the fine-tuning data characteristics.

Secondly, to evaluate the model's performance on each emotion, we also present the per-emotion F1 scores in Table 5. For Indonesian, the lowest F1 score is for surprise (64.76%); for Javanese, it's for fear (55.12%); and for Sundanese, it's for fear (62.07%), closely followed by surprise (62.71%). To better illustrate these results, we plotted the confusion matrices in Fig. 2. Notably, the most common type of error is false negatives, which suggests a lower recall score.

Thirdly, we qualitatively evaluated five test samples with the most number of misclassified emo-

[6]Retrieved from https://hf.co/GoToCompany/gemma2-9b-cpt-sahabatai-v1-base, with scores of 60.04 on the Indonesian subset, 69.88 on the Javanese subset, and 62.44 on the Sundanese subset of the SEA-HELM benchmark.

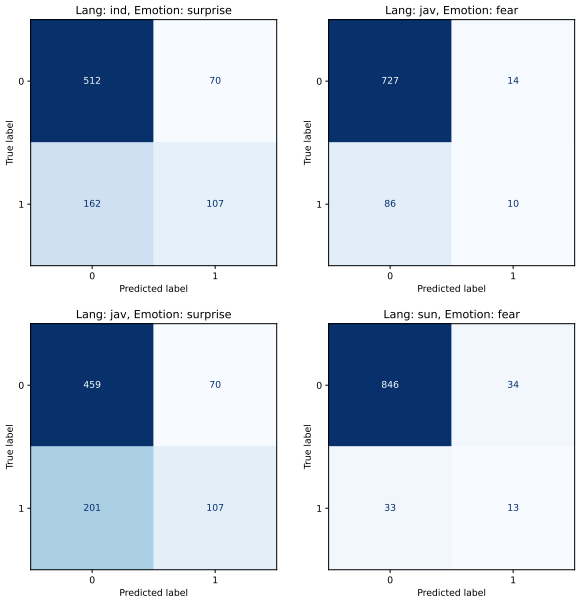

Figure 2: Confusion matrices for different languages and emotions.

tions, focusing on Indonesian texts. As shown in Table 6, we found that texts misclassified as joy often included the slang term *'wkwkwk'* (the Indonesian equivalent of *'hahaha'*). While intended sarcastically, the model struggled to grasp the true semantic meaning. Additionally, negative emotions such as anger, disgust, and fear were more likely to result in false negatives. We also identified particularly challenging samples, such as those containing Javanese slang (e.g., *'cok'*) or references to local public figures (e.g., *'Salsa Bintan'*).

7 Conclusion

In this study, we introduced a novel approach for multi-label emotion classification by fine-tuning LLMs using a sentence-label pairing method, focusing on low-resource languages of Indonesia. Our approach employed parameter- and memory-efficient techniques to optimize computational efficiency while preserving effectiveness. We trained LLMs to classify emotions from text, with Sundanese as the supervised source language and also performed cross-lingual transfer to Indonesian and Javanese. Our results demonstrated that our method outperformed conventional fine-tuning approaches in the supervised fine-tuning subtask. Additionally, our method exhibited strong performance in zero-shot, cross-lingual transfer, yielding notable results on the Indonesian and Javanese test sets. These findings indicate that our approach is a viable solution for multi-label emotion classification,

Text	Labels	Predictions

Table 6: Test set samples from the Indonesian Track C with the highest number of misclassifications, accompanied by English translations for clarity.

particularly in low-resource settings. However, further research is needed to refine these methods and evaluate their real-world applicability.

Limitations

Our study is limited by the scope of the BRIGHTER dataset (Muhammad et al., 2025a), which focuses on Indonesian, Javanese, and Sundanese. While these languages are part of the greater Austronesian family and are among the most widely available language data in Indonesia, they belong to the smaller Central Malayo-Polynesian group (Aji et al., 2022). As a result, our findings may not be directly applicable to all languages of Indonesia nor to the broader Austronesian language family. Additionally, we did not conduct extensive hyperparameter optimization or ablation studies, limiting the potential for fine-tuning the model to achieve optimal performance across different settings and tasks.

A Dataset Details

We present the dataset statistics for each language in Table 7 and provide sample dataset entries translated into English in Table 8.

Languages	Track A (#samples)			Track C (#samples)	
	train	dev	test	dev	test
Indonesian	-	-	-	156	851
Javanese	-	-	-	151	837
Sundanese	924	199	926	199	926

Table 7: Number of samples per language in Track A and Track C.

B Prompts

During fine-tuning, we format the prompt as follows: `"### Text: {text}\n### Emotion: {emotion}\n### Label: "`, where the target text that the model learns to generate is either `"yes"` or `"no"`. This structure helps the model associate

text	anger	fear	joy	sadness	surprise
Colorado, middle of nowhere.	0	1	0	0	1
This involved swimming a pretty large lake that was over my head.	0	1	0	0	0
It was one of my most shameful experiences.	0	1	0	1	0

Table 8: Data samples from the English training set from Track A. 1 represent that the emotion is perceived from the text, and 0 otherwise.

the input text with the correct emotion label, facilitating accurate predictions during the inference process.

RSSN at SemEval-2025 Task 11: Optimizing Multi-Label Emotion Detection with Transformer-Based Models and Threshold Tuning

Abstract

Multi-label emotion classification in NLP requires models to capture complex emotional nuances in text. This study explores transformer-based models, primarily fine-tuning *BERT-base-uncased*, for classifying five perceived emotions: *anger, fear, joy, sadness*, and *surprise*. As part of SemEval 2025 Task 11 (Track A) in English, we preprocess text using tokenization, stopword removal, and lemmatization. Baseline models employing logistic regression with TF-IDF establish performance benchmarks. To address class imbalance, we fine-tune BERT using weighted binary cross-entropy loss, further improving classification with threshold optimization. Experimental results demonstrate that fine-tuned BERT significantly outperforms traditional approaches, achieving a macro F1-score of 0.6675, which rises to 0.7062 after threshold optimization. Comparative analysis against RoBERTa fine-tuning, CNN-TF-IDF hybrids, and XGBoost classifiers highlights the superiority of contextual embeddings for multi-label classification. While threshold tuning enhances recall and precision, challenges like class imbalance and inter-class confusion persist, motivating future research into ensemble models and domain-adaptive training.

1 Introduction

Emotion classification in NLP is essential for identifying *perceived emotions*, which reflect how an audience interprets a speaker's sentiment. Unlike sentiment analysis, which categorizes text as positive, negative, or neutral, multi-label emotion detection captures multiple co-occurring emotions in a single instance.

This study focuses on SemEval 2025 (Track A) for multi-label emotion detection in English, classifying text snippets into six perceived emotions: *joy, sadness, anger, fear, surprise*, and *disgust*. Rather than identifying the speaker's true emotions or reader's reactions, the task centers on commonly inferred emotions, influenced by linguistic and cultural factors.

We fine-tune a BERT-based model to capture contextual dependencies while addressing class imbalance and label co-occurrence challenges. Our approach includes text preprocessing with SpaCy, dataset analysis, and hyperparameter tuning. TF-IDF-based models serve as baselines, and weighted binary cross-entropy loss is used for training. Performance is evaluated via F1-score, the official metric for the task.

Experimental results show that transformer-based models significantly outperform traditional methods, effectively detecting multiple emotions per instance. Despite improvements, challenges like inter-class confusion and label ambiguity remain. This study provides insights into optimizing multi-label emotion classification and outlines directions for future research.

2 Related Work

CM-MEC-21, introduced by Ameer et al. (Tang et al., 2020), serves as a benchmark dataset for multi-label emotion classification in code-mixed (English-Roman Urdu) SMS messages. The study evaluated traditional machine learning, deep learning, and transformer-based models (BERT, XLNet), revealing that n-gram-based features with OVR Naïve Bayes achieved the highest Micro-F1 score of 0.67. This finding underscores the limitations of deep learning in low-resource environments and the continued relevance of feature-driven approaches.

Exploring subjectivity and sentiment analysis, Wiebe et al. (Wiebe et al., 2005) introduced a detailed corpus annotation framework. Their methodology focused on phrase-level subjectivity rather than sentence-level labels, incorporating

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 773–779

nuanced elements such as private states, beliefs, and nested sources of emotion. The framework has since been widely adopted for opinion mining and sentiment classification tasks.

To enhance emotion classification from text, Abas et al. (Abas et al., 2022) proposed a hybrid model combining BERT embeddings with a CNN-based classifier. Their approach leveraged BERT's contextual word representations while utilizing CNNs for final classification. Evaluations on the SemEval-2019 Task 3 and ISEAR datasets demonstrated that the BERT-CNN model outperformed baseline methods, achieving an F1-score of 94% on SemEval and 76% on ISEAR.

Shifting towards non-transformer-based approaches, Liu et al. (Liu et al., 2023) refined the multi-label K-Nearest Neighbors (MLkNN) algorithm for short-text emotion classification. Their model incorporated both local sentence-level features and global contextual dependencies, improving classification accuracy through iterative refinement based on emotion transfer probabilities. Experiments on the Sentiment140 Twitter corpus demonstrated that the enhanced MLkNN model (with optimized $K = 8$ and $\alpha = 0.7$) outperformed traditional MLkNN approaches, achieving a recall rate of 0.8019. Their findings highlight the effectiveness of integrating local and global contextual information for multi-label emotion classification.

3 System Overview

3.1 Data Preprocessing and Exploration

The dataset (Muhammad et al., 2025a) used in this study consists of short text samples annotated with multiple emotion labels. The emotions considered are *anger, fear, joy, sadness, and surprise*. Each text instance may be associated with one or more emotion labels, making it a multi-label classification task. The dataset was loaded and analyzed to understand its structure and characteristics.

3.1.1 Preprocessing Steps

To ensure data quality and enhance feature extraction for the classification model, a series of preprocessing steps were applied:

- **Text Normalization:** All text was converted to lowercase, and punctuation and numerical characters were removed.
- **Stopword Removal:** Non-informative words were filtered using the built-in SpaCy stopword list.
- **Lemmatization:** Words were reduced to their base forms using SpaCy's lemmatizer to standardize textual representations.
- **Negation Handling:** Words following negation terms such as "not", "never", and "no" were concatenated with the negation marker (e.g., *not good* $\rightarrow$ *not_good*).
- **Rare and Frequent Word Removal:** Words appearing with extremely low frequency (less than 2 occurrences) or extremely high frequency (above 95% of total words) were removed to mitigate noise.

After preprocessing, the cleaned text was saved for further analysis and model training.

3.1.2 Dataset Exploration and Visualization

To understand the dataset distribution, various statistical and visual analyses were performed.

Text Length and Word Count Distribution To analyze textual characteristics, the distribution of text lengths (character count) and word counts was visualized. Figures 1 and 2 illustrate these distributions.

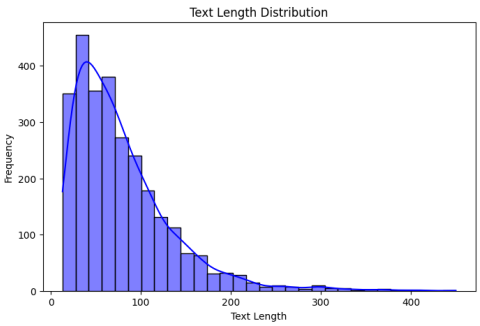

Figure 1: Text Length Distribution

Emotion Correlation Analysis To examine relationships between different emotions, a correlation matrix was computed using the label co-occurrence data. Figure 3 presents the heatmap of correlation values.

The dataset is imbalanced, with *fear* as the most frequent label. Many instances contain multiple emotions, requiring a robust multi-label approach. Most texts are under 100 characters, and

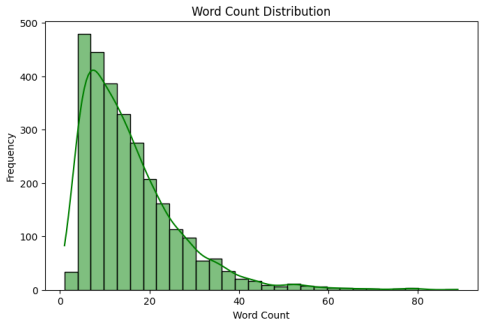

Figure 2: Word Count Distribution

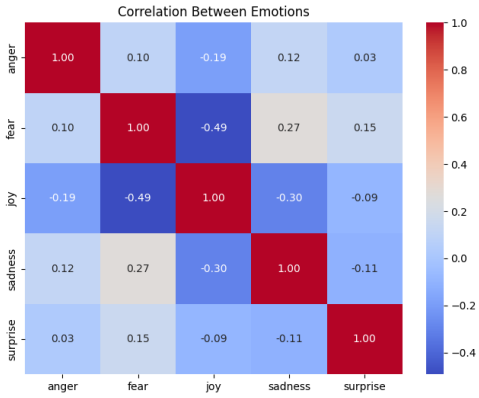

Figure 3: Correlation Between Emotions

co-occurrence analysis highlights strong associations between specific emotion pairs, aiding label dependency modeling.

3.2 Threshold Optimization Methodology

For multi-label classification, we optimize prediction thresholds for each emotion class to maximize F1-scores. The optimization process begins by computing the class probabilities from the model logits using a sigmoid activation function. We then evaluate precision, recall, and F1-scores across a range of thresholds, $\tau \in [0.1, 0.9]$, with a step size of 0.01. For each emotion class, we select the optimal threshold, τ_c^*, which maximizes the F1-score for that class. Specifically, the optimal threshold is determined by:

$$\tau_c^* = \tau \in [0.1, 0.9] \text{argmax} \frac{2 \cdot P_c(\tau) \cdot R_c(\tau)}{P_c(\tau) + R_c(\tau)},$$

where $P_c(\tau)$ and $R_c(\tau)$ represent the precision and recall for class c at threshold τ. Once the optimal thresholds are determined, they are applied during inference to maximize the performance of the classification model.

In particular, for *anger*, lowering the threshold from 0.5 to 0.21 resulted in a significant improvement in recall by 21.5% (from 0.354 to 0.569), at a modest cost to precision (from 0.697 to 0.617). This adjustment helped mitigate the issue of under-detection in *anger* cases. The threshold optimization also highlighted the different characteristics of each emotion class. For *fear*, the optimal threshold was higher, at 0.33, which reflected the confident predictions made for this emotion. In contrast, *sadness* benefited from a lower threshold of 0.21, better capturing its more subtle expressions.

While threshold optimization provided overall performance gains, it also introduced some trade-offs. One such trade-off was the impact on precision, especially for minority classes like *anger*, where the precision dropped by 8% in order to achieve a 21.5% increase in recall. Additionally, false positives increased for some of the minority classes, although this was mitigated by the significant reduction in false negatives, resulting in a 7% overall increase in recall.

The threshold optimization process led to several noteworthy improvements. Specifically, the macro F1-score increased from 0.6435 to 0.6814, reflecting a 5.88% improvement. The most dramatic gain was observed in *anger*, which saw an impressive 26.1% increase in its F1-score. Other emotion classes, such as *joy* and *surprise*, also saw balanced improvements, with their F1-scores increasing by 10.4% and 10.2%, respectively. These results are summarized in Table 1.

4 Baseline Approaches

To establish a foundational benchmark for multi-label emotion classification, we experimented with logistic regression models trained on TF-IDF representations of text. These models were selected due to their efficiency and interpretability in text classification tasks. Multiple variations were explored to examine the impact of feature engineering, class imbalance handling, and threshold optimization.

4.1 TF-IDF with Logistic Regression

The first model utilized a TF-IDF vectorizer with a vocabulary size of 5000, setting a document frequency range of 2% to 90%. A One-vs-Rest logistic regression classifier was trained on these features. The training and evaluation were conducted using an 80-20 train-test split.

4.1.1 Logistic Regression with Class Weights

To mitigate the issue of class imbalance, a weighted logistic regression model was trained using class

Table 1: Threshold Optimization Ablation Study

Emotion	Optimal τ	F1 (0.5)	F1 (Opt)	Imp.	Prec (0.5)	Prec (Opt)	Rec (0.5)	Rec (Opt)
Anger	0.21	0.469	0.592	+26.1%	0.697	0.617	0.354	0.569
Fear	0.33	0.828	0.853	+3.0%	0.848	0.823	0.809	0.885
Joy	0.28	0.633	0.699	+10.4%	0.728	0.696	0.560	0.701
Sadness	0.21	0.669	0.709	+6.1%	0.789	0.665	0.581	0.760
Surprise	0.24	0.625	0.689	+10.2%	0.741	0.681	0.541	0.698

weights computed dynamically based on label distributions. This approach aimed to improve recall for minority classes while maintaining precision for dominant classes.

4.1.2 Feature Engineering and Threshold Optimization

Refinements included expanding TF-IDF to 10,000 tokens with bigrams for better context, applying sublinear scaling to balance term frequencies, and optimizing thresholds to enhance classification performance.

While these refinements contributed to an increase in overall performance, the results highlight the limitations of traditional models in capturing nuanced emotional expressions. These findings motivate the need for more sophisticated representations, such as deep contextual embeddings, to better model complex emotional variations.

5 Advanced Implementations and Experimental Analysis

To tackle multi-label emotion classification, we explored various deep learning approaches, leveraging pre-trained transformers and hybrid architectures integrating TF-IDF and CNNs.

5.1 BERT Fine-Tuning for Multi-Label Emotion Classification

We fine-tuned *BERT-base-uncased* for multi-label classification using tokenized input (max sequence length = 128). Training employed the AdamW optimizer ($2e^{-5}$ learning rate, 0.01 weight decay) with binary cross-entropy loss. While achieving strong performance, particularly in detecting *fear* (F1 = 0.79), the model struggled with *anger* (F1 = 0.46). Threshold optimization improved macro F1-score from 0.6491 to 0.6816.

5.2 RoBERTa Fine-Tuning for Multi-Label Emotion Classification

Using *RoBERTa-base*, we followed a similar fine-tuning approach but with a higher learning rate ($3e^{-5}$) and a 10% warm-up proportion. Initially, it failed to learn representations for most emotions, resulting in a low macro F1-score (0.1493). After threshold optimization, performance improved significantly (macro F1-score = 0.4547), though classification imbalance remained a challenge.

5.3 DistilBERT Embeddings with XGBoost Classifier

DistilBERT's `[CLS]` token embeddings were extracted and used as input for an *XGBoost* classifier (50 estimators, depth 4, learning rate 0.1). Although it leveraged contextual embeddings, it did not match fine-tuned transformers, achieving a macro F1-score of 0.4671 with poor recall for *anger* (F1 = 0.15).

5.4 RoBERTa Embeddings with XGBoost Classifier

RoBERTa embeddings were extracted similarly and trained with XGBoost (100 estimators, 0.05 learning rate). However, its macro F1-score (0.2472) indicated that static embeddings alone were insufficient for effective classification, leading to poor recall for most emotions except *fear*.

5.5 CNN with TF-IDF and DistilBERT Hybrid Model

We combined TF-IDF features (10,000 n-grams) with DistilBERT embeddings in a CNN architecture using convolutional layers, max-pooling, and dropout. The hybrid approach improved representation learning but remained limited by dataset constraints, with a macro F1-score of 0.5125 and relatively weak performance for *joy* and *sadness*.

Fine-tuned BERT and RoBERTa models outperformed other approaches, demonstrating the effectiveness of contextual embeddings. Threshold optimization improved recall, while XGBoost with transformer embeddings failed to capture deep dependencies. CNN-hybrid models leveraged multi-feature representation but remained limited by data constraints.

5.6 Experimental Evaluation and Test Results

We validated our approaches on an external test set using two fine-tuned *BERT-base-uncased* models with different learning rates to assess generalization, optimize classification thresholds, and refine fine-tuning strategies. For all models evaluated in this study, including logistic regression, transformer-based models, and hybrid approaches, we maintained consistency by using the same validation set for threshold optimization and the same held-out test set for final performance evaluation, ensuring fair comparison.

5.6.1 Fine-Tuned BERT Models

The first model was trained with a learning rate of $3e^{-5}$, batch size 16, and a warm-up proportion of 10%, applying early stopping over 10 epochs. The second model used a lower learning rate of $2e^{-5}$ for improved stability. Both models employed AdamW optimization and binary cross-entropy loss for multi-label classification.

Results and Threshold Optimization Before threshold optimization, both models achieved a macro F1-score of approximately 0.667, with *fear* consistently scoring highest and *anger* the lowest. Applying optimized classification thresholds improved the macro F1-score to 0.7047 for Model 1 and 0.7062 for Model 2, enhancing recall, particularly for underrepresented emotions. The results indicate that threshold tuning significantly refines decision boundaries, and variations in learning rates have minimal impact when proper threshold selection is applied.

5.6.2 Final Predictions and Observations

Using the best-performing model (learning rate $2e^{-5}$ with optimized thresholds), predictions on the external test set showed stable F1-scores across all emotions. The model effectively generalized, with threshold tuning improving recall and classification accuracy. However, class imbalance persisted, suggesting potential enhancements through ensemble learning and data augmentation.

Fine-tuned BERT models, combined with threshold optimization, demonstrated superior multi-label classification performance. Learning rate variations had little impact on final results when proper threshold tuning was applied. The study underscores the necessity of threshold optimization for imbalanced datasets, proving the effectiveness of transformer-based fine-tuning for emotion classification in real-world applications.

6 Results and Performance Evaluation

This section presents a comprehensive analysis of the results obtained from our experiments on multi-label emotion classification. The models were fine-tuned on the preprocessed dataset and evaluated based on key performance metrics, including macro F1-score, precision, recall, and accuracy. Additionally, we conducted threshold optimization to enhance the classification performance. The results are consolidated in the following subsections.

6.1 Initial Performance Evaluation

The logistic regression model trained on TF-IDF features exhibited strong performance for frequent emotions (*fear*, *surprise*) but struggled with minority classes (*anger*, *joy*). Introducing class weights improved recall, and further threshold tuning enhanced classification, achieving a macro F1-score of 0.54, as shown in Table 2.

Table 2: Performance of Logistic Regression Models with TF-IDF

Emotion Class	Initial Model	With Class Weights	Optimized Model
Anger	0.03	0.33	0.35
Fear	0.73	0.67	0.76
Joy	0.17	0.42	0.44
Sadness	0.38	0.54	0.58
Surprise	0.43	0.61	0.65
Macro F1-score	0.32	0.50	0.54

The initial evaluation of the fine-tuned *BERT-base-uncased* models, before applying threshold optimization, revealed significant variations in classification performance across different emotion classes. Table 3 summarizes the macro F1-score and per-class F1-scores before threshold optimization.

Table 3: Performance of Fine-Tuned BERT Models Before Threshold Optimization

Emotion Class	Model 1 (LR = $3e^{-5}$)	Model 2 (LR = $2e^{-5}$)
Anger	0.53	0.54
Fear	0.81	0.80
Joy	0.65	0.64
Sadness	0.65	0.67
Surprise	0.71	0.68
Macro F1-score	0.6678	0.6675

The results indicate that *fear* was consistently the best-classified emotion, achieving an F1-score above 0.80 in both models, suggesting that the model effectively captured its contextual cues. In contrast, *anger* had the lowest performance, highlighting the difficulty in distinguishing it from other

emotions in multi-label classification. Additionally, the macro F1-scores of both models remained nearly identical before threshold optimization, indicating that variations in learning rates had minimal impact on classification performance.

6.2 Impact of Threshold Optimization

To refine the predictions and improve model performance, we optimized classification thresholds for each emotion class. Instead of using the default threshold of 0.5, an optimal probability threshold was determined by maximizing the per-class F1-score. The performance gains achieved through this optimization are presented in Table 4.

Table 4: Performance of Fine-Tuned BERT Models After Threshold Optimization

Emotion Class	**Model 1 (LR = $3e^{-5}$)**	**Model 2 (LR = $2e^{-5}$)**
Anger	0.60	0.61
Fear	0.82	0.82
Joy	0.68	0.65
Sadness	0.69	0.69
Surprise	0.74	0.76
Optimized Macro F1-score	0.7047	0.7062

Threshold optimization proved highly effective, increasing the macro F1-score by approximately 3–4%. The most significant improvement was observed in *anger*, where the F1-score rose from 0.53 to 0.61, addressing its previously weak performance. *Surprise* benefited the most, with an F1-score increase of 4–8%, enhancing recall while maintaining precision. Notably, the impact of learning rate variations remained minimal after optimization, with Model 2 showing a slight edge in macro F1-score.

6.3 Performance on Test Set

The final evaluation was conducted on an unseen test set using the best-performing model (Model 2, learning rate = $2e^{-5}$, optimized thresholds). Table 5 presents the final performance metrics.

Table 5: Final Performance on External Test Set

Metric	**Before Optimization**	**After Optimization**
Macro F1-score	0.6675	0.7062
Micro F1-score	0.72	0.75
Weighted F1-score	0.71	0.74
Precision	0.70	0.73
Recall	0.69	0.76

The external test set evaluation confirmed the model's strong generalization, as the macro F1-score remained consistent. Notable improvements were observed in micro and weighted F1-scores, indicating enhanced prediction stability across all emotion classes. Additionally, recall increased by 7% post-optimization, demonstrating that threshold tuning effectively reduced false negatives and improved overall classification performance.

6.4 Conclusion

Fine-tuned BERT models proved highly effective for multi-label emotion classification, outperforming traditional methods like logistic regression with TF-IDF. Threshold optimization significantly improved recall and decision boundaries, especially for underrepresented emotions like anger and joy.

While fear and surprise were well-classified, anger remained the most challenging, highlighting difficulties in distinguishing subtle emotional cues. Alternative models including XGBoost with transformer embeddings fell short, emphasizing the importance of contextualized embeddings. Challenges like class imbalance and inter-class confusion persist, suggesting future work on ensemble learning, contrastive pretraining, and domain-adaptive fine-tuning. Integrating textual, visual, and audio cues through multi-modal approaches could further improve real-world emotion detection.

Abstract

This paper introduces **Context-Aware Vision Language Ranking (CAViLR)**, a novel multimodal approach designed to tackle the challenges of idiomaticity understanding in both text and images for SemEval-2025 Task 1. In Task 1a, our method ranks a set of images based on their relevance to an idiomatic compound in a given context sentence. For Task 1b, we extend this approach by predicting the final image in a sequence and disambiguating whether the idiom is used figuratively or literally. By leveraging state-of-the-art vision-language models like **CLIP**, **Pixtral-12B**, and **Phi-3.5**, along with a **Mixture of Experts (MoE)** framework, CAViLR effectively integrates multimodal information. Our system demonstrates improved performance in both tasks, offering significant advancements in bridging visual and textual semantics and addressing the complexities of idiomatic expressions.

1 Introduction

Idiomatic Expressions (IEs) present a unique challenge in natural language processing. Their meanings often cannot be deduced from individual words, making them difficult for computational models to process (Mi et al., 2024). Unlike literal expressions, IEs require understanding of linguistic conventions, context, and sometimes cultural nuances (Hajiyeva, 2024). Given their prevalence, accurately interpreting idioms is essential for various NLP tasks such as fact-checking, hate speech detection, sentiment analysis, machine translation, and question-answering (Yosef et al., 2023; Tan and Jiang, 2021). Misinterpreting idiomatic meaning can lead to significant errors, impacting the accuracy and reliability of these applications.

The AdMIRe challenge (Pickard et al., 2025) pushes the boundaries of multimodal understanding by focusing on idiomatic nominal compounds in rich visual contexts. The task presents two main challenges:

- **Task 1a: Image Ranking** — Rank five images based on how well they represent the intended sense of an idiomatic compound in a context sentence.
- **Task 1b: Image Sequence Prediction and Idiom Disambiguation** — Predict the final image in a sequence and determine whether the idiom is used literally or figuratively.

We propose a novel approach, **Context-Aware Vision-Language Ranking (CAViLR)**, that integrates **CLIP** as a baseline model with a **Mixture of Experts (MoE)** framework. This hybrid ensemble method addresses the challenges of understanding idiomatic expressions in visual contexts.

Our approach operates in two stages:

1. **Baseline Model (CLIP):** We first use **CLIP** for both image ranking and sequence prediction. CLIP provides a strong foundation by mapping both text and images into a shared embedding space (Kulkarni et al., 2024).
2. **Hybrid Model with MoE:** We then enhance performance using a **Mixture of Experts (MoE)** framework, where the model dynamically selects expert models like **Pixtral-12B** for visual-textual understanding (Agrawal et al., 2024) and **Phi-3.5** for textual analysis, optimizing performance for each task.

This hybrid approach improves both image ranking (Task 1a) and image sequence prediction with idiomatic disambiguation (Task 1b). The **MoE integration** dynamically selects the best expert based on the input, improving performance across tasks.

In the following sections, we detail the dataset and evaluation setup (§3), describe our methodology (§4), present experimental results (§5), and discuss the implications of our findings. Further details can be found on the official task webpage (SemEval-2025 Task 1, 2025).

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 780–784

2 Related Works

While prior research has focused on idiom detection and interpretation from text, the role of multimodality in idiomaticity understanding remains underexplored. Most related studies address figurative language understanding and disambiguation of mixed visual and textual content. Specifically, visual figurative meaning understanding (Saakyan et al., 2024) aims to assess whether a visual premise entails or contradicts a textual hypothesis. In contrast, visual-word sense disambiguation (Raganato et al., 2023) focuses on selecting, from a set of candidate images, those that match the intended meaning of a target word with limited textual context. The AdMIRe challenge (SemEval-2025 Task 1) extends this idea to idiomatic expressions, where idioms are considered as textual descriptions and images that capture their intended meaning.

Transformer architectures, such as **CLIP** (Kulkarni et al., 2024), and visual LLMs like **LLaVA** (Liu et al., 2023), have shown promising performance on various multimodal tasks (Kulkarni et al., 2024; Vaiani et al., 2023; D'Amico et al., 2023; Napolitano et al., 2024). Moreover, advanced visual LLMs, such as **Qwen2.5-VL** (Bai et al., 2025), **Pixtral-12B** (Agrawal et al., 2024), **Phi-3.5** (Abdin et al., 2024) and **Gemini** (The Gemini Team et al., 2023), have been designed to handle multiple images, further enhancing multimodal understanding.

3 Data

This study uses datasets from SemEval-2025 Task 1, with both English and Portuguese data for Subtasks A and B.

3.1 Subtask A - Static Images

The English training data for Subtask A includes 70 items. Each item consists of a sentence with a potentially idiomatic compound and five candidate images, each with a machine-generated caption. The dataset is organized in a `subtask_a_train.tsv` file containing the following fields:

- `compound`: The potentially idiomatic noun compound.
- `sentence`: The target sentence.
- `image{n}_name`: The filenames of candidate images.
- `image{n}_caption`: Descriptive captions for each image.

Each compound has a corresponding subfolder with 5 images.

The Portuguese training data for Subtask A follows the same structure, with 32 items. Additionally, it includes a `image{n}_caption_pt` column for Portuguese captions.

3.2 Subtask B - Sequences

For Subtask B, the English dataset contains 20 items, each consisting of a sequence of images to complete. The `subtask_b_train.tsv` file includes the following fields:

- `compound`: The idiomatic compound.
- `sequence_caption1`, `sequence_caption2`: Descriptive captions for the first two sequence images.
- `expected_item`: The filename of the image that completes the sequence.

Each subfolder contains 6 images, including two sequence images and 4 candidates.

The Portuguese data for Subtask B is structured similarly to the English dataset.

For further details, refer to the official webpage (SemEval-2025 Task 1, 2025).

4 Methodology

Our approach integrates textual and visual features to rank images and predict image sequences based on their relevance to idiomatic expressions in context. We propose a hybrid method, using a **Mixture of Experts (MoE)** approach, where multiple expert models are selectively used for different tasks based on the input data. The methodology is divided into separate steps for both Subtask A and Subtask B.

4.1 Data Preprocessing

- **Text**: Tokenize sentences using the BERT tokenizer.
- **Images**: Normalize and resize images to 224x224 pixels.

4.2 Feature Extraction

For both Subtask A and Subtask B, textual and visual features are extracted separately:

- **Textual Features**: Extract sentence embeddings using the BERT model (768-dimensional).

- **Visual Features**: Extract image embeddings using **ResNet-50** (2048-dimensional) or **ViT** for CLIP (depending on the model choice).

4.3 Models

After feature extraction, we introduce two main model types: the **Baseline Model** and **Language-Visual Model (LMM)**. Both are utilized in a hybrid fashion to process textual and visual inputs.

4.3.1 Baseline Model: CLIP

For the baseline model, we use **CLIP** (Contrastive Language-Image Pre-training), which is an open-source multimodal model that learns a joint embedding space for images and text. CLIP is pre-trained on a large dataset and can be fine-tuned to perform both image ranking and image sequence prediction tasks effectively.

- **Text Encoder**: CLIP's text encoder is based on a Transformer model (similar to BERT), which converts input sentences into embeddings.
- **Image Encoder**: CLIP uses a **Vision Transformer (ViT)** to generate image embeddings.
- **Contrastive Learning**: CLIP uses contrastive learning to match images with their corresponding textual descriptions.

4.3.2 Language-Visual Model (LMM) with MoE

For more advanced performance, we adopt a hybrid model with the **Mixture of Experts (MoE)** approach. The MoE model dynamically selects expert models based on the task and input context, enabling specialization for different subtasks.

- **Model Selection**: Utilize **Pixtral-12B** for visual-textual understanding, and **Phi-3.5** for textual interpretation. Both models are part of the expert set in the MoE framework.
- **MoE Integration**: The MoE framework selects the most appropriate expert (Pixtral or Phi-3.5) based on the input data, enhancing the performance for each task.
- **Expert Specialization**: **Pixtral** specializes in visual analysis, while **Phi-3.5** is used for more detailed textual analysis.

4.4 Task-Specific Architecture

4.4.1 Subtask A: Image Ranking

For **Subtask A**, the goal is to rank images based on their relevance to the given sentence. After multimodal feature extraction, the model ranks images by processing the combined textual and visual embeddings.

- **Text Encoder**: BERT (or CLIP's text encoder) generates sentence embeddings.
- **Image Encoder**: ResNet-50 (or CLIP's image encoder) generates image embeddings.
- **Fusion Layer**: Combines text and image embeddings into a unified representation.
- **Ranking Layer**: A fully connected neural network that outputs a ranking score for each image.

4.4.2 Subtask B: Image Sequence Prediction

For **Subtask B**, the objective is to predict the next image in a sequence based on the previous images and the sentence context. The **LMM with MoE** approach is applied to both textual and visual embeddings to predict the correct image sequence.

- **Sequence Prediction**: The model is trained to predict the image that logically completes a sequence.
- **Textual and Visual Embeddings**: Embeddings from both modalities are used to predict the sequence of images.
- **MoE Layer**: The MoE model selects the appropriate expert based on the sequence and context.

4.5 Training and Evaluation

For both Subtasks A and B, the models are fine-tuned using a **supervised learning** approach. The training process focuses on minimizing the loss between the predicted ranking or sequence and the ground truth.

- **Loss Function**: For Subtask A, **Mean Squared Error (MSE)** is used to optimize ranking accuracy. For Subtask B, **Cross-Entropy Loss** is used to predict the correct image in the sequence.

- **Optimizer**: We use the **Adam optimizer** with learning rate tuning to optimize the model parameters. The learning rate is dynamically adjusted during training for better convergence.
- **Evaluation Metrics**:
  - **Subtask A**: Evaluation is based on ranking accuracy, with the model's ability to rank images correctly in terms of relevance to the sentence.
  - **Subtask B**: Evaluation is based on sequence prediction accuracy, with the model's ability to predict the next image in the correct order.

5 Experiments and Results

In this section, we present the results of our approach for both Subtask A and Subtask B. We begin by evaluating individual models and progressively combine them into a hybrid approach, which yields the best results.

5.1 Subtask A - Image Ranking

We started with a basic model for ranking images, then gradually built up our hybrid model by integrating Pixtral, Phi-3.5, and baseline components. Below are the results:

Model Type	Score
Baseline Model (Text + Image)	0.33
Pixtral Model	0.47
Phi-3.5 Model	0.47

Table 1: Results for Subtask A - Individual Models

Next, we combined Pixtral, Phi-3.5, and the baseline model to form a hybrid approach:

Hybrid Model Type	Score
Pixtral + Phi-3.5 + Baseline Model	**0.53**

Table 2: Results for Subtask A - Hybrid Model (Pixtral + Phi-3.5 + Baseline)

The hybrid model achieved the best result with a score of 0.53, outpacing the individual models.

5.2 Subtask B - Image Sequence Prediction and Idiom Disambiguation

Similarly, we started with individual models for Subtask B and progressively added components to improve performance. Below are the results:

Model Type	Score
Baseline Model (Text + Image)	0.40
Pixtral Model	0.47
Phi-3.5 Model	0.47

Table 3: Results for Subtask B - Individual Models

Hybrid Model Type	Score
Pixtral + Phi-3.5 + Baseline Model	**0.60**

Table 4: Results for Subtask B - Hybrid Model (Pixtral + Phi-3.5 + Baseline)

Next, we combined Pixtral, Phi-3.5, and the baseline model to form the hybrid approach:

The hybrid model once again achieved the best result, with a score of 0.60.

These results demonstrate that the hybrid approach, integrating Pixtral, Phi-3.5, and the baseline model, provides significant improvements in both image ranking and sequence prediction tasks.

6 Discussion

In **Subtask A** (Image Ranking), the main challenge lies in the model's ability to accurately ground idiomatic expressions in both visual and textual contexts. We observed that:

- Some images strongly match the intended meaning, while others introduce ambiguity.
- Fine-grained semantic differences often lead to misrankings, especially in the case of subtle idiomatic nuances.

For **Subtask B** (Image Sequence Prediction), sequence prediction becomes difficult when idioms are used figuratively or literally. The **MoE framework** helps by dynamically selecting the most suitable expert model for different tasks. However, **CLIP** as the baseline struggles with more complex idiomatic interpretations.

Future work will focus on improving the **MoE** framework, enhancing multimodal embeddings, and developing better disambiguation strategies for figurative and literal meanings.

7 Conclusion

We introduced **CAViLR**, a context-aware, hybrid multimodal approach for image ranking and sequence prediction in **SemEval-2025 Task 1**. By combining **CLIP** with a **Mixture of Experts**

(MoE) framework, our method improves task performance by dynamically selecting expert models. While our approach shows promising results, further refinement is needed to handle subtle idiomatic variations and enhance disambiguation between figurative and literal meanings. Our work contributes valuable insights into developing more robust vision-language models.

Abstract

This paper illustrates our ABCD team system approach in ACL 2025 - SemEval-2025 Task 9: The Food Hazard Detection Challenge, aim to solving both Task 1: Text classification for food hazard prediction, predicting the type of hazard and product, and Task 2: Food hazard and product "vector" detection, predicting the exact hazard and product. Precisely, we received a food report and our system needed to automatically detect which category of hazard and product the food belonged to. However, in Task 2, we must classify the food report into the exact name of the food hazard and category. To tackle Task 1, we implement and investigate various solutions, including (1) experimenting with a large battery of BERT-based models; and (2) utilizing generation-based models, and (3) taking advantage of a custom ensemble learning method. In addition, to address Task 2, we make use of different data augmentation techniques like synonym replacement and back-translation. To enhance the context of input, we cleaned some special characters that bring more clarity into text input. Our best official results on Task 1 and Task 2 are 0.786 and 0.458 in terms of F1-score, respectively—finally, our team solution achieved top 8th in task 1 and top 10th in task 2.

1 Introduction

SemEval-2025 Task 9: The Food Hazard Detection Challenge (Randl et al., 2025) The Food Hazard Detection task evaluates explainable classification systems for titles of food-incident reports collected from the web. These algorithms may help automated crawlers find and extract food issues from web sources like social media in the future. Due to the potentially high economic impact, transparency is crucial for this task. Two sub-tasks were proposed for participants in this shared task. The first challenge is called "Text classification for food hazard prediction, predicting the type of hazard and product", in the first task the participants are required to develop a system that can classify food reports into 10 hazard categories and 22 product categories. Task 2, this task bears some resemblance to the first task, yet participants need to classify the text input into the exact vector of 128 hazards and 1068 products.

In today's interconnected world, where information flows ceaselessly across digital platforms, ensuring food safety remains a paramount concern. The ability to quickly and accurately detect food hazards from textual data is not only advantageous but imperative. Natural Language Processing (NLP), with its ability to parse through large amounts of text, plays a pivotal role in this endeavor. Using computational linguistics and machine learning techniques, NLP equips us with the tools to sift through diverse sources of textual information from social media posts to product reviews to identify potential food hazards efficiently. As a result, in this paper, we present our solutions for both Task 1 and Task 2 in SemEval-2025 Task 9: The Food Hazard Detection Challenge (Randl et al., 2025). Specifically, we employ three different approaches to address this task: (1) experimenting with a large battery of BERT-based models, (2) utilizing generation-based models, (3) taking advantage of a custom ensemble learning method.

2 Related Works

Food risk has been a major issue that poses a wide range of dangers for human health throughout history. In recent years, many researchers have taken action to tackle food danger by taking advantage of machine learning and computational force in order to predict early sight of food risk. for example, (Ma and Zheng, 2025) propose an integrated framework for classifying and analyzing food hazards by leveraging social media data from Sina Weibo. Ma and Zheng's (Ma and Zheng, 2025)

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 785–790

framework not only provides a robust method for classifying food hazard-related sentiments but also offers valuable insights for crisis management and policy formulation by mapping how online public opinion evolves during food safety emergencies. Specifically, they have shown the BERT-TextCNN model demonstrates exceptional performance in distinguishing between positive and negative sentiments, effectively capturing subtle emotional nuances in the context of the food hazard incident, and the BERTopic model successfully uncovers stage-specific topics and shows how public discourse evolves over time, offering insights into the thematic shifts during the incident. Besides that, network analysis highlights the pivotal role of certain nodes in information dissemination, confirming that both official media and influential individual users significantly impact public sentiment.

The work by (van den Bulk et al., 2022) explores the use of machine learning models to automate the classification of literature in systematic reviews on food hazards. The aim is to reduce the expert's workload while maintaining high accuracy in selecting relevant studies. Best-Performing Model: An ensemble of Naive Bayes and the Support Vector Machine (NB + SVM) achieved the highest overall performance. The study demonstrates that machine learning, particularly ensemble models (NB + SVM), can effectively support experts in systematic reviews of food hazards. The approach significantly reduces the manual screening effort without compromising quality, making it a valuable tool for food safety research.

3 Task Description

The Food Hazard Detection task focuses on developing interpretable classification models for categorizing titles of food-incident reports sourced from the web. These models have the potential to enhance automated web crawlers in identifying and extracting food-related risks from online platforms, including social media. Given the significant economic implications, ensuring model transparency is a key priority in this task. SemEval-2025 includes 2 sub-tasks, which are Task 1: Text classification for food hazard prediction, predicting the type of hazard and product, and Task 2: Food hazard and product "vector" detection, predicting the exact hazard and product.

3.1 Task 1: Text classification for food hazard prediction, predicting the type of hazard and product

The objective of the task is to classify food incident reports by predicting two categorical labels, "product-category" and "hazard-category" along with their corresponding entity vectors, "product" and "hazard." The dataset exhibits a significant class imbalance, with 22 product categories (e.g., meat, egg, and dairy products, cereals and bakery products, fruits and vegetables) and 10 hazard categories defining different types of food-related risks.

3.2 Task 2: Food hazard and product "vector" detection, predicting the exact hazard and product

The task focuses on the prediction of two key entity vectors: "product" and "hazard", which are extracted from food incident reports. The dataset presents a high level of granularity, encompassing 1,142 distinct product types, such as ice cream, chicken-based products, and cakes. Similarly, the hazard vector consists of 128 unique hazard types, including microbiological contaminants like "Salmonella" and "Listeria monocytogenes" as well as allergenic substances such as milk and products therefore.

3.3 Dataset Description

The dataset for this task comprises 6,644 short texts, with character lengths ranging from a minimum of 5 to a maximum of 277 and an average length of 88 characters. These texts are manually labeled food recall titles collected from official food regulatory agencies, such as the FDA. Each entry has been annotated by two domain experts specializing in food science or food technology to ensure high-quality labeling.

4 Methodology

In this section, we present our approaches for Task 1 and Task 2 in SemEval-2025 shared tasks in detail.

4.1 Data Processing

4.1.1 Data Cleaning

Before making our first approach to this task, we investigated the dataset text input, and we saw that the data contained a moderate number of noises, for instance, special characters, unnecessary white

spaces, and HTML tags. Therefore, our team decided to take some pre-processing stages:

- **Removing special characters**: the data text input contained some special characters such as $%#&ˆ and especially hyphens character which may cause some drawbacks when developing our system.
- **Removing HTML tags**: after observing the dataset, our team recognized that a great deal of HTML tags exist in text input, and this could be significant noise that can decrease the efficiency of our solutions to tackle this task.
- **Removing line break**: we consider removing line break or newline characters as noises because this appears too much in the dataset and has no positive effect on the data.
- **Text Expansion:** we also perform text expansion in English, for example: "*I'll*" into "*I will*" or "*he'd*" into "*he would*". Text expansion was utilized for data consistency, and this can help the model to generalize better.

4.1.2 Data Augmentation

The data distribution in the training dataset witnessed a significant imbalance between hazard and product labels. To be more precise, we can take hazard category labels as an example. "allergens", and "biological" labels have 1854 and 1741 records, respectively. While "food additives and flavorings", and "migration" only have 24 and 3 samples, which can be considered as very small in comparison to "allergens", and "biological" labels. Consequently, our team attempted to address unbalanced data by utilizing two data augmentation techniques, which are Back-Translation and Synonyms Replacement.

Back-translation involves translating a given text (typically from a high-resource source language) into a pivot language (often a different language with high-quality translation models) and then translating it back into the original language. This process introduces natural linguistic variations while preserving the semantic integrity of the original text. The goal is to generate revised versions of the original sentences, which can serve as additional training data to improve the robustness of the model. Our team takes advantage of the Google translator framework to perform the Back-translation method. To be more precise, we first take the whole text input, then translate it into French, and finally, the input is translated back into English.

Synonym Replacement is a data augmentation technique in Natural Language Processing that involves substituting words in a given text with their synonyms while preserving the overall semantic meaning. The primary objective is to introduce lexical variations in the training data, thereby enhancing the robustness and generalization of the model. Our process typically starts with the tokenization step, which tokenises input into individual words or subwords. After that, words suitable for replacement are identified. Typically, stop words, named entities, or domain-specific terms are excluded to avoid loss of meaning. Next, synonyms for selected words are retrieved from the lexical databases, which is WordNet from the NLTK corpus. Finally, A subset of the identified words is randomly replaced with their synonyms.

4.2 BERT-based Models Approach

Instead of experimenting with a classic machine learning method like the baseline code provided by the organizer, our team decided to take advantage of the deep learning power of BERT-based models. BERT-based models offer substantial advantages for food risk classification due to their ability to comprehend nuanced language semantics and context. Unlike traditional machine learning approaches that rely on keyword matching or shallow syntactic features, BERT excels in capturing intricate relationships within textual data. This capability is crucial in the domain of food risk classification, where understanding the subtleties of risk-related language is paramount. BERT-based models represent a significant improvement in food risk classification by leveraging their deep contextual understanding, bidirectional processing, and comprehensive language representation. These capabilities enable them to outperform traditional methods, offering more accurate and reliable assessments of food safety risks based on textual data. Our team has fine-tuned four models with different sizes.

- FacebookAI/roberta (Liu et al., 2019)
- FacebookAI/xlm-roberta (Conneau et al., 2019)
- answerdotai/ModernBERT (Warner et al., 2024)

Model	Token length	F1-score
roberta-large	512	**0.821**
deberta-v3-large	512	0.802
ModernBERT-large	512	0.789
xlm-roberta-large	512	0.785
deberta-v3-large	256	0.782
roberta-large	256	0.724
ModernBERT-large	256	0.663
xlm-roberta-large	256	0.657

Table 1: The experimental results of BERT-based classification approach on the validation set Task 1.

- microsoft/deberta-v3 (He et al., 2021)

We experiment on each model in different hyperparameter settings, and our team witnessed a significant improvement in results, which surpassed the baseline approach. Moreover, we only utilize "text" and "title" columns for input. As observed in Table 1, we can see that all our BERT results are much better than the baseline result (0.4965) in terms of the F1 score. Moreover, 2 models register more than 0.8 F1-score, which are *roberta-large* and *deberta-v3-large* in 512 token length. This is a great sign of improvement in our method. We first experimented on 256 token length due tothe limitation of GPU hardware resources, and after seeing a promising result, we only fine-tune models with 512 token length. Beside that, just after *modernBERT* was released, our team immediately utilised its new advantages in food risk classification tasks like this.

4.3 Generative-based Model Approach

In this approach, using a generative-based model, our team opted to experiment with the BART model (Lewis et al., 2020) by adapting it for a classification task through fine-tuning. BART functions as a denoising auto-encoder designed for pretraining sequence-to-sequence models. It is trained by intentionally introducing noise into text and then learning to reconstruct the original content.

Similar to the BERT-based approach, we used a tokenizer to tokenize the text inputs, which were then fed into BART. Moreover, we utilized the pretrained *facebook/bart-large* (Lewis et al., 2019). More specifically, we experiment with BART in both 512 and 1024 token lengths. As a result, the generative-based model achieved remarkable results compared to the BERT-based model, as shown in Table 2. Despite the fact that BART have a better performance than most of the BERT-based models and it has a longer token length, it did not surpass *roberta-large* result.

Model	Token length	F1-score
Weighted Voting	512-1024	**0.827**
roberta-large	512	0.823
bart-large	1024	0.821
bart-large	512	0.819
deberta-v3-large	512	0.802

Table 2: The experimental results of BART vs BERT-based vs Class weighted majority soft voting approach on the validation set Task 1.

4.4 Class weighted majority voting

Our last experiment is about an ensemble learning method, which is soft voting, yet we make some changes to make better performance. We can see the result in Table 2, Class-weighted voting techniques have a slight improvement in F1-score result which is **0.827**.

4.4.1 Step 1: Model Prediction Generation

Given an input sample, multiple independently trained classification models (e.g., Roberta, DeBERTa-V3, and BART) generate discrete class predictions. Each model assigns a single class label to the input based on its learned decision boundaries. Mathematically, for a given sample x_i, each model m produces a predicted label:

$$y_i^m \in C \tag{1}$$

where C represents the set of possible classes.

4.4.2 Step 2: Defining Class-Specific Weights

To account for differences in model reliability across categories, a set of predefined class-specific weights is introduced. These weights can be derived from various sources, such as the F1-score of each class from model evaluation, expert knowledge, or application-specific priorities. The weight function $w(c)$ assigns a weight to each class c, ensuring that classes of greater importance or higher reliability exert a stronger influence on the final decision.

$$w = \{c_1 : w_1, c_2 : w_2, \ldots, c_C : w_C\} \tag{2}$$

where w_c represents the assigned weight for class c.

4.4.3 Step 3: Weighted Vote Computation

For each sample, the class predictions from all models are collected, and a weighted voting mechanism is applied. Instead of counting votes equally, each vote is weighted by the corresponding class-specific weight. The weighted vote count for each class c is computed as follows:

$$V(c) = \sum_{m=1}^{M} 1(y_i^m = c) \cdot w(c) \tag{3}$$

where:

- M is the total number of models,
- $1(y_i^m = c)$ is an indicator function that returns 1 if model m predicts class c, and 0 otherwise,
- $w(c)$ is the predefined weight for class c.

4.4.4 Step 4: Final Prediction Selection

The final class prediction for the sample is determined by selecting the class with the highest weighted vote count:

$$\hat{y}_i = \arg\max_{c \in C} V(c) \tag{4}$$

This ensures that models' votes are not only considered in a majority rule fashion but are also adjusted based on class-specific importance.

5 Experimental Setup

We conducted our training process using HuggingFace (Wolf et al., 2020), and all BERT-based models were trained for 8 epochs. The AdamW optimizer was utilized to optimize the models. We selected a learning rate of 5e-5,4e-5 for BERT-based models. The batch sizes were set to 16 and 32, the random seed was set to 221, and the maximum token length was 512.

Cross-validation is a statistical resampling technique used to evaluate the generalization performance of models. Given the high dimensionality and complex structures of textual data, effective Cross-validation strategies are crucial to prevent overfitting, ensure robustness, and improve model reliability across unseen data. Given the imbalanced nature of the dataset, we employed the stratified K-fold cross-validation technique (Bates et al., 2023) with $K = 10$ to mitigate the effects of data imbalance on the models. Stratified cross-validation ensures that the class distribution remains consistent across folds, thereby reducing bias in performance estimation caused by unequal class distributions in random splits. This approach enables a more reliable evaluation of model performance across diverse subsets of the data.

Due to computational resource limitations, we had to adjust system settings for fine-tuning the BART model. Specifically, we reduced the batch size to 8 and employed gradient accumulation to effectively train on larger effective batch sizes. This technique allows us to accumulate gradients over multiple smaller batches before updating the optimizer, mitigating memory constraints. Furthermore, we utilized mixed precision training (FP16) and gradient checkpointing to accelerate training and reduce memory usage. Mixed precision training combines 16-bit and 32-bit floating-point operations, enabling efficient training of large-scale models like transformers. Dynamic loss scaling was employed to maintain numerical stability. Given GPU limitations, we trained BART for only 6 epochs and opted for the AdaFactor optimizer, known for its efficiency in training large models, instead of AdamW. All models were evaluated using the metric provided by the task organizers. Our team leveraged a P100 GPU, available for up to 30 free hours per week on Kaggle, for computational resources.

6 Main results

In the official final result released by the organizer, our team results in Task 1 and Task 2 are 0.786 and 0.458 in terms of F1-score, respectively. This result was achieved by using the class-weighted majority voting strategy, which combines BART, Roberta, and DeBERTa-V3 models. Moreover, in both tasks, our team also applied Back-translation and Synonyms replacement to augment the specific classes with fewer records to ease the negative effect of data imbalance. However, in Task 2, our team only leveraged a generative-based model classification approach, which is BART, to achieve a 0.458 F1-score. Task 2 has worse results since the imbalance between classes was too tremendous. Our team solution achieved top 8th in task 1 and top 10th in task 2.

7 Limitations

We think our greatest limitation is that our team can only leverage the "text" and "title" text features, but using other numerical or categorical features such as the date or country columns. This is also reduce the diversity and specificity for mod-

els to generalize the data better. In addition, our generative-based approach takes a great deal of time to train since the size of generative models is mostly larger than that of BERT-based models. The class weighted majority voting also needs as a much longer inference time, so we think it can not be used in a real-time application.

8 Conclusion and Future works

In this paper, we presented our approach for SemEval-2025 Task 9: The Food Hazard Detection Challenge. Our system leveraged BERT-based models, generative-based models, and an advanced class-weighted majority voting strategy to enhance classification performance. Through extensive experimentation, we demonstrated that combining multiple models with a weighted ensemble technique improves predictive accuracy. Our best results achieved F1-scores of 0.786 for Task 1 and 0.458 for Task 2, highlighting the effectiveness of our approach. For future work, we aim to explore additional features beyond textual data, such as metadata from food reports, to improve classification accuracy. We also plan to experiment with prompt-based learning using large language models (LLMs) and investigate efficient fine-tuning techniques to reduce computational costs.

Sakura at SemEval-2025 Task 2: Enhancing Named Entity Translation with Fine-Tuning and Preference Optimization

Alberto Poncelas and Ohnmar Htun
Rakuten Institute of Technology
Rakuten Group, Inc.
{alberto.poncelas,ohnmar.htun}@rakuten.com

Abstract

Translating name entities can be challenging, as it often requires real-world knowledge rather than just performing a literal translation. The shared task "Entity-Aware Machine Translation" in SemEval-2025 encourages participants to build machine translation models that can effectively handle the translation of complex named entities. In this paper, we propose two methods to improve the accuracy of name entity translation from English to Japanese. One approach involves fine-tuning the model on entries, or lists of entries, of the dictionary. The second technique focuses on preference optimization, guiding the model on which translation it should generate.

1 Introduction

The translation of Named Entities is a challenging aspect in machine translation (MT) field, as translating proper names, locations, etc. is not always straightforward.

For instance, "カールじいさんの空飛ぶ家" (meaning "Carl Grandpa's Flying House") is the Japanese version of the name of the film "Up" (see entry "Q174811"[1] in Wikidata). Machine Translation (MT) systems would not be able to translate the title without having explicit knowledge of such name entity.

The "SemEval-2025 Task 2: Entity-Aware Machine Translation" (Conia et al., 2024, 2025) is a task[2] that challenge the participants to develop MT models capable to translate sentences containing complex named entities.

This task becomes even more difficult when translating into Japanese due to the variations in script. Japanese writing uses three scripts, i.e. kanji, hiragana and katakana, each with its own set of rules and purposes. Some words might be written in kanji, while others may require hiragana or katakana.

For instance, in the previously-mentioned film title, カール (*Carl*) is written in katakana, which is typically used for foreign words or names; じいさん (*Grandfather*) appears in hiragana, reserved for native Japanese words and grammatical elements; and 空飛ぶ家 (*flying house*) is in kanji, employed for more complex or meaningful words.

Typically, to integrate new knowledge into an Large Language Model (LLM) techniques like Supervised Fine-Tuning (SFT) are employed. However, doing SFT only with dictionaries may lead to overfitting, as the model might become too focused on single-word translations.

We participated in the Entity-Aware Machine Translation (team *sakura*) to address these challenges. In this paper, we describe and compare different methods of integrating these dictionaries into the training process.

2 Related Work

Several efforts have been made to influence the generation process so that the models produce words that are closer to the desired ones. Many techniques involve fine-tuning the model with biased data. This can be done through data selection (Biçici and Yuret, 2011; Parcheta et al., 2018; Poncelas et al., 2019) or synthetic data generation (Hämäläinen and Alnajjar, 2019).

Dictionaries are also used during decoding by either adding lexical constraints (Hokamp and Liu, 2017; Susanto et al., 2020) or incorporating the dictionary directly into the prompt (Ghazvininejad et al., 2023).

In this paper, we explore entity translation as an LLM alignment (Wang et al., 2024; Kong et al., 2025) problem. Our goal is to promote outputs that are closer to human expectations. Specifically, we apply Preference Optimization, a machine learning

[1] https://www.wikidata.org/wiki/Q174811
[2] https://sapienzanlp.github.io/ea-mt/

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 791–796

technique designed to improve models by focusing on preferences. Rather than relying on a single ground truth target for predictions, it fine-tunes the model using preference data. The objective is to learn the relative desirability of different outcomes, rather than simply predicting a label.

A policy π represents the model's strategy for choosing between different possible outcomes. Therefore, given an input x and two outputs y_w and y_l (with the first output being more desirable than the second) the goal is to find a policy π_θ so that it favors $\pi_\theta(y_w|x)$ over $\pi_\theta(y_l|x)$

An approach to achieve this is Direct Preference Optimization (DPO)(Rafailov et al., 2023) which involves adjusting a policy π_θ compared to a reference π_{ref} in order to increase the log-ratio for the preferred outcome, i.e. $r_w = log\frac{\pi_\theta(y_w|x)}{\pi_{ref}(y_w|x)}$, and decrease for the non-preferred, i.e. $r_l = log\frac{\pi_\theta(y_l|x)}{\pi_{ref}(y_l|x)}$, minimizing the loss

$$L = -\mathbb{E}_{(x,y_w,y_l)\sim D} = [log\sigma(\beta(r_w - r_l))]$$

where β is a scaling factor hyperparameter and σ is the sigmoid function.

3 Proposal

Our goal is to identify an effective method for integrating a dictionary of named entity translations into the knowledge of an MT model. Generally, to adapt a model for specific translation tasks, it is fine-tuned using in-domain data. However, fine-tuning with dictionaries could lead to the model producing shorter sentences, which might hurt the overall translation performance.

3.1 Fine-Tune Lists of Words

We first explore how the performance of the model changes when, instead of providing training instances as pairs of individual named entities, we present them as a list of entities. For example, instead of (source,target) pairs such as (*Kazinform*,カズインフォルム) which correspond to an individual entry in the dictionary. As an alternative we may have "*Kazinform* | *Yasuo Kamon* | *Hinda District* | *Yū Aosawa*" in the English side and "カズインフォルム | 嘉門安雄 | ヒンダ郡 | 蒼澤悠" in the Japanese side. Both sides contain words that are mapped one-to-one with each other, but these name entities are provided as a list. By doing this, we expect the model to not be biased towards translating individual words or concept, but longer sequence.

3.2 Align the Model to a Dictionary

As mentioned, fine-tuning a model with such data may not be a good idea. Therefore, as an alternative, we also explore the behavior of the model when instead of fine-tuning, we use preference-based feedback. Instead of teaching the model new knowledge, our proposal is to alter the translation probabilities of the name entity so the model generates those indicated by the dictionary. We expect to rerank the possible translation candidates so those in the dictionary are promoted.

An example is presented in the diagram of Figure 1. The *base-sft* model translates the term "Akegawa" as 阿部川. However, according to the "Q11515045" entry in Wikidata, it should be translated as 曙川. During Preference Optimization, we train the model to promote the translation of the dictionary over the current output. Consequently, the model can generate the desired output.

In order to do Preference Optimization, the training set consist of triplets of (source,chosen,rejected) as shown in Table 1. We provide more details on how this dataset has been built in Section 4.3.

4 Experimental Settings

4.1 Evaluation

The performance of the models can be evaluated in different aspects:

- Entity Translation Accuracy: The models should translate the name entities in the source sentence accurately, according to the entries in Wikidata. The metric used for this is Manual Entity Translation Accuracy (M-ETA) (Conia et al., 2024), which computes the proportion of entities that are correctly (exact match) translated and is computed as M-ETA $= \frac{\text{\# correctly translated entities}}{\text{\# entities in the reference translations}}$
- Overall Translation Quality: Models should generate accurate translations of the provided English sentence. In order to measure this, we use both Character n-gram F-score (CHRF) (Popović, 2015), which is based on character overlap, and Cross-lingual Optimized Metric for Evaluation of Translation (COMET)[3] (Rei et al., 2022) metrics.

[3]Unbabel/wmt22-comet-da

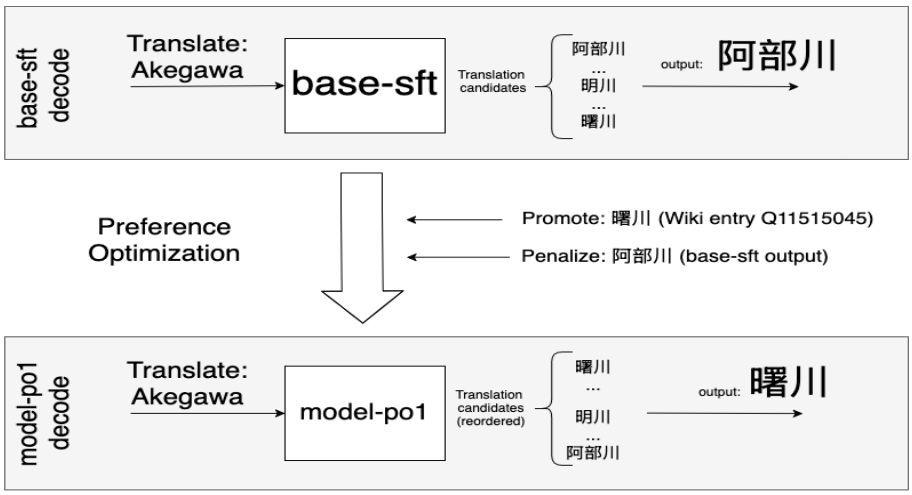

Figure 1: Overview of Preference Optimization. The model *base-sft* produces a translation that does not match the entry in the Wikidata dictionary (above). During Preference Optimization, we specify which terms should be promoted (i.e. the correct translation from the dictionary), and which should be penalized (i.e. the incorrect output from the *base-sft* model). The resulting model, *model-po1*, is able to reorder the translation candidates and produce the correct translation (bottom).

Wiki id	Source	Chosen	Rejected
Q5760427	Hikaru Museum	光ミュージアム	光美術館
Q407486	Air Madrid	エア・マドリード	エアマドリッド
Q11515045	Akegawa	曙川	阿部川

Table 1: Example of preference data.

We report the performance scores on two sets provided by the organizers[4], i.e. *valid* (723 lines) and *test* (5108 lines).

4.2 Baseline Model

In the first stage, we build a strong model in the English to Japanese direction. We decided to use the *RakutenAI-7B-chat*[5] model (Rakuten Group, Inc. et al., 2024) as it has been specially tailored for various Natural Language Processing (NLP) tasks in both English and Japanese languages. In addition to that, it has demonstrated strong performance on translation (Htun and Poncelas, 2024).

We fine-tune this model on English-Japanese parallel sentences in order to build a model specialized in the translation task. For this, we use the *mintaka*[6] dataset (Sen et al., 2022) provided by the organizers of the shared task which contains 7K parallel sentences. By doing this, we increase the performance of the model on the translation task (for example, the performance of in the test set increased from 31.4 CHRF points to 45.1). We will use this fine-tuned model, i.e. *base-sft*, for our experiments.

The model has been fine-tuned on this dataset for one epoch. This approach was applied to all the models presented in this paper, and each was tuned for one epoch.

4.3 Experiments

To explore how to incorporate dictionary knowledge into a model, we follow the approaches described in Section 3 to build new models.

We use *Paranames* (Sälevä and Lignos, 2022) dataset[7] which contains a list of terms and their translations in Japanese according to Wikidata. In total it contains 1.1M terms in Japanese. We translate these terms using *base-sft*, and remove those entries that our model is already capable of translating accurately. We keep the entries where the target Japanese and our translation is not an exact match. After this process, the size of the filter dictionary is

[4] https://huggingface.co/datasets/sapienzanlp/ea-mt-benchmark

[5] https://huggingface.co/Rakuten/RakutenAI-7B-chat

[6] https://github.com/amazon-science/mintaka

[7] https://huggingface.co/datasets/bltlab/ParaNames

850K.

We use this filtered dictionary to create sets of parallel data as described in Section 3.1. In particular, we build three datasets: (i) individual dictionary entries; (ii) lists of five entries, and (iii) lists of ten entries. We fine-tune *base-sft* model with these datasets to build three models: *model-sft1*, *model-sft5* and *model-sft10*.

Additionally, we build preference data as triplets of (source, chosen, rejected) as described in Section 3.2. The source consists of the English-side of the dictionary. We use the Japanese-side of *Paranames* as "chosen" and the translation provided by *base-sft* as "rejected". This is because we want to promote the original entry in the dictionary and downgrade those generated by our model.

We build three versions of the preference data: by grouping the terms in lists of sizes 1, 5 and 10. We use each dataset to build another three models: *model-po1*, *model-po5* and *model-po10* following Preference Optimization technique.

5 Results and Analysis

The results of the models are shown in Table 2 for the valid set, and Table 3 for the test set. After the incorporation of the dictionary we see improvements in terms of M-ETA. However this also impact the translation quality.

5.1 Fine-Tuned Models

The most notable improvement in M-ETA scores occurs when the model is fine-tuned with a dictionary containing single -name entities, i.e. *model-sft1*. This model achieves the highest M-ETA scores, with 25.7 points for the valid set and 29.6 for the test set. However, this comes at the cost of the biggest decline in translation quality, making it the only model that is more than 1 COMET points behind.

Although no models fine-tuned with dictionaries show an improvement in translation quality, we find that fine-tuning with larger entry lists, such as *model-sft5* and *model-sft10*, leads to a smaller reduction in quality. As the list length grows, the decrease in translation quality becomes less pronounced. However, this results in smaller gains in M-ETA scores, and in some cases, such *model-sft10* in the *valid* set, Table 2, it shows lower M-ETA than the baseline. The optimal list length remains unclear, as using 10 entries results in a decrease in M-ETA for the valid set, but the test set shows a score comparable to that achieved when trained with 5 entries.

5.2 Preference Optimization Models

Regarding the models where Preference Optimization technique was used, we observe that the translation quality is similar to the baseline. There is a discrepancy between COMET and CHRF metrics, while CHRF indicates a slight decline, COMET shows either same or improved quality. In any case, the differences compared to the baseline are minimal (less than 1 point difference for both metrics).

In terms of entity translation accuracy, models with Preference Optimization generally show increased the M-ETA scores over *base-sft*. However, these scores are still lower compared to those of fine-tuned models.

These models seem to be unaffected by the number of name entities in the dictionary. Increasing the number of entries does not have an impact on the performance.

6 Conclusion

Our system demonstrated competitive results in both M-ETA and COMET metrics. The leaderboard[8] shows that its performance can be comparable to some of the larger models.

In this paper, it has been shown that fine-tuning the model on the dictionary can improve translation accuracy. However, this comes at the cost of reduced quality. Therefore, we proposed two alternatives that achieve a balanced trade-off between translation quality and entity translation accuracy. The first approach involves fine-tuning with lists of named entity pairs, which helps mitigate the quality decline while improving M-ETA scores. The second alternative utilizes preference optimization, which also results in improved M-ETA scores, while maintaining a similar level of translation quality.

In this study, we utilized the *RakutenAI-7B-chat* model, originally developed for Japanese and English. Consequently, our experiments focused on these languages only. Nonetheless, we believe the proposed approach can be generalized to other language pairs. Furthermore, we want to investigate whether this is applicable to bigger models, like those presented in the leaderboard of the workshop.

Table 3: Entity translation accuracy and translation quality evaluated in the *test* set. The column Δ indicates the score difference between the model and the baseline *base-sft*.

One limitation of this work is that we added the dictionary knowledge as lists of one, five, and ten words. In the future, we would like to explore what sizes are optimal to achieve the best performance. In addition, we want to explore whether adding a combination of these would lead to better results. Another way to further explore this work is to generate synthetic sentences from the dictionary instead of sticking to the list of words.

GOLDX at SemEval-2025 Task 11: RoBERTa for Text-Based Emotion Detection

Bill Clinton
Institut Teknologi Bandung
summerrs528@gmail.com

Abstract

This document describes an approach to solve the SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection, specifically for Track A: Multi-label Emotion Detection and Track C: Cross-lingual Emotion Detection. In this document, the method utilizes an ensemble of RoBERTa models, each trained with different hyperparameters to enhance robustness and performance. For Track C, an additional neural machine translation (NMT) approach is added. The results demonstrate the effectiveness of model ensembling and translation preprocessing in tackling the challenges posed by Task 11.

1 Introduction

The SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection focuses on multi-label emotion detection, which is a key challenge in the natural language processing (NLP) world. Its applications include sentiment analysis, user engagement analysis, and mental health monitoring. This task involves predicting the presence or absence of specific emotions (in the form of 0 or 1) for a given text. Track A requires detecting five different emotions: anger, fear, joy, sadness, and surprise, using a labeled dataset in a single language (for English). Track C, on the other hand, introduces a cross-lingual setting where no labeled training data is provided in the target language. Moreover, Track C includes an additional emotion category, which is disgust, increasing the total number of labels to six in certain languages. Participants must develop strategies to generalize across languages without access to direct supervision in the target language.

In this paper, the approach leverages an ensemble of RoBERTa models, each trained with different hyperparameters, to improve the robustness and performance. For Track A, the training is done using the provided labeled dataset (English). For Track C, a cross-lingual transfer learning strategy is adopted (training on Chinese data and inferring on Indonesian). Additionally, MarianMT, a neural machine translation model developed by Helsinki-NLP, is employed to translate non-English data before classification, helping bridge the linguistic gap.

Through this participation, strong results are achieved, obtaining a Macro-F1 score of 0.762 for Track A and 0.4291 for Track C. This system performed competitively relative to other submissions, demonstrating the effectiveness of model ensembling and translation-based adaptation.

2 System Description

2.1 Overview

In this paper, the approach is based on pretrained Transformer model from Hugging Face, specifically using the RoBERTa model for multi-label emotion classification. This system is designed to optimize macro-F1 scores for each emotion through hyperparameter tuning. An ensemble of RoBERTa models in implemented, each trained with different hyperparameters to improve performance.

For Track A, the training directly used the provided labeled dataset in English. For Track C, where no labeled target-language data is available, a cross-lingual approach is used:

- The model is trained on Chinese emotion-labeled data.
- The inference is conducted on Indonesian test data using the trained model

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 797–800

Additionally, MarianMT (Helsinki-NLP) is leveraged for the translation preprocessing, ensuring consistency between training and test languages.

2.2 Model and Hyperparameter Tuning

To optimize the model's performance, experiments are done with multiple hyperparameter settings, selecting the best configuration based on macro-F1 scores per emotion. The following hyperparameters were tuned:

- Batch Size: {8, 16, 24, 28, 32, 40, 48, 54}
- Learning Rate: {2e-5, 5e-5, 1e-4}
- Epochs: {4, 5, 8, 10, 12, 16}

For each experiment on the test dataset in the development phase, the model achieving the highest macro-F1 score for each individual emotion was selected for inference.

2.3 Cross-Lingual Transfer in Track C

One of the main challenges in Track C is the lack of labeled training data in the target language. To address this, here is the approach:

- Chinese is used as the training language, leveraging its availability of labeled data
- MarianMT is applied to translate both the training and test data into English before being processed.
- The output from the ensemble models are aggregated to determine the final classification.

3 Data

3.1 Dataset Overview

The experiments in this paper utilized the BRIGHTER dataset collection, which is a comprehensive resource for multi-label emotion recognition across 28 languages, predominantly focuing on low-resource languages from regions, such as Africa, Asia, Latin America, and Eastern Europe. Each dataset comprises the text instances annotated by fluent speaker. This captured a diverse range of emotional expressions. The primary emotions annotated are anger, fear, joy, sadness, surprise, and disgust. Notably, the presence of the disgust label varies across languages. For instance, the label is included in the Chinese dataset but not in the English dataset.

3.2 Data Collection and Annotation

The data collection process involved sourcing text from various domains to ensure a rich and diverse representation of emotional expressions. Fluent speakers of each language were recruited to annotate the datasets. This ensured cultural and contextual relevant in the emotion labels. Annotators were provided with guidelines to label each text instance with one or more emotions, reflecting the multi-label nature of the task. This approach acknowledges the complexity and nuance of human emotions, where a single sentence can convey many emotions.

4 Experimental Setup

4.1 Data Splits and Usage

For both Track A and Track C, the dataset was split into train (80%) and dev (20%) from the labeled data. The train set was used for training the models, while the dev set was used for hyperparameter tuning.

4.2 Preprocessing

There is an extra preprocessing step for track C, which is using MarianTokenizer. This is used fro the translation step for both the Chinese training data and the Indonesian test data.

4.3 Model and Hyperparameter Tuning

This system utilized a model ensemble approach, where multiple versions of the same base model were trained with different hyperparameters. The best model for each emotion label was chosen based on its macro-F1 score on the dev set.

- Data Split for Model Training:
    - Labeled data split: 80% training, 20% development
    - Test set: Used only for final evaluation
- Hyperparameter Search:
    - Learning rate: {2e-5, 5e-5, 1e-4}
    - Batch size: {8, 16, 24, 28, 32, 40, 48, 54}

- Epochs: {4, 5, 8, 10, 12, 16}

4.4 Hardware and External Libraries

- Hardware: Experiments were conducted using an NVIDIA A100 GPU on Google Collab Pro
- External Libraries:
  - Hugging Face Transformers (transformers)
  - PyTorch (torch)
  - NumPy (numpy)
  - Pandas (pandas)

5 Results

The system is evaluated in two phases:

- Development Phase (Until January 16, 2025)
- Test Phase (Until February 1, 2025)

5.1 Track A Results

Emotion	Dev	Test
Anger	0.8	0.6817
Fear	0.8271	0.8488
Joy	0.8214	0.7732
Sadness	0.8056	0.7738
Surprise	0.7797	0.7324
Macro-F1	**0.8067**	**0.762**

Table 1: Track A Results.

5.2 Track C Results

Emotion	Dev	Test
Anger	0.5897	0.4884
Fear	0.1951	0.2589
Joy	0.5536	0.6392
Sadness	0.3243	0.5507
Surprise	0.3736	0.4797
Disgust	0.125	0.1575
Macro-F1	**0.3602**	**0.4291**

Table 2: Track C Results.

Selected Models:

- Model I:
  - Batch Size: 32
  - Learning Rate: 5e-5
  - Epoch: 5
  - Emotions: Anger
- Model II:
  - Batch Size: 40
  - Learning Rate: 5e-5
  - Epoch: 5
  - Emotions: Disgust, Fear, Joy, Surprise
- Model III:
  - Batch Size: 28
  - Learning Rate: 5e-5
  - Epoch: 4
  - Emotions: Sadness

The results indicate that the ensemble approach and cross-lingual transfer strategy are quite effective. Track C, despite its challenges, achieves a good performance, highlighting the benefits of multilingual training and translation-based inference.

Abstract

This paper describes the system implemented by the EMO-NLP team for track A of task 11 in SemEval-2025: Bridging the Gap in Text-Based Emotion Detection. The task focuses on multiple datasets covering 28 languages for multi-label emotion detection. Most of these languages are low-resource languages. To achieve this goal, we propose a multilingual multi-label emotion detection system called XLMCNN, which can perform multi-label emotion detection across multiple languages. To enable emotion detection in various languages, we utilize the pre-trained model XLM-RoberTa-large to obtain embeddings for the text in different languages. Subsequently, we apply a two-dimensional convolutional operation to the embeddings to extract text features, thereby enhancing the accuracy of multi-label emotion detection. Additionally, we assign weights to different emotion labels to mitigate the impact of uneven label distribution. In this task, we focus on nine languages, among which the Amharic language achieves the best performance with our system, ranking 21st out of 45 teams.

1 Introduction

SemEval-2025 task 11[1] consists of three subtasks, each focusing on different aspects. We focus only on track A. Track A aims to conduct multi-label emotion detection in 28 languages, including Amharic, Hausa, German, English, Oromo, Afrikaans, Algerian Arabic, Chinese, Emakhuwa, Hindi, Javanese, Kinyarwanda, Marathi, Moroccan Arabic, Nigerian-Pidgin, Portuguese(Brazilian), Portuguese(Mozambican), Romanian, Russian, Somali, Spanish(Latin American), Sundanese, Swahili, Swedish, Tatar, Tigrinya, Ukrainian, Yoruba, identifying the emotion labels contained in a given sentence of a specific language(Muhammad et al., 2025b). Every sentence in datasets may contain zero, one, or multiple emotions.

Emotion detection is one of the important research directions in the field of natural language processing. Many emotion detection applications exist, such as recommendation systems (Hu et al., 2021) and public opinion monitoring (Boon-Itt and Skunkan, 2020). However, the majority of research on emotion detection has focused on high-resource languages, with relatively little attention given to low-resource languages. The BRIGHTER dataset as well as datasets of Amharic, Oromo, Somali, and Tigrinya languages (Muhammad et al., 2025a; Belay et al., 2025) collected for SemEval-2025 Task 11 includes low-resource languages from Africa, Asia, Latin America, and other regions, providing data support for multi-label emotion detection in low-resource languages.

We focus on the multi-label emotion detection of nine languages in Track A, including Amharic, German, English, Oromo, Russian, Portuguese (Brazilian), Sundanese, Somali, and Tigrinya. For these nine languages, we propose the XLMCNN, a multilingual multi-label emotion detection system, which can directly process preprocessed sentence texts from different languages and detect their sentiment categories. We employ the pre-trained model XLM-RoberTa-large to obtain the vector representations of sentences. Subsequently, we utilize a Convolutional Neural Network (CNN) for feature extraction to enhance the accuracy of sentiment detection. Moreover, when calculating the loss, we assign different weights to different emotion labels to mitigate the adverse effects caused by the imbalance of emotion label count.

2 Related Work

Emotion analysis is an important area in natural language processing, and the methods used in its research have evolved from lexicon-based

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 801–806

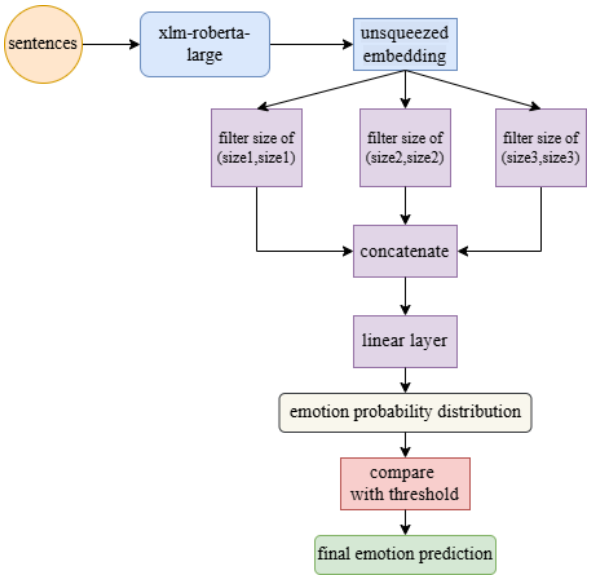

Figure 1: The overall architecture of XLMCNN system

approaches to mainstream approaches, machine learning, and deep learning methods (Medhat et al., 2014). The granularity levels of sentiment analysis research include aspects (Pontiki et al., 2014), documents (Wei et al., 2020), multimodal (Hu et al., 2022), and so on. Research on sentiment polarity has achieved significant success in high-resource languages. However, for multi-label emotion detection, especially in low-resource languages, methods suitable for single-label emotion detection are not applicable due to the co-occurrence of emotion labels (Ahanin et al., 2023). So, more and more researchers have begun to explore new methods for multi-label text emotion detection. In 2014, Jabreel and Moreno (Jabreel and Moreno, 2019) proposed a method combining attention models with Bidirectional Gated Recurrent Units (Bi-GRU) to identify the associations between emotion label and the words in a sentence, thereby achieving multi-label sentiment classification. In 2021, Alhuzali and Ananiadou (Alhuzali and Ananiadou, 2021) used a BERT encoder to make emotion labels and the entire sentence as input to capture the associations between emotion label and all words in the sentence. In 2023, Ameer et al.(Ameer et al., 2023) implemented multi-label emotion detection using RoBERTa and multi-layer attention mechanisms. In 2023, Zahra Ahanin et al.(Ahanin et al., 2023) used a combination of deep learning-based features and human-engineered features to improve the accuracy of multi-label text classification.

3 System Overview

In this section, we provide an overview of the system implementation process and offer an introduction to the details of the system.

3.1 System Architecture

Figure 1 illustrates the overall architecture of our XLMCNN system. The process includes obtaining sentence vectors, performing convolution operations, and predicting the results.

Since the XLM-RoBERTa-large model can process multiple languages and meet the requirements of our experiments, we use this model to obtain vector representations of sentences. We preprocess the input sentences into a form that the model can accept and then use the model's output 'last hidden state ' as the vector representation of the sentences. Since convolutional neural networks can extract localized information, we use it to extract localized emotional information in text. To adapt to the input of a two-dimensional convolutional neural network, we expand the obtained vectors by adding an additional dimension. Then, we perform convolution operations on the expanded vectors using a network with three different convolution kernel sizes. The results of the convolution operations are concatenated along the last dimension. The concatenated results are passed through a fully connected layer as the final classifier. Since this task is for multi-label sentiment classification, where labels are not mutually exclusive but can co-occur, we use the sigmoid function to obtain the final sentiment probability distribution:

$$\hat{y} = \sigma(W_c h + b_c) \tag{1}$$

In the equation, $W_c \in \mathbb{R}^{d_h \times |Y|}$, and $b_c \in \mathbb{R}^{|Y|}$, $|Y|$ represents the number of classes of emotion labels.

3.2 Loss Function

For this multi-label emotion detection task, we use BCEWithLogitsLoss as the loss function. However, after analyzing the number of instances for each emotion label in the dataset, as shown in Figure 2, we found an imbalance among the label counts, which could negatively impact the classification results. Therefore, we employ a weighted BCEWithLogitsLoss to mitigate the impact of the imbalanced label data:

$$Loss = BCEWithLogitsloss(weight = [cw_1, cw_2, \ldots]) \tag{2}$$

total	20207	5057	-

Table 1: The sentence numbers in training set, validation set, test set for nine languages.

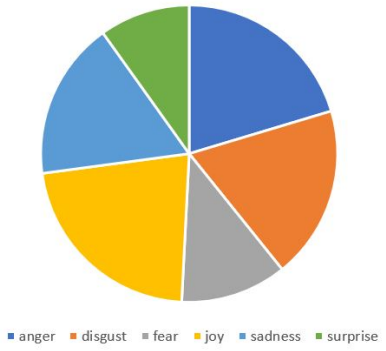

Figure 2: The emotion labels distribution in training set

For the calculation of weights, since the model may overlook emotion labels with fewer instances during training, while the model tends to focus more on labels with a higher number of instances, we use the reciprocal of the proportion of each emotion label in the total number of labels as the weight for that emotion label:

$$cw_i = total/label_i \quad (3)$$

In this equation, cw_i represents the weight of the i-th label, and $total$ represents the total number of emotion label, and $label_i$ represents the number of the i-th emotion label.

4 Experiment

In this section, we introduce the dataset of SemEval-2025 task 11 and how we preprocess these data. Additionally, we also show our experiment configurations.

4.1 Dataset and Preprocess

Our experiments focus on nine languages. They are Amharic, German, English, Oromo, Russian, Portuguese (Brazilian), Sundanese, Somali and Tigrinya. For the dataset of these nine languages, each sentence in the English dataset has five emotion labels: anger, fear, joy, sadness, and surprise. For the datasets of the other eight languages, each sentence has six emotion labels, including an additional label of **disgust** compared to the English dataset. For each emotion label, if a sentence contains a particular emotion, it is marked as 1; if it does not contain the emotion, it is marked as 0.

We add the **disgust** emotion label to the English dataset and label it entirely as 0, in order to unify the label categories of the English dataset with those of the other datasets. We divide the training data of each language into training and validation sets at a ratio of 8:2. Then, we combine the training sets of the nine languages and the validation sets of the nine languages separately, resulting in the training dataset and validation dataset used in our experiments. The data distribution of the training set, validation set, and test set are shown in Table 1. Moreover, the datasets are collected from diverse sources, including social media, news, and speeches (Muhammad et al., 2025a), which leads to the inclusion of some noise in the dataset. Specifically, certain sentences contained emojis, punctuation marks, parentheses, extra whitespace, special characters like # , and other similar elements. These types of noise can interfere with the process of emotion detection and classification. Therefore, during the experiment, we remove these types of noise from the dataset.

4.2 Implementation Details

The entire system is implemented on the Kaggle platform, utilizing GPU T4 $\times$ 2. During the experiments, we employ the macro f1 score as the evaluation metric for model performance. By com-

Hyperparameter	value
num class	6
epoch	7

weight decay	$1e^{-2}$
dropout	0.5
threshold	0.5
hidden size	1024
filter size	$3, 4, 5$
number of filter	64

Table 2: The hyperparameter setting during the experiment

paring the average results on the validation sets of the nine languages, we identify the optimal hyperparameters, which are then saved and applied to the test set to assess the model's performance. The XLMCNN employs the 'FacebookAI/xlm-roberta-large'[2] model to generate sentence vectors. Subsequently, it utilizes the two-dimensional Convolutional Neural Network (CNN) for feature extraction. Finally, a linear layer is applied to obtain the probability distribution of emotion classes. The final emotion labels of a sentence are determined by comparing the probability of the emotion class with a predefined threshold. Table 2 shows the specific parameter settings for these three processes. Finally, we use Adam Optimizer (Kingma and Ba, 2015) to optimize the network parameters, and equation 3 implements class weights' setting in the loss function.

5 Result and Analysis

In this section, we present the test set results that are ultimately submitted to the system, comparing the results between the cases of assigning weights to the labels and not assigning weights. Table 3 shows the results for each language on individual emotion labels and the macro f1 score when weights are assigned to the labels and when no weights are assigned to the labels.

Our proposed system, XLMCNN, performs better, and the computed macro f1 scores are higher on Amharic, German, Oromo, Portuguese, Russian, Somali, and Tigrinya than the system that does not assign weights to the labels. Meanwhile, the XLMCNN system also achieves a slightly higher average macro f1 score across these nine languages compared to the system without label weighting. In addition, the emotion labels **fear** and **surprise** have relatively fewer instances than the other labels. It can be observed that using the XLMCNN system, the f1 score for predicting **fear** is slightly higher for half of the nine languages. Similarly, the XLMCNN system achieves a slightly lower f1 score for predicting **surprise** only in English and Sundanese, while it performs better in predicting **surprise** for the other languages. To some extent, this demonstrates that the weighting method in the system is effective in dealing with the negative impact caused by the imbalance of the number of emotion labels. Moreover, both the XLMCNN and the no-label weighting method perform poorly in the Oromo, Sundanese, Somali, and Tigrinya languages, which indicates that our system still needs some improvements for emotion detection of low-resource languages. Finally, regardless of the system used, the prediction of the **fear** emotion in Sundanese, Oromo and Tigrinya performed very poorly. Among the nine languages, our submitted system exceeds the baseline in two languages.

6 Conclusion

In this paper, we employ a method that combines the xlm-roberta-large model with a convolutional neural network while weighting emotion labels to achieve multi-label text emotion detection in multiple languages. The final experimental results indicate that XLMCNN has better overall performance in handling multi-label emotion detection than the method without label weighting. The method we use generally performs across languages, especially Sundanese, Oromo, and Tigrinya, with a very poor prediction for **fear** emotion. In future work, we will explore the issues within the proposed method and improve the performance of XLMCNN in low-resource languages.

Abstract

This paper represents our participation in SemEval-2025 Task 9 focusing on food hazard detection challenge. In particular, we participate in Sub-task 1 of Task 9, that is, predicting "hazard-category" and "product-category" labels. To address this challenge, we leverages Support Vector Machine (SVM) and Multinomial Naive Bayes (MNB) in our submissions. We also utilizes Bag of Words (BoW), Term Frequency-Inverse Document Frequency (TF-IDF), and GridSearchCV in this work. Our obtained macro F1-Score results in the evalution phase are 0.6472 and 0.107 for SVM and MNB, respectively.

1 Introduction

Food safety is a critical public health concern that requires efficient monitoring and early detection of potential hazards (Fung et al., 2018). Food hazard detection challenge conducted in SemEval-2025 Task 9 is an important initiative aiming to develop explainable classification systems for detecting food safety issues based on textual data (Randl et al., 2025). This task is crucial because it can help automated crawlers identify and extract food-related incidents from sources like social media, which is crucial given the potential for significant economic impact. The challenge covers English-language food recall titles and is described in detail in the task overview paper of food hazard detection of SemEval-2025 (Randl et al., 2025).

Our system utilizes a multi-pronged approach to address the text classification task in Sub-task 1. First, we focus on robust text preprocessing of the dataset, such as removing special characters and numbers, converting text to lowercase, stemming, and excluding stop words. This preprocessing helps to standardize the input data and focus on the most relevant features (Kunilovskaya and Plum, 2021; Strasser and Klettke, 2024). For extracting features, we employ Bag of Words (BoW) (Salton and McGill, 1986) and Term Frequency-Inverse Document Frequency (TF-IDF) (Ramos et al., 2003) representations. These techniques capture the frequency and importance of key terms within the text providing informative input to our classification models.

To tackle the classification task, we leverage Support Vector Machines (SVM) (Cortes and Vapnik, 1995) as our classifier, while we use GridSearchCV for hyperparameter tuning (Bergstra and Bengio, 2012). The SVM classifier has the ability to handle high-dimensional feature spaces and identify optimal decision boundaries, which has proven to be a robust choice for this type of text classification problem. Furthermore, the use of GridSearchCV allows us to systematically explore a range of hyperparameter configurations, ultimately selecting the optimal settings for our specific task and dataset.

Participating in this challenge has provided valuable insights into the strengths and limitations of our system. Through an evaluation on the evaluation phase using test data, we are able to obtain an macro F1-score of 0.6858 in Sub-task 1. Although this obtained result might be categorized acceptable, we have identified areas where our system struggles, such as correctly classifying certain hazard and product categories that are less represented in the dataset.

2 Background

SemEval-2025 Task 9 is the food hazard detection challenge focused on developing explainable classification systems to identify food-related safety issues from textual data. The task involves predicting the type of hazard and product category given a textual input, such as the title of a food incident report. The input for this task consists of short English-language texts describing food recalls, with an average length of 88 characters. The dataset provided by the organizers includes 6,644 such texts, which were manually labeled by food

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 807–811

science and technology experts (Randl et al., 2025).

Task 9 consists of two sub-tasks. Sub-task 1's goal is to predict the "hazard-category" and "product-category" labels, while Sub-task 2's purpose is to predict the exact "hazard" and "product" values. Participants in the Task 9 can take part in both subtasks or they can choose to participate in one sub-task only. The Task 9's organizer (Randl et al., 2025) considered several phases, namely, a trial phase for model development, a conception phase for validation of unlabeled data, and an evaluation phase for final testing on labeled data. In this Task 9, we participate in Sub-task 1 only.

Related work in the area of explainable text classification for food safety risk detection is limited but growing. Recent studies have explored both model-specific (Assael et al., 2016) and model-agnostic (Ribeiro et al., 2016b,a) approaches to provide explanations for predictions. However, the unique challenges of this domain, such as the imbalanced class distribution and the need for precise hazard and product labels, present opportunities for novel contributions.

Our work aims to build upon these existing methods and address the specific requirements of the Sub-task 1 of SemEval-2025 Task 9. In particular, we strive to develop a robust and explainable system for detecting food safety risks from textual data by leveraging advanced text preprocessing techniques and powerful machine learning algorithms.

3 System Overview

Our system takes a multi-pronged approach to address the text classification task os Sub-task 1 in the SemEval 2025 Task 9. We focus on robust text preprocessing, effective feature extraction, and the use of powerful machine learning algorithms with hyperparameter optimization.

3.1 Data Preprocessing

The first step in our system's workflow is data preprocessing to standardize the input and focus on the most relevant features. We begin by removing special characters and numbers from the text, as these elements are often not directly relevant to the classification task. Next, we convert all text to lowercase to ensure consistency. To further enhance the quality of our features, we apply stemming using the Porter Stemmer, which reduces words to their base forms.

3.2 Feature Extraction

After the text preprocessing phase, we extract features from the cleaned text using two established techniques: Bag of Words (BoW) and Term Frequency-Inverse Document Frequency (TF-IDF). The BoW approach captures the frequency of key terms within the text, providing a basic representation of the textual content. The BoW feature vector can be represented as:

$$XBoW = [f_1, f_2, ..., f_n]$$

The TF-IDF method, on the other hand, assigns higher weights to terms that are more important and distinctive within the corpus, further enhancing the informative nature of the feature representation. The TF-IDF value for a term t in a document d is calculated as:

$$TF - IDF(t, d) = TF(t, d) * IDF(t)$$

where TF(t, d) is the term frequency of t in d, and IDF(t) is the inverse document frequency of t in the entire corpus.

3.3 Classification

For the text classification task, we leverage Support Vector Machine (SVM) and Multinomial Naive Bayes (MNB) classifiers. Naive Bayes is a popular choice for text classification due to its simplicity, efficiency, and robustness. The Multinomial variant is particularly well-suited for discrete features, such as word counts, which is the case for our TF-IDF transformed text data.The Multinomial Naive Bayes classifier models the probability of a class c given the input features x as:

$$P(c|x) = (P(x|c) * P(c))/P(x) \quad (1)$$

where P(x|c) is the likelihood of the features given the class, P(c) is the prior probability of the class, and P(x) is the marginal probability of the features. Assuming the features are independent, the likelihood P(x|c) can be calculated as:

$$P(x|c) = P(x_i|c) \quad (2)$$

In the other hand, SVM is powerful machine learning algorithms that can effectively handle high-dimensional, sparse feature spaces, which is the case for our TF-IDF transformed text data (Cortes and Vapnik, 1995). The SVM method determines the best hyperplane to divide the classes by the

greatest amount. This is done by solving the following optimization problem:

$$\frac{1}{2}\|\mathbf{w}\|^2 + C\sum_i \xi_i \quad (3)$$

$$y_i(\mathbf{w}^\top \mathbf{x}_i + b) \geq 1 - \xi_i \quad (4)$$

$$\xi_i \geq 0 \quad (5)$$

where w is the normal vector to the hyperplane, b is the bias term, ξ_i are the slack variables that allow for misclassifications, and C is the regularization parameter that controls the trade-off between the margin size and the number of misclassifications. We use the Linear SVC implementation from the scikit-learn library, which is suitable for large-scale linear classification tasks (Muppidi et al., 2021).

To optimize the performance of our classification models, we employ GridSearchCV, a technique that systematically explores a range of hyperparameter configurations and selects the optimal settings for our specific task and dataset. This approach allows us to fine-tune the SVM's hyperparameters, such as the regularization parameter (C) and the kernel function, to achieve the best possible classification results.

Our system aims to develop explainable and high-performing classification models for the Subtask 1 of SemEval-2025 Task 9, which is the food hazard detection challenge, by combining robust text preprocessing, effective feature extraction, and powerful machine learning algorithms with hyperparameter optimization.

4 Experimental Setup

We have set up our experimental workflow to run on Google Colab, a cloud-based Jupyter Notebook environment. Google Colab provides a free and accessible platform for running machine learning experiments, with access to GPU and TPU resources.

We utilized the provided train dataset containing a total of 5,082 samples. We did have not split the provided dataset into training, development, and test sets because the organizer also provided data for evaluation. To evaluate our trained models, we used a provided development dataset. The goal was to develop explainable and high-performing classification models for the Sub-task 1 of SemEval-2025 Task 9.

To prepare the input data for the classification models, we apply a series of text preprocessing steps as follows:

- Removal of special characters and numbers: We utilize regular expressions to remove all non-alphabetic characters from the text, leaving only the necessary words.
- Conversion to lowercase: All text is converted to lowercase to ensure consistency in the textual representation.
- Stemming using the Porter Stemmer: We employ the Porter Stemmer, a widely-used algorithm for reducing words to their base forms, to capture the semantic similarities between related terms.
- Stop word removal: We eliminate common words that do not carry significant meaning for the classification task, such as "the," "a," and "is," using the pre-defined list of English stop words from the NLTK library.

After the preprocessing stage, we extract features using two techniques as follows:

- Bag of Words (BoW): The BoW representation captures the frequency of key terms within the text, providing a basic representation of the textual content
- Term Frequency-Inverse Document Frequency (TF-IDF): This approach assigns higher weights to terms that are more important and distinctive within the corpus, further enhancing the informative nature of the feature representation.

We use BoW and TF-IDF to capture different aspects of the textual data and investigate which feature representation performs better for the classification task.

We use the training dataset to train and optimize the models. This will allow us to perform hyperparameter tuning and select the best-performing models. We leverage GridSearchCV from Scikit-learn, a technique that systematically explores a range of hyperparameter configurations and selects the optimal settings.

In the evaluation stages, the SemEval-2025 Task 9 focuses on the macro average F1-Score as an evaluation metric focusing on the hazard class (Randl et al., 2025)

.

	MNB	SVM
Macro average	0.1076	0.6858

Table 1: The obtained F1-Score of our models in the evaluation phase.

	Hazard	Product	Average
MNB	0.7903	0.4974	0.6439
SVM	0.9047	0.7322	0.8184

Table 2: The obtained F1-Score of our models on the training dataset.

5 Results

We submitted two models in the evaluation phase to participate in this Sub-task 1 of SemEval-2025 Task 9. In particular, our submission consisted of Multinomial Naive Bayes (MNB) and SVM models. Table 1 shows our obtained macro average F1-Score in the evaluation phase.

Our obtained results in Table 1 indicate that our SVM model could perform better than the MNB one. This SVM better performance corresponds to the obtained F1-Score of our models on the training dataset, as shown in Table 2. In particular, results in Table 2 shows that SVM could predict the hazard class correctly around 90%. On the other hand, results in Table 2 also demonstrates that MNB could not work as good as SVM, where the MNB predicted the hazard class correctly about 79% only. This disparity performance between SVM and MNB on the training dataset (Table 2) might affect the performance of our SVM and MNB models in the evaluation phase (Table 1) that focused on predicting the hazard class.

6 Limitations

The stark performance discrepancy of the Multinomial Naive Bayes (MNB) classifier—training macro F1-score of 0.64 versus evaluation macro F1-score of 0.10—stems from multiple interrelated factors. First, while hyperparameter tuning was rigorously applied during training via GridSearchCV to address initial low performance, an oversight led to the inadvertent use of default hyperparameters during evaluation. This inconsistency disrupted the model's calibrated probability estimates, amplifying its inherent sensitivity to imbalanced class distributions and sparse feature representations. MNB's reliance on term independence assumptions further clashed with the evaluation set's domain-specific contextual dependencies (e.g., multi-word hazards like "heavy metal contamination"), which BoW/TF-IDF failed to disentangle. The absence of optimized regularization during evaluation underscores the necessity of end-to-end hyperparameter consistency, particularly for models like MNB that lack intrinsic mechanisms to mitigate distribution shifts or lexical ambiguities in short, specialized texts.

7 Conclusion

Our system for the Sub-task 1 of SemEval-2025 Task 9 has been designed to tackle the complexities of identifying and categorizing food safety incidents from textual data. Through a rigorous experimental setup, we have developed a text classification solution that leveraged state-of-the-art techniques in data preprocessing, feature engineering, and model optimization. Our obtained submission results in the evaluation phase indicated that SVM could perform better than MNB. In particular, our SVM and MNB models achieved 0.6858 and 0.1076 of macro average F1-Scores, respectively. We assume this mediocre performance due to our models had difficulties in predicting the hazard class in the evaluation phase. For this reason, focusing on predicting the hazard class should be paid attention seriously in the future to deal with this challenging task.

Abstract

The Food Hazard Detection (SemEval-2025 Task 9) advances explainable classification of food-incident reports collected from web sources, including social media and regulatory agency websites, to support timely risk mitigation for public health and the economy. This task is complicated by a highly imbalanced, long-tail label distribution and the need for transparent, reliable AI. We present a robust Knowledge-Augmented Data approach that integrates Retrieval-Augmented Generation (RAG) with domain-specific knowledge from the PubMed API to enrich and balance the training data. Our method leverages domain-specific knowledge to expand datasets and curate high-quality data that enhances overall data integrity. We hypothesize that Knowledge-Augmented Data improves Macro-F1 scores, the primary evaluation metric. Our approach achieved a top-2 ranking across both subtasks, demonstrating its effectiveness in advancing NLP applications for food safety and contributing to more reliable food hazard detection[1].

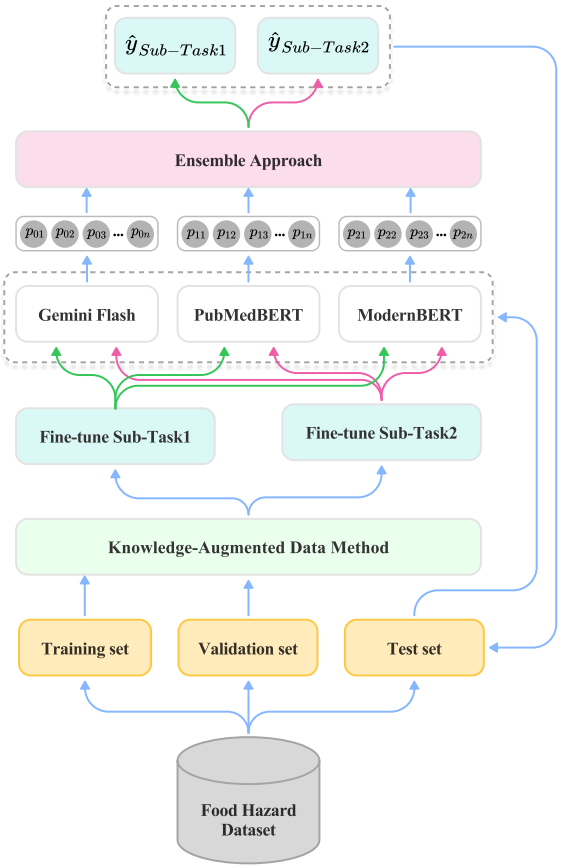

Figure 1: Overall System Architecture for Food Hazard Detection Challenge Using the Knowledge-Augmented Data Method.

1 Introduction

The increasing volume of food incident reports from various online sources highlights an urgent need for automated detection systems. These reports come from social media and official food agency websites and reflect economic and public health risks associated with foodborne illnesses and contamination. SemEval-2025 Task 9 addresses these challenges by developing systems that classify food incident reports and predict potential hazards. Current methodologies, particularly data augmentation from large language models (LLMs), face hurdles such as hallucination, which complicates the development of reliable, scalable solutions. These challenges are further exacerbated by class imbalance in datasets and the need for transparent, explainable AI.

To address these issues, we introduce a Knowledge-Augmented Data approach that integrates RAG (Lewis et al., 2020) to enhance data quality with domain-specific knowledge. Our method involves retrieving relevant data from PubMed, generating augmented samples using advanced LLMs, filtering out low-quality data, and fine-tuning models to maximize detection accuracy. This comprehensive strategy enriches the dataset and improves data integrity, leading to significant

[1] https://github.com/phanben110/KAD-FoodHazard

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 812–822

gains in Macro-F1 scores, the primary evaluation metric for this task.

Our team achieved outstanding results in the competition, securing 2nd place in Subtask 1 and Subtask 2. These outcomes demonstrate the strength of our food hazard detection approach, integrating domain-specific knowledge to overcome data limitations and highlighting RAG's potential in generating high-quality training data.

2 Background

2.1 Food Hazard Detection Dataset

SemEval-2025 Task 9 (Randl et al., 2025) focuses on explainable classification of food incident reports from web sources. It aids automated crawlers in identifying food-related issues on platforms like social media. The task comprises two subtasks: (1) text classification for food hazard and product category prediction (ST1), predicting both the type of hazard and the product category; (2) food hazard and product *"vector"* detection (ST2), predicting the exact hazard and product mention.

The dataset comprises 6,644 expert-labeled recall titles *(year, month, day, country, title, full text)* from various sources, covering 1,142 products in 22 categories and 128 hazards across 10 categories. Table 1 shows the data splits. The data exhibit class imbalance and label diversity (see Appendix D).

Dataset	Samples	Classes			
		hazard-cat.	product-cat.	hazard	product
Train	5,082	10	22	128	1,022
Val	565	9	18	93	312
Test	997	10	20	110	447

Table 1: Statistics of the SemEval-2025 Task 9 dataset, including the number of samples and class distributions for training, validation, and test sets.

2.2 Related Works

Data augmentation techniques, such as back translation (Sennrich et al., 2016) and Easy Data Augmentation (EDA) (Wei and Zou, 2019), have been widely used in NLP to address data limitations, though they risk altering meaning (Feng et al., 2021). LLMs like ChatGPT (Achiam et al., 2024) and Llama (Touvron et al., 2023) further enhance augmentation, improving performance across various tasks (Ding et al., 2024). For instance, the CLaC team in SemEval-2024 Task 4 (Nayak and Kosseim, 2024) used paraphrase augmentation to mitigate data scarcity, while GPT-4 has been employed in biomedical relation extraction to enhance model performance (Phan et al., 2024).

RAG has also been explored for biomedical information retrieval, with a study by Li et al. (2025) highlighting its potential to improve answer relevance, noting challenges in grounding and contextual accuracy. Additionally, retrieval-based approaches using the PubMed API have been employed to inject external knowledge into NLP tasks. For example, Thomo (2024) used PubMed queries to extract relevant literature, integrating retrieved documents into language models to enhance medical question answering. Building on this line of work, our Knowledge-Augmented Data method leverages RAG to improve food hazard detection with higher accuracy and reliability.

3 System Overview

Our proposed method, Knowledge-Augmented Data for Food Hazard Detection, enhances the quality and diversity of training data by integrating external knowledge and advanced filtering techniques. As illustrated in Figure 2, it leverages LLMs combined with Retrieval-Augmented Generation (RAG) using external sources such as the PubMed API[2] to generate high-quality augmented data, boosting model robustness and performance.

The framework consists of four main steps: (1) simplifying complex queries using LLMs to retrieve relevant external knowledge; (2) generating augmented samples based on the retrieved context; (3) filtering low-quality data through a score-based validation process; and (4) fine-tuning multiple deep learning models on the enriched dataset merging original and high-quality augmented samples. Finally, as shown in Figure 1, an ensemble mechanism combines predictions from different models to achieve optimal results in food hazard detection.

3.1 Information Retrieval System

The Information Retrieval System is crucial in augmenting data by incorporating external knowledge. Since complex queries often fail to return results via the PubMed API, the system first simplifies the original query Q_{complex} into a more concise form Q_{simple} using LLMs with *Prompt 1* (see Appendix B). The complex query Q_{complex} typically contains detailed scientific terminology, multiple conditions, or lengthy descriptions of food safety concerns, which can be overly specific for effective

[2] https://pubmed.ncbi.nlm.nih.gov/

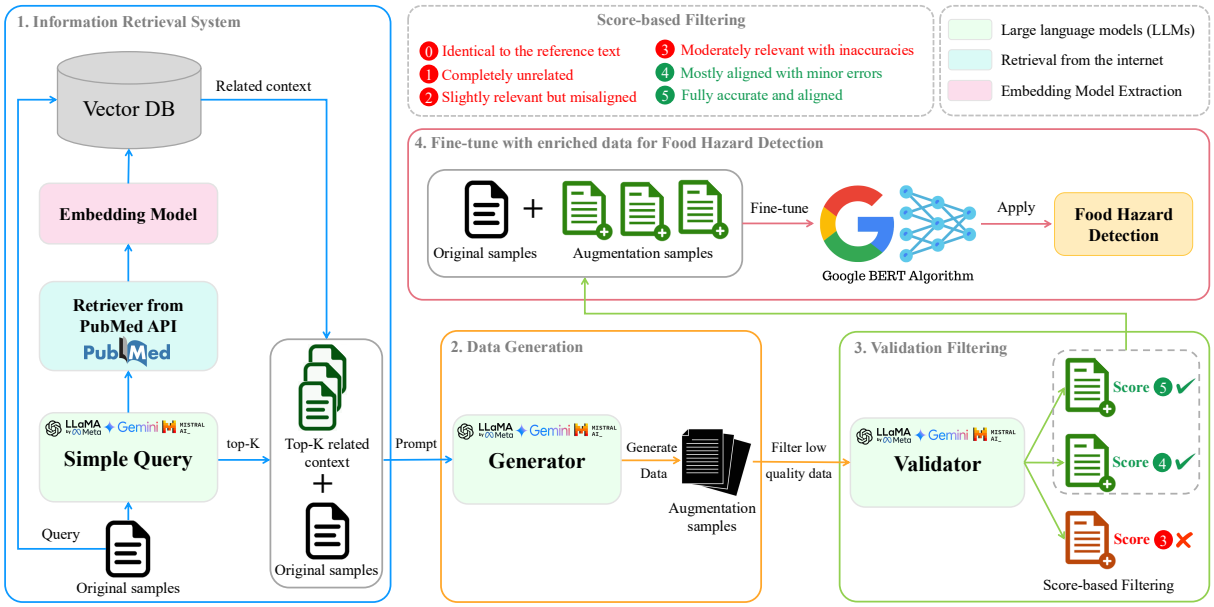

Figure 2: The Knowledge-Augmented Data method for food hazard detection comprises four components: (1) Information Retrieval, which collects relevant data from the PubMed API; (2) Data Generation, where large language models (LLMs) generate augmented samples; (3) Validation Filtering, which scores and removes low-quality data; and (4) Fine-tuning, which enhances LLMs and deep learning models to improve detection accuracy.

API retrieval. Through LLM-based transformation, Q_{simple} retains the core information needs while using more generalized terminology and focusing on essential keywords, thereby increasing the likelihood of successful matches in the database.

This simplification ensures more effective document retrieval. The refined query is then used to fetch top-K relevant documents from PubMed, which are subsequently embedded into dense vector representations for efficient storage and retrieval. To identify the most relevant documents, cosine similarity is calculated between the original query vector v_{original} and each document embedding v_d:

$$\text{sim}(v_{\text{original}}, v_d) = \frac{v_{\text{original}} \cdot v_d}{\|v_{\text{original}}\| \|v_d\|} \quad (1)$$

The top-K most relevant documents are then selected based on their similarity scores:

$$D_{\text{retrieved}} = \{d_i \mid i \in \text{argmax}_K \ \text{sim}(v_{\text{original}}, v_{d_i})\} \quad (2)$$

Only documents with a similarity score above a predefined top-K threshold are selected for augmentation, ensuring the dataset remains contextually relevant and informative. Integrating this retrieval system with RAG improves model accuracy in detecting food hazards, as demonstrated in Section 5.

3.2 Data Generation

In this step, augmented samples are generated by leveraging the retrieved context $D_{\text{retrieved}}$ and the original samples S_{original}. LLMs create new data points by integrating the retrieved context with the original content. This augmentation process enhances dataset diversity while maintaining semantic relevance and contextual consistency. The data generation process follows a structured approach using *Prompt 2* template provided in Appendix B to ensure consistency and control over the augmentation process.

3.3 Validation Filtering

After data generation, each augmented sample is scored by an LLM-based function G_{val}, evaluating its relevance and accuracy against the retrieved context $D_{\text{retrieved}}$ using *Prompt 3* (see Appendix B). The filtered set S_{filtered} is defined as:

$$S_{\text{filtered}} = \{s \mid G_{\text{val}}(s, D_{\text{retrieved}}) \geq 4\} \quad (3)$$

As shown in Figure 2, only samples scoring **4** or **5** are retained for their quality and contextual alignment. Samples scoring **0** are discarded as redundant, while those scoring **1, 2, 3** are excluded for inaccuracy or irrelevance, ensuring strong contextual relevance and reliability.

Table 2: Leaderboard results for SemEval-2025 Task 9 (Top 20). Our team ***My My*** (**ST1:** 2nd, **ST2:** 2nd) delivered consistent, high-level performance across both subtasks, demonstrating the robustness and adaptability of our feature set and modeling strategy. In contrast to top teams that showed significant variance between subtasks, such as **Anastasia** (**ST1:** 1st, **ST2:** 21st) and **SRCB** (**ST1:** 3rd, **ST2:** 1st), our approach achieved both stability and accuracy throughout the competition. *META* refers to temporal and geographical features (*YEAR, MONTH, DAY, COUNTRY*).

3.4 Fine-tuning with Enriched Data

The combined dataset, consisting of the original training data D_{train} and filtered augmented samples S_{filtered}, forms the final training set:

$$D_{\text{final}} = D_{\text{train}} \cup S_{\text{filtered}} \tag{4}$$

We fine-tune multiple pre-trained models: Gemini Flash 2.0 (Team et al., 2024), PubMedBERT (Gu et al., 2021), and ModernBERT (Warner et al., 2024). This ensures that each model is adapted to the enriched data for optimal performance.

3.5 Ensemble Strategy

To enhance prediction accuracy, we employ an **ensemble strategy** that aggregates predictions from multiple models. The predicted labels for each subtask are computed using weighted sums of class probabilities:

$$\begin{cases} \hat{y}_{\text{Subtask1}} = \arg\max\limits_{y \in Y_1} \sum\limits_i w_i P_{\text{task1},i}(y) \\ \hat{y}_{\text{Subtask2}} = \arg\max\limits_{y \in Y_2} \sum\limits_i w_i P_{\text{task2},i}(y) \end{cases} \tag{5}$$

Here, w_i denotes the weight assigned to the i-th model's prediction. In our case, we use equal weighting, i.e., $w_i = \frac{1}{N}$, where N is the total number of models. $P_{\text{task1},i}(y)$ and $P_{\text{task2},i}(y)$ represent the predicted class probabilities for Subtask 1 and Subtask 2, respectively. This ensemble strategy facilitates robust, consensus-based decision-making, leading to more accurate food hazard predictions. The detailed algorithm is provided in Appendix A.

4 Experimental Setup

4.1 Model Training and Augmentation

Our experimental setup integrates knowledge-augmented data generation with fine-tuning on an enriched Food Hazard dataset. From the dataset, we utilize the following features: *YEAR*, *MONTH*, *DAY*, *COUNTRY*, *TITLE*, and *TEXT*. These fields are used for retrieval and input context for data augmentation and model training. For data augmentation, we employ GPT-3.5 Turbo[3], Gemini Flash 2.0 (Team et al., 2024), Llama 3.1 8B (Touvron et al., 2023), and Mixtral 8x7 B (Jiang et al., 2023) as LLMs, with a temperature setting of 0.7 to balance creativity and factual consistency. Knowledge retrieval is performed using vector embeddings from nomic-embed-text-v1 (Nussbaum et al., 2025) stored in a Chroma vector database. The input texts are chunked into 500-token segments with 100-token overlaps. We also incorporate ex-

[3] https://platform.openai.com/docs/models/gpt-3-5-turbo

Method	Subtask 1							Subtask 2						
	hazard-category			product-category			Macro-F1	hazard			product			Macro-F1

PubMebBERT	0.7706	0.7837	0.7766	**0.8703**	0.788	0.8096	0.7931	0.6748	0.708	0.6787	0.3662	0.3867	0.3622	0.5204
ModernBERT	0.7807	0.7688	0.7734	0.8233	0.7548	0.774	0.7737	**0.6879**	0.6883	0.6768	0.3578	0.3774	0.3534	0.5151
Ensemble (MyMy)	**0.7958**	**0.8121**	**0.8032**	0.8677	**0.8083**	**0.8193**	**0.8112**	0.6866	**0.7107**	**0.6892**	**0.3705**	**0.3928**	**0.3665**	**0.5278**

Table 3: Performance comparison of methods for the Food Hazard Detection Challenge. The table reports precision (P), recall (R), and F1-score (F1) for hazard-category and product-category in Subtask 1, and hazard and product in Subtask 2. Final Macro-F1 scores highlight the ensemble as the top-performing method across both subtasks.

ternal knowledge via the PubMed API to support retrieval-augmented generation (RAG). All augmentation tasks are run on a dual NVIDIA GeForce RTX 4090 GPU setup.

For fine-tuning, we use Gemini Flash 2.0 (Team et al., 2024), PubMedBERT (Gu et al., 2021), and ModernBERT (Warner et al., 2024). Models are trained on the augmented dataset for 200 epochs using an NVIDIA A100 and RTX 4090. The training is configured with a learning rate of 5e-5, a sequence length of 512, and a batch size of 90. This pipeline effectively combines LLM-based augmentation, retrieval-augmented generation, and fine-tuning to enhance data quality and downstream model performance.

4.2 Evaluation

We evaluate **Subtask 1** and **Subtask 2** using the *macro-averaged F1-score*. The macro-F1 for hazards, computed over all hazard classes $\mathcal{C}_h$, is:

$$F1_{\text{hazards}} = \frac{1}{|\mathcal{C}_h|} \sum_{c \in \mathcal{C}_h} \frac{2 \cdot P_c \cdot R_c}{P_c + R_c} \tag{6}$$

where P_c and R_c are the precision and recall for hazard class c, $|\mathcal{C}_h|$ represents the number of hazard classes, and $\mathcal{C}_h$ is the set of all hazard classes. For products, we compute F1 only on the subset S where hazard predictions are correct:

$$S = \left\{ i \mid y_h^{\text{pred}}(i) = y_h^{\text{true}}(i) \right\} \tag{7}$$

where i is a sample index, $y_h^{\text{pred}}(i)$ is the predicted hazard label, and $y_h^{\text{true}}(i)$ is the ground truth hazard label for sample i. The product macro-F1 over subset S is:

$$F1_{\text{products}} = \frac{1}{|\mathcal{C}_p|} \sum_{k \in \mathcal{C}_p} \frac{2 \cdot P_k^S \cdot R_k^S}{P_k^S + R_k^S} \tag{8}$$

where P_k^S and R_k^S are the precision and recall for product class k computed over subset S, $|\mathcal{C}_p|$ is the number of product classes, and $\mathcal{C}_p$ is the set of all product classes. The final score averages both F1 scores:

$$\text{Score} = \frac{F1_{\text{hazards}} + F1_{\text{products}}}{2} \tag{9}$$

This scoring emphasizes hazard prediction. Product outputs only count when hazards are correctly predicted. A perfect system scores 1.0, correct hazards but failed products score 0.5, and incorrect hazards result in a score of 0.0, regardless of product predictions.

5 Results

5.1 Overview of the SemEval-2025 Task 9

Table 2 presents the detailed leaderboard results. Out of more than 260 participating teams worldwide, 27 system description papers were submitted for peer review. The table highlights the rankings of the top 20 systems, showcasing the diverse approaches in the shared task [4].

The SemEval-2025 Task 9: The Food Hazard Detection Challenge attracted significant global attention, emphasizing the growing research interest in automated food hazard detection. The competition was organized into two independent subtasks. Our team, ***My My*** (**ST1:** 2nd, **ST2:** 2nd), achieved substantial and consistent results, ranking second in both Subtask 1 (score: 0.8112) and Subtask 2 (score: 0.5278).

Our approach demonstrated superior overall balance across the two subtasks compared to other top-performing teams. For instance, while **Anastasia** (**ST1:** 1st, **ST2:** 21st) ranked first in Subtask 1, their performance dropped significantly to 21st place in Subtask 2. Conversely, **SRCB** (**ST1:** 3rd, **ST2:** 1st) ranked first in Subtask 2 but only third in Subtask 1. In contrast, ***My My*** maintained top-tier performance across both tasks, indicating the robustness and adaptability of our system to varying task requirements and evaluation criteria.

[4] https://food-hazard-detection-semeval-2025.github.io/

5.2 Performance of Our Ensemble Approach

Our ensemble method, which combines Gemini Flash, PubMedBERT, and ModernBERT, consistently outperformed individual models across both Food Hazard Detection Challenge subtasks. As shown in Table 3, the ensemble achieved a Macro-F1 score of 0.8112 in Subtask 1, surpassing PubMedBERT's score of 0.7931, with strong F1-scores in both hazard-category (0.8032) and product-category (0.8193) classification. In Subtask 2, the ensemble recorded a Macro-F1 score of 0.5278, exceeding ModernBERT's score of 0.5151, and also achieved the highest F1-scores for hazard (0.6892) and product (0.3665) detection. These results demonstrate that the ensemble approach effectively balances precision and recall, particularly in the context of imbalanced and diverse food hazard datasets.

The advantage of ensembling lies in leveraging the complementary strengths of each model: PubMedBERT's biomedical expertise, ModernBERT's ability to handle long contexts, and Gemini Flash's efficiency and effectiveness when fine-tuned on short-text classification tasks. By aggregating predictions, the ensemble reduces the risk of individual model biases and improves robustness, especially for rare and underrepresented classes. Our system's consistent top-2 ranking in the SemEval-2025 Challenge across both subtasks further highlights this approach's practical value and reliability for real-world food safety applications.

5.3 Analysis

Our Knowledge-Augmented Data Method stands out for its balanced performance across both subtasks, demonstrating strong robustness. Unlike Team Anastasia (fixed token chunking and ensembling) or Team SRCB (two-stage DeBERTa+LLM pipeline), our approach leverages RAG with validation filtering to ensure high-quality augmentation. This streamlined pipeline addresses class imbalance and enhances representation for rare categories, leading to consistent results across hazard and product classifications.

As shown in Appendix D, our method achieves a more balanced distribution of underrepresented classes while maintaining competitive performance. The confusion matrices in Appendix C, which provide class-wise prediction breakdowns for both subtasks, show significantly reduced false negatives in rare hazard categories, confirming our system's effectiveness. These results underscore the scalability and practicality of our method for real-world food hazard detection tasks.

6 Conclusion

Our research demonstrates that a Knowledge-Augmented Data approach significantly improves the accuracy and reliability of food hazard detection. By integrating RAG with advanced data filtering, our system achieved top rankings in SemEval-2025 Task 9, showcasing the effectiveness of domain-specific knowledge in addressing data limitations. This highlights the potential of knowledge-driven AI to enhance food safety by rapidly and accurately identifying incidents from diverse online sources. Future work will optimize model efficiency for large-scale deployment and improve recall in product classification to maximize real-world impact. Importantly, our results underscore the value of explainability and transparency, which are essential for building trust and facilitating adoption in practical food safety applications.

7 Limitations

Although effective, our knowledge-augmented data approach has limitations. The retrieval process from external sources, such as PubMed, can occasionally return irrelevant or incorrect results, compromising data quality. Dependency on external knowledge also introduces latency, limiting real-time applicability. The validation filtering process may also exclude valuable samples below the scoring threshold, reducing dataset diversity. Finally, the ensemble method increases computational costs, making it less suitable for resource-constrained environments. Future work will improve retrieval accuracy, refine validation techniques, and optimize computational efficiency.

Acknowledgments

We sincerely thank the SemEval-2025 Task 9 Food Hazard Detection Challenge organizers for their valuable contributions and efforts. We also extend our gratitude to the broader SemEval community for fostering innovation in semantic evaluation and NLP research. Furthermore, we gratefully acknowledge the support of the Intelligent Information Retrieval Laboratory (IIR Lab) at National Cheng Kung University (NCKU).

A Knowledge-Augmented Data Algorithm

Algorithm 1 outlines the Knowledge-Augmented Data Method, enhancing food hazard detection

via document retrieval, LLM-based augmentation, quality filtering, and ensemble fine-tuning.

Algorithm 1 Knowledge-Augmented Data Method

Require: Food Hazard Dataset D
Ensure: Predictions $\hat{y}_{\text{Subtask1}}, \hat{y}_{\text{Subtask2}}$
▷ Step 1: Data Splitting
Split D into $D_{\text{train}}, D_{\text{val}}, D_{\text{test}}$
▷ Step 2: Knowledge-Augmented Data Generation
▷ *2.1 Information Retrieval System*
$Q_{\text{simple}} \leftarrow G_{\text{query}}(Q_{\text{complex}})$
$D_{\text{pubmed}} \leftarrow \text{RETRIEVEPUBMED}(Q_{\text{simple}}, K)$
$V_{\text{pubmed}} \leftarrow \text{Embed}(D_{\text{pubmed}})$ ▷ Convert to embeddings
VectorDB $\leftarrow \text{Store}(V_{\text{pubmed}})$ ▷ Store into vector database
$\text{sim}(v_{\text{original}}, v_d) \leftarrow \frac{v_{\text{original}} \cdot v_d}{\|v_{\text{original}}\| \|v_d\|}$ ▷ Compute similarity
$D_{\text{retrieved}} \leftarrow \{d_i \mid i \in \text{argmax}_K(\text{sim}(v_{\text{original}}, v_d))\}$ ▷ Retrieve top-K documents
▷ *2.2 Data Generation*
$S_{\text{augmented}} \leftarrow G_{\text{gen}}(D_{\text{retrieved}}, S_{\text{original}})$
▷ *2.3 Validation Filtering*
$S_{\text{filtered}} \leftarrow \{s \mid G_{\text{val}}(s, D_{\text{retrieved}}) \geq \tau\}$
▷ *2.4 Fine-tune with Enriched Data*
$D_{\text{final}} \leftarrow D_{\text{train}} \cup S_{\text{filtered}}$
▷ Step 3: Fine-tune Models
for $M \in$ {Gemini Flash, PubMedBERT, ModernBERT} **do**
  $M \leftarrow \text{FINETUNE}(D_{\text{final}}, M)$
end for
▷ Step 4: Inference
for $M \in$ {Gemini Flash, PubMedBERT, ModernBERT} **do**
  $P_{\text{task1},M} \leftarrow \text{INFERENCE}(D_{\text{test}}, M)$
  $P_{\text{task2},M} \leftarrow \text{INFERENCE}(D_{\text{test}}, M)$
end for
▷ Step 5: Ensemble Approach
$\hat{y}_{\text{Subtask1}} \leftarrow \arg\max_{y \in Y_1} \sum_i w_i P_{\text{task1},i}(y)$
$\hat{y}_{\text{Subtask2}} \leftarrow \arg\max_{y \in Y_2} \sum_i w_i P_{\text{task2},i}(y)$
return $\hat{y}_{\text{Subtask1}}, \hat{y}_{\text{Subtask2}}$

B Prompt Template

Prompt 1: Simple Query

Simplify verbose queries from the internet into concise ones while retaining essential terms.

Follow these rules:

1. Identify and retain all critical keywords, names, and technical terms.
2. Simplify the query to be concise and under 10 words.
3. Ensure the simplified query preserves the original meaning.

Example:

- **Verbose:** The Canadian Food Inspection Agency warns consumers about undeclared pecans in Originale Augustin Ice Cream in Quebec.
- **Simplified:** Undeclared pecans in Originale Augustin Ice Cream recall.

Task: Simplify the input query: {passage}, and output only the simplified query.

Prompt 2: Data Generation

You are tasked with paraphrasing the given passage to generate data for food hazard detection.

Follow these rules:

1. Retain critical information such as food product names, batch numbers, contamination types, and affected regions.
2. Ensure contextual accuracy: the paraphrase must be precise and align with the original context. Do not alter the meaning or factual content.
3. Highlight key hazards (e.g., contamination, undeclared allergens) and their potential risks to public health.

<context> {context} </context>

Here is your task: Given the input: {passage}

- Paraphrase it according to the rules above, ensuring the augmented text highlights key food hazards and is consistent with the context.
- Output only the paraphrased result, with no additional comments.

Prompt 3: Validation Filtering

You are tasked with evaluating paraphrased text as a form of data augmentation, using the following scoring system:

Scoring System:

- **0: The data augmentation result is the same as the reference text.**
- **1: The data augmentation result is completely unrelated to the reference text.**
- **2: The data augmentation result has minor relevance but does not align with the reference text.**
- **3: The data augmentation result has moderate relevance but contains inaccuracies.**
- **4: The data augmentation result aligns with the reference text but has minor errors or omissions.**
- **5: The data augmentation result is accurate and aligns perfectly with the reference text.**

Task:

- Given the original text: {original_text}
- Given the augmented text: {augmented_text}
- Evaluate the paraphrased text and assign a score from 0 to 5.

We designed three prompt templates to enhance food hazard detection: Simple Query (Prompt 1), Data Generation (Prompt 2), and Validation Filtering (Prompt 3).

Prompt 1: Simple Query condenses verbose queries while preserving key terms for effective

knowledge retrieval.

Prompt 2: Data Generation paraphrases data while maintaining critical details, improving dataset diversity, and addressing class imbalance.

Prompt 3: Validation Filtering evaluates augmented samples, retaining only high-quality data to ensure dataset integrity.

These prompts optimize retrieval, augmentation, and quality control, strengthening food hazard detection.

C Confusion Matrices

The confusion matrices in Figures 3 and 4 show that my method gives good results. Most predictions are along the diagonal, indicating high accuracy for both tasks. Misclassifications are limited and mainly between similar classes, demonstrating the approach's effectiveness. This pattern also suggests that the model can be generalized well even for underrepresented categories.

D Data Augmentation Pipeline Analysis

D.1 Addressing Class Imbalance

The Food Hazard Detection Dataset shows significant class imbalance across several categories, as illustrated in Figures 5, 6, 7, and 8. For example, Figure 8 reveals a highly skewed *product* distribution, with a few dominant classes and over 1,142 unique product types, most of which are underrepresented. Similarly, Figure 5 shows that certain hazard types disproportionately dominate the dataset.

The data augmentation pipeline effectively mitigates these imbalances, as shown by the more balanced distributions (in red). Underrepresented classes are significantly boosted in both *hazard-category* and *product-category*. In particular, Figure 8 highlights the improved balance post-augmentation, reducing the dominance of frequent classes and ensuring fairer representation. These adjustments are essential for enhancing model performance on rare but important categories.

D.2 Model Success Rates

Table 4 provides insights into the success rates of different models used in the augmentation pipeline. The success rate is calculated using the formula:

$$\text{Success Rate (\%)} = \frac{\text{Filtered}}{\text{Augmentation}} \times 100 \quad (10)$$

Method	Augmentation	Filtered	Success Rate (%)
Llama 3.1 8B	30,000	22,659	75.53
GPT 3.5 Turbo	8,000	6,500	81.25
Gemini Flash 2.0	6,800	5,625	82.72
Mixtral 8x7B	32,171	25,187	78.27

Table 4: Comparison of different language models in the data augmentation pipeline. The table presents the total number of augmented samples, the number of filtered samples that passed quality checks, and the overall success rate (%) for each model.

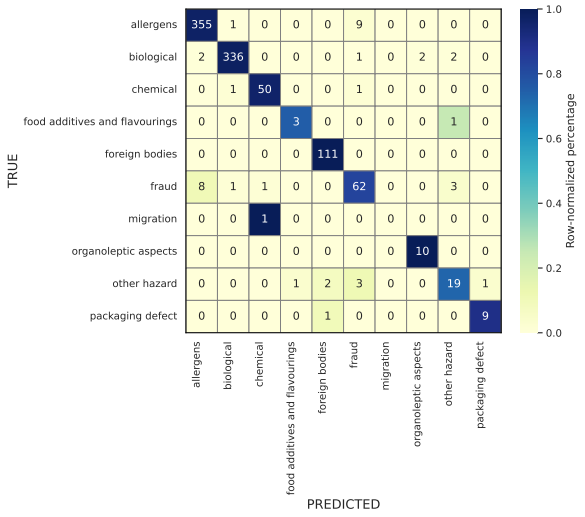

Figure 3: Confusion matrix for **hazard-category**. Each cell indicates the instances where the predicted label (columns) matches the true label (rows), with color intensity representing the row-normalized percentage.

For example, Llama 3.1 8B generated 30,000 samples with 22,659 passing quality checks, achieving a success rate of 75.53%. Similarly, Mixtral 8x7B produced 32,171 augmented samples with 25,187 filtered samples, resulting in a success rate of 78.27%. Smaller models like GPT 3.5 Turbo and Gemini Flash 2.0 generated fewer samples but achieved higher success rates of 81.25% and 82.72%, respectively.

These results highlight a trade-off between scale and filtering efficiency in augmentation. Larger models like Llama and Mixtral excel at generating high-volume data but have slightly lower success rates due to their broader scope. On the other hand, smaller models such as GPT and Gemini produce fewer samples but maintain higher precision during filtering. This balance between quantity and quality is crucial for optimizing data augmentation pipelines.

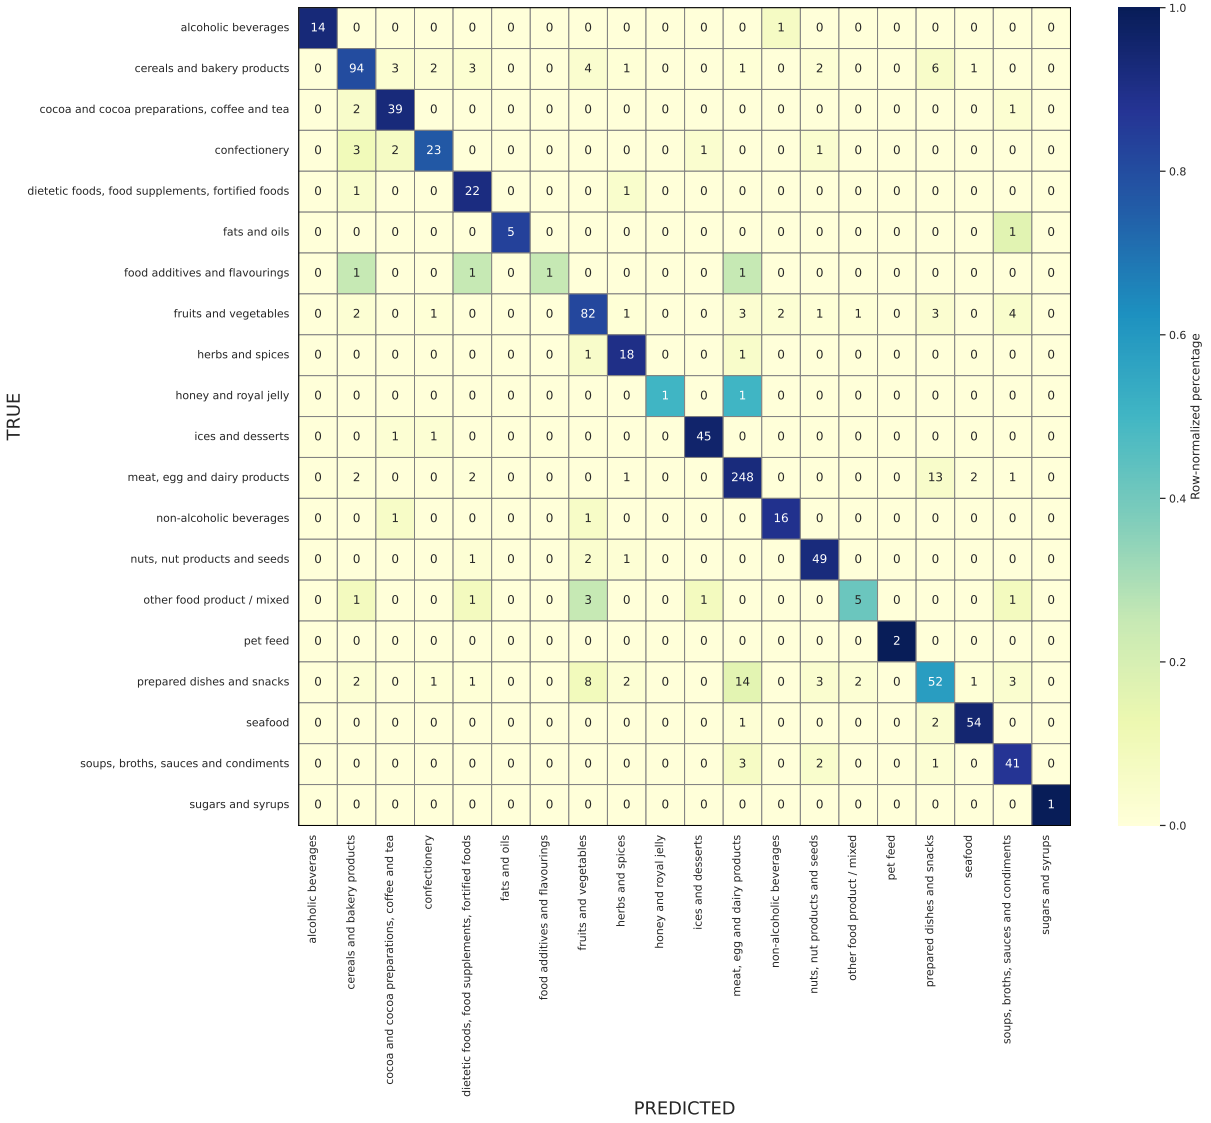

Figure 4: Confusion matrix for **product-category**. Each cell indicates the instances where the predicted label (columns) matches the true label (rows), with color intensity representing the row-normalized percentage.

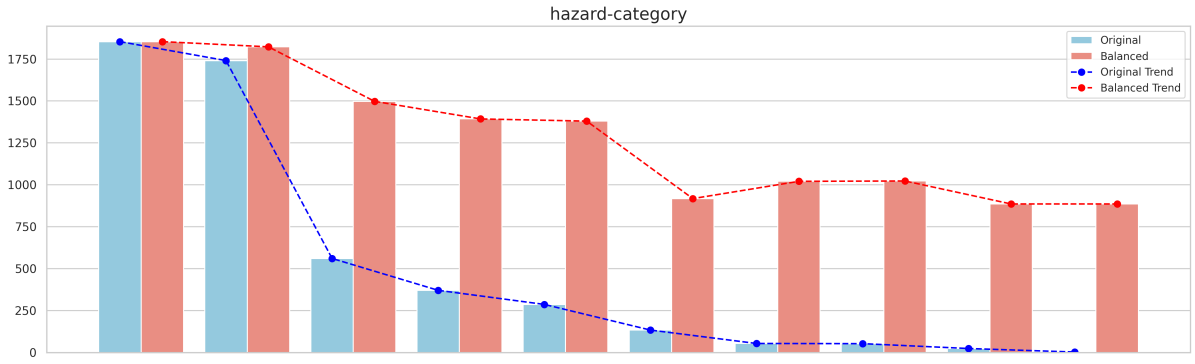

Figure 5: Comparison of **hazard-category** distributions before and after balancing.

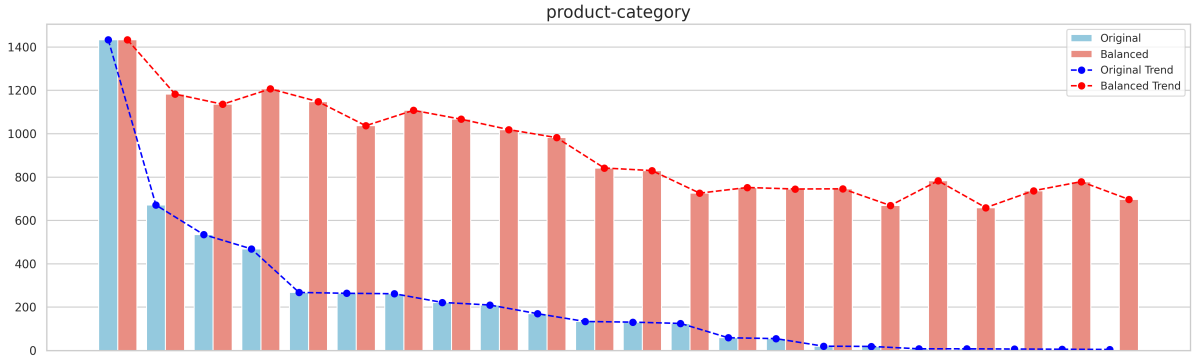

Figure 6: Comparison of **product-category** distributions before and after balancing.

Abstract

Emotion detection research has primarily focused on English, leaving a gap for low-resource languages. To address this, we present KReLaX, a multilingual ensemble model for multi-label emotion detection, combining three BERT-based encoders with a weighted voting layer. Within the shared task, our system performed well in multi-label classification, ranking 2nd in Tatar and achieving strong results in Hindi, Russian, Marathi, and Spanish. In emotion intensity classification, we achieved 4th place in Hausa and 5th for Amharic. While our system struggled in the zero-shot track, it achieved 7th place in Indonesian. These results highlight both the potential and the challenges of multilingual emotion detection, emphasizing the need for improved generalization in low-resource settings.

1 Introduction

Emotion detection goes beyond traditional sentiment analysis by interpreting the emotional tone, mood, or psychological state conveyed in an utterance. Emotions are multi-dimensional, context-dependent, and differ across cultures and individuals (Mohammad and Kiritchenko, 2018), making their interpretation in language challenging.

SemEval-2025 Task 11 (Muhammad et al., 2025b) focuses on perceived emotions—determining which emotions most people would attribute to a speaker given a short text. While significant progress has been made in emotion detection in high-resource languages, particularly English (De Bruyne, 2023), there remains a gap in resources and systems for low-resource languages.

To address this, the task encourages the development of multi-label emotion detection systems for underrepresented languages, spanning three tracks:

1. **Track A:** Multi-Label Emotion Detection - predicting multiple emotions per text.
2. **Track B:** Emotion Intensity Classification - predicting the intensity of each emotion.
3. **Track C:** Cross-Lingual Multi-Label Emotion Detection, testing generalization to unseen languages.

In this paper, we present our multilingual ensemble system, KReLaX,[1] developed for all three tracks. Our approach leverages cross-lingual transfer learning (Lin et al., 2019) to improve emotion detection in low-resource languages and applies data augmentation to improve robustness (Wei and Zou, 2019; Dai et al., 2023). Our system is a transformer-based ensemble model that combines multiple multilingual BERT variants with a weighted prediction layer. Prior work has shown that ensemble architectures can help mitigate bias and improve generalization in text classification tasks (Krishnan, 2023; Kumar et al., 2020).

We evaluate our system across all tracks, analyzing the impact of multilinguality, data augmentation, and ensemble learning on performance. Our results show strong performance in multi-label classification (ranking 3rd in Tatar) and emotion intensity classification (6th in Amharic and Hausa). However, zero-shot performance in Track C was challenging, highlighting the need for improved cross-lingual generalization.

2 Task Description

The focus of the task is on perceived emotions: determining which emotions most people would associate with a speaker based on a sentence or short text.

The BRIGHTER collection of emotion recognition datasets was created for the purposes of the task; it contains datasets for 28 languages, including many low-resource languages (Muhammad

[1]Github repository located at https://github.com/HJYnoDebug/KReLaX

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 823–833

et al., 2025a). Four additional languages were drawn from the EthioEmo dataset (Belay et al., 2025). A breakdown of the provided languages and datasets is shown in Table 4.

The training data for the task consists of small texts from various sources in 28 languages for track A, and 11 languages for track B; as track C concerns cross-lingual emotion detection, no training data is provided for this track. Each text is annotated as follows, depending on the task:

- **Track A & Track C (Multi-Label Emotion Detection):** Each emotion — anger, disgust, fear, joy, sadness, and surprise — is labeled as either present ("1") or absent ("0").
- **Track B (Emotion Intensity Classification):** Each emotion is labeled with an intensity score, ranging from 0 to 3.

Each text can have multiple emotion labels, resulting in label imbalance where certain emotions are underrepresented. To address this, we assume independence between emotion labels and approach the task as a series of binary classification problems.

2.1 Evaluation Metric

Track A and Track C are evaluated using the macro F1 score based on our predicted labels and the gold standard labels. The F1 score is the harmonic mean of Precision and Recall for a given class and ensures that model performance is evaluated fairly across all of the labels.

For track B the Pearson Correlation score is used, as it measures the linear relationship between the predicted emotion intensity score and the gold standard scores. This ensures that the models are evaluated based on how well they capture variations in the intensity rather than absolute accuracy.

2.2 Baseline Model

Task organizers provided a fully fine-tuned RemBERT (Chung et al., 2021) model as the baseline. For Tracks A and B, the model was trained and evaluated individually for each language. Class weighting was used in training for track A and C. For track C (Zero-Shot Cross-Lingual Emotion Detection), a family-based leave-one-out approach was used: the target language (i.e. the language being evaluated) was excluded from the training data while retaining other languages from the same family. Baseline results are included in tables 1, 2, and 3.

3 System Overview

Our system implements an ensemble learning approach, where multiple models make predictions, and final predictions are determined via a weighted soft voting layer to determine the final classification. The model architecture diagram is shown in Figure 1.

We fine-tuned three multilingual models in the BERT family - XLM-RoBERTa (Conneau et al., 2019), LaBSE (Wang et al., 2022), and RemBERT (Chung et al., 2021) on sequence classification. Each model was trained on all languages included in track A's training data, excluding Afrikaans due to the difficulty in handling the label alignment (the Afrikaans dataset only included 5 out of 6 emotions — the same was true for English, but we opted to still use the English data due to it being one of the larger datasets provided).

3.1 Stratified Cross-validation

We use stratified K-fold cross-validation (3 folds) to ensure that each fold maintains equal distribution of the labels. The model that performed best on validation data was then selected for final evaluation.

3.2 Class Weighting

To address class imbalance, class weights w_j were computed based on inverse class frequency. First, a scaling factor f_j is derived by dividing the total number of samples N by the product of the number of labels L and the sample count for class j, s_j, with a small smoothing term ϵ to prevent numerical instability:

$$f_j = \frac{N}{L \cdot s_j + \epsilon}, \quad j = 1, 2, \ldots, L. \tag{1}$$

Next, a clipping operation is applied to f_j to ensure that the computed class weights remain within a predefined range, preventing excessively large or small values that could destabilize training. Specifically, the final class weight w_j is constrained within the bounds defined by the lower and upper scaling factors l_b and u_b:

$$w_j = \text{clip}\Big(f_j,\ l_b\, f_j,\ u_b\, f_j\Big). \tag{2}$$

This approach balances the impact of different classes while maintaining numerical stability, thereby improving the robustness and generalization of the model during training.

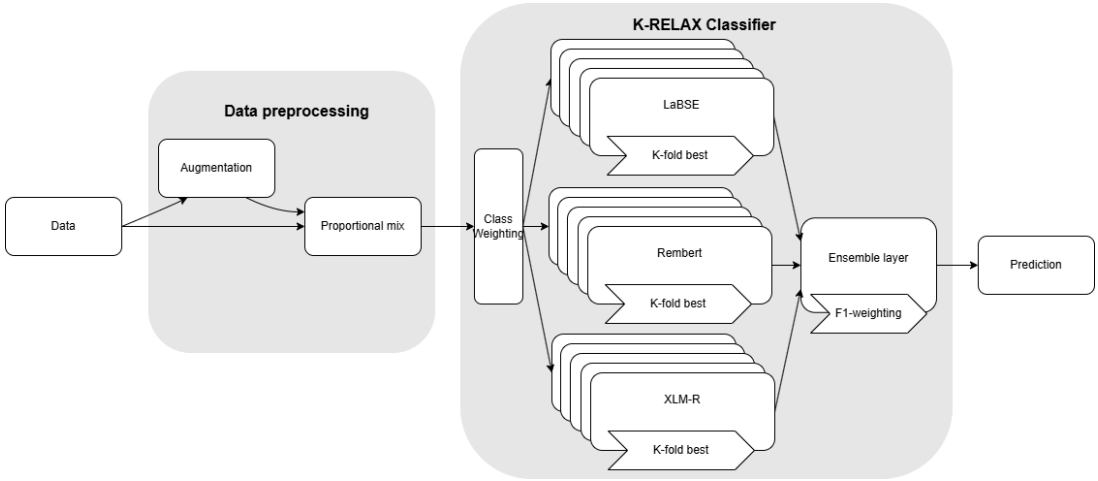

Figure 1: Diagram of the model architecture.

3.3 Classification head for track B

For track B, additional fine-tuning was done using a multi-label multi-class classification head. The model predicts multiple emotion labels per input, where each label has multiple discrete classes.

3.4 SF1-voting

The prediction layer uses a weighted voting system to allow the better performing models more influence over the final classification. The weight for each model is determined by squaring the average F1 score and using it to scale its predictions. By squaring the F1 score we amplify the difference between models in order to give higher performing models more weight and lessen the influence of the poor performing models. The final predictions are obtained by summing the weighted probabilities and normalizing them by the sum of the squared F1 scores as shown in the equation below:

$$\text{final\_probs}(c) = \frac{\sum_{i=1}^{N} (F1_i)^2 \cdot P_i(c)}{\sum_{i=1}^{N} (F1_i)^2} \quad (3)$$

$$\hat{y} = \arg\max_{c} \text{final\_probs}(c) \quad (4)$$

The average F1 score for each individual model is shown in Table 5 in the appendix.

4 Experimental Setup

Our system was fine-tuned on the combined training and development data for track A, excluding Afrikaans. Samples from the augmented data were randomly selected to be included in the training and validation data to balance the classes via stratified sampling, while keeping the proportion of augmented data below 20%. More information on our data augmentation techniques are included in the section below. The training and development datasets were combined and split into 3 proportional folds for cross validation.

We used the AdamW optimizer (Loshchilov and Hutter, 2019) with a learning rate of 1e-5, a batch size of 16 and a maximum sequence length of 128. Overall, 19.1% of the texts provided for the task were longer than this, with minimal variance across the training, development and test splits, but with large differences between languages (from 0.2% in Spanish to 57.5% in German). Text length seemed to have little effect on accuracy. The model was trained over 20 epochs using 3-fold cross validation with early stopping and a weight decay of .01.

We opted not to use augmented data for track B. This is because substitution and rephrasing may unintentionally affect emotional intensity, and we had no objective way to test for this effect.

4.1 Data Augmentation

We performed data augmentation using methods such as synonym replacement, random swap, back translation, and random deletion as used by Wei and Zou (2019). In the context of this task, random deletion may change the emotion detected in the sentence, and initial tests on back-translation did not lead to any measurable improvements, so we focused on synonym replacement and random swap.

We leveraged a multilingual LLM to generate rephrasings of the training texts as was done in Dai et al. (2023). Suzume-8b (Devine, 2024), a multilingual fine-tuned model based on Llama 3

(Grattafiori et al., 2024) was prompted using 3-shot prompting, an example of which can be found in A.1. The LLM-generated texts were additionally checked for similarity to the original text using the BERT score metric (Zhang et al., 2020). Only generated sentences given a BERT score greater than 70% were used. Augmented data for Amharic, Brazilian Portuguese, English, German, Russian, Somali, Sudanese, and Tigrinya were generated by the LLM.

5 Results

The following sections detail our results in each track. Each model was fine-tuned on the collated training data for track A, which consisted of the languages listed in Table 4, excluding Afrikaans.

5.1 Track A

Our system achieved an average F1 score of .636 across the 24 languages in Track A that we made a submission for, as seen in Table 1. A more detailed breakdown of scores by emotion can be seen in the appendix, in Table 7.

The best overall performance was seen in Hindi, Russian, Marathi, Tatar, and Spanish. Excluding Tatar, where a drop in performance was observed for disgust, our system showed a balanced performance in classification across each emotion. The highest ranking achieved in the task was 2nd place in Tatar.

Across languages, our system was able to consistently detect Joy and Sadness, perhaps due to the larger presence of these emotions across the dataset. Fear, Disgust and Surprise were frequently underrepresented across the dataset, which would support our observations that these emotions were difficult to detect. These emotions may also rely on context and subtle cues that may vary across cultures or languages, making it difficult for the models to generalize cross-linguistically.

5.2 Track B

For emotional intensity classification, our system reached an overall average Pearson correlation score of .6724. As shown in Table 2, our model performed best with classifying Russian, Spanish and Amharic, securing a 5th place ranking in Amharic, 4th place in Hausa, and 6th place in Russian. Detailed scores for each emotion are shown in Table 8 in the appendix.

The most consistent performance across emotions was seen in Russian. Among the emotions,

UKR	.3994	.5608	8

Table 2: Pearson r scores by language in Track B emotion intensity classification.

Joy was the most consistently detected, with strong correlations scores across multiple languages. In contrast, our model struggled to accurately predict the intensity of Surprise, likely due to its low representation in the dataset.

5.3 Track C

Only five of the languages included in the task were not used in training our model; therefore in track C we only submitted results for these five languages, shown in Table 3. Our system faced challenges in zero-shot classification for low-resource languages; the highest-performing language was Indonesian, with a macro F1 score of .5077, ranking 7th. Detailed results are shown in the appendix in Table 9.

The lower performance in isiZulu and isiXhosa could be attributed to their typological differences from the languages included in the training data. In contrast, Indonesian and Javanese may have benefited from the inclusion of Sundanese in the training data, and Afrikaans with German, as they are classified into similar typological language families. Indonesian classification may also have benefited from the large number of loanwords Indonesian has taken from languages such as Hindi, Portuguese, and English (Tadmor, 2009). However, further investigation is needed to determine the extent of language similarity effects on model performance.

6 Conclusion

Using an ensemble method and data augmentation, we developed an emotion classification system that performs well across multiple languages. Our system achieved strong results in Track A, particularly

Language	Baseline	F1 Score	Rank
AFR	.3504	0.3132	10
IND	.3764	**0.5077**	7
JAV	.4638	0.3473	9
XHO	.1273	0.1075	8
ZUL	.1526	0.1309	8

Table 3: The macro F1 score per language for zero-shot emotion classification. The best performing language is in bold.

in Hindi, Russian, Marathi, Spanish, and Tatar, and showed competitive performance in Track B for Amharic, Hausa, and Russian. However, Track B posed greater challenges as the data augmentation methods we used in Track A were not directly applicable to emotion intensity classification. Future work could explore alternative augmentation strategies to preserve intensity information.

Our results in Track C highlight the difficulties of zero-shot classification, particularly for low-resource languages and languages with typological differences from the training data. Performance on unseen languages appears to be influenced by linguistic similarity to training languages, suggesting that further cross-lingual generalization techniques could improve robustness.

Potential future improvements include addressing the label misalignment, experimenting with decoder-based architectures, and refining data augmentation techniques for enhancing both emotion intensity predictions and generalization to unseen languages.

7 Ethical Considerations

With any emotion detection system, there exists a risk that it may be used for harmful purposes, such as governments monitoring social media for negative attitudes in order to target dissidents, or predatory marketing targeting people in a vulnerable emotional state (Mohammad, 2022).

Bias in emotion classification is another challenge, as emotions vary across cultures and languages. Models trained on skewed datasets risk misclassifying or marginalizing underrepresented groups (Janyce Wiebe and Cardie, 2005; Mohammad, 2023; Woensel and Nevil, 2019; De Bruyne, 2023). To mitigate this, transparency in data sources, biases, and limitations are essential to ensuring responsible and fair deployment.

Acknowledgments

We thank the SemEval-2025 Task 11 organizers for their time and efforts in preparing the data and organizing the event so it could run smoothly.

We would also like to thank Çağrı Çöltekin for his encouragement and advice throughout all stages of the task.

College of Data Science[2]
Qingdao University of Science and Technology, China

Abstract

This paper describes the participation of QUST_NLP in the SemEval-2025 Task 7. We propose a three-stage retrieval framework specifically designed for fact-checked claim retrieval. Initially, we evaluate the performance of several retrieval models and select the one that yields the best results for candidate retrieval. Next, we employ multiple re-ranking models to enhance the candidate results, with each model selecting the Top-10 outcomes. In the final stage, we utilize weighted voting to determine the final retrieval outcomes. Our approach achieved 5th place in the monolingual track and 7th place in the crosslingual track. We release our system code at: https://github.com/warmth27/SemEval2025_Task7.

1 Introduction

SemEval-2025 Shared Task 7 focuses on the retrieval of monolingual and crosslingual fact-checked claims, aiming to tackle the global challenge of misinformation spread (Peng et al., 2025).

We engaged in two tracks of the SemEval-2025 Shared Task 7: monolingual and crosslingual. The monolingual track demands methods capable of retrieving the relationship between social media posts and fact-checked claims within the same linguistic environment. This task presents challenges such as noise arising from the large volume of data and difficulties related to the imbalance of language resources (Xu et al., 2024b). The crosslingual track requires methods that can retrieve fact-checked claims related to social media posts regardless of whether the language of the post matches the language of the related fact-checked claim. The primary challenge in crosslingual retrieval lies in translation inconsistencies, particulaedrly for low-resource languages (Qi et al., 2023; Magueresse et al., 2020). The absence of high-quality translation tools exacerbates the complexity of achieving accurate crosslingual semantic alignment.

To tackle the aforementioned challenges, we propose a three-stage retrieval framework. Initially, we evaluate and employ several pre-trained language models for preliminary retrieval of candidate results (Gao et al., 2024; Huang et al., 2024a), thereby mitigating the noise caused by the large data volume and alleviating the adverse effects of language resource imbalance. Subsequently, a re-ranking model is applied to refine the ranking of the candidate results, enhancing the position of fact-checked claims most relevant to the social media posts. For the crosslingual retrieval task, we utilize machine-translated data for preliminary retrieval, followed by ranking the results using a re-ranking model fine-tuned with English data. Finally, a weighted voting strategy is employed to combine the outputs from multiple re-ranking models, further enhancing the system's accuracy.

Our approach achieved 5th place in the monolingual track and 7th place in the crosslingual track, thereby validating its effectiveness and feasibility in addressing the aforementioned challenges.

2 System Description

Our approach utilizes a three-stage retrieval framework: Retrieval stage, Re-ranking stage, and Weighted Voting stage. This staged design excels at balancing retrieval efficiency and accuracy, making it particularly suitable for handling large-scale datasets. By generating candidate results during the initial retrieval stage, fine-tuning them during the re-ranking phase, and finally aggregating predictions from multiple models in the weighted voting stage, we are able to obtain the final solution. The detailed process is shown in Figure 1.

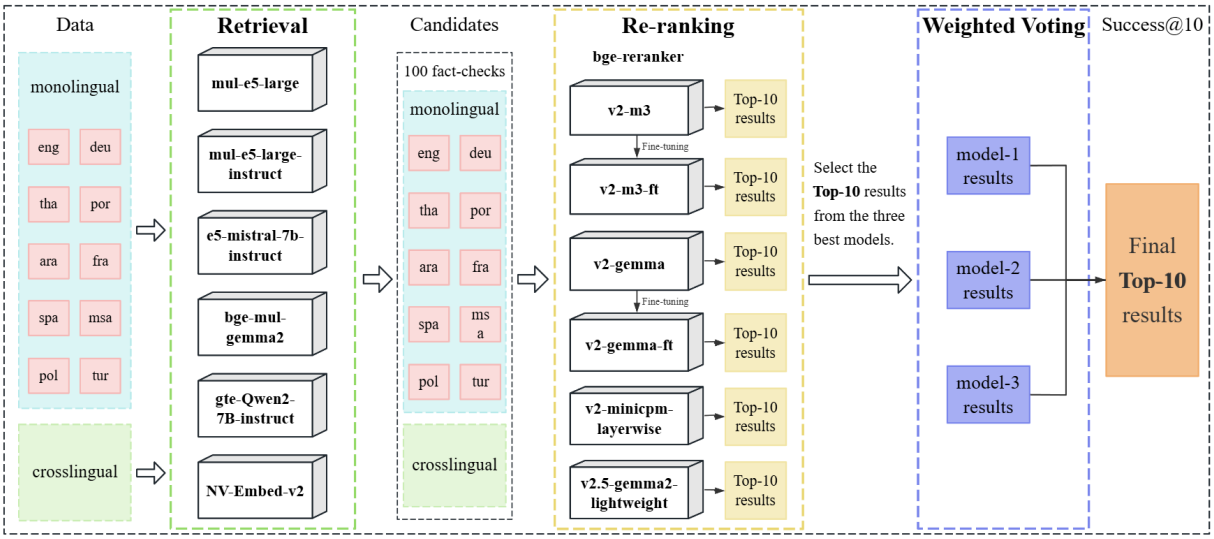

Figure 1: Illustration of the overall workflow in this paper.

2.1 Retrieval Stage

The retrieval model calculates the similarity between the query and the documents, ranking them from most to least relevant based on their similarity. This aids in filtering out a subset of candidate data from a large pool of fact-checked claims, thereby reducing noise. Accordingly, we compare several pre-trained retrieval models and employ the top-performing models in each language to retrieve candidate fact-checked claims.

The key advantage of this strategy lies in significantly reducing the computational complexity of the subsequent re-ranking phase, effectively minimizing the noise caused by the large volume of candidate fact-checked claims by pre-generating the results. The choice of the number of candidate results ensures breadth while avoiding irrelevant information, providing sufficient diversity and selection space for the re-ranking phase, thus ensuring that the final output maintains high relevance.

2.2 Re-ranking Stage

The re-ranking model can make a more refined evaluation of the results of the initial retrieval stage, put the most relevant claims at the front, and further improve the accuracy of retrieval. Therefore, we select a series of re-ranking models and fine-tuning them using the data from the training set, training a set of re-ranking models for each language (Jiang, 2023). Additionally, we combine a re-ranking model with larger parameters to re-rank the 100 candidate results generated in the initial retrieval stage. Through more precise evaluation, we improve the ranking of the most relevant fact-checked claims related to the input social media posts, thereby optimizing the retrieval results.

2.3 Weighted Voting Stage

The weighted voting strategy combines the strengths of different models through weighted fusion, minimizing the potential biases and errors inherent in individual models (Wang et al., 2023b). Therefore, we adopt the weighted voting strategy to integrate the predictions of the re-ranking models. The weight of each re-ranking model is assigned based on its performance on the validation set, with better-performing models receiving higher weights. This ensemble method leverages the strengths of multiple models, synthesizing their predictions to produce more accurate top 10 (Top-10) results. For the crosslingual task, we apply the same strategy.

3 Experimental Setup

3.1 Data

Following the guidelines, we partitioned the original dataset into both monolingual and crosslingual train and development (dev) datasets (Pikuliak et al., 2023). For the monolingual data, we further categorize it by language, producing separate sub-train and sub-dev datasets for eight languages. The data statistics are presented in Appendix A

3.2 Preprocessing

In the data preprocessing phase, we transform the CSV file into JSON format, utilize regular expressions to extract key fields containing the original text and its translation, such as "ocr", "text", "title",

and "claim", and separate them into original text, translated text, and language identifiers. Missing values (NaN) are consistently marked as null, and all text data is encoded in UTF-8 format.

3.3 Evaluation Metrics

The task employs Success@10 (S@10) as the primary evaluation metric. Specifically, when multiple correct fact-checked claims are present, the task is deemed successful if any one of the correct results appears on the Top-10 list, allowing the social media post to receive a score.

4 Experiments and Results

4.1 Retrieval

Monolingual During the development phase, we conduct systematic experiments to confirm the effectiveness of the multilingual feature combination strategy. As shown in Table 1, the combination of the original text (O) and the machine translated text (T) improves the S@10 score of the model, which means that the combination of the original text and the translated text (O, T) can improve the performance of the model on monolingual retrieval tasks (Muennighoff et al., 2022). The introduction of the translated text can help the model better understand the content of the original text, thereby improving the retrieval accuracy, especially when dealing with complex or ambiguous expressions.

Building upon the combined input of the original text and the translation, we further incorporate the "verdicts" field (V). The experimental results reveal that for several languages (Spanish, Portuguese, Malay, and Thai), the scores decrease by about 2% after including the "verdicts" field. However, the scores for English, French, and Arabic improve after incorporating the "verdicts" field, with Arabic showing an increase of approximately 5%. This suggests that in specific languages, the "verdicts" field can offer valuable supplementary information, aiding in the enhancement of retrieval accuracy.

Simultaneously, we compare the performance of several retrieval models, including mul-e5-large (Wang et al., 2024), mul-e5-large-instruct, e5-mistral-7b-instruct (Wang et al., 2023a), bge-mul-gemma2 (Xiao et al., 2023), NV-Embed-v2 (Lee et al., 2024), and gte-Qwen2-7B-instruct[1] (Li et al., 2023). As shown in Table 1, the experimental results demonstrate that e5-mistral-7b-instruct achieves the best performance in eng (85.98%), spa (91.21%), deu (80.72%), por (88.41%), fra (93.61%) and tha (97.61%), while bge-mul-gemma2 performs better in msa (91.42%) and mul-e5-large-instruct achieves the highest score in ara (89.74%). This indicates that different retrieval models exhibit specific advantages or limitations depending on the language.

Crosslingual In the crosslingual task, we compare the performance of multiple retrieval models. The results shown in Table 2 demonstrate that the effect of using pure translation input is better than mixed input (combining original and translated text) and pure original text input. Among them, e5-mistral-7b-instruct performs the best, with S@10 reaching 72.64%. In crosslingual retrieval, the semantic expression of the translation is more consistent and accurate, thereby improving retrieval performance. On the contrary, combining the original and translated text or using pure original text input may introduce noise due to language differences, resulting in reduced retrieval performance. This further highlights the key role of translation consistency in crosslingual semantic matching.

4.2 Re-ranking

We utilize the models that performe well during the retrieval phase to extract 100 fact-checked claims as candidate data from the sub-dev sets of each language. Subsequently, we employ re-ranking models from the BAAI/bge-reranker[2] series to reorder the candidate data and derive the Top-10 as the re-ranking results.

Monolingual The experimental results in Table 3 demonstrate that v2.5-gemma2-lightweight outperforms the other models, achieving an S@10 score of 92.74%. In comparison, v2-minicpm-layerwise and v2-m3 (Chen et al., 2024) exhibit weaker performance. This outcome can be attributed to the disparities in model parameters. v2.5-gemma2-lightweight benefits from a larger parameter size and enhanced learning capability, enabling it to capture semantic information more efficiently. Conversely, v2-minicpm-layerwise and v2-m3 have relatively smaller parameter sizes, which hinder their ability to handle complex retrieval tasks, likely contributing to their suboptimal performance.

We experiment with applying the rerank model directly to reorder Arabic (ara) data, resulting in an S@10 score of 85.89% . In comparison to us-

ing the retrieval model alone, the rerank model does not demonstrate a clear advantage and introduces additional computational costs. This implies that relying exclusively on the rerank model does not fully utilize the system's overall performance, and combining the retrieval model with the rerank model is clearly the more effective strategy.

Additionally, we conduct fine-tuning on the complete training set for the v2-m3 and v2-gemma models. The experimental results reveal that the fine-tuned models demonstrate a significant improvement, with gains of 19.74% and 2.17% over the original models, respectively. Remarkably, the fine-tuned v2-gemma outperforms the larger parameter model v2.5-gemma2-lightweight, which provides strong evidence of the effectiveness of fine-tuning the rerank model.

Crosslingual In crosslingual, we fine-tuning the v2-m3 and v2-gemma models using the translation data in the crosslingual training set and compare them with v2-gemma and v2.5-gemma2-lightweight (Cui et al., 2025). Considering that the performance is better when only English translation data is used in crosslingual tasks, we also add a comparison with two models (v2-m3 and v2-gemma) fine-tuned on the English monolingual training set. The experimental results show that the v2.5-gemma2-lightweight model performs best with an S@10 of 80.25%, while the model fine-tuned on crosslingual data performs worse than the model fine-tuned on English monolingual data. We speculate that this difference may be attributed to the quality of the translations in the crosslingual training set, which may affect the language representation learned by the model, resulting in poor crosslingual matching performance.

4.3 Weighted Voting

Finally, we employ a weighted voting ensemble strategy to integrate the results of the monolingual and cross-lingual re-ranking models in Table 3 and Table 4. Experimental results demonstrate that the S@10 scores after integration are equal to or exceed those of the individual re-ranking models in all languages. The average of monolingual S@10 is 1.41% higher than that of the highest re-ranking model, and the crosslingual S@10 is 3.8% higher than that of the highest re-ranking model.

4.4 Evaluation on the Test Set

Test Data Augmentation For the newly introduced Polish (pol) and Turkish (tur) in the test set, we translate the original text from training set data in other languages into pol for data augmenta-

Model	Avg
v2-m3-ft(cross)	76.44
v2-m3-ft(eng)	79.16
v2-gemma	75.72
v2-gemma-ft(cross)	78.62
v2-gemma-ft(eng)	79.34
v2.5-gemma2-lightweight	**80.25**
Voting	84.05

Table 4: The results of the re-ranking model in the crosslingual track. The (cross) indicates the model fine-tuned using the crosslingual training set data, and the (eng) indicates the model fine-tuned utilizing the English monolingual training set data. **Bold** indicates the S@10 score (%) of the best re-ranking model. **Voting** is the result of the third-stage weighted voting.

tion and to fine-tune the re-ranking model (Huang et al., 2024b; Xu et al., 2024a). The results reveal that the S@10 score of the re-ranking model v2-m3, fine-tuned using the data augmentation method on Polish, is 83.2%, while the v2-gemma model achieved a score of 85.4%. Both scores are lower than the 88.6% score obtained by directly using the re-ranking model with a larger parameter size.

Furthermore, for Portuguese (por), which exhibited relatively low scores during the test phase, we aimed to augment the data by translating training data from other languages into Portuguese (Hangya et al., 2022). The experiment showed that models fine-tuned with the augmented training data achieved an S@10 score of 87.2% for Portuguese, representing a 1.4% decrease compared to the previous models and falling short of the anticipated improvement.

This suggests that while translated data can enhance the dataset's diversity, the translation process may introduce semantic distortions and information loss. The meaning and context of the original text may not be entirely preserved, leading to issues like translation inconsistency and data mismatch, which prevent the model from benefiting from the augmented training data.

Official Test Results In the final test phase, based on the official evaluation metric S@10, our approach achieved the highest score of 93.64% in the monolingual track, securing the 5th place (5/28). In the crosslingual track, our best score was 79.25%, ranking 7th (7/29), further validating the effectiveness of our method. The scores of each language are shown in Table 5.

Mono_Avg	eng	fra	deu	por	spa
93.65	89.40	95.00	90.20	89.00	94.80

5 Conclusion and Limitation

This paper introduces a monolingual and crosslingual fact-checked claim retrieval method utilizing a three-stage retrieval framework. By integrating retrieval models, re-ranking models, and weighted voting, we effectively address challenges such as data noise and imbalanced language resources. Our findings suggest that employing a mixed input strategy markedly enhances retrieval performance, while fine-tuning further optimizes re-ranking efficacy. Our method achieved 5th place in the monolingual track and 7th place in the crosslingual track.

We acknowledge that our method has limitations in terms of translation consistency and quality. Future work will focus on enhancing translation quality and refine model fine-tuning strategies to overcome these challenges.

Abstract

We present the system developed by the Central China Normal University (CCNU) team for the SemEval-2025 shared task 8, which focuses on Question-Answering (QA) for tabular data. Our approach leverages multiple Large Language Models (LLMs), conducting tabular QA as code completion. Additionally, to improve its reliability, we introduce a two-stage corrections mechanism, in which we instruct the LLM to correct the code according to the judges of whether the code is executable and whether the answer obtained from executing the code is semantically consistent with the question. The experiment demonstrates that code correction works but answer correction does not. Finally, we discuss other unsuccessful approaches explored during our development process.

1 Introduction

Large language models (LLMs) have demonstrated strong performance in question answering (QA) tasks (Kamalloo et al., 2023; Mao et al., 2024), including tabular QA (Chen, 2023), where inputs consist of non-database tables. To systematically evaluate the performance of LLMs on tabular QA, Grijalba et al. (2024) introduced DataBench, a benchmark comprising a diverse collection of tabular datasets spanning various domains and question types.

Unfortunately, as noted in the evaluations by Grijalba et al. (2024), LLMs remain unreliable for tabular QA, with substantial room for improvement across all question types and domains. To address this challenge, Os'es Grijalba et al. (2025) organized SemEval-2025 Task 8, based on the DataBench benchmark, to investigate the capability limits of LLMs in tabular QA. This paper presents the solution developed by the Central China Normal University (CCNU) team.

Interestingly, the evaluations by Grijalba et al. (2024) revealed that framing tabular QA as a code completion task can significantly enhance the performance of large language models (LLMs) compared to directly answering questions. Specifically, instead of providing the entire input table, they only exposed the LLM to its meta-information (e.g., column names) and instructed it to generate a Python function that computes the answer to the given question.

As discussed in Grijalba et al. (2024), one limitation of framing QA as code completion is the reliance on a third actor—the Python interpreter—introducing multiple steps in the QA process, each of which can introduce errors. Specifically: (1) The code generated by LLMs may contain errors, leading the Python interpreter to return error messages instead of valid answers. In the evaluations by Grijalba et al. (2024), many incorrect responses were not actually undesired answers but rather error messages. (2) Since LLMs in this paradigm generate code without directly accessing the final outputs their code produces, the answers may be semantically irrelevant to the question. This issue arises because LLMs cannot inherently ensure that the generated answers match the expected type or format of the question.

Our solution builds upon the concept of QA as code completion while specifically addressing the two inherent issues mentioned earlier. To achieve this, we introduce *Two-Stage Corrections*. In the first stage, beyond simply generating code, our approach instructs LLMs to refine their output by incorporating corrections based on error messages from the Python interpreter. In the second stage, LLMs are prompted to verify whether the results obtained from executing the code are semantically consistent with the given questions.

In the following sections, we provide a detailed introduction to the DataBench benchmark (Section 2) and our proposed solution (Section 3). We then

Type	Example
boolean	True/False, Y/N, Yes/No
category	apple
number	10, 20, 30
list[category]	[apple, orange, banana]
list[number]	[1,2,3]

Table 1: Types of QA pairs in DataBench.

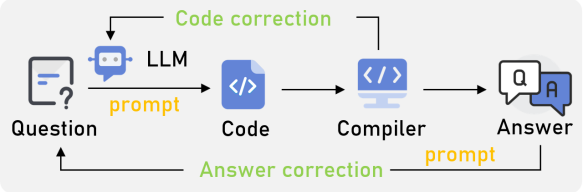

Figure 1: Overview of two-stage corrections for table QA as code completion.

analyze the effectiveness of our Two-Stage Corrections (Section 4). While our results indicate that code correction is successful, answer correction falls short—likely due to the limitations of LLMs in accurately evaluating semantic consistency. Finally, we discuss other unsuccessful approaches we explored during this shared task (Section 5) and reflect on our key findings.

2 Task Description

SemEval-2025 Task 8 is built upon the DataBench benchmark. DataBench consists of 65 tabular datasets from various domains (Grijalba et al., 2024). For each dataset, they hired human participants to write 20 questions, which resulted in 1,300 questions in total. To further improve diversity, it was ensured that the collected questions covered 5 different question types, including *boolean, category, list[category], and list[number]*, as shown in Table 1.

Additionally, Grijalba et al. (2024) also compiled a reduced version of DataBench with an aim of evaluating LLMs that are unable to process large tables, namely, DataBench Lite. Specifically, for each table in each dataset in DataBench, DataBench Lite uses only the first 20 rows.

3 Methodology

As mentioned earlier, we follow Grijalba et al. (2024) in formulating tabular QA as code completion and introduce a Two-Stage Corrections mechanism to address errors arising in the two key stages of this approach: code completion and code execution. This mechanism consists of code correction and answer correction, which aim to improve the reliability of generated solutions. An overview of our method is illustrated in Figure 1. In this section, we first describe how we incorporate the approach of Grijalba et al. (2024) into our solution for tabular QA, followed by a detailed explanation of the Two-Stage Corrections mechanism.

Previous error: {error_message} **Please correct the following code**: {code}

Table 2: Prompt for Code Correction

3.1 Question Answering as Code Completion

Following Grijalba et al. (2024), we came up with the prompt shown in Listing 1 for Tabular QA as code completion.

Listing 1: Prompt for QA as Code Completion

```
# Task Description:
# 1. Determine the type of the answer,
    which should belong to one of the
    following five types: boolean,
    category, number, list[category],
    list[number].
# 2. After determining the type,
    complete the following function in
    one line to answer the question.
# 3. Please specify the type as a
    comment before the code, for example
    : # Type: number

# Question: {question}
# Dataset columns: {columns}
def answer(df: pd.DataFrame):
    df.columns = {columns}
    return
```

The prompt begins with several lines of comments that define the task the LLM needs to accomplish. Specifically, it instructs the LLM to generate a single line of code based on the given question and the meta-information of the table. To enhance the model's awareness of the question type, we introduce a modification to the approach of Grijalba et al. (2024) by adding an extra comment line that asks the LLM to explicitly specify the question type as a line of comment before completing the code. The prompt concludes with the beginning of a function definition, leaving the final line for the LLM to complete. Once generated, the completed code is executed in a Python interpreter to produce the final answer.

Main Task: As a professional data analyst, your task is to determine if the generated answer is correct based on the provided tabular knowledge and question. Correctness is defined as: the answer is completely consistent with the tabular knowledge and accurately answers the question.
Judgment Criteria:

1. If the generated answer is completely consistent with the factual content in the tabular data and directly answers the question, it is judged as "Correct".
2. If the generated answer is inconsistent with the tabular data or the requirements of the question, whether it is a partial error or a logical error, it should be judged as "Incorrect".

Reasoning Requirements: As an expert, you need to provide a step-by-step reasoning process, explaining how to extract relevant information from the tabular knowledge and verify the generated answer. The reasoning process should include the following:

- Identify the source of information in the table that is relevant to the question.
- Explain how this information supports or refutes the generated answer.
- Compare the differences between the generated answer and the tabular data, and explain the reasons for the judgment.

Output Format:

- **Correctness Judgment:** [Correct/Incorrect]
- **Reasoning Process:** Detailed reasoning process, explaining whether the answer is correct and the reasons for it.

Example:
Input:
{example}
Current Input:
Tabular Knowledge: {table_knowledge}
Question: {question}
Generated Answer: {generated_answer}

Table 3: Prompt for judging the correctness of an answer.

3.2 Two-Stage Corrections

After obtaining the code, we perform our two-stage corrections: before and after the Python interpreter successfully generates the final output.

3.2.1 Code Correction

If the code contains errors, which often occur due to the LLM's misinterpretation of the tabular structure, the interpreter returns an error message instead of a valid output. To correct the code, we prompt the LLM to revise its own code based on the error message, using the instruction provided in Table 2.

3.2.2 Answer Correction

To verify whether the answers generated from successfully executed code are semantically consistent with the given questions, we employ two strategies: (1) Direct Answer Evaluation: We instruct another LLM to assess whether the answer is correct or incorrect based on the given question and table, using the prompt in Table 3. Instead of providing a simple yes or no, the LLM is also required to explain the reasoning behind its judgment. (2) Answer Type Consistency Check: Since determining the correctness of an answer may be too challenging for LLMs, an alternative approach is to evaluate whether the type of the generated answer aligns with the expected question type, using the prompt in Table 4. Finally, the LLM receives both judgment and explanation, which it then uses to refine and regenerate the code accordingly.

Analyze the following question and determine the expected answer type:

Question: {question}
Possible types:

- *boolean*: yes/no questions.
- *number*: questions requiring numeric answers.
- *list[number]*: questions requiring a list of numbers.
- *list[category]*: questions requiring a list of categories, where categories can include date (e.g., 1970-01-01), text, or url.
- *category*: questions requiring a single category, which can be a date, text, url, or other categorical value.

Return only the type name, nothing else.

Table 4: Prompt for judging the correctness of an answer's type.

4 Experiments

In this section, we start with introducing the backbone LLMs we used in our experiments and report the experimental results.

4.1 Backbone LLMs.

In our experiments, we tried a range of open-sourced LLMs as backbone models. Specifically, the models included Code Llama (Rozière et al., 2023), Qwen2.5-72B-Instruct (Hui et al., 2024), Llama-3-1-8B (Touvron et al., 2023), DeepSeek-Coder-6.7B-Instruct (Guo et al., 2024), DeepSeek-V3 (DeepSeek-AI, 2024), Qwen2.5-72B-Instruct (Team, 2024), and DeepSeek-

Model	w/o CC	w/ CC
Code Llama	20.31	19.38
Qwen2.5-Coder-7B	67.50	68.44
Llama-3-1-8B	66.25	64.69
DeepSeek-Coder-6.7B	72.19	74.38
DeepSeek-V3	80.31	83.44
Qwen2.5-72B	82.81	85.00
DeepSeek-R1 (w/o Think)	79.69	85.00

Table 5: Results of different backbone LLMs with and without Code Correction (CC) on the development set of DataBench.

Model	w/o CC	w/ CC
Code Llama	19.68	17.81
Qwen2.5-Coder-7B	67.19	69.69
Llama-3-1-8B	61.88	64.06
DeepSeek-Coder-6.7B	71.88	72.50
DeepSeek-V3	80.62	82.19
Qwen2.5-72B	81.56	85.31
DeepSeek-R1 (w/o Think)	72.81	85.72

Table 6: Results of different backbone LLMs with and without Code Correction (CC) on the development set of DataBench Lite.

R1 (DeepSeek-AI, 2025). For DeepSeek-R1, we did not enforce it to "think", which may limit its reasoning ability (making it often work in the same way as DeepSeek-V3) but makes its outputs more straightforward and easier to use in subsequent processing steps.

4.2 The Effect of Code Correction

Table 3 and Table 4 present the performance of various LLMs, with and without code correction, on DataBench and DataBench Lite, respectively. The results indicate that code correction improves the performance of nearly all backbone LLMs across both datasets, demonstrating its effectiveness.

When comparing different backbone LLMs, we find that DeepSeek-R1 (without Think) with code correction achieves the highest performance on both datasets.

4.3 The Effect of Answer Correction

To assess the effectiveness of answer correction, we evaluated the accuracy of two judgment tasks: determining the correctness of answers using the prompt in Table 3 and verifying the correctness of answer types using the prompt in Table 4. An experiment using LLaMA-3.1-8B-Instruct as the judge yielded accuracies of 31.10% for answer correctness and 91.38% for answer type consistency. However, subsequent attempts to integrate this judgment mechanism into our system proved unsuccessful, as it either decreased overall performance or had no measurable impact.

4.4 Final Solution

In summary, our final solution adopts DeepSeek-R1 (without Think) as the backbone LLM, utilizing only code correction to enhance performance.

5 Other Unsuccessful Attempts

We also experimented with an ensemble solution, where multiple tabular QA systems generated answers in parallel, followed by a majority vote to determine the final response. However, this approach underperformed compared to simply using DeepSeek-R1 (without Think) with code correction, suggesting that accuracy may lie in the hands of a select few models rather than a collective consensus.

6 Conclusion

This paper presents the Central China Normal University (CCNU) team's solution to SemEval-2025 Task 8, the DataBench task, which requires systems to perform tabular QA. Building on the idea of tabular QA as code completion, we further propose a two-stage correction mechanism comprising code correction and answer correction to enhance reliability. Experimental results show that code correction effectively improves performance, while answer correction does not.

Abstract

Large Language Models (LLMs) suffer from a critical limitation: hallucinations, which refer to models generating fluent but factually incorrect text. This paper presents our approach to hallucination detection in English model outputs as part of the SemEval-2025 Task 3 (*Mu-SHROOM*). Our method, HalluRAG-RUG, integrates Retrieval-Augmented Generation (RAG) using Llama-3 and prediction models using token probabilities and semantic similarity. We retrieved relevant factual information using a named entity recognition (NER)-based Wikipedia search and applied abstractive summarization to refine the knowledge base. The hallucination detection pipeline then used this retrieved knowledge to identify inconsistent spans in model-generated text. This result was combined with the results of two systems, which identified hallucinations based on token probabilities and low-similarity sentences. Our system placed 33rd out of 41, performing slightly below the 'mark all' baseline but surpassing the 'mark none' and 'neural' baselines with an IoU of 0.3093 and a correlation of 0.0833.

1 Introduction

The rise of Large Language Models (LLMs) has brought attention to an important limitation they have, a phenomenon often referred to as LLM 'hallucinations'. This phenomenon occurs when an AI-generated text contains or describes facts that are not supported by the provided reference. These facts do not necessarily need to be false to be labeled a hallucination. Instead, they are cases where the answer text is more specific than it should be, given the information available in the provided context. To further clarify what a hallucination is, we provide the following example introduced by Dopierre et al. (2021):

- **Source Text**: *I am not sure where my phone is.*
- **Model-Generated Paraphrase**: *How can I find the location of any Android mobile?*

As seen in this example, the generated text is fluent but inaccurate concerning the source text. This is noted by the generation of information that is not found originally in the source text, specifically referring to 'Android mobile'.

The generation of false information can hinder a model's usefulness in many applications. Moreover, it can also be the cause for ethical concerns: when a text is syntactically sound, people quickly assume that it is also semantically sound. A user being presented with false information can cause considerable harm in many different domains.

The detection of hallucinations is an important task in improving model trustworthiness, so it is vital to develop and improve methods of hallucination detection. In this context, SemEval-2025 Task 3: *Mu-SHROOM, the Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes* was organized (Vázquez et al., 2025)[1]. This year, the task inquires about the exact text spans in which hallucinations occur, as opposed to last year's binary classification task (Mickus et al., 2024). The organizers provided validation data in ten different languages, from which we only considered English.

Our approach to this particular task implements a combined model that implements Retrieval-Augmented Generation (RAG) in combination with factual information from Wikipedia and Llama-3, as well as supplementary prediction models based on token probabilities and low-similarity sentences. Our method achieved place 33 out of 41 for the English track in SemEval-2025 Task 3, performing slightly below the 'mark all' baseline.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 846–851

2 Related work

First, we will discuss some related work that was done during the previous iteration of this shared task, SemEval-2024 Task 6 (Mickus et al., 2024). One of the most common techniques across the papers written on this task is the use of transformer-based models and semantic similarity measures. Markchom et al. (2024) employed SentenceTransformers to generate embeddings for hypothesis and target texts, comparing them via cosine similarity. The aim was to detect hallucinations based on low similarity scores.

Other groups pivoted towards prompt-based methods. Borra et al. (2024) focused on zero-shot and few-shot learning. In zero-shot learning, the model relied on its pre-trained knowledge, using carefully crafted prompts. Few-shot learning incorporated a small set of labeled data, improving the model's ability to detect more subtle hallucinations. A large number of groups that participated used similar models: models like Vectara, Mistral/Mixtral, DeBERTa, and GPT (3.5 or 4) were used very commonly. The organizers note that especially the GPT-based models work well: four out of six top-scoring teams incorporated it in their approach (e.g., Mehta et al. (2024); Obiso et al. (2024)).

Outside of the context of the Shared Task, much work has been done regarding the use of RAG in hallucination reduction. The main intuition behind this approach is that the inclusion of factual information (the 'Retrieval' part) will reduce the generation of factually incorrect content (Gao et al., 2024). The use of RAG for hallucination reduction has been proven to be effective for multiple use cases, like conversation (Shuster et al., 2021) or structured outputs like workflow generation (Ayala and Bechard, 2024). Considering RAG's usefulness in hallucination reduction, it will be interesting to see whether the addition of relevant retrieved data also extrapolates to improved hallucination detection. This approach is not well-represented in the literature yet, so the merits of the method are yet to be seen.

3 Data

The Shared Task data was provided in 14 languages total, but for our approach, only the English data was considered.

The organizers of the shared task released both a validation set as well as a test set. The English validation set comprised 50 data points, while the test set, released at the start of the evaluation phase (initially without labels), comprised 154 data points. Each of the data points consists of the following elements:

- **ID**: The identification of the data point.
- **Lang**: The language used.
- **Model Input**: The prompt given to the model.
- **Model Output Text**: The model-generated output, which might contain hallucinations.
- **Model ID**: The identification for the model.
- **Model Output Tokens**: The tokenized model output text.
- **Model Output Logits**: The raw, unnormalized model output text.
- **Soft Labels**: The start and end indices of a hallucination along with a probability score.
- **Hard Labels**: The start and end indices of a hallucination, determined using majority voting among the annotators.

For the English datasets, the data points were annotated by up to 13 annotators. Each annotator was provided with the model output text and relevant context. Then, they were instructed to highlight each span of model output text that was inconsistent with the given context. Annotators were instructed to be as conservative as possible when marking hallucinations.

Dataset	% soft labels	% hard labels
Validation	77.6%	28.9%
Test	78.4%	34.9%

Table 1: The % of model output text that was marked as a hallucination.

Table 1 shows the percentages of model output text that was marked as a hallucination by the annotators for both labels. This shows that the soft labels show a relatively less conservative level of annotation than the hard labels, which only span roughly a third of the output text instead of three-quarters for the soft labels.

The authors additionally released an unlabeled training data set, comprising 809 data points for English. However, we did not use this training set for the development of our model as it did not fit within our chosen approach.

4 Method

As mentioned previously, our approach leverages a form of RAG, an LLM, and two prediction models. For efficiency, we split our pipeline into two segments: 1. Knowledge retrieval, and 2. Hallucination detection. This pipeline is illustrated in Figure 1.

4.1 Knowledge Retrieval

To retrieve relevant contextual information, we first extracted all named entities present in the model input, or prompt, provided by the dataset. For this, we used `spaCy`'s NER-tagger (Honnibal and Montani, 2017). After collecting these named entities, we filter out the unwanted labels (e.g., monetary entities). The remaining named entities are then used to fetch any Wikipedia page using the Wikipedia API that possibly contains relevant information, which was saved with its respective data point. As a result, the number of retrieved pages per data point varied depending on the length of the prompt as well as the overall popularity of the categories found in the prompt. This varied from 1 or 2 pages to dozens of pages.

After retrieval, we computed the similarity between each sentence on each retrieved page and calculated the average similarity score of each page. We used the MPNet model [2] to calculate these similarity scores, where a high score indicates that the given sentence has a high chance of containing relevant information. By setting a similarity threshold, we narrowed down the amount of contextual information by only utilizing the pages (max = 3) with the highest similarity score. These pages were preprocessed to remove notes, links, and references and were saved to be summarized.

4.2 Summarization

Another crucial part of the knowledge retrieval pipeline is the summarization model. As there were still instances where the retrieved contextual information was too elaborate, even after setting a threshold, we implemented a summarization model. This model transformed the contextual information into a more concise and informative version, creating summarizations between 20 and 1291 words. We used `DistilBART-CNN-12-6`[3] to carry out this summarization task, which is a transformer-based model fine-tuned for abstractive summarization. This model was chosen because it is relatively fast and computationally light, minimizing the total computational load of our pipeline.

As the model has a maximum token limit of 1024 tokens, information of a longer length needed to be split into segments of text that were small enough to fit within the model's token limit while still preserving meaningful context. After tokenization, each chunk was provided to the model, which was then transformed more concisely while maintaining key information. Finally, repeated phrases were filtered out to ensure that redundant or overlapping content was minimized.

4.3 Hallucination Detection

Prompting For prompting, we used the Llama-3 (8B) Instruct model along with its tokenizer (AI@Meta, 2024). We experimented with several prompting techniques, including zero-shot, few-shot, and Chain-of-Thought (CoT). As our model had difficulty taking on examples or instructions to reason step-wise, the best-performing method was the zero-shot technique. Additionally, we tested different ways of instructing the model to extract hallucinations: either as character spans or as lists of words. We found that requesting words directly was more effective. The final prompt was as follows:

```
Text: {output_text}

Factual Information: {wiki_summary}

Compare the text with the factual
information. What spans in the text
are not consistent with the factual
information provided?

Provide a list of words or spans in
the exact format:

["word1", "word2", ...]

Do not return anything other than the
list of spans.

If there are no hallucinations,
return [].
```

The hallucination spans were extracted from the model's response using regular expressions.

Token Probability Analysis To detect low-confidence tokens, we computed token probabilities from the Llama-3 model as our next step. Specifically, we calculated the log probabilities for each token and converted them into probabilities

[2] https://huggingface.co/sentence-transformers/multi-qa-mpnet-base-cos-v1

[3] https://huggingface.co/sshleifer/distilbart-cnn-12-6

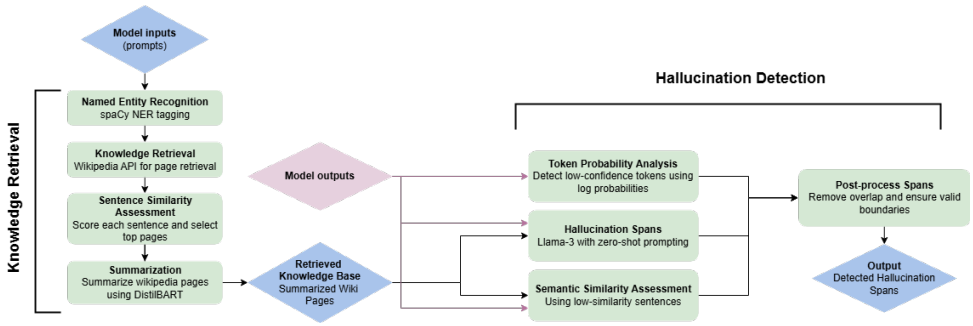

Figure 1: Overview of our two-stage hallucination detection pipeline.

using the softmax function. We analyzed all tokens in the generated text but paid particular attention to content words (e.g., named entities, numbers, and nouns) since these were more likely to contain factual claims. We identified low-probability tokens by setting a threshold of 0.01. Tokens with probabilities below this threshold were considered uncertain and were saved as potential hallucinated character spans. The underlying intuition was that the model assigns lower probabilities to tokens when it is uncertain about their correctness, which often correlated with hallucinated content.

Semantic Similarity-Based Detection In addition to probability analysis, we performed semantic similarity assessment using a transformer-based sentence embedding model, SentenceTransformers' multi-qa-mpnet-base-cos-v1 (Reimers and Gurevych, 2019). All sentences in the model output were compared against the retrieved factual knowledge using this model to retrieve a cosine similarity score. A cosine similarity threshold of 0.5 was used, where a maximum similarity score below this threshold was flagged as a potential hallucination.

Assembling Spans Since multiple methods generated hallucination spans, we merged overlapping spans and removed spans exceeding text boundaries. These text boundaries refer to the length of the model output text, as in some cases, identified spans went beyond this length.

4.4 Evaluation Metrics

To evaluate the performance of our method for hallucination detection, we used the official shared task metrics: Intersection over Union (IoU) and Spearman Correlation. The IoU score measures the overlap between detected and ground-truth hallucination spans:

$$\text{IoU} = \frac{|\text{Predicted Spans} \cap \text{Ground Truth Spans}|}{|\text{Predicted Spans} \cup \text{Ground Truth Spans}|}$$

IoU is 1.0 if neither the reference nor the prediction contains hallucinations. Otherwise, it calculates the ratio of overlapping character indices between predicted and gold-standard hallucination spans.

The Spearman Correlation was used to evaluate the ranking similarity between predicted and reference soft labels. If either of them contains no variation, the score is binary. Otherwise, it computes the Spearman rank correlation between the two probability distributions over characters.

Any results are also compared to the baselines provided by the Shared Task authors, which consisted of a baseline that marked all characters as hallucinations, a baseline that marked no characters as a hallucinations, and a simple neural model based on XLM-RoBERTa[4].

5 Results

In Table 2, the results of our method on the test data are displayed, compared to the baseline scores and the scores obtained by the best-performing team. Additionally, in Table 3, we present our model's performance on the validation set. Our system scores below the 'mark all' baseline on the IoU metric, indicating that we fail to capture all hallucination spans. However, the correlation results suggest that our system tends to over-identify spans overall. In particular, we observed that the next-token-based approach frequently flagged multiple short spans, but our chosen LLama3 model does this as well for some sentences. This inflated our false positive count and thus lowered our correlation score. We think this is partly due to not

[4]https://huggingface.co/FacebookAI/xlm-roberta-base

implementing additional logic to merge or filter overlapping segments. Despite these shortcomings, our approach still surpasses the 'mark none' and 'neural' baselines on IoU and scored 33rd overall.

Model	IoU	Correlation
Best Team (iai_MSU)	0.6509	0.6294
Baseline (mark all)	0.3489	0.0000
HalluRAG-RUG	0.3093	0.0833
Baseline (mark none)	0.0325	0.0000
Baseline (neural)	0.0310	0.1190

Table 2: Our test set results, compared to the provided baselines and the best-performing team.

Precision	Recall	F1-score	IoU
0.30	0.96	0.40	0.30

Table 3: Performance of our model on the validation set.

To improve upon some shortcomings, we experimented with removing the summarization module from our pipeline, as well as removing the next token prediction. All of these experiments lowered the IoU considerably. Adjusting the prompt seemed to have the biggest impact on the IoU. We also experimented with retrieving words instead of character spans, and then reconstructing indices afterward, however this consistently produced worse scores overall.

To better understand our model's behavior, we analyze three representative cases that contain errors.

Input: *"What did Petra van Staveren win a gold medal for?"*
Model Output: *"Petra van **Stoveren** won a **silver** medal at the **2008 Summer Olympics in Beijing, China**."*
Gold Spans: *[(25, 31), (45, 49), (69, 83)]*
Detected Spans: *[(12, 13), (15, 24), (25, 34), (35, 44), (45, 80)]*
Analysis: The model correctly flagged key errors (misspelled name, incorrect medal, fabricated location) but over-predicted by marking additional parts of the sentence as hallucinated. This suggests a need for better span-merging techniques.

Input: *"How many genera are in the order Erysiphales?"*
Model Output: *"The **Elysiphale** order contains **5** genera."*
Gold Spans: *[(30, 31)]*
Detected Spans: *[(25, 35)]*
Analysis: The model mistakenly detected a larger hallucination span than needed. It correctly identified the incorrect taxonomic name but over-marked the number as part of a broader span. A more refined approach could improve precision by more accurately isolating factual errors.

Input: *"When did Chance the Rapper debut?"*
Model Output: *"Chance the Rapper debuted in **2011**."*
Gold Spans: *[(29, 33)]*
Detected Spans: *[(0, 34)]*
Analysis: Instead of isolating the incorrect year, our system flagged the entire sentence as a hallucination. This exemplifies a common issue where token probability-based hallucination detection overextends spans.

These cases highlight key failure points in our approach: entity misrepresentation, overgeneration, and excessive span marking.

6 Conclusion and Future Work

In this work, we presented a retrieval-augmented pipeline for detecting hallucinated spans in LLM output, focusing on English data from the MuSHROOM task. Our system combined token probability, factual checks, and summarized Wikipedia context to highlight hallucinated spans. While our approach outperformed two out of three baselines, it often detected an overabundance of spans, reducing precision and diluting overall performance. In addition, the practical constraints of our chosen model regarding input length and model parameters restricted performance. Despite these challenges, our results suggest that integrating retrieval methods and careful prompt engineering can help with validating LLM output.

Future Work

Future work could include refining the method for merging overlapping hallucination spans, potentially creating a higher threshold for span inclusion. Furthermore, exploring LoRA-style downscaling or newer open-source models like DeepSeek might help improve the performance of a RAG-based approach.

Acknowledgments

We would like to thank Malvina Nissim and Huiyuan Lai for their guidance and advice during this project, as well as the Mu-SHROOM organizers for their helpfulness in clarifying any doubts and questions.

SALT at SemEval-2025 Task 2: A SQL-based Approach for LLM-Free Entity-Aware-Translation

Tom Völker and **Jan Pfister** and **Andreas Hotho**
Center for Artificial Intelligence and Data Science (CAIDAS)
Data Science Chair, Julius-Maximilians-Universität Würzburg (JMU)
{voelker,pfister,hotho}@informatik.uni-wuerzburg.de

Abstract

Entity-aware machine translation faces significant challenges when translating culturally-adapted named entities that require knowledge beyond the source text. We present SALT (SQL-based Approach for LLM-Free Entity-Aware-Translation), a parameter-efficient system for the SemEval-2025 Task 2. Our approach combines SQL-based entity retrieval with constrained neural translation via logit biasing and explicit entity annotations. Despite its simplicity, it achieves state-of-the-art performance (First Place) among approaches not using gold-standard data, while requiring far less computation than LLM-based methods. Our ablation studies show simple SQL-based retrieval rivals complex neural models, and strategic model refinement outperforms increased model complexity. SALT offers an alternative to resource-intensive LLM-based approaches, achieving comparable results with only a fraction of the parameters.

1 Introduction

Despite ever-progressing language model capabilities, they continue to struggle with tasks requiring precise factual knowledge and cross-cultural understanding (Wang et al., 2024; Lin et al., 2022; Hu et al., 2024). One such challenge is named entity translation, where direct word-for-word approaches often miss cultural nuances (Díaz-Millón and Olvera-Lobo; Gaballo et al., 2012). Accurate entity-aware translation is essential for preserving meaning across languages. For example, Roald Dahl's The Witches became Hexen hexen ("Witches bewitch") in German – a choice no model could infer from the source alone.

Recent advances in machine translation, particularly with large language models (LLMs), have greatly improved translation quality (Team et al., 2022; Tang et al., 2020; Workshop et al., 2023; Zhu et al., 2024). However, translating culturally adapted entity names remains difficult (Hershcovich et al., 2022) due to: 1) The need for transcreation—creative adaptation beyond literal translation (Gaballo et al., 2012) 2) Constantly emerging entities, which frozen LLM weights cannot capture (Lazaridou et al., 2021; Hu et al., 2024) 3) Variability in translation based on cultural, geographical, or temporal context (Hershcovich et al., 2022)

The SemEval-2025 Task 2 on Entity-Aware Machine Translation (EA-MT) (Conia et al., 2025) addresses this challenge by requiring systems to translate English sentences with named entities into ten target languages, spanning both Latin (e.g., German, Spanish) and non-Latin scripts (e.g., Japanese, Arabic). For example, "What year did Roald Dahl release the novel The Witches?" should be translated into German as "In welchem Jahr veröffentlichte Roald Dahl den Roman Hexen hexen?" – using the localized title.

We present SALT [1] (SQL-based Approach for LLM-Free Entity-Aware-Translation), a simple yet effective solution to this challenge. While based on neural machine translation (Team et al., 2022), SALT avoids the complexity of additional neural components for entity handling and the parametric overhead of modern LLMs. Instead, it leverages efficient SQL-based entity retrieval, constrained neural translation via logit biasing, and explicit entity annotations. Our system achieves state-of-the-art results among approaches without gold-standard data (e.g., Wikidata IDs) during testing, while maintaining significantly lower computational costs (Conia et al., 2025).

Our key contributions are:

- A parameter-efficient entity-aware translation approach that achieves competitive results without additional trainable components beyond the base model.
- Evidence that, for well-structured multilingual

[1] github.com/LSX-UniWue/Semeval-2025-Task-2

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 852–864

knowledge bases, simple SQL-based retrieval can rival complex neural methods while being significantly more efficient.
- Comprehensive ablation studies comparing retrieval and integration strategies, showing that explicit knowledge integration via entity annotations and logit biasing outperforms added neural complexity or increased parameter counts (Zhang et al., 2018; Lewis et al., 2021).

While LLM-based approaches achieve marginally better results in our ablation studies, SALT 🧂 comes remarkably close with only a fraction of the parameters.

Named Entity Linking. Named Entity Linking (NEL) maps entity mentions in text to knowledge base entries. Early methods used string matching and heuristics (Shen et al., 2015), while modern approaches usually employ neural models that encode mention context and entity representations via transformers and graph neural networks for better disambiguation (Kolitsas et al., 2018; Cao et al., 2018; Wu et al., 2020; Conia et al., 2024). Many state-of-the-art systems follow a two-stage process: efficient candidate generation followed by neural re-ranking (Lai et al.; Hebert et al.).

Augmented Neural Translation. Neural Machine Translation (NMT) often struggles with low-frequency or novel entities. Retrieval-augmented techniques incorporate external translations at inference time (Zhang et al., 2018), while lexically constrained decoding enforces correct entity translation (Hokamp and Liu, 2017). Other methods integrate external knowledge via data augmentation or explicit entity translation modules (Campolungo et al., 2022; Zeng et al.; Conia et al., 2024).

3 System Description

We propose a surprisingly simple yet effective two-stage pipeline for entity-aware machine translation, that focuses on parameter efficiency. Our approach consists of (3.1) a deterministic entity retrieval and translation lookup phase, followed by (3.2) a constrained neural translation step. Despite exploring more complex methods in our ablation studies (Section 6), this streamlined approach achieves highly competitive results with significantly lower computational cost.

3.1 Entity Retrieval and Translation Lookup

Given an English source sentence and a target language, our system first identifies relevant named entities and retrieves their translations from a knowledge base. This forms the first stage of our pipeline. With Wikidata containing over 71 million entities[2], efficient candidate filtering is essential. To this end, we implement a normalized string matching approach, leveraging SQL indexing for fast retrieval.

For an input sentence $x = \langle w_1, \ldots, w_n \rangle$, we generate all possible n-grams[3], normalize them (lowercasing and removing special characters), and query our database for exact matches with identically normalized entity names.[4] Only entities with available translations in the target language are considered.

For each exact n-gram matched entity s in the database, we compute a relevance score prioritizing longer entity matches:

$$\text{score}(s, x) = 0.5 \cdot \frac{|\text{chars}(s)|}{|\text{chars}(x)|} + 0.5 \cdot \frac{|\text{words}(s)|}{|\text{words}(x)|}$$

This ensures multi-word entities are ranked higher (e.g., "The Lord of the Rings" would score higher than just "Rings"). This is based on our observation that longer, multi-word entities are more likely to have non-trivial translations requiring special handling, while shorter matches might simply be components of these larger entities. Ties are broken using entity popularity (measured by Wikidata history length, representing past edit activities).

For each input sentence x, this process yields a set of entity-translation pairs $\mathcal{E}_x = \{(e_1, t_1), \ldots, (e_k, t_k)\}$, where e_i represents the source entity text and t_i its translation in the target language.

This approach offers excellent scalability advantages: it handles Wikidata's massive entity collection efficiently through indexing, and unlike neural approaches, can be dynamically updated with new entities without retraining. This allows the system to remain current as new entities emerge in the real world.

3.2 Neural Translation with Knowledge Integration

The second stage of our pipeline adapts the knowledge integration approach introduced by Conia et al.

[2] wikidata.org/wiki/Wikidata:Statistics

[3] Up to $k = 15$, as this covers all entities in the datasets.

[4] The database construction scripts are available in our GitHub repository under the `/data/wikidata` directory.

(2024) to incorporate the retrieved entity translations into the translation process. Based on their findings, we use the encoder-decoder 600M NLLB-200 model (2022) as our base architecture.

Given a source text $x = \langle w_1, \ldots, w_n \rangle$ and its corresponding entity-translation pairs $\mathcal{E}_x$, we construct an augmented input sequence:

$$x^+ = \langle w_1, \ldots, w_n, \texttt{<meta>}, e_1, \texttt{<translates\_to>}, t_1 \rangle,$$

where special tokens explicitly mark entity-translation pairs. This augmented sequence provides the model with direct access to the high-quality entity translation sourced from our knowledge base.

Unlike Conia et al., who provided the translation model with multiple translation candidates, our ablation studies (Section 6.3) show that selecting only the highest-scoring candidate significantly improves performance. When no matched entity is found in our SQL-based lookup, we simply refrain from amending entity-translation pairs to the input sentence. This defaulting-to-base strategy ensures that unmatched entities do not degrade overall translation quality. In principle, more sophisticated fallback methods (e.g., approximate string matching or partial re-ranking) could address near-miss matches, but we found our simpler approach to be sufficient for most test instances (Section 6.1).

To further encourage the model to use these curated translations in its output, we implement logit biasing during the beam search decoding process. This effectively creates a soft constraint that encourages the model to incorporate the retrieved entity translations while maintaining the flexibility to adapt to target language grammar and ensure overall translation fluency. To this end, we positively bias all logits corresponding to tokens present in the retrieved translation target (t_1), as these represent gold-standard entity renderings in the target language (shown to be effective by Zhang et al. (2018)):

$$p(y_t | y_{<t}, x^+) \propto \exp(\text{logits}(y_t) + b \cdot \mathbb{1}[y_t \in \text{tokens}(t_i)])$$

where b is the bias parameter and $\mathbb{1}$ the indicator function. This mechanism allows us to guide the translation process without forcing rigid token copying that might result in grammatically incorrect output. Our approach improves upon Conia et al. (2024) in two ways: 1) selecting only one entity translation per instance, which enhances accuracy (Section 6), and 2) combining explicit knowledge integration with logit biasing, ensuring high entity translation accuracy without compromising overall fluency.

4 Experiments and Results

4.1 Experimental Setup

We evaluate our approach on the XC-Translate dataset (Conia et al., 2024), which includes 7,000 development and 50,000 test samples evenly distributed across ten target languages.

Following task guidelines, we train on both the development split and external data. For the latter, we use the Mintaka dataset (Sen et al.), a multilingual QA dataset with Wikidata annotations, suitable for entity-aware translation. To maintain quality comparable to XC-Translate, we apply strict filtering: 1) The translated entity must appear in the target sentence. 2) The Levenshtein distance (Miller et al., 2009) between source and target entity translation must exceed two characters to exclude trivial cases. This retains 40% of Mintaka while aligning it with XC-Translate's sample characteristics. [5]. We combine these filtered samples with the development set in a 1:1 ratio, which our ablation studies (Section 6) show to strike a fair balance between performance and training time.

4.2 Training Configuration

We fine-tune the 600M NLLB-200 model (Team et al., 2022) using AdamW (Loshchilov and Hutter, 2019) with a 1e-5 learning rate. Training takes ≈1.5 hours on NVIDIA L40 GPUs, while evaluation, including COMET score computation, requires significant additional time. Full training parameters are in Appendix A.

4.3 Evaluation

The task employs two complementary metrics: METRA (Manual Entity Translation Accuracy) measures entity translation quality by checking for correct translations in system outputs via case-insensitive substring matching (Conia et al., 2024). COMET (Rei et al.) assesses overall translation quality using a neural model trained to predict human judgments of fluency and adequacy given the target translation. Systems are ranked using the

[5] Mintaka provides data for Arabic, French, German, Hindi, Italian, Japanese, Portuguese and Spanish, of which we use the six languages that overlap with XC-Translate (Arabic, German, Spanish, French, Italian and Japanese). This means we lack Mintaka data for Korean, Chinese, Thai and Turkish.

harmonic mean of both metrics, ensuring neither entity accuracy nor translation fluency is disproportionately favored.

5 Results

Table 1 compares our system's performance to selected others across ten target languages. Our approach achieves an M-ETA score of 71.66% and a COMET score of 92.52, ranking highest among systems not accessing gold-standard Wikidata entity IDs in inference, with a HM-Score of 80.42.

Our SQL-based retrieval and constrained neural translation prove effective across all languages, outperforming both the top overall LLM-based system by FII-UAIC-SAI (78.17) and the next best non-LLM-based system by team Zero (47.79).[6] The substantial 25-point gain over the baseline by Conia et al. (55.32) underscores the value of our small but substantial methodological refinements outlined above.

Performance is strongest on languages with substantial Mintaka training data (Arabic, German, Spanish, French, Italian, and Japanese), where M-ETA scores range from 72.20% to 81.72%. Chinese remains the most challenging (45.27% M-ETA), with FII-UAIC-SAI surpassing our system by 17.23 points.

For reference, we include the top-performing shared task submission (pingan_team) in gray, achieving a remarkable 91.79 overall using gold Wikidata annotations at inference. While this limits real-world applicability, it demonstrates the high potential upper bound of the dataset.

6 Ablations and Analyses

Having established the effectiveness of our minimal approach, we now investigate both the validity of our design choices and the potential gains in more complex alternatives, allowing us to quantify trade-offs while confirming our core architectural decisions.

6.1 What are the Limits of String Matching?

Our SQL-based approach achieves 83.05% Recall@1 for identifying the correct entity ID and 72.07% Rec@1 for retrieving the exact translation used in the target sentence (Table 2). The 83.05% entity identification performance is comparable to the 85.90% Rec@1 reported by Conia et al. using a neural retriever, suggesting our lightweight method offers a good efficiency-performance trade-off.

Dataset analysis highlights inherent retrieval limitations: "only" 97.74% of correct entities appear verbatim in the source, setting an upper bound, while another 0.46% differ slightly (edit distance $\leq$3). The remaining 2.26% vary significantly, where dense retrieval might help, but we felt the computational cost wouldn't justify these minimal theoretical gains, making our string matching approach a reasonable compromise.

Even with gold-standard entity IDs, only 84.39% of Wikidata translations match target sentence renderings, with 10.52% differing substantially (edit distance >3). This discrepancy imposes an 84.39% M-ETA ceiling, irrespective of retrieval method.

6.2 Should we use an LLM-based Reranker?

To assess how close we can get to the theoretical upper bounds identified above, we evaluate two well established neural reranking approaches beyond our SQL-based retrieval (Appendices B and C.1): a fine-tuned transformer-based cross-encoder and an LLM-based method (Table 3). The pre-trained transformer showed negligible gains in zero-shot settings, but fine-tuning improved Rec@1 by 6.22 points from 72.07% to 78.29%. For the LLM-based approach, we employ GPT-4o mini[7] with a structured prompt that considers sentence context and entity metadata, achieving a slightly worse 77.26% Rec@1.

When integrated into the full translation pipeline (Table 4), it is able to retain almost all the improvement, boosting the M-ETA score by 5.47% to 77.13% without affecting translation quality. However, we chose to exclude neural rerankers to keep the pipeline simple, transparent, and computationally efficient and "explainable".

6.3 How Many Entities to Provide for Translation?

Contrary to expectations based on Conia et al.'s (2024), who provided the top-3 candidates to the translation model (Section 3.2), we found that appending only one entity candidate performed significantly better (Figure 1). This may be due to reduced ambiguity: while 12.9% of correct entity translations appear only in positions 2-5 and are

[6] We define LLM-based approaches as those utilizing decoder-only transformer models with billions of parameters, such as GPT (Brown et al.) or Llama (Grattafiori et al.) variants, as opposed to our encoder-decoder architecture with significantly fewer parameters.

SQL-only (3.1)	72.07%	80.59%	81.60%
Transformer reranker	78.29%	81.43%	81.77%
LLM reranker	77.26%	79.81%	79.88%

Table 3: Comparison of entity reranking approaches.

	Average across all languages		
Reranking method	**M-ETA**	**Comet**	**HM-Score**
SQL-only (3.1)	71.66%	92.52%	80.42%
Transformer reranker	77.13%	92.75%	84.22%

Table 4: Reranking impact on translation performance.

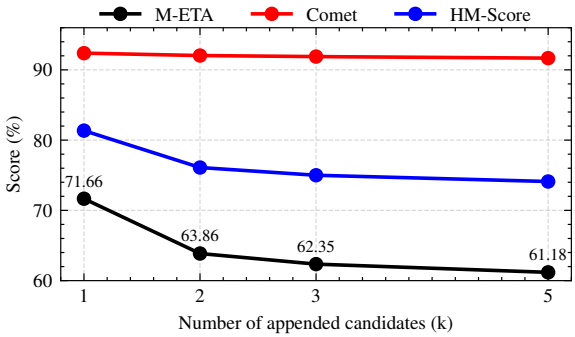

Figure 1: Impact of different Top-k append strategies.

omitted, the confusion from multiple candidates apparently outweighs this potential gain.

This insight shaped our system design, revealing that while the translation model effectively uses our amended syntax as a glossary, it struggles when simultaneously tasked with selecting between entity candidates. In our parameter-efficient neural translation pipeline, clarity in entity mapping proves more valuable than maximizing coverage.

6.4 Should we Augment the Training Data?

We evaluated four training data configurations Table 5): XC-Dev only (~7,000 samples, 78.90% HM-Score), filtered Mintaka only (~50,000 samples, 75.41% HM-Score), and two combinations in different ratios. While XC-Dev outperformed Mintaka alone, their combination yielded the best results (80.42% and 80.58% HM-Score for 1:1 and 7:1 ratios, respectively). The 1:1 ratio (our choice) balances performance and training efficiency, whereas the 7:1 ratio (full datasets) offers only marginal gains at much higher computational cost. These findings highlight the datasets' complementary nature and the diminishing returns of increasing amounts of data beyond a certain point.

6.5 What's the Impact of our Logit Biasing?

As the last substantial difference between our approach and that of Conia et al. (2024), we analyze the impact of our logit biasing strategy and compare it to an additional constraining mechanism. Our main system employs logit biasing (Zhang et al., 2018), applying a positive bias to tokens from the retrieved entity translation during generation, guiding output without adding model parameters.

As an alternative, we evaluate a pointer-generator mechanism (See et al.), which augments the model with a trainable copy component. Like logit biasing, it aids token selection but is learnable. Instead of direct copying, it computes an attention-based probability distribution over input tokens alongside the vocabulary distribution, combining them via a learnable gate to balance generation and

	Average across all languages		
Training data	**M-ETA**	**Comet**	**HM-Score**
XC-Dev only	69.62%	91.03%	78.90%
Mintaka only	64.87%	90.03%	75.41%
Mintaka + XC-Dev (1:1)	71.66%	92.52%	80.42%
Mintaka + XC-Dev (7:1)	71.78%	92.61%	80.58%

Table 5: Impact of different training data combinations.

copying. While successfully applied in translation (Zeng et al.), it increases architectural complexity and requires additional parameters.

	Average across all languages		
Constraint method	**M-ETA**	**Comet**	**HM-Score**
No constraint	68.30%	92.71%	78.65%
Logit bias (3.2)	71.66%	92.52%	80.42%
Pointer generator	69.10%	92.63%	79.16%
PG + Logit bias	73.47%	92.31%	81.81%

Table 6: Performance of different constraint methods.

As shown in Table 6, our logit biasing approach improves M-ETA by 3.36 percentage points over the unconstrained baseline with minimal impact on translation quality, justifying its inclusion in our main pipeline. The pointer generator also enhances entity translation but less effectively than logit biasing, despite adding parameters.

Interestingly, combining both methods achieves the best results (M-ETA 73.47%, HM-Score 81.81%), suggesting a synergistic effect between the biasing and the pointer generator's mechanism.

For our final system, we retain the simpler logit biasing approach, balancing performance and parameter efficiency to maintain a lightweight yet effective model.

6.6 "Why didn't you just use an LLM?"

	Average across all languages		
LLM approach	**M-ETA**	**Comet**	**HM-Score**
SALT (no LLM)	71.66%	92.52%	80.42%
+ Reranker&Pointer	77.77%	92.63%	84.55%
LLM direct translation	78.77%	93.42%	85.17%
Vanilla NLLB + LLM	72.35%	87.48%	78.87%
Finetuned NLLB + LLM	77.13%	91.81%	83.63%

Table 7: Comparisons to our best non-LLM configuration (+ Reranker&Pointer) which combines transformer reranking (Section 6.2) with pointer generator and logit biasing (Section 6.5).

Lastly, we explore LLMs in our translation pipeline, testing three GPT-4o mini[7]-based approaches (Table 7). For comparison, we include our baseline SALT (80.42% HM-Score) and our best non-LLM system (84.55%), which integrates a transformer reranker, pointer generator, and logit biasing (Sections 6.2 and 6.5).

First, we assess whether an LLM can refine finetuned NLLB translations by correcting entity mistranslations while preserving overall quality (Appendix C.4), as unlike our neural translation model (Section 6.3), LLMs should excel at disambiguation tasks like this. Providing the translation and top-5 entity candidates yields an 83.63% HM-Score, slightly below our best non-LLM system. A similar approach using vanilla (non-finetuned) NLLB translations performs worse (78.87%), suggesting LLMs struggle with lower-quality base translations (Appendix C.3).

Surprisingly, our best result (85.17% HM-Score) comes from direct LLM translation, using only the source text and entity candidates (Appendix C.2). However, the modest 0.62-point gain over our best non-LLM system comes at a cost: higher computation, API expenses, latency (>2s per sample), and reliance on closed-source models. This narrow performance gap validates our parameter-efficient pipeline as a competitive alternative that avoids these limitations.

7 Conclusion

We introduced SALT, a parameter-efficient, entity-aware machine translation approach that achieves first place among models not using gold data during translation. Our ablation studies challenge several intuitive assumptions: simpler retrieval methods often outperform complex ones; clarity trumps coverage when providing entity candidates; and lightweight techniques like logit biasing can match parameter-heavy approaches. The narrow gap between our system and LLM-based alternatives (0.62 pp) demonstrates that parameter efficiency need not sacrifice translation quality. Our work counters the prevailing trend toward ever-larger models, suggesting that targeted knowledge integration can be more effective than simply scaling parameters for specialized translation tasks.

Whilst achieving state-of-the-art results without gold-standard data, challenges remain, particularly in our Chinese translations and in generalizing to more diverse real-world translation scenarios.

Limitations

Despite SALT 🧂 's strong performance, a few limitations remain: (1) our approach is bounded by Wikidata coverage, with a theoretical M-ETA ceiling of 84.39% (Section 6.1) far from the top submissions in the task, which use gold data; (2) performance varies across languages, with Chinese translations presenting a particular challenge (Section 5) – a limitation we were unable to address due to language barriers; (3) our single-entity selection strategy (Section 6.3) works well for the benchmark at hand but would likely struggle with more diverse texts containing multiple complex entities per sentence; (4) approximately 2.26% of cases with substantial entity transformations remain problematic (Section 6.1) – a percentage likely to increase in less curated texts; and (5) though our parameter–efficient approach comes within 0.62 percentage points of LLM-based alternatives (Section 6.6), more sophisticated LLM implementations could potentially widen this gap.

A Training

All experiments were conducted on NVIDIA L40 GPUs. A complete training and evaluation run took approximately 3 hours, with a significant portion dedicated to evaluation, including the computation of COMET scores.

We used the `facebook/nllb-200-distilled-600M`[8] model (Team et al., 2022) as our base architecture. The hyperparameters used for the subsequent fine-tuning are listed in Table A1. For a complete list of hyperparameters, we refer to our configuration file at `src/conf/translation_config.yaml`.

Parameter	Value
Number of epochs	10
Batch size	16
Gradient accumulation steps	4
Effective batch size	64
Optimizer	AdamW
Learning rate	1e-5
Loss function	Cross-entropy
Max sequence length (In & Out)	512
Precision	bfloat16
Logit bias parameter (b)	5.0
Beam search	5 beams

Table A1: Training hyperparameters used in our experiments.

B Transformer Reranker Details

For our transformer-based reranking approach, we utilized the Roberta (Liu et al., 2019) based pre-trained `jina-reranker-v2-base-multilingual`[9] cross-encoder model that takes a query-document pair as input and produces a relevance score. The model operates as follows:

Given a source text x and a candidate entity e_i with associated metadata (including name, description, and available translations), we represent the relevance score as:

$$s(e_i, x) = f_\theta(x, r(e_i))$$

where f_θ is our transformer model with parameters θ, and $r(e_i)$ is a textual representation of the entity that concatenates its title, description, and

[8] https://huggingface.co/facebook/nllb-200-distilled-600M

[9] https://huggingface.co/jinaai/jina-reranker-v2-base-multilingual

translation. We fine-tune the model using margin ranking loss:

$$\mathcal{L} = \max(0, s(e^-, x) - s(e^+, x) + \gamma)$$

where e^+ is the correct entity, e^- is an incorrect entity, and γ is the margin (set to 0.3).

The model is fine-tuned using a learning rate of 2e-5 with the AdamW (Loshchilov and Hutter, 2019) optimizer. Training samples are created by using the correct entity as the positive example and sampling hard negatives from the top 5 results of our SQL-based retrieval. Training converged rapidly, requiring less than one epoch on a quarter of the development set to achieve optimal performance.

C LLM prompt

In all LLM interactions, the DsPy[10] framework (Khattab et al.) is used to automatically parse the input and output of the LLM with the prompts being defined via "Signatures" as outlined

C.1 Reranking prompt

The following prompt is provided to the LLM to rerank the retrieved entities.

```
Retrieve all distinct entity candidates
from a provided context that might be
relevant for disambiguation in a
machine-translation task.

Requirements:
1. High Recall:
- Include every candidate that could be the
correct reference, knowing that
the correct one is almost always among the
list.
2. Translation Quality:
- Do not add candidates with ambiguous
translations; if unsure, include them
and let later stages decide.
3. Handle Ambiguity:
- When entities share names, include all
with potential relevance based on their
descriptions.
4. Ranking:
- Return a sorted list of candidate
identifiers prioritizing:
* Contextual clues from the input sample,
* Popularity and provided score,
* Clear descriptive evidence matching the
candidate's role in the sentence.

Objective:
Ensure that the correct candidate is
positioned at the top of the candidate
list.

Input Fields:
- context (str):
Original input sample that provides the
context for disambiguation.
- candidates (list of EntityCandidate):
A list of candidate entities, each with
detailed metadata obtained via fuzzy
matching.

Output Field:
- selected_candidates (list of str):
Disambiguated list of relevant candidate
identifiers (e.g., wikidata_ids),
sorted by contextual relevance.
```

C.2 Self Translation prompt

The following prompt is provided to the LLM to generate the translations by itself, only provided with the input sentence, target language and entity candidates.

```
Generate a high-quality translation by
accurately rendering named entities from
candidate data.

Given only the original source sentence,
the model should generate the translation
on its own, while using the candidate
entity information—each with a high
likelihood
of containing the correct translation—to
incorporate the appropriate named entities.
Not every provided candidate is relevant,
so selectively apply those that enhance
the contextual accuracy of the translation.

Input Fields:
- source_sentence (str):
The original input sentence in English that
requires translation into the target
language.
- target_locale (str):
The target language locale, e.g. 'de' for
German.
- candidates (list of EntityCandidate):
A list of candidate entities with their
potential translations and associated
metadata. Each candidate has a high
likelihood of being correct, but not every
candidate is necessarily relevant.

Output Field:
- final_translation (str):
The final translation generated by the
model, with accurately rendered named
entities based on the candidate evidence.
```

C.3 Vanilla NLLB Translation Refiner prompt

The following prompt is provided to the LLM to refine translations from the vanilla NLLB model.

[10] https://github.com/stanfordnlp/dspy

```
  Refine a vanilla NLLB translation by
selectively incorporating named entities
from candidate data.

The vanilla translation produced by
the NLLB model might contain errors or
omissions in the rendering of named
entities.
Utilize the provided candidate entity
information—each holding a high probability
of correctness—to adjust the translation,
ensuring accurate rendering of those
entities while recognizing that not all
candidates are relevant to the context.

Input Fields:
- nllb_translation (str):
The initial translation produced by the
vanilla NLLB model, which may contain
omissions or errors in the depiction of
named entities.
- target_locale (str):
The target language locale, e.g. 'de' for
German.
- candidates (list of EntityCandidate):
A list of candidate entities with their
potential translations and related
metadata.  Although these candidates are
highly likely to include the correct
entity translations, not every candidate
may be applicable in the specific context.

Output Field:
- final_translation (str):
The final translation where the named
entities have been refined to accurately
align with the most relevant candidate
data.
```

C.4 Finetuned Translation Refiner prompt

The following prompt is provided to the LLM to refine translations from the finetuned NLLB model.

```
 Refine a finetuned translation by ensuring
that all named entity translations
align with the candidate data, which is
considered correct.

Occasionally, the finetuned nllb model may
apply a completely wrong candidate
or miss additional relevant candidates for
named entities.
Use the provided candidate details, whose
translations are considered the gold
standard,  to  fix  any  wrong  entity
translations and to add any missing ones.
Only adjust the named entity expressions,
preserving the overall translation quality.

Input Fields:
- finetuned_translation (str):
The  high-quality  translation  from  the
finetuned nllb model, which may contain
errors in named entity translations.
- target_locale (str):
The target language locale, e.g. 'de' for
German.
- candidates (list of EntityCandidate):
A list of candidate entities with their
expected translations and metadata.
These candidate translations are considered
correct and should be applied to fix
or  supplement  the  named  entity
translations.

Output Field:
- refined_translation (str):
The final translation where named entity
translations are corrected to match the
gold standard candidate information.

Abstract

Table Question Answering (TQA) involves extracting answers from structured data using natural language queries, a challenging task due to diverse table formats and complex reasoning. This work develops a TQA system using the DataBench dataset, leveraging large language models (LLMs) to generate Python code in a zero-shot manner. Our approach is highly generic, relying on a structured Chain-of-Thought framework to improve reasoning and data interpretation. Experimental results demonstrate that our method achieves high accuracy and efficiency, making it a flexible and effective solution for real-world tabular question answering. The source code for our implementation is available on GitHub [1].

1 Introduction

As tabular data becomes increasingly prevalent across domains such as finance, healthcare, and scientific research, there is a growing need for systems that can effectively interpret and extract information from structured data using natural language queries. Table Question Answering (TQA) addresses this challenge by enabling users to query tables without requiring a structured query languages like SQL. However, TQA remains a difficult task due to the diversity in table structures, ambiguous question formulations, and the need for numerical and logical reasoning.

In this paper we present a full pipeline for TQA. We prompt large language models (LLMs) to generate executable Python code dynamically. This method allows for flexible reasoning over tabular data without requiring task-specific training. Additionally, we introduce a structured Chain-of-Thought (CoT) framework that enhances the model's interpretability by decomposing reasoning into explicit Hint Generation and Code Generation steps.

To make our framework as dynamic as possible, we performed extensive prompt tuning to adapt to variations in table structures and data distributions. Since tabular data can change significantly across different domains, we iteratively refined our prompts to ensure robustness across datasets. We also analyzed errors to identify common mistakes and adjusted our approach accordingly. Additionally, we conducted a grid search over model parameters to optimize performance, balancing computational efficiency and accuracy. These optimizations allow our system to generalize effectively across diverse TQA scenarios.

We evaluate our approach on the DataBench dataset (Grijalba et al., 2024), a diverse benchmark featuring real-world tables and human-generated queries. Our results demonstrate that our method effectively handles a wide range of question types, including direct retrieval, numerical reasoning, and categorical filtering, while maintaining computational efficiency.

2 Related Work

Recent advances in TQA typically rely on two main approaches: Text-to-SQL models (Zhong et al., 2017; Yu et al., 2019), which translate natural language into executable queries, and end-to-end (E2E) models (Yin et al., 2020), which directly infer answers from table representations. While Text-to-SQL excels in structured retrieval and arithmetic reasoning, it struggles with unstructured tables and ambiguous queries. E2E models are more flexible but often lack precision in structured data retrieval. Hybrid approaches (Zhang et al., 2024a) have attempted to combine these strengths, but they typically require extensive pretraining and fine-tuning, limiting their adaptability across datasets.
In parallel, recent work has explored enhancing

[1] https://github.com/omarmoo5/semeval2025-task8

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 865–873

these models through Chain-of-Thought (CoT) reasoning techniques. Building on this line of research, the Chain-of-Table framework (Wang et al., 2024) introduces a novel method for table-based reasoning by integrating structured tabular transformations into the reasoning process of Large Language Models (LLMs). It enables dynamic table evolution, where each reasoning step applies operations such as adding columns, selecting rows, grouping, or sorting. These operations create intermediate tables that serve as proxies for the model's thought process.

Despite these advances, existing methods often require pretraining, fine-tuning, or introduce significant computational overhead. To address these limitations, we propose a zero-shot TQA approach that eliminates the need for any model-specific training. Our method leverages the Chain-of-Thought (CoT) framework to improve interpretability and overall system performance. The resulting approach is lightweight and easily adaptable across different datasets.

3 Task Overview

The main objective of the shared task (Osés Grijalba et al., 2025) is to develop a system capable of accurately answering questions based on real-world datasets presented in tabular formats.
The dataset utilized in this task is DataBench (Grijalba et al., 2024), a diverse collection of tabular datasets presented in English. It comprises 65 tables from various domains.
Each table is accompanied by 20 human-generated questions, resulting in a total of 1,300 questions and answers.
The task includes two subtasks:

- **Task I:** DataBench QA. Answer the questions using only the data provided in the dataset.
- **Task II:** DataBench Lite QA. Similar to Task I but uses a sampled version of each dataset (maximum of 20 rows per dataset), which is particularly useful for evaluating models with smaller input window sizes.

4 Approach

Our approach is primarily code-based, building upon the baseline model (Grijalba et al., 2024). We leverage LLMs by prompting them to generate executable Python code snippets for answering questions over tabular data.

In our initial experiments, the LLaMA-3 model served as the baseline, tested using a simple prompt (Figure 5 & 6) to evaluate its raw performance. Due to computational limitations, the model weights were quantized to 4 bits.
The baseline analysis revealed several challenges, detailed in the Experiments section. Specifically, the model struggled with non-intuitive data units, often misinterpreting values in the thousands, and lacked awareness of column values, leading to incorrect filtering and null outputs. To address these issues, we introduced several improvements:

- **Meta-Information Enrichment:** Prompts were enhanced by providing detailed meta-information, including all possible categories for categorical columns and statistical summaries (mean, minimum, and maximum) for numerical columns. This helped the model better interpret the data.
- **Chain-of-Thought (CoT) Paradigm:** Inspired by CoT reasoning, we divided the workflow into two distinct modules:
  - **Hints Generation:** predicts two key aspects: the expected answer type and the relevant columns needed to answer the question.
  - **Code Generation:** Takes the generated hints, along with the meta-information, and prompts the LLM to generate Python code capable of querying the dataframe and extracting the correct answer.
- **Post-Processing Module:** To further improve robustness, we introduced a post-processing step. If the generated code fails to execute, an automatic retry with an additional LLM call is triggered. This module also refines outputs—for instance, by converting a Pandas Series to a list to ensure type consistency with the ground truth.

This structured, multi-step approach, illustrated in Figure 1, significantly improved the model's reasoning abilities and produced more accurate and interpretable outputs.

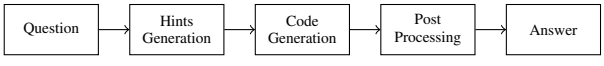

Figure 1: Final Approach

5 Experiments

5.1 Experiment 1: Enhancing the Baseline Prompt

In our initial attempts, we used the **Meta-Llama-3.1-8B-Instruct** model and modified the baseline prompt to provide more detailed information about the dataset. Specifically: For categorical columns, we listed all possible categories. For numerical columns, we included key statistics such as the mean, minimum, and maximum values. This enhancement improved the model's understanding of the dataset and helped prevent errors such as incorrect value indexing.

Example:

Question: How many billionaires are there from the 'Technology' category?

Part of the Generated Code:

```
billionaires = df[df['finalWorth']
>= 100000000]
```

However, in the dataset, 100000000 is expressed as 100 million, leading to potential indexing mistakes.

5.1.1 Experiment 2: Evaluating Alternative Models

To further improve performance, we tested other models using the same prompt structure. Specifically, we experimented with **Qwen2.5-Coder-7B-Instruct** (Hui et al., 2024), which significantly improved the results.

We also attempted to use **TableLLAMA** (Zhang et al., 2024b), but it performed poorly, as it frequently hallucinated answers rather than retrieving them directly from the dataset. Unlike other models, TableLLAMA takes the table as input and generates an answer without explicitly retrieving values, making evaluation and output constraints more challenging.

5.2 Experiment 3: Adding a Hint Module for Answer Type Prediction

To refine the model's responses, we introduced a hints module (Figure 9) to enrich the input prompt. The first hint required the model to predict the expected answer type, which was well-defined in the competition:

- `list[number]`
- `category`
- `number`
- `boolean`
- `list[category]`

Then the expected type is then passed to a code generation prompt. This adjustment helped prevent errors where the model focused too much on the logic of the question rather than retrieving the actual answer.

Example:

Question: Is the city with the most billionaires in the United States?

Incorrect Answer: Pottsville

By guiding the model with an answer-type constraint as shown in Figure 10, we reduced such errors.

5.3 Experiment 4: Building Upon Hints Module

To further improve accuracy, we introduced a second hint that predicted the relevant columns in the data frame needed to answer each question (Figure 12). This strategy narrowed the search space, helping the model focus on the most relevant data and reducing errors.

6 Results

All experiments were conducted on a V100 GPU (32GB memory), with all models quantized to 4 bits to fit within memory constraints.

For each experiment, we tested multiple temperature settings to assess their impact on performance.

The experiments were evaluated using the databench eval package.

6.1 Experiment 1:

Temperature	0.4	0.5	0.6	0.7	0.8
Full Dataset	0.5290	**0.5405**	0.5237	0.5366	0.5054
Lite Dataset	**0.5489**	0.5382	0.5175	0.5428	0.5306

Table 1: Results of Experiment 1.

6.2 Experiment 2:

Temperature	0.4	0.5	0.6	0.7	0.8
Full Dataset	**0.6758**	0.6758	0.6651	0.6689	0.6643
Lite Dataset	**0.6941**	0.6865	0.6827	0.6766	0.6766

Table 2: Results of Experiment 2.

6.3 Experiment 3:

Temperature	0.4	0.5	0.6	0.7	0.8
Full Dataset	**0.7000**	**0.7000**	0.6957	0.6888	0.6957
Lite Dataset	**0.7056**	0.7049	0.7000	0.6918	0.6972

Table 3: Results of Experiment 3.

6.4 Experiment 4:

Temperature	Full Dataset	Lite Dataset
0.1	0.7484	0.7629
0.2	0.7454	**0.7691**
0.3	0.7500	0.7660
0.4	0.7500	0.7637
0.5	0.7400	0.7607
0.6	0.7484	0.7610
0.8	0.7385	0.7599
0.9	**0.7561**	0.7614
1.0	0.7431	0.7607

Table 4: Results of Experiment 4.

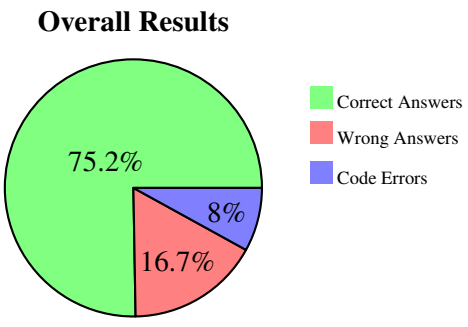
7 Results and Analysis

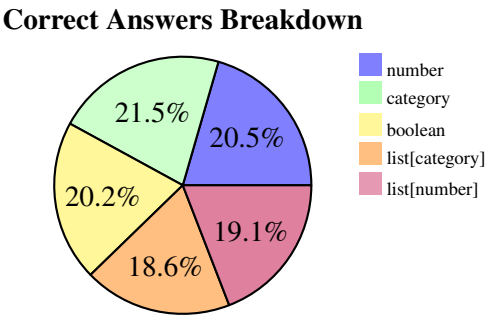
The analysis in the table below is conducted using Experiment 4 with a temperature of 0.7 on the dev set. The results were obtained by using the databench eval package.

Category	Full	Lite
Avg Accuracy	0.75225	0.77824
Boolean	0.75954	0.79389
Number	0.77692	0.78462
Category	0.80608	0.80989
List[Category]	0.70115	0.73946
List[Number]	0.71756	0.76336

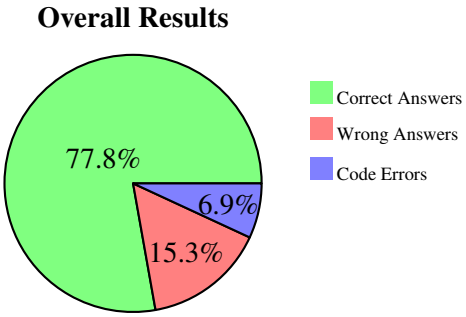
Table 5: Accuracy of Predicting Different Question Types for Full and Lite Datasets

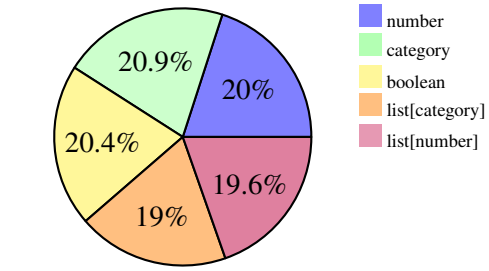
7.1 Results on the Full Dataset (Dev)





7.2 Results on the Lite Dataset (Dev)





7.3 Results on the Test Dataset

On the test dataset, we used larger models. We made two submissions as follows:

Model	Full	Lite
Qwen2.5-Coder(14B) Q4	71.64	75.28
Qwen2.5-Coder(32B) Q4	75.67	78.73

Table 6: Accuracy on the test Dataset

7.4 Error Analysis

In this section, we present an error analysis of our final pipeline, evaluated using the model **Qwen2.5-Coder-32B-Instruct** on the training dataset with a temperature setting of **0.7**. Due to computational constraints, we were unable to conduct a large number of experiments with this model.

There are multiple reasons that we identified for the errors:

7.4.1 Data cleaning issues

Some tables, such as **054_Joe** and **007_Fifa**, have columns renamed with type annotations (e.g., **column_name<gx:data_type>**). However, the LLM sometimes incorrectly omitted the datatype suffix during code generation, leading to code failures. An example from the **054_Joe** table is shown below (Figure 2).

```
{
    "Question": "What are the two
        highest numbers of retweets a
        tweet in the dataset?",
    "Table": "054_Joe",
    "Generated Code":
    def answer(df):
        return df['retweets'].nlargest
            (2).tolist(),
    "Answer": "Code Error",
    "Ground Truth": [205169, 101314]
}
```

Figure 2: Example of Data Cleaning Error

In this case, the column should have been referenced as **retweets<gx:number>** instead of **retweets**, resulting in a code failure. These types of errors require further investigation of the answer tables and additional cleaning to remove such inconsistencies.

7.4.2 Limitations in Handling Corner Cases Requiring Multiple Steps of Reasoning

Some questions involved corner cases that required multiple steps of reasoning, which the LLMs struggled to handle. One such issue occurred in table **046_120**, where the same athlete appeared multiple times, leading to incorrect results in the top 3 weights (Figure 3).

```
{
    "Question": "What are the three
        highest weights of athletes?",
    "Table": "046_120",
    "Generated Code":
    def answer(df):
        return df['Weight'].nlargest(3).
            tolist(),
    "Answer": [214.0, 214.0, 198.0],
    "Ground Truth": [214.0, 198.0,
        190.0]
}
```

Figure 3: Example of Handling Corner Cases Errors

This problem arises because the LLM does not account for duplicate entries of the same athlete, resulting in multiple counts of the same weight. This error in such questions could be mitigated through few-shot training, which encourages the model to consider all possible scenarios, or by adding an additional layer for Chain of Thought (CoT) while solving the question

7.4.3 Logic Code Errors

There also exist some logical code errors. In the case of table **002_Titanic**, the generated code failed due to an incorrect use of the **.any()** function (Figure 4).

```
{
    "Question": "Did any children below
        the age of 18 survive?",
    "Table": "002_Titanic",
    "Generated Code":
    def answer(df):
        return (df['Age'] < 18) & (df['
            Survived']).any(),
    "Answer": [False, False, False,
        False, False, False, False,
        False, True, False, False, False
        , False, False, False, True,
        False, False, False, False],
    "Ground Truth": True
}
```

Figure 4: Example of Logic Code Error in Titanic Dataset

The issue arises because the **.any()** function is applied to the **df['Survived']** column only, rather than evaluating the condition for each row. This leads to an incorrect output. To reduce such errors in the future, the model code generation capabilities must be improved.

8 Conclusion

In this work, we explored multiple LLMs and experimented with various prompt modifications. Our findings indicate that enhancing prompts with richer data context significantly improves the model's understanding of the dataset and its values. Additionally, decomposing the problem into smaller tasks—such as predicting the answer type, identifying relevant columns, and then integrating this information to generate the final code—proved to be more effective than attempting to generate the code in a single step.

This structured approach helped us improve upon baseline results by reducing errors and enhancing accuracy. Furthermore, systematic data analysis and tracking model errors played a crucial

role in identifying the model's weaknesses, allowing us to refine our approach and achieve better performance.

Our final system achieved a score of **79.31** in the final ranking of the *full DataBench* test set, ranking **24th overall** and **16th among open-source models**. On the *DataBench Lite* test set, our system ranked **17th overall** and **11th among open-source models**. Notably, these results were obtained using a **quantized version of the LLM**. Given these results, we believe that running our approach on a full-precision model could further enhance accuracy by leveraging richer representations and reducing potential quantization-related losses. This highlights the adaptability of our framework and its potential to achieve even stronger performance with greater computational resources.

9 Future Work

In the future, we plan to explore the use of larger models to further improve our results. Due to resource constraints, we were unable to use larger models and instead relied on quantized versions. We strongly believe that scaling up to larger models would significantly enhance performance.

Additionally, adopting a more interactive approach to analyze model errors and dynamically modify prompts could lead to better outcomes. Another area for exploration involves testing more models, particularly recent ones such as DeepSeek. Although we attempted to use this model, we encountered challenges related to constraining the generated output, which required parsing effort during the development phase. Further efforts will be necessary to refine and optimize the use of this model for improved results.

Team UBD at SemEval-2025 Task 11: Balancing Class and Task Importance for Emotion Detection

Cristian Daniel Păduraru
University of Bucharest, Romania
cristian.paduraru@s.unibuc.ro

Abstract

This article presents the systems used by Team UBD in Task 11 of SemEval-2025. We participated in all three sub-tasks, namely Emotion Detection, Emotion Intensity Estimation and Cross-Lingual Emotion Detection. In our solutions we make use of publicly available Language Models (LMs) already fine-tuned for the Emotion Detection task, as well as open-sourced models for Neural Machine Translation (NMT). We robustly adapt the existing LMs to the new data distribution, balance the importance of all emotions and classes and also use a custom sampling scheme. We present fine-grained results in all sub-tasks and analyze multiple possible sources for errors for the Cross-Lingual Emotion Detection sub-task.

1 Introduction

In this project, we address the three sub-tasks (tracks) of Emotion Detection (ED), Emotion Intensity Estimation (EIE), and Cross-Lingual Emotion Detection (CL-ED) from SemEval-2025 Task11 (Muhammad et al., 2025b). While the organizers provided a dataset with samples from 28 different languages (Muhammad et al., 2025a), we only focused on English, German and Spanish for the first two sub-tasks and Romanian, Portuguese, Ukrainian, Russian, Hindi and Indonesian in the last one.

Our solutions mainly rely on language-specific encoders that have already been fine-tuned for the emotion detection task and robustly adapt them to the new data distribution. To bridge the gap between languages in the last task we use an open-source NMT system to translate the test sets of other languages, and also experiment with cross-lingual LMs (XLMs).

We find that the emotion-specific performance of our systems correlates well with the frequency of positive examples in the first two sub-tasks. This indicates that data scarcity can still be a problem, even when it is addressed through common means. For the CL-ED sub-task we find multiple factors that lead to degraded performance on new languages, some of which are system-specific, while others are common to both of them. Notably, the relatedness of languages does not correlate well with cross-lingual performance in our experiments.

The implementation of our solutions will be published on github[1].

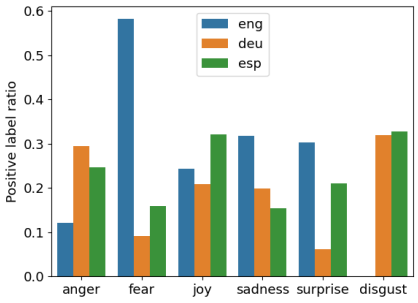

Figure 1: The ratio of positive labels in the train set of the three languages addressed in the ED sub-task.

2 Background

Related Work The task of Emotion Detection has found diverse applications (del Arco et al., 2024), such as analyzing social interactions, monitoring mental well-being (Chiruzzo et al., 2024; Paduraru and Anghelina, 2024), highlighting mental health concerns or understanding people's emotions during stressful events (Sosea et al., 2022). While earlier works have tried to use a mix of low-level features and more abstract ones, obtained from Deep Neural Networks (Khanpour and Caragea, 2018), the Transformers architecture (Vaswani et al., 2017) has become the default architecture for this task (Acheampong et al., 2021) in recent years, with people using even specialized

[1] https://github.com/PaduraruCristian/MachineTranslation

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 874–884

pre-training objectives (Sosea and Caragea, 2021) to improve results in this downstream task.

For the Cross-Lingual variant of the task, multiple solutions have been proposed. Some notable ones are: using multilingual encoders and training detectors on language agnostic representations of the texts (Alejo et al., 2020; Zhang et al., 2024; Hassan et al., 2022), distilling monolingual detectors into cross-lingual models (Wang et al., 2024), translating texts into a language where annotated training data is available (Alejo et al., 2020; Hassan et al., 2022) and even using Large Language Models as zero-shot detectors (Kadiyala, 2024).

Dataset We work on the dataset provided by Muhammad et al. (2025a), which contains texts from 28 different languages, annotated with the 6 emotions from Ekman's model (Ekman and Friesen, 1981).

3 System Overview

In our solutions we use language-specific encoders, based on the Transformer (Vaswani et al., 2017) architecture, that have already been fine-tuned for the emotion detection task, in order to extract deep representations of the textual samples. We then add a linear classification layer to the encoders and train them with dynamic weights to balance the importance of each class and emotion.

3.1 Track A: ED

Linear Probing By keeping the encoders frozen we can individually train the classifiers for each emotion, as their optimization is completely independent from one another. To address the imbalance between positive and negative classes we computed the individual loss of each sample, averaged the losses of samples from the same class, and finally averaged the losses for the positive and negative classes. After training a linear classifier we also adjust its detection thresholds by iterating through a range of values and selecting the one that leads to the highest dev set F_1 score.

Fine-tuning In order to robustly fine-tune the encoders, we follow Kumar et al. (2022) and initialize the linear classification layer with the one previously trained on the frozen encoder embeddings. We then jointly update both this layer and the encoder's parameters, balancing the classes in the same manner as before. As the detectors for all emotions are simultaneously trained in this case, we further balance the importance of each one by averaging the emotion specific losses.

Besides this balancing, we also implemented a custom sampling scheme to make it unlikely for a batch to have no positive examples for an emotion. At each step, we uniformly select a random emotion and label and then retrieve a sample from the dataset with the selected label on that emotion.

The fine-tuning process does not ensure that the classification layers are optimal for each emotion with respect to the current encoder parameters. We thus decided to keep the fine-tuned encoder and remake the classification layers for each emotion individually, with the same procedure previously presented. We provide in the Appendix (Tab. 5) the F_1 scores on the dev set for the fine-tuned detectors and the second linear probes for comparison.

3.2 Track B: EIE

As the intensity levels for the emotions were discrete, we modeled this sub-task as a multi-label classification problem. We trained linear probes on text embeddings from the same encoders used in Track A (the frozen ones and their fine-tuned variants) with the class-balanced loss described in Sec. 3.1.

3.3 Track C: CL-ED

For this sub-task, we chose to translate the test sets of multiple languages into Spanish, using an NMT system from the NLLB (NLLB et al., 2022) family of LMs. We then use a classifier trained in Task A for Spanish in order to detect the emotions in these translated texts.

In the development period of the task we have also experimented with classifiers based on cross-lingual LMs. The classifiers were trained using only texts written in the three languages addressed in Track A, and then applied on texts from other languages of this sub-task.

4 Experimental Setup

In all sub-tasks we use only the data provided by the task organizers, without applying data augmentations or any pre-processing before tokenizing the texts. We used the data splits provided by the organizers (train/dev/test), with a single exception in the experiments based on cross-lingual models, where 15% of the train data is used for validation and the dev split is used for testing. All classifiers were trained using the

Language	Emotion						Macro F_1
	anger	fear	joy	sadness	surprise	disgust	
English	48.08	77.26	68.97	68.69	62.35	-	65.07
German	63.79	32.63	63.59	52.54	19.18	64.96	49.44
Spanish	74.15	75.00	74.87	76.36	70.8	79.36	75.09

Table 1: Test set F_1 scores in Track A of the linear probes trained on frozen embeddings.

Language	Emotion						Macro F_1	Official Ranking
	anger	fear	joy	sadness	surprise	disgust		
English	55.51	79.82	68.97*	68.69*	67.06	-	68.01	58/74
German	73.62	37.31	67.47	52.54*	29.76	64.96*	54.27	32/44
Spanish	75.09	75.00*	74.87*	78.74	72.16	81.28	76.19	25/44

Table 2: Test set F_1 scores in Track A, mixed between the linear probes trained on embeddings from the frozen encoders (marked with *) and those on embeddings from the fine-tuned encoders. These are the results of our final submission in Track A.

AdamW (Loshchilov and Hutter, 2019) optimizer implemented in Pytorch (Ansel et al., 2024) and the pre-trained encoders were downloaded from HuggingFace[2]. The following encoders were used in Tracks A&B for each language:
English: SamLowe/roberta-base-go_emotions[3]
German: visegradmedia-emotion/Emotion_RoBERTa_german6_v7[4]
Spanish: pysentimiento/robertuito-emotion-analysis[5] (del Arco et al., 2020; Pérez et al., 2021; Pérez et al., 2022)

4.1 Track A

Linear Probing We used the hidden state of the CLS token from the last transformer block as the sequence representation, ignoring the pooler layer if the encoder happened to have one. The linear probes were trained for 50 epochs with the binary cross entropy loss, a learning rate and weight decay of 1e-3, a batch size of 512, and a cosine annealing learning rate schedule with a minimum learning rate of 1e-5. The linear probes are trained individually for each emotion with three different random seeds and the final weights are selected based on the dev set F_1 score. The detection threshold on the logits is adapted for each emotion by iterating through values in the [-2, 2] interval with a step of 0.1, computing the F_1 score on the dev set at each threshold, and selecting the best one.

Fine-tuning Due to the low number of examples we only adjust the parameters of the last two transformer blocks and the final classification layer. The weights are tuned with the binary cross entropy loss, a learning rate of 1e-5, weight decay of 1e-2, and batch size of 256. To ensure the stability of training, we also clipped the gradients to a maximum global value of 3. The weights are trained for up to 500 steps and evaluated on the dev set every 25 steps (due to the uniform sampling the concept of *epoch* is no longer well-defined).

4.2 Track B

In this sub-task we trained a linear classifier for each emotion with the cross-entropy loss and the same hyper-parameters from Track A's Linear Probing setup. Due to the lower number of samples for higher intensity levels, we increased the batch size to 1024 and the number of epochs to 150, to make up for the reduced number of steps per epoch.

4.3 Track C

We translated the texts into Spanish using the distilled NLLB-1.3B (NLLB et al., 2022) model, always producing up to 200 tokens. English could not be used as a target language for translation because it lacks a classifier for the *disgust* emotion, while for German the results in Track A were worse compared to the other two languages. We didn't apply any post-translation processing on the texts to ensure that the LM did not start hallucinating or went in a loop, repeating the same token at output.

Table 4: Test set F_1 scores in Track C, obtained by the linear probes trained on fine-tuned embedding for Spanish texts in Track A. The results from Track A on Spanish are also added for comparison. The results on the other six languages correspond to our final submission in Track C.

For the experiments with cross-lingual LMs we have performed linear probing on embeddings extracted with the LEALLA-large (Mao and Nakagawa, 2023) and QWEN2.5-7B (Yang et al., 2025) models and also fine-tuned the LEALLA model. The complete setup is detailed in Appx. A.

5 Results

Track A The results of the linear probes on the test set of the competition are presented in Table 1. We observe that the detectors trained on Spanish texts are the only ones to consistently perform well on all emotions. For texts written in German, the detectors for *fear* and *surprise* lack in performance when compared to the detectors for other emotions. In the case of English texts, the detector for *anger* is the only one that is well below the average performance level, while *fear* is highly above it. This pattern is correlated with the frequency of positive labels in the provided train sets (see Fig. 1) for English and German. For detectors trained on Spanish texts however, we notice that this correlation does not hold anymore. The correlations on English and German data are still maintained even after fine-tuning (see Table 2). We also notice that each emotion attains different levels of improvements in the second linear probing (Table 5 in the Appendix), but this is not correlated with the initial performance of the fine-tuned detectors.

The frequency of positive samples alone is not a good indicator for the final performance. While *joy* and *sadness* have similar frequencies in German data, there is a 10% gap in F_1 score between them in the linear probing scenario (Table 1). Also, the *disgust* label has similar frequency in German and Spanish data, but the difference in F_1 score is close to 15%. We believe that this is where the inherent task difficulty and quality of the encoders used are most likely to make the difference.

For certain emotions, the initial linear probes performed better than those trained on the fine-tuned encoders. Thus, we decided to select for each emotion the test set predictions from the linear probe that had the highest F_1 score on the dev set. The results of this **final submission** are presented in detail in Table 2.

Track B The test set results for the previously described experiments in this sub-task are presented in Table 3. Using the fine-tuned encoder resulted in increased performance in almost every case (the only exception is the *sadness* label for the English data). The largest improvements are in the German

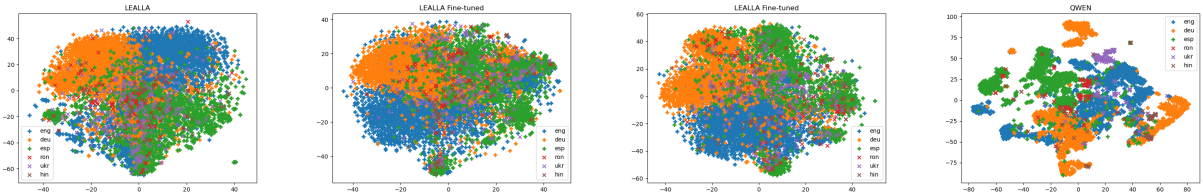

Figure 2: t-SNE visualizations of language specific embeddings extracted with LEALLA-large pre-trained (left), 4 blocks fine-tuned (middle left), 8 blocks fine-tuned (middle right) and QWEN2.5-7B (right) from the train set of Track A for English, German and Spanish, and from the dev set of Track C for Romanian, Ukrainian and Hindi.

data, which also had the worst performance without fine-tuning. The improvement on each emotion is also not uniform - the highest gains are on the emotions that initially had the lowest scores. We consider this to be thanks to the balancing of emotions from the previous sub-task, which helped the encoder attend more to the ones with higher loss, but without disregarding the others, so that their performance did not degrade through fine-tuning. The results of the **final submission** are marked in Table 3 with a gray background.

Track C The results of our system for this Track are presented in Table 4, along with the results for Spanish from Track A, only for comparison. While a decrease in overall performance (Macro F_1) was expected, we note that this decrease is not uniform across the individual emotions and languages. Certain detectors transfer well only to a single language, losing less than 5% in terms of F_1, but most of the times the decrease is well above 10%. Surprisingly, the detector for *joy* achieved better performance on texts translated from Romanian than on the texts from Track A, originally written in Spanish. We also noticed that the drop in performance is not necessarily correlated with the similarity of Spanish and the target languages. For example, the performance on Hindi texts is the highest on average, surpassing the Romance languages considered (Romanian and Portuguese).

In the described framework we have identified multiple sources of errors. The first one is the quality of the translations - we validated that in certain cases the NMT system started repeating a single token multiple times. Nonetheless, as almost all languages have at least one emotion with an F_1 higher than 60% (Ukrainian is the sole exception), we expect this type of errors to be limited. Another possibility is for low-level cues for the perceived emotions (e.g. punctuation) to be lost in the process or for the choice of words to be unusual due to translationese (Rabinovich et al., 2017). We expect these problems to be correlated to the data distribution used for training the NMT model.

A general source of errors is the distributional shift between languages, regarding the topics they covered. We manually determined that texts in Romanian seemed to be mainly scraped from news websites and covered topics like politics and the recent COVID-19 pandemic, whereas the texts in English contained mostly short texts that were likely written on social media websites. These particularities might bias the detectors towards detecting certain topics, not the emotions themselves, resulting in degraded performance in other contexts.

Through our experiments in the dev period with Cross-Lingual models we have noticed that they also suffer a great performance degradation on new languages (consult Appx. A for the results). We provide in Fig. 2 a t-SNE visualization of text embeddings extracted with the LEALLA-large and QWEN2.5-7B models. We observed that the data tends to form language-specific clusters, which we assume to be the main reason for the poor generalization of the trained detectors to new languages. This embeddings space structure can be caused both by the topic changes between languages, and the language specificity of the embeddings.

In order to quantify the impact of the two factors mentioned above one would require high quality translations pairs, as well as topic annotated samples. We leave this detailed study as future work and only investigate in Appendix A the text pairs translated with the NLLB model in Track C. While no clear conclusion can be reached, we reason based on the observed evidence that severe translations errors are surely present.

6 Conclusions

In this work we have presented our systems and results for the three tracks of Task 11 from SemEval-2025. For the ED task we observed that properly balancing the classes and emotions in the fine-

tuning of LMs leads to consistent performance improvements. In the EIE one we have shown that fine-tuning with the simple detection objective from before can greatly increase performance in this task, especially for the under-performing emotions. Lastly, in the CL-ED task we have tested two types of systems, one relying on NMT and one on cross-lingual LMs. We presented the specific and common issues of both system types, proposing future research directions for quantifying the impact of these error sources.

Acknowledgments

The authors would like to thank Sergiu Nisioi and Ana-Sabina Uban for the provided references and resources, and also for reviewing an earlier version of this article. We also thank the anonymous reviewers for their feedback and suggestions for improving the article.

A Cross-Lingual Models

t-SNE visualization Regarding the t-SNE plots from Figure 2, we want to highlight that the tanh activation of the pooler layer in the LEALLA-large model is likely the main reasons why all the embeddings are clumped together more tightly than the embeddings of the QWEN model.

Setup In our experiments with cross-lingual LMs from the development period, we used the output of the pooler layer for the LEALLA encoder as sequence representation, while for the QWEN LM we used the last hidden state of the last token. The QWEN embeddings were extracted from a 4-bit quantized version of the model, using the Unsloth[6] library, and L_2 normalized. The linear classifiers were trained with the same methodology and hyperparameters as before, but without further adjusting the detection thresholds.

LEALLA encoder The results of the linear probes trained on embeddings from the LEALLA-large model are presented in Table 6. We also fine-tuned the LEALLA encoder on all 3 languages addressed in Track A, following the recipe presented in the main article (see Table 7 for the results). The performance degradation on new languages is higher than 10% in most of the cases. Another observation is that training the linear probes only on embeddings from Spanish texts leads to better cross-lingual performance on Ukrainian and Hindi than training on all 3 languages from Track A.

We also observe that the cross-lingual performance improvements from fine-tuning are not uniform across the new languages. For Romanian the macro F_1 score either improves by less than 1%, or decreases by almost 2%, while on Ukrainian we observe and improvement of 5-7% and 13-15% for Hindi.

QWEN embeddings The results of the linear probes trained on QWEN embeddings are presented listed in Table 8. We also trained logistic regression models using the implementation in sklearn (Pedregosa et al., 2011) with the *lbfgs* and *linear* solvers. The results of these models (see Table 8) were actually worse than the results with LEALLA embeddings. We initially assumed that overfitting was the most likely cause, as the dimensionality of the embeddings was 14 times larger. To address this, we used PCA to reduce the dimensionality of the embeddings and then retrained the linear classifiers with the Pytorch implementation. We present in Table 9 the results with increasing number of principal components. As the validation Macro F_1 score keeps increasing with the number of components we conclude that the dimensionality reduction actually removes useful information from the embeddings. We also note that for Ukrainian and Hindi the best results are obtained with fewer components, not with the original embeddings, meaning that the dimensionality reduction also removed some information that was damaging for cross-lingual transferability.

Similarity of translated text pairs We provide in Figure 3 a set of t-SNE plots for LEALLA-large embeddings of the test set from Track C for the 6 addressed languages, both in its initial form and the version translated into Spanish with the NLLB model. We observe that the translated variants are more spread out than the originals, but they remain centered in the same region as the initial embeddings.

In Figure 4 we present histograms for the cosine similarity of original and translated text pairs, encoded with the pre-trained LEALLA model. The low cosine values can indicate both translation errors and language specificity of embeddings. While it is not clear based on these figures what the main source of errors is in the cross-lingual setting of ED, we believe that very low cosine values (less than 0.2) are most likely caused by severe translation errors. We assumed this based on the tendency of deep networks to restrict their outputs to a narrow cone (Liang et al., 2022). Thus, embeddings that largely deviate from this cone are most likely extract from nonsensical inputs, which are outside the distribution of texts used for training the encoder.

As for the generally poor performance of the models trained from this encoder (including the inditribution setting), we assume that this is caused by the data used for pre-training, which may not contain emotion-showcasing samples. The pre-training objective itself is more oriented towards matching information, not emotions, thus the em-

beddings are unlikely to capture emotions-related features. While fine-tuning can help address this issues, a complete one would fair better than the partial fine-tune that we have done. Even in this case, one would have to take measures to prevent the occurrence of catastrophic forgetting (McCloskey and Cohen, 1989), making sure that the encoder remains language agnostic.

B Language Families Covered

Abstract

This paper presents our findings for SemEval 2025 Task 2, a shared task on entity-aware machine translation (EA-MT). The goal of this task is to develop translation models that can accurately translate English sentences into target languages, with a particular focus on handling named entities, which often pose challenges for MT systems. The task covers 10 target languages with English as the source. In this paper, we describe the different systems we employed, detail our results, and discuss insights gained from our experiments. In our initial approach, we selected the distilled 600M-parameter variant of NLLB-200, which had been fine-tuned using the training dataset provided by the task organizers. For the second and third approaches, we opted for prompt engineering using two templates on Google's Gemini-1.5 model. The two templates were based on zero-shot and few-shot learning techniques respectively. Ultimately, the Gemini results demonstrated superior performance compared to the fine-tuned NLLB model. Furthermore, our approach revealed that European languages had higher overall scores compared to other languages. However, it is worth noting that we observed an interesting performance from Turkish, which even outperformed some European languages.

1 Introduction

The quality of translations produced by machine translation (MT) systems has improved considerably (Abdulmumin et al., 2024). However, despite these advancements, translations into the target language still contain errors, often due to the challenges associated with translating named entities (Rikters and Miwa, 2024). Entity-aware machine translation is a type of MT that considers specific entities, such as names, locations, and organizations, to enhance translation accuracy and fluency (Conia et al., 2024). Several approaches have been proposed to improve these models' ability to translate named entities more effectively, accounting for the need for transliteration in some cases while generating equivalent translations in others.

In this paper, we describe our submissions to SemEval 2025 Task 2: Entity-Aware Machine Translation shared task (Conia et al., 2025). Our systems include sequence-to-sequence entity-aware supervised models trained to improve the translation of English sentences into French, German, Spanish, Italian, Japanese, and Arabic. A pretrained NLLB (NLLB Team et al., 2022) model was fine-tuned for bilingual translation with the provided training data in each of these languages. Furthermore, we investigated the performances of a closed-source Large Language Model (LLM), Gemini (Team et al., 2024), on these languages, in addition to Chinese, Korean, Thai, and Turkish. Our results indicate that Gemini, in a zero-shot setup, achieved the best overall performance, with only a few languages showing improvements when examples from the training data were incorporated in few-shot setups.

2 Related Works

Several studies have explored approaches to improving named entity (NE) translation in machine translation (MT) systems. Xie et al. (2022) proposed an entity-aware model that employs classifiers in both the encoder and decoder to handle named entities more effectively. Other methods include hierarchical encoders with chunk-based processing (Ugawa et al., 2018), IOB-tagging for improved NE annotation (Modrzejewski et al., 2020), and a decoupled NE handling approach that enhances translation quality without modifying the NMT architecture (Mota et al., 2022). Zeng et al. (2023) developed an Extract-and-Attend strategy that first identifies and translates named entities separately before incorporating them into the trans-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 885–892

lation process.

Recent advancements also include entity-aware multi-task training on pre-trained models such as T5, which improves NE translation quality and also increases the number of named entities generated in German translations of English texts (Rikters and Miwa, 2024). Yang et al. (2024) introduced the AMFF and CAMFF frameworks, which utilize attention mechanisms to improve named entity recognition (NER) by incorporating multilevel contextual features. Jauhari et al. (2024) introduced Entity-Aware Techniques (EaT) that integrate semantic parsing to help MT models recognize and accurately translate named entities. Awiszus et al. (2024) evaluated NE translation in speech translation systems, highlighting persistent challenges despite improvements in recall and precision. While these methods improve entity translation, our approach fine-tunes the pre-trained NLLB model using both the provided training data and extracted named-entity translations from Wikidata. Additionally, we evaluate the closed-source Gemini model without fine-tuning, assessing its performance in both zero-shot and few-shot setups. Our work focuses on achieving a balance between overall translation quality and ensuring the accurate translation of critical named entities.

3 Proposed Approaches

The team adopted four approaches for this task. The first two approaches included fine-tuning the NLLB pre-trained model in a bilingual setup for **eng**→**xxx** translation. The two other approaches were the use of two different prompt templates to evaluate the performance of Google's Gemini closed-source model. The team combined the traditional fine-tuning technique and prompt-engineering strategies to assess their relative effectiveness in preserving entity integrity during bilingual translation.

3.1 Supervised Fine-tuning

This method was employed to train bilingual translation models for six languages, as training data was not available for all target languages. In the first fine-tuning approach, we fine-tuned the base NLLB model using the provided training data. The second approach involved leveraging the SpaCy (Honnibal et al., 2020) NER framework to extract named entities from the training data and then searching for their equivalent translations on Wikidata (Vrandečić and Krötzsch, 2014). The resulting entity pairs for each source-target language pair were used as additional training data to fine-tune the models. Rather than focusing solely on the named entities provided in the task, we opted to use all entities present in the training data. This approach aimed to improve the models' ability to translate a broader range of entities rather than limiting ourselves to the subset specified in the task. While restricting to the provided subset might have resulted in better performance, we prioritized enhancing the model's accuracy, even at the potential cost of competitiveness. This second approach led to the development of an entity-optimized variant of the NLLB-200 model, refined through targeted fine-tuning using the extracted named entities.

3.2 Prompt Engineering

Complementing these fine-tuning methods, two prompt-based strategies were implemented. The zero-shot approach utilized minimalist templates instructing the model to "preserve entity integrity" during translations. The few-shot variant extended this with 10 curated demonstration pairs from the training data in the task repository. The choice of these two prompts was to see the effect on performance of the Gemini model when given an example outputs with preserved entities. For target languages without training data, the template provided no examples. The examples followed a structured template showing entity preservation by providing the Wikidata-id of the entity as present in the training dataset.

4 Experiments

4.1 Dataset and pre-processing

The dataset used to fine-tune the NLLB-200 model was made available as part of the shared task (Conia et al., 2024), with the number of data points in the different splits detailed in Table 2. This repository included training data for English-to-Arabic, German, French, Spanish, Italian, and Japanese translations, which were also used for the few-shot prompting approach. Additionally, the validation and test data for all 10 languages are provided, with the test data being unlabelled.

We also extracted the NEs from Wikidata[1], resulting in 4,587 unique entities and their translations (where available); see Table 3. We used these

entities when fine-tuning the NLLB model and as part of the few-shot prompting. Training the NLLB model required tokenizing the training data; this was achieved using the NLLB tokenizer. The prompt engineering approach did not require any data preprocessing.

4.2 Models and environment setup

The fine-tuning approach involved training the NLLB-200 model, specifically the distilled 600M[2] parameter variant. The fine-tuning was conducted using the default Hugging Face hyperparameter setup: a batch size of 32, sequence lengths of 128 for both source and target, a generation beam search width of 5, a dropout rate of 0.1, and a training duration of 10 epochs. Early stopping was applied if there was no improvement in the model's performance after two consecutive epochs.

For the prompt engineering method, we utilized Langchain's (Chase, 2022) ChatPromptTemplate[3] and ChatGoogleGenerativeAI[4] modules to evaluate the performance of Gemini Flash 1.5[5]. We provide the prompt templates that were used in Templates 1 and 2. The results were saved in JSON format as required from the task submission description.

4.3 Evaluation

We used the metrics provided for the shared task to evaluate our systems. These metrics are COMET (Rei et al., 2020) and Manual Entity Translation Accuracy (M-ETA; Conia et al. 2024). COMET is a machine translation evaluation metric that leverages a pre-trained model to generate quality scores by comparing system outputs to human translations. M-ETA assesses the accuracy of entity translations in machine translation by computing the proportion of correctly translated entities against a gold standard. Untranslated source texts are scored 0. The overall score, Equation (1), is computed as the harmonic mean (F1 score) of the COMET and M-ETA metrics, ensuring that systems are rewarded for balanced performance across both rather than excelling in only one.

$$\text{Overall Score} = 2 \times \frac{\text{COMET} \times \text{M-ETA}}{\text{COMET} + \text{M-ETA}} \quad (1)$$

5 Results

Table 1 below gives a summary of the models' performances across the proposed approaches. The NLLB column contains only results for languages that have training data.

The results indicate that while all 3 approaches achieved similar COMET scores at sentence level, the Gemini model, both in it's 0- and few-shot settings, performed better at translating the named entities in the source text. This can be observed by the higher M-ETA scores obtained by Gemini compared to NLLB. In almost all the target languages where we have results, Gemini has almost twice the M-ETA scores of NLLB. At the language level, English-to-Spanish translation achieved the best performance across all the evaluated approaches on all the evaluation metrics. This is in contrast to the Chinese language translation from English, with a paltry overall score of 14.83.

It is important to highlight the performance disparity between European and Asian languages. European languages, including Spanish, Italian, French, and German, consistently achieved higher scores across all methods, except for Japanese. Italian, for instance, achieved scores of 55.68 and 54.92 with Gemini's approaches, while NLLB managed 22.28. In contrast, Asian languages presented lower scores, with Chinese recording the lowest scores (15.55 and 14.83) among all languages tested. Japanese, while performing moderately well with Gemini (50.57 and 50.68), showed lower scores compared to European languages in NLLB but higher than the other Asian language: Arabic. Overall, Spanish and Italian achieved better results than the others in NLLB.

As highlighted earlier, not all the target languages had training data, so this affected the testing of these languages with the NLLB model, thus resulting in no scores for Chinese, Korean, Thai, and Turkish. However, an interesting finding was Turkish's performance with Gemini (56.63 and 57.40) despite the absence of few-shot examples, yet it's performance was second to only Spanish.

A comparison of the two Gemini implementations revealed minimal differences between the zero-shot and few-shot approaches. This suggests that elaborate few-shot prompting may not be necessary to achieve optimal results in entity translation tasks.

6 Conclusion

Prompt engineering for large language models like Gemini proves effective for entity-aware machine translation. Comparative studies with fine-tuning the NLLB-200 model show a consistent performance advantage for Gemini's zero-shot and few-shot prompting across target languages, highlighting its ability to preserve entity integrity in translation. While our results reveal nuances in performance across language families, with European languages exhibiting stronger overall scores and an intriguing performance from Turkish, the overarching trend favors prompt-based methodologies.

7 Limitations

Our evaluation was constrained by the lack of training data for Chinese, Korean, Thai, and Turkish in the task repository, preventing us from fine-tuning NLLB models for these languages. Additionally, due to limited computational resources, we were only able to fine-tune the distilled 600M-parameter variant of NLLB-200, rather than a larger model that could potentially yield better results.

Ethics Statement

This work followed the guidelines provided in SemEval 2025.

zsarifau@gmail.com

Abstract

This paper presents Trans-Sent, our system developed for Track A: Multi-label Emotion Detection of SemEval-2025 Task 11: Bridging the Gap in Text-based Emotion Detection. The aim of this task is to predict the emotions that a speaker may convey i.e. perceived emotions. A target text snippet is given and our goal is to label the text by 1 and 0 as 'yes' and 'no' for different emotional classes like joy, sadness, fear, anger, surprise and/or disgust. Trans-Sent is a Transformer-based sentiment extraction model. It uses various pre-trained Bidirectional Encoder Representations from Transformers or BERT models for individual language to generate emotions and classify the emotion-labels. We have participated in the task for 7 different languages and achieve competitive results. Our system gives best result for Russian language, as it is ranked ninth among all ranked teams.

1 Introduction

Research on natural language processing is getting a lot of attention recently. Nevertheless, the majority of research is still limited to a few languages with plenty of available training data. Emotions are both recognizable and mysterious. We all express and control our emotions on a daily basis. However, these are intricate, subtle, and occasionally challenging to describe (Wiebe et al., 2005, Mohammad et al., 2018). Some basic emotions are —joy, sadness, anger, fear, surprise, and disgust etc. Emotion recognition is a broad term encompassing tasks like detecting a speaker's emotions, identifying emotions in text, and recognizing emotions evoked in a reader. Since people express and perceive emotions in complex, variable ways, it is impossible to determine one's feelings with absolute certainty (Mohammad, 2022). Here the goal of this task is to determine perceived emotion i.e. what emotion most people will think the speaker may be feeling given a sentence or short text snippet uttered by the speaker.

Two popular methods for processing categorical data in machine learning are multi-class and multi-label classification. In multi-class classification, each instance is assigned to only one category from a predefined set of mutually exclusive classes. One instance of a multi-class problem is sentiment analysis, which involves classifying a text as either good, negative, or neutral. Labels are not mutually exclusive in multi-label classification, however, since an instance can be a part of more than one category at the same time (Yen et al., 2016). This is especially helpful for jobs like emotion recognition, where a single text can simultaneously convey several emotions, like surprise and joy. Multi-label classification frequently uses sigmoid activation, whereas multi-class classification usually uses softmax activation.

In this paper, we have introduced Trans-Sent, a Transformer-based Sentiment extraction model to extract multi-label emotion from the text data. It uses various pre-trained Bidirectional Encoder Representations from Transformers or BERT models for individual language to generate emotions (Acheampong et al., 2021) and classify the emotion-labels. Some preprocessing measures are used on training data, then it is oversampled, as mostly the dataset is imbalanced for various emotion-labels. Then, feature extractions and feature engineering are performed to extract sentence-level contexts. Finally, different pre-trained BERT models are used to extract emotions.

2 Dataset

BRIGHTER (Muhammad et al., 2025) is a large-scale collection of multi-label emotion recognition datasets covering 28 languages, with a strong focus on low-resource languages from Africa, Asia, Eastern Europe, and Latin America. Unlike many

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 893–898

existing datasets that primarily focus on high-resource languages, BRIGHTER was specifically developed to bridge this gap. The dataset includes text samples sourced from various domains, including social media platforms like Twitter, Reddit, and Weibo, as well as news articles, literary texts, personal narratives, and speeches. Each text instance is annotated by fluent speakers and labeled with one or more of six basic emotions—joy, sadness, anger, fear, surprise, and disgust—along with a neutral category. The dataset has been carefully curated through preprocessing, quality control measures, and reliability assessments to ensure accuracy. By making this dataset publicly available, the authors hope to encourage research on emotion recognition across diverse languages and cultural contexts, improving the inclusivity and effectiveness of NLP applications (Muhammad et al., 2025).

EthioEmo (Belay et al., 2025) is another multi-label emotion classification dataset specifically designed for four Ethiopian languages: Amharic, Afan Oromo, Somali, and Tigrinya. It includes six core emotions—anger, disgust, fear, joy, sadness, and surprise—along with a neutral class. The dataset was constructed using text collected from multiple sources, including Twitter (X), Facebook comments, YouTube comments, and news headlines, ensuring a diverse range of emotionally expressive content. To maintain high annotation quality, native speakers were employed to label the data.

In this context, the task organizers have proposed a baseline model in the task description paper (Muhammad et al., 2025) for all the languages. But we have participated in the task for 7 languages – Amharic, German, English, Hindi, Marathi, Russian, Romanian. In the dataset, there are train, dev and test set of text-data. Initially, training data was labelled with the emotions, but dev and test data had only un-labelled texts. Later, the organizers published the labelled version of dev set too. We have used both the labelled train and dev data to train our model and tested the performance of the model by test set of data.

3 System Overview

Trans-Sent, our system is built on BERT (Bidirectional Encoder Representations from Transformers), fine-tuned for multi-label emotion classification. Initially, we experimented with traditional machine learning techniques (Siam et al., 2022), using TF-IDF embeddings with models such as Logistic Regression, Decision Trees, and Random Forest etc. To handle the multi-label nature of the task, we applied Label Powerset and Classifier Chaining (Dembczynski et al., 2012) techniques, which, despite providing structured predictions, were ineffective due to their inability to capture the semantic meaning and context of words. The architecture of our proposed Trans-Sent model is shown on Figure 1.

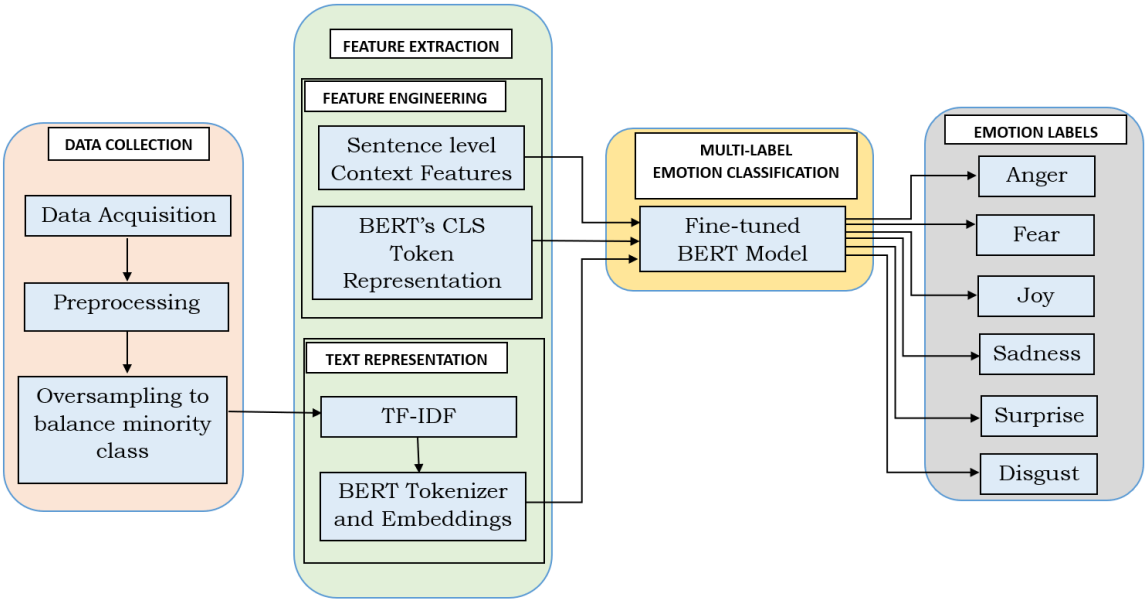

Figure 1: The architecture of the proposed approach, Trans-Sent

Input Sentence: "I am feeling very sad and angry today."

Tokenized input:

['[CLS]'	'i'	'am'	'feeling'	'very'	'sad'	'and'	'angry'	'today'	'[SEP]']

Label Encoding: [0, 1, 0, 0, 1, 0] # Corresponding to [Anger, Joy, Disgust, Fear, Sadness, Surprise]

Figure 2: Tokenization, attention-mask and label-encoding with an example.

The primary issue we encountered was that traditional models relied on word frequency-based representations, which struggled with incomplete or ambiguous text samples. Given that emotions are highly context-dependent and often co-occur, we needed a model capable of understanding semantic nuances and bidirectional dependencies. This led us to transition to a BERT-based approach, leveraging the pre-trained models like bert-base-uncased, ai-forever/ruBert-base etc and fine-tuning it for our specific task. The methodology behind working of Trans-Sent is explained below.

3.1 Data Preprocessing

Few data preprocessing techniques are applied before feeding the text into the model, such as data cleaning, tokenization, input formatting and level encoding. Removal of special characters, lowercasing, punctuation normalization are used for text cleaning and tokenizers, such as WordPiece tokenizer for bert-base-uncased model, are used for tokenization. Each text sample or token is converted into 'input_id's and 'attention-masks'. Tokenized sentences are converted into numerical form and attention-mask is introduced to indicate valid tokens (1) and padding (0). Finally, one-hot encoding is done to get the multi-label emotions i.e. a single sentence can have multiple 1s and 0s for different emotions. Various steps in data preprocessing are explained in Figure 2 with an example.

3.2 Oversampling

Training data set for various languages are imbalanced i.e. some labels are occurring far more frequently than others. Oversampling technique is used to improve performance and erase biasness of models trained by these data. As an example, train set of English (eng) data is highly imbalanced and it is shown in Figure 3. One of the most common method, Synthetic Minority Over-sampling Technique (SMOTE) (Chawla et al., 2002) is used by us to perform oversampling. It focuses on generating synthetic samples near the decision boundary to improve class separability. This eliminates the possibility of our model to become biased for any label.

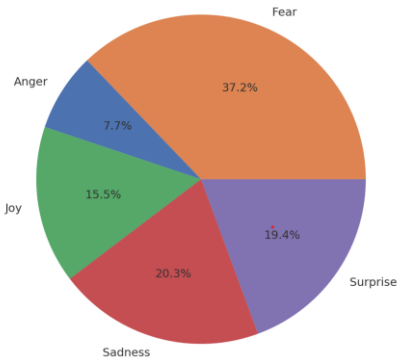

Figure 3: Imbalanced training data for English

3.3 BERT-Model Architecture

As a BERT is a transformer-based model (Tang et al., 2020) that utilizes bidirectional self-attention, enabling it to process words in context rather than in isolation. The architecture of BERT (Devlin et al., 2019) consists of multiple layers of self-attention mechanisms, making it highly effective for tasks requiring deep linguistic understanding. Our implementation uses the BertForSequence Classification model, which consists of a BERT Encoder, a Dropout Layer and a Classifier Head, a fully connected linear layer that maps the 768-dimensional BERT embeddings to five/six output neurons, corresponding to the five/six possible emotion labels. Different pre-trained BERT models[1] used for seven different languages are mentioned in Table 1.

[1] https://huggingface.co/models

Text in Language	BERT Model Used
Amharic (amh)	rasyosef/bert-medium-amharic
German (deu)	dbmdz/bert-base-german-cased
English (eng)	bert-base-uncased
Hindi (hin)	l3cube-pune/hindi-bert-scratch
Marathi (mar)	l3cube-pune/marathi-bert
Russian (rus)	ai-forever/ruBert-base
Romanian (ron)	dumitrescustefan/bert-base-romanian-cased-v1

Table 1: List of Pre-trained BERT models used for different languages.

4 Experimental Setup

To fine-tune the BERT-based model for multi-label emotion classification, we employed a structured training strategy designed to optimize performance while preventing overfitting. The optimization process was carried out using the AdamW optimizer, an improved variant of Adam that includes weight decay correction to mitigate over-regularization of important parameters. The learning rate was set to 2e-5, a commonly used value for fine-tuning transformer-based models, ensuring a balanced trade-off between convergence speed and stability. A batch size of 8 was chosen, considering the computational constraints of training large-scale transformer models while maintaining a sufficient number of samples for each gradient update.

To ensure effective learning, the model was trained for 3 epochs, as preliminary experiments indicated that performance plateaued beyond this point, and additional epochs led to minimal improvement while increasing the risk of overfitting. Weight decay was set to 0.01 to regulate the model's parameters and reduce the effect of less significant features, thereby enhancing generalization.

5 Results and Analysis

5.1 Evaluation Metric

For evaluation, we implemented an epoch-wise evaluation strategy, where the model's performance was assessed at the end of each epoch using standard classification metrics such as macro F1-score and micro F1-score. This approach allowed us to monitor the model's learning progression, detect potential overfitting or underfitting, and adjust hyperparameters if necessary. The final model selection was based on the best-performing checkpoint, ensuring optimal generalization to unseen data.

5.2 Results

Initially, training is done on train data and results are checked for dev set of data, the results are submitted through portal and then a score is generated by the organizer as per macro F1 and shown on the leaderboard. Once this phase is over, the final labelled version of dev data set for all languages are also released. For the final phase, we have used train and labelled dev set of data for training our model and testing its performance for test data. The performance of Trans-Sent is shown in a tabular form in Table 2.

Language	Anger	Disgust	Fear	Joy	Sadness	Surprise	Micro F1	Macro F1
Amharic (amh)	0.6485	0.7452	0.0010	0.7042	0.7011	0.4828	0.6821	**0.547**
German (deu)	0.7389	0.6743	0.0981	0.6563	0.5533	0.1576	0.62	**0.4797**
English (eng)	0.5629	-	0.8184	0.7209	0.7234	0.6936	0.7439	**0.7038**
Hindi (hin)	0.8185	0.8273	0.8522	0.8289	0.7665	0.8531	0.823	**0.8244**
Marathi (mar)	0.7648	0.9091	0.8148	0.747	0.7773	0.8227	0.7932	**0.8029**
Russian (rus)	0.9061	0.8571	0.9327	0.9155	0.8192	0.871	0.8855	**0.8829**
Romanian (ron)	0.5536	0.6627	0.8512	0.9562	0.7544	0.4735	0.7309	**0.7086**

Table 2: Performance of Trans-Sent for different languages on test data

In the result, it shows the performance of our model for different labels and micro F1 as well as macro F1. The organizers have chosen Macro F1 score as final score of any model. And on that basis, final ranking is published by them. Trans-Sent has performed reasonably well as ranked best for Russian language and stood 9th rank amongst all rank holders.

5.3 Analysis

From the result Table 2, we observe that different languages exhibit varying performance in multi-label emotion classification. The Macro F1 scores indicate that languages like Russian (0.8829), Marathi (0.8029), and Hindi (0.8244) perform better, whereas languages like German (0.4797) and Amharic (0.547) lag behind. Several factors contribute to these differences:

A) Morphological Complexity

Some languages have complex grammar and morphology, making it harder for models to generalize. For example, German has compound words and flexible word order, which could make sentence structures more ambiguous for emotion classification models. On the other hand, Hindi has more predictable syntactic patterns, which contributed to better results.

B) Pretrained Model Support

Languages with stronger NLP resources and pre-trained embeddings (like English, Russian, and Hindi) benefit from better contextual understanding. In the contrary, for Marathi language the pre-trained model misses various contextual understandings, which leads to the performance drop for this language.

C) Emotion Representation Across Cultures

Emotional expression varies by culture. Some languages may have clearer distinctions between emotions, while others might use the same words for multiple emotional states. For example, in Russian and Hindi, emotion-laden words might be more explicitly defined, aiding classification.

D) Tokenization Challenges

Languages with rich inflections and complex scripts (like Amharic) face difficulties in tokenization, leading to suboptimal embeddings. In contrast, languages with simpler tokenization (like Russian and Hindi) allow the model to capture meaning more effectively.

6 Conclusion

We introduced Trans-Sent, a Transformer-based model for multi-label emotion detection in SemEval-2025 Task 11, leveraging pre-trained BERT models to classify joy, sadness, anger, fear, surprise, and disgust across seven languages. Our approach combined data preprocessing, SMOTE-based oversampling, and fine-tuning, achieving competitive results, with Russian ranking ninth overall. Performance varied across languages due to morphological complexity, availability of pre-trained models, cultural nuances, and tokenization challenges. While Russian, Marathi, and Hindi performed well, German and Amharic faced difficulties due to grammatical complexity and ambiguous sentence structures. We have also highlighted the impact of data imbalance, as some emotions appeared more frequently than others, influencing classification accuracy. Traditional machine learning models struggled with the nuances of multi-label classification, reaffirming the effectiveness of Transformer-based architectures.

Despite its strengths, Trans-Sent has room for improvement. Future work could explore better data augmentation, cross-lingual learning, and ensemble models to refine classification. Additionally, incorporating context-aware modeling and multimodal data could enhance accuracy. Expanding to low-resource languages through domain-specific fine-tuning is another promising direction.

A Appendix

A.1 Result on dev Set

As mentioned earlier, the organizers of the task has provided dataset, which consists of train, dev and test data set. Initially, we trained our model on train set and then tested the model on dev set. It eventually becomes labeled and generates a .csv file. To check the performance i.e. accuracy, micro F1 and macro F1 etc of the model, this file was submitted to the portal. Finally, a score was generated. Based on those scores our model was updated technically. During that we have achieved the result mentioned in Table 3. We have participated in 4 languages only.

It is observed that the results are quite similar for both dev set and our final result, which we got for test set. Only for Marathi text a significant drop of performance is seen as macro F1-score gets decreased. For test set we achieved macro F1-score 0.8029, but on dev set it was 0.9066. Though it's very tough to analyze this performance drop, we pointed out a few probable reasons for this in the analysis section. Lack of contextual awareness of the pre-tuned model about Marathi language, cultural differences on emotions for various Marathi spoken people are some reasons we can list out here.

Language	Amharic (amh)	English (eng)	Hindi (hin)	Marathi (mar)
Anger	0.637	0.6207	0.8276	0.88
Disgust	0.703	-	0.6667	0.9524
Fear	0.001	0.7883	0.9333	0.9286
Joy	0.6556	0.6667	0.72	0.9189
Sadness	0.658	0.6875	0.6667	0.8
Surprise	0.3429	0.7143	0.8421	0.96
Micro F1	0.6453	0.724	0.7862	0.9006
Macro F1	0.4994	0.6955	0.7761	0.9066

Abstract

In response to the growing challenge of propaganda through online media in online news, the increasing need for automated systems that can identify and classify narrative structures in multiple languages is evident. We present our approach to the SemEval-2025 Task 10 Subtask 2, focusing on the challenge of hierarchical multi-label, multi-class classification in multilingual news articles. Working with a two-level taxonomy of narratives and subnarratives in the Ukraine-Russia War and Climate Change domain, we present methods to handle long articles based on how they are naturally structured in the dataset, propose a hierarchical classification MLP with respect to the narrative taxonomy structure, and establish a continual learning training strategy that takes into advantage the multilingual nature of our data and tries to examine how different language orders affect performance. Our final system was evaluated in five languages, achieving competitive results while demonstrating low variance compared to similar systems in our leaderboard position.

1 Introduction

From early days, propaganda has been a tool in shaping people's beliefs, actions, and behaviours. The most effective propaganda techniques often go undetected, influencing readers without even their knowledge (Muller, 2018). With the rapid growth of the Internet and the Web revolutionizing the way people share and access information, it has also opened doors to propagandistic techniques being disseminated more effectively, reaching vast audiences worldwide (Tardáguila et al., 2018).

At research level, most work on propaganda detection has focused on high-resource languages like English, and little effort has been made for low-resource languages. Similarly, previous work examined content at the document level (Rashkin et al., 2017), where they work focused on analyzing entire articles to differentiate between propaganda, trusted news, and satire rather than analysing specific narrative structures. SemEval-2020 Task 11, which focused on propaganda and news analysis, was introduced to address this (Da San Martino et al., 2020) featuring the classification of portions of documents across 44 propagandistic techniques.

SemEval-2025 Task 10[1] (Piskorski et al., 2025; Stefanovitch et al., 2025) was introduced as a significant advancement that focuses on the automatic identification of specific narrative structures, their classification, and the roles of entities involved in online articles in a multilingual setting.

This study focuses on the Narrative Classification subtask of SemEval-2025 Task 10. Unlike previous tasks, it centers around the identification of both the broader narratives of articles and their specific subnarratives. In this paper, we explore how hierarchical MLPs can model this nested taxonomy structure, investigate methods for handling long article inputs, and examine how different language orders can affect model performance in a continual learning training strategy.

Researchers have studied whether language order affects catastrophic forgetting in continual learning, but optimal order could vary across tasks and language sets. Our research builds on their findings, attempting to address the following research question: "Is there an optimal language order in language-specific continual learning for narrative classification? If so, which is the best and which is the worst?"

During our participation in the challenge, our primary approach, consisting of an ensembled version of a continual learning training strategy was evaluated in five languages achieving top-five rankings in across all languages[2]. Our analysis revealed that the order in which our model is trained matters

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 899–908

significantly in model performance, with certain language orders outperforming others.

Reproducibility

The complete codebase for this work, including data preprocessing, model architectures, and training methodologies, is available as documented Jupyter notebooks in our public GitHub repository.

1.1 Related Work

1.1.1 Related Tasks

Coan et al. (2021) present a classification task that focuses solely on contradictory claims of climate change in a similar hierarchical taxonomy. Their work emphasized on structuring claims into multiple levels of specificity following a parent-child relationship. Piskorski et al. (2022) builds upon climate change, by showcasing an effective and interesting way of handling limited training data using data augmentation techniques by maintaining the meaning intact, and thus also preserve label consistency. In a different but conceptually relevant domain, Kotseva et al. (2023) developed a hierarchical classification system for COVID-19 misinformation narratives, spanning over 58,000 articles in a similar multilingual setting.

1.1.2 Continual Learning in NLP

Continual learning (Wang et al., 2024) has gained attention in NLP for its ability to transfer knowledge across different tasks. The major challenge in this is catastrophic forgetting phenomenon, where a continually trained model tends to forget the knowledge it has learned (Kirkpatrick et al., 2017).

In the NLP area, continual learning has been established in different domains. Mi et al. (2020) demonstrates this with a dialogue system that is trained on sequential data. In a next token prediction task, Gogoulou et al. (2024) experimented with training a model in different languages using continual learning. That is, the model was trained first on a single language, then the training would continue with a different language, and so on. They discovered that the language order in which the model is trained, plays a crucial role – a carefully selected language order also seemed to reduce catastrophic forgetting.

1.2 Dataset

The dataset is composed of news articles in five languages: Bulgarian, Russian, Portuguese, English, and Hindi. These articles were collected and annotated specifically for the Ukraine-Russia War and Climate Change domains.

The data is divided into training (1,781 articles), development (178), and test (460) sets. The distribution of training data across languages is shown in Appendix Figure 5.

The articles vary significantly in length, a characteristic that introduces challenges we discuss in Section 1.3 and address in Subsection 2.1.

1.3 Challenges

The initial challenge resides in the way our labels are structured for classification. Each article can belong to one or more narratives that each map to one or more subnarratives, creating this two-level hierarchy. This presents challenges not only in hierarchical depth, since both levels must be predicted correctly, but also in managing the large number of possible labels. The scale of this can be better understood by looking at Figure 1, which shows a partial taxonomy of narratives and subnarratives for the Ukraine-Russia War domain.

Figure 1: Sample taxonomy for Ukraine-Russia War, showing the hierarchical relationship between narratives (inner ring) and their corresponding subnarratives (outer ring).

Cross-lingual Variations Working across multiple languages presents several specific challenges. Different languages tend to favor certain narrative patterns over others due to geopolitical factors. Appendix Figure 4 demonstrates this, with the Russian language focusing solely on the Ukraine-Russia War Taxonomy, while others exhibit a more balanced distribution between domains.

The combination of cross-lingual variations with limited training data poses data imbalance issues,

where certain narrative-subnarrative pairs appear much more frequently than others, something we discuss about in Subsection 2.3.

Article Length Variability Articles vary significantly in length, ranging from short to extensive (mean 403 words, std dev 237 words; between 88 to 924 words across languages).

Most (best) text classification models are specifically trained (or fine-tuned) to give good sentence embeddings; however, these models typically have a maximum token limit (usually 512 or 1024 tokens), which becomes problematic when processing large articles into representations that our classification models can then understand.

We carefully handle longer news articles in Section 2.1 to overcome a situation where article representation adversely affects the classification task.

2 System Overview

2.1 Article Representation

When articles are very long, most NLP work handles this by either including summarization preprocess step of the article into their pipeline (Tsirmpas et al., 2023), or paragraph splitting / hierarchical encoding (Dai et al., 2022).

We propose an alternative chunking approach, one that follows the natural structure of news articles in the dataset. Specifically, we observed that the articles consistently followed a header/body/footer organization, and we used this to perform a more targeted, semantically informed splitting.

However, combining the separated sections into a single embedding that describes the whole article is also something we need to address. We explored various strategies for doing so:

- Average pooling between sections: Average of all section embeddings, preserving each section equally.
- Weighted average based on section length: Similar to averaging, but sections contribute proportionally to their length.
- Sum of section embeddings: Element-wise addition of all section embeddings, essentially preserving all information.

2.2 Model Architecture

Initial experiments with simple classification models like logistic regression served as our first baselines by treating the problem as a flat classification without considering the label hierarchy. This approach revealed limited performance, and led us to explore approaches that could leverage this hierarchy.

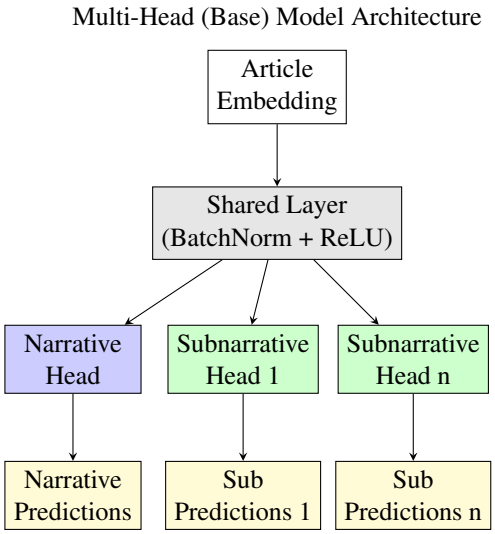

Figure 2: Architecture of the base multi-head model showing the flow from article embedding through shared layer to narrative and subnarrative heads.

However, the problem is structured in such a way that it differs from a two-head classification model, where we have a head for classifying narratives and a separate for subnarratives. Each narrative has its own set of subnarratives creating this natural hierarchy.

We developed a base multi-head, multi-task model approach where we have a single head for predicting narratives, then multiple heads for predicting the subnarratives for the given narrative hierarchy. We then explored several variants of this model as for experiments.

2.2.1 Multi-Head Base Architecture

Our base architecture (Figure 2) consists of three main components:

- A shared base layer that learns features and provides its output to the lower layers.
- A narrative head for predicting the top-level narratives.
- Multiple heads, one per narrative hierarchy, each predicting the corresponding subnarratives for that hierarchy.

2.2.2 Hierarchical Variants

Concatenation Model Our base model treated narrative and subnarrative predictions indepen-

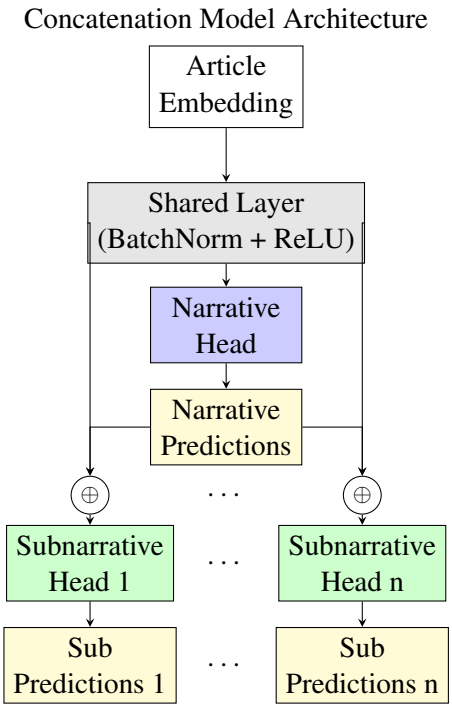

Figure 3: Architecture overview of the architecture for the concatenation model, showing how narrative predictions are combined with shared layer output to feed into subnarrative heads.

dently. That is, subnarrative predictions were computed as:

$$P(subnarr_j|x) = \sigma(h(x)) \quad (1)$$

where $h(x)$ is the output of the shared layer (the gray box) for article embedding x.

We enhanced this by concatenating the narrative probabilities with the shared layer output:

$$P(subnarr_j|x) = \sigma([h(x); P(narr_i|x)]) \quad (2)$$

where $narr_i$ is the parent narrative of $subnarr_j$.

This is intuitive, because:

- If the probability of the narrative is high, the subnarrative head will be more likely to predict the relevant subnarratives.
- If the probability is low, the model will learn to ignore the corresponding subnarratives.

Multiplication Model As an alternative to concatenation, we implemented element-wise multiplication between the output of the shared layer and the narrative probabilities.

$$P(subnarr_j|x) = \sigma(h(x) \odot P(narr_i|x)) \quad (3)$$

where $h(x)$ is the shared layer output for article embedding x.

This conceptually creates a stronger hierarchical dependency, acting as a natural "gate" in the hierarchy:

- If the narrative probability is close to 0, the corresponding subnarrative head's input will be scaled down, effectively disabling that subnarrative head.
- If the narrative probability is close to 1, the shared layer output passes through somewhat unaffected.

2.3 Loss Function

Our loss function is designed to handle both imbalanced labels and the need to stay consistent in our hierarchical predictions.

Weighted BCE We use a weighted version of Binary Cross Entropy to account for the class imbalance. Each label is assigned a weight that is proportional to its frequency in the dataset. This way, rare labels contribute proportionally more to the loss.

Hierarchy and Misclassifications We penalize inconsistencies in the hierarchy and label misclassifications. A complete loss break down is presented in Appendix A.2.

2.4 Continual Learning

Our initial experiments with the base architectures revealed significant performance instability across training runs (Section 3). This instability problem motivated us to try an alternative approach, one that changes the way the model learns from the training data resembling it in a way knowledge builds upon existing foundations.

Just as learning Ukrainian becomes easier when you know Russian, we hypothesized that this sequential order can help our model find meaningful patterns per language. In particular, for our problem:

- Russian language can provide a good base for the URW taxonomy.
- Bulgarian builds on top of Russian as both are Slavic languages.
- Every single language that follows keeps enriching the model's understanding with its unique characteristics.

Upon reaching our target language for classification during the training phase, we give the model more time to adapt by increasing its training patience and lowering the learning rate.

3 Experiments and Results

Below we present the comparison results across model variants, embedding models, and aggregation strategies. We report both Coarse-F1 (for narratives) and Fine-F1 (for subnarratives), along with their standard deviations. However, the primary focus of the task is on the Fine-F1 score.

All comparisons are performed specifically for the English validation dataset, as it demonstrated the most balanced distribution of narratives in the dataset across the two domains and is widely recognized as the most prominent language in NLP research.

Each model was run five times, and the results were aggregated to ensure a fair comparison. We evaluated our experiments with two embedding models: KaLM[3] and Stella[4]. We specifically chose these embedding models because they are both multilingual, instruction-based that achieved high performance on the MTEB (Massive Text Embedding Benchmark) leaderboard[5].

During the stage of transforming our article sections into meaningful numbers that our classification models can understand, we instructed the embedding models to:

"Produce an embedding useful for detecting relevant war- or climate-related narratives from a taxonomy."

3.1 Model Architecture and Embedding Performance

3.1.1 Hierarchical Architecture Variants

Table 1 shows the mean performance across model base variants. The high standard deviation (±0.02-0.03) indicates run-to-run instability.

Concat variant shows a sign of effectiveness in comparison to the Simple model by slightly outperforming it. Multiplication variant lags behind for both approaches, indicating that the hard-gating mechanism might be too restrictive. If our narrative predictions are not confident or even, and most importantly, not correct, the subnarrative head will receive very weak input because of the hard gating.

Metric	Simple	Concat	Mult
Coarse-F1	0.489 ± 0.03	0.497 ± 0.02	0.477 ± 0.02
Coarse std	0.385 ± 0.01	0.386 ± 0.01	0.384 ± 0.01
Fine-F1	0.329 ± 0.03	$\mathbf{0.333} \pm 0.02$	0.311 ± 0.02
Fine std	0.320 ± 0.02	0.327 ± 0.02	0.321 ± 0.01

Table 1: Mean performance comparison between the base hierarchical model and its variants (averaged over 5 runs).

3.1.2 Embedding Model Comparison

Table 2 shows performance between embedding models.

Metric	KaLM	Stella
Coarse-F1	0.497 ± 0.02	0.450 ± 0.02
Fine-F1	0.333 ± 0.02	0.298 ± 0.02

Table 2: Performance comparison across embedding models.

KaLM embeddings consistently appear to outperform Stella in all metrics.

However, when analyzing different aggregation strategies, our experiments revealed different patterns between embedding models: KaLM performed best with sum aggregation, while Stella showed superior results with weighted aggregation. A more in-depth analysis is presented in Appendix A.3.1.

3.1.3 Threshold Optimization

Our previous experiments tried to find the most optimal thresholds separately for narratives and subnarratives, exploring values up to 0.6. These thresholds determine the minimum probability for a narrative or subnarrative to be considered active in the predictions.

We later found out that the weighted aggregation strategy benefits significantly from increasing this threshold range up to 0.9, with the most noticeable improvement for Stella Embeddings. Detailed results and analysis can be found in Appendix A.3.2.

3.2 Continual Learning Performance

Table 3 shows the results between several language sequences and embedding combination strategies using the Concat hierarchical variant.

Impact of Aggregation Strategy At first glance, we see that the combination strategy is sensitive to

Order	Sum	Avg	W. Avg
RU→BG→PT→HI→EN	**0.378**	0.351	0.316
RU→BG→HI→PT→EN	0.356	0.323	0.341
BG→RU→PT→HI→EN	0.314	0.343	0.316
HI→PT→RU→BG→EN	0.302	0.312	0.330
PT→HI→RU→BG→EN	0.300	0.289	**0.352**
Ensemble of All Orders	0.350	0.349	**0.357**

Table 3: Impact of language ordering on Fine-F1 scores across different embedding combination strategies using Stella embeddings and 0.6 thresholds.

the language order:

- Sum strategy shows drastic response to the language ordering, with Fine-F1 scores ranging from 0.300 to 0.378.
- Mean strategy shows similar-to-moderate sensitivity, with Fine-F1 scores ranging from 0.289 to 0.351.
- Weighted average demonstrates the most balanced performance across orders, with Fine-F1 scores ranging from 0.316 to 0.357.

Specifically the weighted average strategy performs consistently better across different orders. In contrast to other strategies, it focuses on certain sections which might help the classification task, making thus the order less significant. However, when evaluating the effectiveness of a language order, we should primarily focus on the Sum and Avg strategies (which do not introduce any weighting). Both of these strategies agree that the first order produces the best results.

Impact of Language Order When evaluating for English data, the sequence that starts with Russian followed by Bulgarian outperforms every other sequence. Even swapping between these languages shows a performance drop. This suggests that when training the model with sequential data, starting with certain languages helps it build strong foundation patterns, strongly influencing final performance. In Appendix A.3.3 we do an in-depth order significance analysis.

Impact of Embedding Choice Interestingly, while KaLM embeddings outperformed Stella in our stand-alone experiments (Section 2), we observed different behavior in continual learning, with KaLM model under performing. This might suggest that Stella embeddings might be more appropriate in a knowledge transfer setup.

3.2.1 Threshold Optimization for Continual Learning

While we are at it, we extended our threshold optimization in Appendix A.3.2 to cover Continual Learning.

4 Discussion

4.1 Test Set Performance

For our final submission, we created an ensemble combining multiple models trained on different language orders, (where better performing language orders get more weight in the final prediction) using the Concat hierarchical variant. We positioned each target language, as the final stage of the learning sequence, which we give more patience and a lower learning rate.

The training configuration used Stella embeddings with a searching threshold of up to 0.6 and a sum aggregation strategy for section embeddings.

The results for our initial submission for the test set are presented in Table 4.

Lang	Rank	C-F1	std-C	F-F1	std-F
EN	16/30	0.409	0.314	0.239	0.243
PT	4/14	0.478	0.201	0.309	0.153
RU	6/15	0.596	0.257	0.333	0.234
BG	7/13	0.510	0.322	0.333	0.300
HI	6/14	0.384	0.418	0.282	0.402

Table 4: Version 1 of the leaderboard for the test set performance across the different languages.
C-F1: Coarse-F1, F-F1: Fine-F1, std-C/F: Standard deviation for coarse/fine metrics.

An important aspect of our results is stability. The proportion of F1 score and std is lower in comparison to teams near our entry. This shows a sign that our model is able to generalize and learn robust features. In comparison however to top teams, it's architecture might not be sufficient to capture more complex ones.

We conducted a brief post-competition analysis applying a higher threshold (0.9), which led to improved performance, particularly for English that is interesting to observe. Details and a comparison table are provided in Appendix A.3.4.

Limitations

Our approach used powerful pre-trained embeddings and a clear limitation is that we did not perform any fine-tuning on pre-trained models, something that was time and resource consuming for this

research. Top-performing teams likely used larger language models which offer greater performance but at higher computational costs. Our method provides some advantages in computational efficiency but the performance gap is evident. A promising direction would be to explore how incorporating larger models while maintaining our framework would respond to this new architecture.

Acknowledgments

This research was conducted as an undergraduate semester thesis project.

I would like to thank Panos Louridas and John Pavlopoulos for their guidance and AUEB for supporting this work.

A Appendix

A.1 Dataset Analysis

Figure 4 shows the complete distribution of domains across languages. As shown, Russian articles focus exclusively on the Ukraine-Russia War domain, while other languages show more balanced distribution between domains.

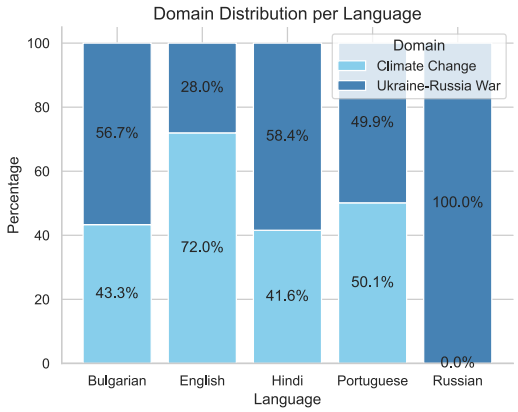

Figure 4: Distribution of domain across the five languages in the training set.

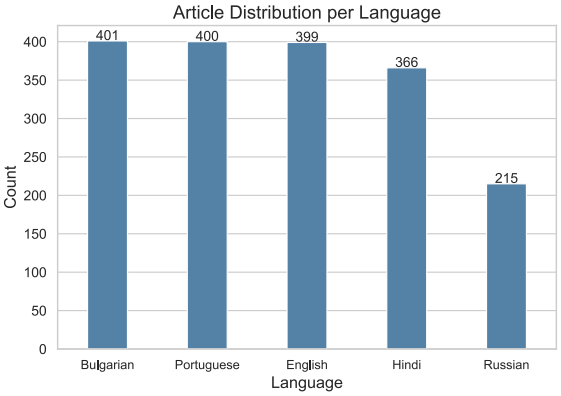

Figure 5: Distribution of articles across the five languages in the training dataset.

A.2 Loss Function Details

We penalize inconsistencies in the hierarchy and label miss-classifications. More specifically, the loss consists of:

$$\mathcal{L}_{\text{total}} = (1-W_{\text{sub}})\cdot\mathcal{L}_{\text{narr}}+W_{\text{sub}}\cdot\mathcal{L}_{\text{sub}}+W_{\text{cond}}\cdot\mathcal{L}_{\text{cond}} \quad (4)$$

$\mathcal{L}_{\text{narr}}$ represents the weighted BCE loss for narrative predictions, while $\mathcal{L}_{\text{sub}}$ captures the weighted BCE loss for subnarrative predictions. The term $\mathcal{L}_{\text{cond}}$ serves as a conditioning term that enforces hierarchical relationships.

The conditioning term enforces the hierarchical structure through:

$$\mathcal{L}_{\text{cond}} = \text{mean}(|p_{\text{sub}}\cdot(1-p_{\text{narr}})|+p_{\text{narr}}\cdot|p_{\text{sub}}-y_{\text{sub}}|) \quad (5)$$

The first part ($|p_{\text{sub}} \cdot (1 - p_{\text{narr}})|$) penalizes the model for predicting subnarratives when their parent narrative is inactive. The remaining part ensures subnarrative predictions match ground truth when their parent narrative is active.

A.3 Experimental Analysis

A.3.1 Model Evaluation Across Embedding Types and Architectures

Tables 5 and 6 present Fine-F1 scores (our primary goal is to improve subnarrative classification, we limit this analysis to solely Fine-F1 scores for simplicity) across model variants and aggregation strategies per embedding model.

Model	Sum	Mean	Weighted
Simple	0.329 ± 0.03	0.285 ± 0.01	0.325 ± 0.02
Concat	0.333 ± 0.02	0.305 ± 0.01	0.300 ± 0.02
Mult	0.311 ± 0.02	0.287 ± 0.02	0.283 ± 0.01

Table 5: Fine-F1 scores for KaLM embeddings across model variants and aggregation strategies.

Model	Sum	Mean	Weighted
Simple	0.309 ± 0.01	0.259 ± 0.01	$\mathbf{0.343} \pm 0.01$
Concat	0.298 ± 0.02	0.256 ± 0.02	0.338 ± 0.02
Mult	0.260 ± 0.01	0.260 ± 0.01	0.327 ± 0.01

Table 6: Fine-F1 scores for Stella embeddings across model variants and aggregation strategies.

Sum aggregation strategy appears to perform best across all other strategies for the KaLM Embeddings. This shows that KaLM benefits from preserving all information.

On the other hand, the weighted strategy seems to suit well with Stella, consistently outperforming all other strategies.

A.3.2 Extended Threshold Analysis

Optimizing Classification Thresholds Table 7 presents results for model variants, weighted aggregation strategy and Stella embeddings after exploring for higher thresholds, up to 0.9.

The weighted aggregation strategy benefits from higher thresholds likely because it prioritizes certain sections based on length. Higher thresholds

Model	C-F1	F-F1	F-std
Simple	0.538 ± 0.021	$\mathbf{0.426} \pm 0.010$	0.375 ± 0.008
Concat	0.554 ± 0.025	$\mathbf{0.442} \pm 0.019$	0.375 ± 0.016
Mult	0.556 ± 0.014	$\mathbf{0.426} \pm 0.017$	0.362 ± 0.011

Table 7: Performance metrics for Stella embeddings with weighted aggregation with 0.9 threshold.
C-F1: Coarse-F1, F-F1: Fine-F1, F-std: Fine-std

help filter out noise in these weighted sections, requiring greater confidence for predictions. This leads to fewer but more precise positive classifications.

In contrast, other aggregation strategies combined with different embedding models tend to produce higher variance in their results.

Threshold Optimization in Continual Learning Following our discovery that weighted aggregation benefits from higher thresholds, we applied this approach to our continual learning training method. Table 8 presents these results.

Language Order (Thresh)	C-F1	F-F1	F-std
RU→BG→PT→HI→EN (0.75/0.50)	**0.614**	**0.449**	0.349
RU→BG→HI→PT→EN (0.75/0.55)	0.608	0.437	0.352
RU→HI→PT→BG→EN (0.80/0.60)	0.600	0.444	0.359
BG→RU→PT→HI→EN (0.70/0.55)	0.575	0.404	0.364
PT→HI→RU→BG→EN (0.75/0.60)	0.586	0.424	0.359
HI→PT→RU→BG→EN (0.70/0.50)	0.561	0.376	0.371
Ensemble (0.75/0.60)	0.570	0.424	0.362

Table 8: Performance of continual learning models, 0.9 thresholds, using Stella embeddings with weighted aggregation.
C-F1: Coarse-F1, F-F1: Fine-F1, F-std: Fine-std

Again, higher thresholds benefit the continual learning approach in all language orders. The optimized thresholds vary slightly between different language sequences (ranging from 0.70-0.80 for narratives and 0.50-0.60 for subnarratives), suggesting that language-specific patterns influence the optimal decision boundary.

A.3.3 Statistical Analysis of Language Order Effects

For testing the significance of language order, we performed 25 independent experiments (5 random data batches per language × 5 random seeds per order) to ensure stability and performed statistical significance for the theoretically best order, against the other variants.

Order	Fine	Coarse	p-value
RU→BG→PT→HI→EN	**.350** ± .017	.513 ± .013	6.89×10^{-5}
RU→BG→HI→PT→EN	.323 ± .022	.485 ± .020	.601
HI→PT→RU→BG→EN	.312 ± .005	.479 ± .007	.025
RU→HI→PT→BG→EN	.210 ± .016	.369 ± .027	1.45×10^{-23}
PT→HI→RU→BG→EN	.289 ± .011	.476 ± .011	1.17×10^{-7}

Table 9: Impact of language order on model performance across different article batches and random seeds for sum aggregation strategy.

Effects with Sum Aggregation Strategy The in-theory best sequence (RU→BG→PT→HI→EN) achieved the highest score for the Fine F1 score. The variant that starts with Bulgarian and follows Russian, led to a slight decrease in performance.

Our hypothesized worst language order (RU→HI→PT→BG→EN) gave poor performance, with a very small p-value (1.17e-07), meaning it's very unlikely this poor performance occurred by chance.

Overall, the results show that when trying to create a model for English data, having certain languages early on in the sequence tends to help the model perform better.

Effects with Weighted Aggregation Strategy While we are at it, we also did a thorough analysis for the weighted strategy, which outperformed the sum strategy.

Order	Fine	Coarse	p-value
RU→BG→PT→HI→EN	**.423** ± .006	.583 ± .020	.068
BG→RU→PT→HI→EN	.355 ± 0.034	.501 ± .015	1.10×10^{-9}
HI→PT→RU→BG→EN	.398 ± 0.014	.571 ± .021	9.17×10^{-6}
RU→HI→PT→BG→EN	**.440** ± .013	.611 ± .018	3.09×10^{-6}
PT→HI→RU→BG→EN	.405 ± 0.014	.576 ± .015	.0029

Table 10: Impact of language order using weighted average strategy across different article batches and random seeds.

Weighted strategy revealed different patterns compared to sum.

Both RU→BG→PT→HI→EN and RU→BG→HI→PT→EN orders maintain strong performance, their difference is not statistically significant (p = 0.068). Language order RU→HI→PT→BG→EN performs surprisingly well, better than our best order for sum strategy and contrasting with its poor performance under the same approach.

Impact of Aggregation Strategy on Language Order Sensitivity The weighted strategy appears to be more robust to order variations, showing gen-

erally higher performance across all orderings compared to sum strategy. This shows that embedding aggregation affects the importance of language order. Sum aggregation preserves all article information equally, making language order clear and much more significant. Weighted average weights sections by their length, it shows more balanced performance across different orders, making language order less significant to performance.

A.3.4 Post-competition Analysis

In our post-competition analysis, we applied our findings about weighted aggregation with higher thresholds (0.9) to the test set. This post-analysis showed a positive sign in our results, particularly for English (Table 11).

Lang	Rank	C-F1	std-C	F-F1	std-F
EN	5/27	0.556	0.396	0.362	0.370
PT	3/14	0.539	0.214	0.329	0.171
RU	5/15	0.571	0.344	0.400	0.283
BG	5/13	0.523	0.371	0.357	0.349
HI	5/14	0.453	0.441	0.341	0.456

Table 11: Version 2 leaderboard results for test set performance across languages.
C-F1: Coarse-F1, F-F1: Fine-F1, std-C/F: Standard deviation for coarse/fine metrics.

Tables 12 and 13 compare performance using the weighted aggregation strategy with different thresholds (0.6 vs 0.9).

Language	F1 samples	F1 std samples
EN	0.287	0.296
PT	0.329	0.171
HI	0.340	0.434
BG	0.355	0.311
RU	0.398	0.292

Table 12: Post submission comparison of test set performance using threshold 0.6 with weighted strategy and Stella Embeddings.

Language	F1 samples	F1 std samples
EN	**0.362**	0.370
PT	0.326	0.208
HI	0.341	0.450
BG	0.357	0.349
RU	0.400	0.283

Table 13: Post submission comparison of test set performance using threshold 0.9 with weighted strategy and Stella Embeddings.

The results show improvements in all languages when using the weighted strategy. The increased range of threshold values up to 0.9 proved significant for the English dataset. However, for the rest of the languages, having an increased threshold did not seem to contribute to better performance, with some languages even experiencing higher variance.

DUTJBD at SemEval-2025 Task 3: A Range of Approaches for Predicting Hallucination Generation in Models

Shengdi Yin, Zekun Wang, Liang Yang*, Hongfei Lin

Abstract

This paper describes our system designed for SemEval-2025 Task 3 : Mu-SHROOM, the Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes. We explored using various methods to train models for predicting the occurrence of large language model hallucinations. The main techniques of our system are: 1) data augmentation, 2) model training, 3) API keys. We also experimented with various prompt engineering techniques and different closed-source large language models to predict the occurrence of hallucinations in a given text.

1 Introduction

In Task 3 (Vázquez et al., 2025), our goal is to predict the occurrence of hallucinations in text generated by various text generation models. In practice, we are provided with LLMs outputs (as strings, lists of tokens, and lists of logits) and we must calculate the probability that each character in the LLM output string is flagged as a hallucination. We can investigate 14 languages: Arabic (Modern Standard), Basque, Catalan, Chinese (Mandarin), Czech, English, Persian, Finnish, French, German, Hindi, Italian, Spanish, and Swedish, and can experiment and make predictions on one or more of the tasks. Task 3, compared to previous tasks, focuses more on the output of LLMs and the location where hallucinations occur. Therefore, it is more conducive to addressing problems caused by hallucinations.

We used the T5 model (Raffel et al., 2020a), a natural language processing model proposed by Google Research in 2019. Compared to other models, T5 can transform all NLP tasks into a text-to-text format. Therefore, T5 can handle various different tasks within the same model architecture, without the need to design separate models for each task.

At the same time, we also tested prompt engineering with several closed-source large language models, including ChatGPT 4o, Gemini 1.5, Qwen Chat, and DeepSeek V3 (Liu et al., 2024). Finally, Gemini 2.0 Flash was used to correct some specific text.

2 Background

2.1 Dataset Description

The training set includes a total of four languages: English, Spanish, French, and Chinese. Each language contains approximately 800 unlabeled data entries.

Each sample in the training set includes a *model_id* key indicating the source of the hallucinated text. The samples also include the *logits* for each generated token, representing the model's confidence in each generated word. Additionally, the output *tokens* represent the model-generated text encoded in subword form. These samples are used to train the model to answer similar questions and generate accurate, natural text replies.

2.2 Related Work

Hallucination detection is an important research direction in the field of natural language generation, especially in the application of large language models (LLMs). Generative models, particularly Transformer-based models such as the GPT series and T5, have achieved significant results on multiple NLP tasks. However, they often generate false or inaccurate content, a phenomenon known as hallucination (Raffel et al., 2020b). Research on hallucination detection aims to improve the practicality and reliability of these models by identifying and correcting such inaccurate generated content (Bender et al., 2021) conducted a detailed analysis of the hallucination problem in generative models, emphasizing that the hallucination phenomenon is closely related to the model's ability to understand the world, and proposed several potential solutions.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 909–913

Building on this (Liu et al., 2019) proposed a multi-task learning framework to improve the accuracy of hallucination detection through cross-task multi-model integration, particularly when addressing generation tasks in diverse domains. Similarly (Ziegler et al., 2019) adopted a reinforcement learning method, reducing hallucinations in generated text by combining the output of multiple models, thereby enhancing detection performance.

In multilingual environments, hallucination detection becomes more complex due to the significant differences in grammar, semantics, and cultural backgrounds across languages. The MuSHROOM task specifically addresses this challenge by focusing on multilingual hallucination detection, encompassing 14 languages including English, Arabic, and Chinese (Liu et al., 2020) proposed a cross-lingual hallucination detection framework in their research, which utilizes multilingual pre-trained models for hallucination annotation and achieves promising results. Furthermore, unified text-to-text frameworks, such as T5 (Raffel et al., 2020b), provide strong support for multi-task learning. The T5 model's ability to transform various NLP tasks into text generation tasks allows it to handle multiple tasks like translation, summarization, and question answering within a single framework. This unified approach not only simplifies the model training process but also enhances adaptability for hallucination detection, especially in multi-task learning scenarios, ultimately improving detection accuracy through shared model parameters.

3 System Overview

Our system is designed to effectively identify hallucinations in generated text within the MuSHROOM task. To achieve this goal, we employ a confidence-based pseudo-labeling approach, which relies on the following key steps: First, we convert the model's logits into confidence scores, thereby quantifying the model's certainty for each generated token. We then distinguish between hallucinated and non-hallucinated portions of the text by setting a threshold. Subsequently, we generate pseudo-labels based on the threshold, providing the model with learnable targets. Finally, we train the model using cross-entropy loss and backpropagation, validating the T5 model trained in this way on the hallucination task.

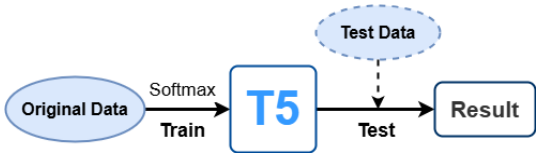

Figure 1: Illustration of the T5 model training process

3.1 Model Training Procedure

To effectively detect hallucinations in the MuSHROOM task, we designed a training procedure consisting of the following three key steps:

3.1.1 Transforming Logits to Probabilities

The logits produced by the model when generating each token represent unnormalized scores, directly reflecting the model's preference for that token. However, the numerical range of logits is often large and difficult to interpret directly. To obtain more interpretable and comparable confidence scores, we employ the softmax function to transform the logits into a probability distribution. The softmax (Bridle, 1990) function not only maps the logits to a range between [0, 1] but also ensures that the probabilities of all tokens sum to 1, forming a valid probability distribution. This transformation allows us to interpret the model's output as the degree of confidence it has in each token. The softmax function is defined as follows:

$$Softmax(z)_i = \frac{e^{z_i}}{\sum_{j=1}^{K} e^{z_j}}$$

where z represents the vector of logits, z_i represents the logit value for the i-th token, and K is the total number of tokens. Through the softmax function, the logits are converted into probabilities within the range $[0, 1]$, representing the model's confidence in generating that token. A higher probability corresponds to higher confidence, indicating that the model has a high degree of certainty about the generated content for that token; conversely, a lower probability indicates that the model is less confident about generating that part of the content, potentially suggesting a hallucination.

3.1.2 Hallucination Discrimination

After obtaining the confidence score for each token, we need a method to distinguish between hallucinated and non-hallucinated portions of the text. To achieve this goal, we compare the confidence scores output by the model with a pre-set threshold. This threshold represents the minimum level

of confidence at which we believe the model can reliably generate content.

Specifically, for each token, if its confidence score is below the threshold (e.g., 0.2), we mark it as "hallucination"; conversely, if the confidence score is above the threshold, we mark it as "non-hallucination." The choice of this threshold is crucial, as it directly affects the quality of the pseudo-labels. Selecting a threshold that is too high may lead to the labeling of much factual information as hallucination, while selecting a threshold that is too low may prevent the effective identification of true hallucinations. This method allows us to transform unlabeled data into pseudo-labeled data with hallucination labels, providing a target for subsequent training and enabling the model to learn to distinguish between factual information and hallucinations in the text.

3.1.3 Model Optimization

To train the model to identify and reduce hallucinations in generated text, we explore the use of regression loss. Here we define the regression loss as a Mean Squared Error (MSE) between two values. Specifically, our model aims to minimize the hallucination by optimizating the following objective during training procedure:

$$L_R^i = \text{MSE}(y_1^i, y_2^i)$$

where y_1^i and y_2^i are the target and the predicted values respectively. The backpropagation algorithm updates the model parameters based on the gradient of the loss function, enabling the model to better predict hallucinations in the next iteration. Furthermore, to prevent overfitting, we also employ regularization techniques such as dropout and weight decay.

3.2 Logit-Based Hallucination Detection

In the testing phase, our goal is to detect hallucinations in the generated text using the T5 model trained with pseudo-labels. Similar to the training phase, we use the logits produced by the T5 model to generate pseudo-labels for the test set and identify potential hallucinations.

The process starts by inputting the generated text from the test set into the trained T5 model. The model then generates logits for each token. We apply the softmax function to convert these logits into confidence scores, reflecting the model's certainty about the generated content. Tokens with confidence scores below a pre-defined threshold are flagged as potential hallucinations. This approach allows us to automatically detect and highlight possible hallucinations in the generated text without relying on human annotations.

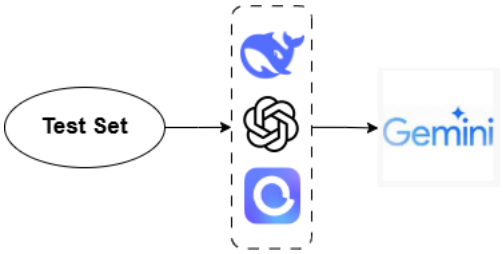

Figure 2: Employing prompt engineering to invoke diverse large language models.

3.3 Experimental Results

The T5 model, trained using our proposed logit-based pseudo-labeling approach, demonstrated a significant improvement in performance on the MuSHROOM hallucination detection task. Specifically, our model achieved an accuracy increase of 2 percentage points over the baseline, showcasing the effectiveness of our training methodology. This improvement demonstrates the ability of our method to learn effective representations for hallucination detection, enabling more accurate identification of spurious content in generated text.

4 Prompt Engineering

This chapter explores the feasibility of addressing the hallucination detection task in a zero-shot setting by leveraging prompt engineering to invoke several cutting-edge APIs, including ChatGPT 4o, Gemini 1.5, Qwen Chat, and DeepSeek V3. These APIs possess robust text generation and understanding capabilities, offering a potential avenue for detecting hallucinations in text without the need for training dedicated models. We will investigate how to harness the inherent abilities of these APIs for direct application to the hallucination detection task.

4.1 Prompting Strategy

We designed a series of prompts and directly submitted them to the aforementioned APIs. Each API received the same task: to detect hallucinations in the generated text and return the corresponding results. By comparing the responses from different APIs, we were able to evaluate their performance on the hallucination detection task. The specific content of the APIs will be provided in the appendix.

Model	Result
GPT 4o	**0.0571**
Gemini 1.5	0.0389
DeepSeek V3	0.024
Qwen Chat	0.0187

Table 1: Results of different large language models on the experimental data.

4.2 API Evaluation

To evaluate the effectiveness of these APIs in hallucination detection, we utilized a diverse set of generated texts and tested them individually with ChatGPT 4o, Gemini 1.5, Qwen Chat, and DeepSeek V3. Each API generated hallucination annotations based on the defined prompts, assisting in the identification of potential hallucinated segments.

4.3 Experimental Results

Based on our experimental results, the approach of invoking APIs using prompt engineering did not achieve ideal outcomes. We hypothesize that this may be due to the fact that these large models themselves are prone to generating hallucinations, thus limiting their ability to effectively identify them. As the quality of the generated text is constrained by the inherent limitations of the models, they struggle to differentiate between plausible content and that which is fictitious or erroneous. While large models may produce errors during generation, they typically lack the ability to proactively identify and flag these inaccuracies, particularly when dealing with complex hallucination detection tasks.

To further investigate this phenomenon, we attempted to elicit the reasoning processes of these large models, hoping to reveal their logic when judging hallucinations. However, the results indicated that the models did not genuinely comprehend the concept of hallucination. In our reasoning, a hallucination equates to fabricated content—i.e., generated text that contradicts facts in the real world. Yet, for these large models, a hallucination is merely a simple error; they tend to focus more on spelling errors, grammatical errors, or irregularities in sentence structure, rather than correctly identifying fictional content. This suggests that the core issue in large models' handling of hallucination detection tasks may be a discrepancy between their focus and our definition of hallucination.

5 Conclusion

This paper explores two approaches for tackling the hallucination detection task: the first involves training a T5 model with pseudo-labels, and the second leverages prompt engineering to invoke multiple large language model APIs. Initially, by training the T5 model and applying pseudo-label generation, we successfully improved hallucination detection performance. Experimental results indicate that the T5 model achieved approximately a 2 percentage points increase in detection accuracy compared to the baseline.

In addition, we attempted to directly invoke large language models such as ChatGPT 4o, Gemini 1.5, Qwen Chat, and DeepSeek V3 via prompt engineering for hallucination detection. However, experimental results revealed that this approach did not yield the anticipated results. The primary reason for this is likely that these large models themselves are prone to generating hallucinations, consequently limiting their ability to effectively identify them. While these models excel in generating text, they tend to focus more on spelling and grammatical errors when handling hallucination detection tasks, struggling to effectively identify hallucinated content.

A Appendix

The following is the pseudocode for the prompts we used.

"You are an expert in identifying hallucinations in large language models. Please help me identify which tokens in the sentence are hallucinations.

I will be providing you with input similar to the following:

<Examples from the training set>

"model_input" will be the input to another large language model, "model_output_text" its text output, and "model_output_tokens" its output tokens. You can refer to that model's "model_output_logits" as a reference. Your output should be both hard and soft predictions for the output tokens.

```
{
 "soft_labels":[
   {"start":10,"prob":0.2,"end":12},
   {"start":12,"prob":0.3,"end":13},
   {"start":13,"prob":0.2,"end":18},
   {"start":25,"prob":0.9,"end":31},
   {"start":31,"prob":0.1,"end":37},
   {"start":45,"prob":1.0,"end":49},
   {"start":49,"prob":0.3,"end":65},
   {"start":65,"prob":0.2,"end":69},
   {"start":69,"prob":0.9,"end":83}
 ],
 "hard_labels":[[5,31],[45,49]]
}
```

The "prob" for soft predictions represents the hallucination probability between tokens, and the hard prediction is the starting position of tokens that you identify as hallucinations. Please provide an example output based on the instructions above.

<text>

Important: Do not output your reasoning. Provide the answer directly in the requested format."

BrightCookies at SemEval-2025 Task 9: Exploring Data Augmentation for Food Hazard Classification

Abstract

This paper presents our system developed for the SemEval-2025 Task 9: The Food Hazard Detection Challenge. The shared task's objective is to evaluate explainable classification systems for classifying hazards and products in two levels of granularity from food recall incident reports. In this work, we propose text augmentation techniques as a way to improve poor performance on minority classes and compare their effect for each category on various transformer and machine learning models. We explore three word-level data augmentation techniques, namely synonym replacement, random word swapping, and contextual word insertion. The results show that transformer models tend to have a better overall performance. None of the three augmentation techniques consistently improved overall performance for classifying hazards and products. We observed a statistically significant improvement ($P < 0.05$) in the fine-grained categories when using the BERT model to compare the baseline with each augmented model. Compared to the baseline, the contextual words insertion augmentation improved the accuracy of predictions for the minority hazard classes by 6%. This suggests that targeted augmentation of minority classes can improve the performance of transformer models.

1 Introduction

Foodborne diseases affect millions of people every year. The World Health Organization highlights that food contamination leads to more than 200 diseases, resulting in severe health complications and affecting the socioeconomic stability of communities and nations (World Health Organization, 2024). There is a vast amount of publicly available information on food safety-related websites. Given the importance of early detection of food hazards, there is a need to timely and accurately analyze all this publicly available information to detect food hazards.

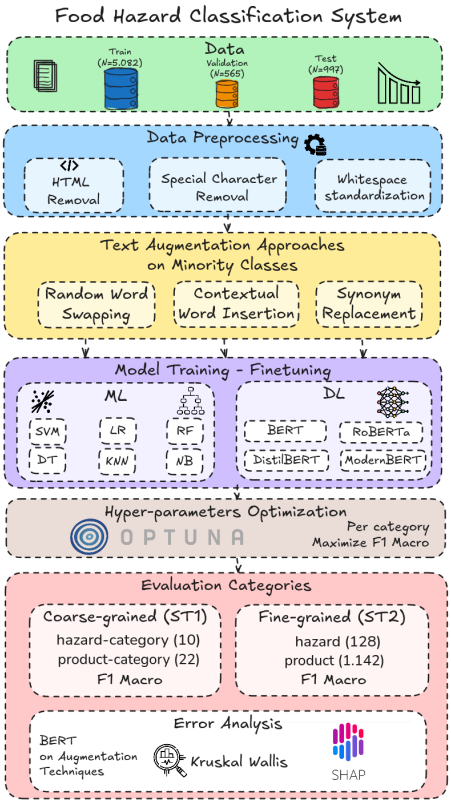

Figure 1: An overview of our developed system's architecture.

The SemEval-2025 Task 9: Food Hazard Detection Challenge (Randl et al., 2025) was proposed to facilitate automated classification of food hazards in food safety-related documents. It stimulates research that combines food safety and natural language processing (NLP) for explainable multi-class classification of food recall incident reports. SemEval-2025 Task 9 includes two sub-tasks: classifying coarse food hazard and product categories (ST1) (`hazard-category, product-category`), and fine-grained hazard and product categories (ST2) (`hazard, product`).

A significant challenge with the SemEval-2025 Task 9 dataset is its substantial class imbalance. There is a long-tailed distribution across classes,

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 914–930

especially in the fine-grained categories. This imbalance can give poor performance of classifiers, especially for deep learning (DL) models (Henning et al., 2023). Text augmentation techniques have been shown to mitigate the effects of imbalanced data to an extent (Khan and Venugopal, 2024). Text augmentation can range from simple string manipulations, such as those used in Easy Data Augmentation (EDA) (Wei and Zou, 2019), to more advanced methods involving transformer-based text generation (Henning et al., 2023). This helps to boost the representation of minority classes, which can result in a more balanced dataset and robust models.

We investigated three basic text augmentation techniques (synonym replacement, contextual word insertion, and random word swapping) to boost the representation of under-represented classes in multi-class classifications of food recall incident reports. Our main research question is:

Can text augmentation techniques on under-represented classes enhance a food hazard multi-class classifier's performance?

We evaluated the performance of various machine learning (ML) algorithms and encoder-only transformer models, both in their baseline form and after applying each augmentation technique. To participate in the task, only one submission was allowed. We submitted our predictions in the official test set after we evaluated our models in the development set, selecting the best-performing ones for each category. In ST1, our system ranked 15$^{\text{th}}$ out of 27 participants, with an F_1-macro score difference of 0.0613 from the first, and in ST2, it ranked 11$^{\text{th}}$ out of 26, with a 0.0944 score gap from the top (see subsection 6.1 for the exact scores). Our work provides valuable insights into the efficacy of text augmentation in this field. [1]

2 Related Work

2.1 Research on food hazard classification

Little work has been conducted using text data for fine-grained food hazard classification (Randl et al., 2024b), as most existing literature focused on binary classification of food hazards. A recent study by Randl et al. (2024b) introduced the dataset that we used in SemEval-2025 Task 9 and they benchmarked multiple ML and DL algorithms. Randl et al. (2024b) proposed a large language model (LLM)-in-the-loop framework named Conformal In-Context Learning (CICLe), that leveraged Conformal Prediction to optimize context length for predictions of a base classifier. By using fewer, more targeted examples, performance increased and energy consumption reduced compared to regular prompting.

2.2 Text augmentation for minority classes

Data augmentation creates synthetic data from an existing dataset by inserting small changes into copies of the data (Shorten et al., 2021). Data augmentation mitigates the class imbalance issues for DL (Henning et al., 2023). According to Shorten et al. (2021), Data augmentation approaches in NLP can be divided in two types: symbolic and neural. Symbolic techniques, such as rule-based EDA (Wei and Zou, 2019), employ simple word-level operations like synonym replacement and random insertion. Symbolic techniques are effective in small datasets. Neural techniques rely on auxiliary neural networks such as back-translation or generative augmentation. A recent study showed that LLMs for data augmentation, such as to generate new samples, increase accuracy and address class imbalance in skewed datasets (Gopali et al., 2024). In our study, we explore both symbolic and simple neural augmentation strategies, such as contextual words insertion using BERT, to improve classification performance.

Additionally, in the SemEval shared task of 2023, Al-Azzawi et al. (2023) explored the effects of data augmentation, particularly back translation, on minority classes. They compared it with augmenting the entire dataset using transformer-based models. They observed that targeting the under-represented classes for augmentation proved more effective than broad dataset augmentation. Following their approach, we also focus our augmentation strategies on the minority classes rather than the entire dataset.

3 Data

The Food Recall Incidents dataset used in SemEval-2025 Task 9 contains 6,644 food-recall announcements in the English language (Randl et al., 2024a). This dataset is split into 5,082 announcements in the train set, 565 in the development set, and 997 in the test set. The data is collected from 24 different websites (Table 4). The samples consist of a `title` and `text` describing announcements from a recalled food product and includes other metadata.

[1] Our code is available at https://github.com/WFSRDataScience/SemEval2025Task9

Experts manually labeled each sample into four coarse classes of hazards (`hazard-category`) and products (`product-category`) and fine-grained classes (`hazard` and `product`). The classes and the number of classes per category are listed in Table 10, and examples are presented in Table 11.

The distribution of the four categories' classes is highly imbalanced, showing a long-tail effect (Figure 4, Figure 5). In coarse categories, 75% of classes have 513 samples in `hazard-category` and 263 in `product-category`, while the largest classes contain 1,854 and 1,434 samples, respectively. This imbalance is even more severe in the fine-grained `hazard` and `product` classes, with 75% of classes having at most four samples per `product` and 24 samples per `hazard`, while the largest class has 185 samples per `product` and 665 samples per `hazard`.

4 Methods

We used ML and DL and implemented multiple data augmentation strategies. The next sections describe this in more detail.

4.1 Machine Learning

We used Term Frequency-Inverse Document Frequency (TF-IDF) (Sparck Jones, 1972) representation of text as input to our ML classifiers. We trained different classifiers and evaluated their performance on both subtasks for each category. The classifiers used were Linear Support Vector Machine (SVM), Decision Tree (DT), Random Forest (RF), Logistic Regression (LR), Multinomial Naive Bayes (NB), and K-Nearest Neighbors (KNN). We used the implementation from Scikit-learn library[2].

4.2 Deep learning

We used deep learning-based transformer language models for sequence classification (Vaswani et al., 2023). We chose encoder-only models that directly produce an input sequence's representation, which is fed into a classification head to make predictions. We trained various transformers for a sequence classification task, including BERT (Devlin et al., 2019), RoBERTa (Liu et al., 2019), DistilBERT (Sanh et al., 2020), and ModernBERT (Warner et al., 2024) (see subsection A.4 for more details). We leveraged the Hugging Face's Transformers library[3] (Wolf et al., 2020).

[2] `https://scikit-learn.org/stable/`

[3] `https://huggingface.co/docs/transformers`

Operation	Sentence
Original	Certain Stella Artois brand Beer may be unsafe due to possible presence of glass particles
CW	certain **notable** stella **by** artois brand beer may be **judged** unsafe **primarily** due to **his** possible presence of glass particles
SR	Certain **Frank stella** Artois brand Beer may be **insecure imputable** to **potential** presence of glass particles
RW	Certain Stella Artois brand Beer may **due be** unsafe to **presence possible** of glass particles

Table 1: Examples of text augmentation techniques applied to a `title` of a food recall using contextual word insertion (CW), synonym replacement (SR), and random word swapping (RW).

4.3 Data augmentation on minority classes

In addition to baseline training of the aforementioned models, we explored how data augmentation affected the performance of minority classes for each category.

We employed three different augmentation strategies using the NLP AUG library[4] (Ma, 2019): random word swapping (RW), synonym replacement (SR), and insertion of contextual words (CW). RW swapping randomly swaps adjacent words. SR substitutes similar words from a lexical database for the English language (WordNet (Miller, 1995)). CW uses contextual word embeddings from BERT to find the top similar words and insert them for augmentation. An example of each technique applied to a `title` is shown in Table 1.

For each strategy, we generated new samples in the training data for minority classes per category by altering titles and texts to preserve their inherent meaning while maintaining the annotated classes. For coarse categories (`hazard-category` and `product-category`), we augmented classes with fewer than 200 samples by generating 200 samples for each class. For fine-grained categories (`hazard` and `product`), we created 100 samples for classes with fewer than 100 samples for the `hazard` category and 50 samples for the `product` category. After examining the entire class distributions, we chose these numbers of added samples and thresholds for low-support classes because they reflect a compromise between improving the representation of minority classes and maintaining low computational costs, but not completely resolving the imbalance issue. We first iterated through the existing data samples for each under-represented class of each category. We then distributed the specified

[4] `https://nlpaug.readthedocs.io/`

total number of augmentation samples proportionally across these samples (adjusting the final one to ensure the addition matches the set target number of samples to add) to generate new samples based on the augmentation technique used. A pseudocode description is provided in subsection A.5 and its impact on class statistics is provided in subsection A.6. All methods were implemented in Python.

5 Experiments

In the next subsections, we further describe the preprocessing, hyperparameter fine-tuning, and evaluation details.

5.1 Preprocessing

Preprocessing included removal of HTML markup and special characters (newlines, tabs, Unicode character symbols) using regular expressions from `title` and `text` and text normalization such as whitespace standardization. This preserves semantic content while eliminating and filtering unnecessary formatting.

5.2 Hyperparameter fine-tuning

We fine-tuned the hyperparameters of baseline and augmented models on the **development** set using the Tree-structured Parzen Estimator (TPE) sampler in the Optuna hyperparameter optimization framework (Akiba et al., 2019). TPE is a Bayesian-based optimization approach that uses a tree structure to link between the hyperparameters and our objective function (maximizing F_1-macro score per category) to discover the optimal hyperparameters.

We ran ten trials per model and for each augmentation technique. For the ML for ST1, we ran 50 trials since the computation time was low. We optimized the parameters of the TF-IDF vectorizer, such as the minimum document frequency (min_df), and hyperparameters applicable to each classifier for ML, such as the maximum number of iterations (max_iter) in SVM, and the learning rate scheduler, batch size, and epochs for DL (subsection A.8). All experiments involving transformer models were conducted on different GPU clusters (subsection A.3)[5].

[5]Our best fine-tuned models are available at https://huggingface.co/collections/DataScienceWFSR/semeval2025task9-food-hazard-detection-680f43d99cc294f617104be2.

Table 2: F_1-macro scores for each model in the official test set given by the organizers utilizing the `text` field per category and subtasks scores (ST1 and ST2) rounded to 3 decimals. With bold, we indicated the higher score per category and subtask score.

5.3 Evaluation on leaderboard

We submitted our results to the leaderboard for both subtasks, which calculated the final score by averaging the hazard F_1-macro (computed on all samples) with the product F_1-macro (computed only on samples with correct hazard predictions) for the coarse (ST1) and fine-grained categories (ST2). For example, if all hazards were predicted correctly, but all products were predicted incorrectly, the overall result would be a 0.5 F_1-macro score (subsection A.7).

6 Results

The next subsections show quantitative results for each model in the official test set using the `text` field (trained in training and development sets) and an error analysis on the BERT baseline model versus its augmented-trained versions.

6.1 Quantitative results

Transformer models outperformed ML across all categories, as shown in Table 2, with the

$ModernBERT_{base}$ leading across transformer models, in the **baseline** version, in all categories except `product-category`.

Among ML, SVM, LR, and RF showed competitive performance: LR_{CW} scored highest in `hazard-category` (0.713) and `product-category` (0.682); RF_{RW} in `hazard` (0.567), and SVM_{CW} in `product` (0.256). Among the transformer models, $ModernBERT_{SR}$ scored highest in the `hazard-category` with a score of 0.790, while $BERT_{CW}$ scored highest in other categories. Augmentation increased performance but was not consistent across the categories. It was more pronounced in ST2 categories than ST1 categories, with the largest score increase (0.11) between $BERT_{base}$ and $BERT_{CW}$ augmentation in the `product` category.

To understand the impact of augmentation, we conducted individual pairwise Kruskal-Wallis tests comparing the F_1-macro scores on the $BERT_{base}$ model with the augmented versions, training each version three times per category (Table 9). Statistical significance ($P < 0.05$) was found in `product-category` with RW, in `hazard` with all augmentation techniques, and `product` with CW and RW (Table 3). This indicates that augmentation techniques for BERT enhanced performance in minority classes more effectively in fine-grained categories than in coarse categories.

We submitted a combination of BERT and RoBERTa models for each category to the leaderboard (subsection B.3), which resulted in an F_1-macro score of 0.761 for ST1 and of 0.453 for ST2 in the test set. These models were chosen since they indicated the best F_1-macro scores on the development set. The other models were also evaluated on the test set, but not included in the leaderboard. The best scores achieved on ST1 was 0.769 and ST2 was 0.491, indicated in bold in Table 2. Moreover, experiments using only `title` were conducted (where their results can be found in Table 8). We continue with the error analysis on the models using `text` field since we observed better performance.

6.2 Error Analysis - Confusion Matrices

We investigated the performance and shortcomings on the BERT model, which improved most with the CW technique compared to the baseline.

When comparing the majority and minority classes that were augmented, the $BERT_{CW}$ model predicted the minority classes slightly better than $BERT_{base}$, with a rise from 39 to 41 for `hazard-category` and from 261 to 277 for `hazard` (around 6% increase) (Figure 2). However, the model predicted the majority classes slightly worse, decreasing from 656 to 632 for `hazard`, showing that there is a trade-off between improving the predictions for the minority versus the majority classes. Additionally, while the augmentation slightly improved the prediction of majority classes for the `product-category`, it decreased the minority class predictions from 106 to 101 samples.

Category	CW	RW	SR
hazard-category	0.5127	0.2752	0.2752
product-category	0.2752	0.3758	**0.0463**
hazard	**0.0495**	**0.0495**	**0.0463**
product	**0.0463**	**0.0495**	0.5127

Table 3: Raw P-values from individual pairwise Kruskal-Wallis tests between $BERT_{base}$ model and each of the three augmentation techniques (rounded up to 4 decimals).

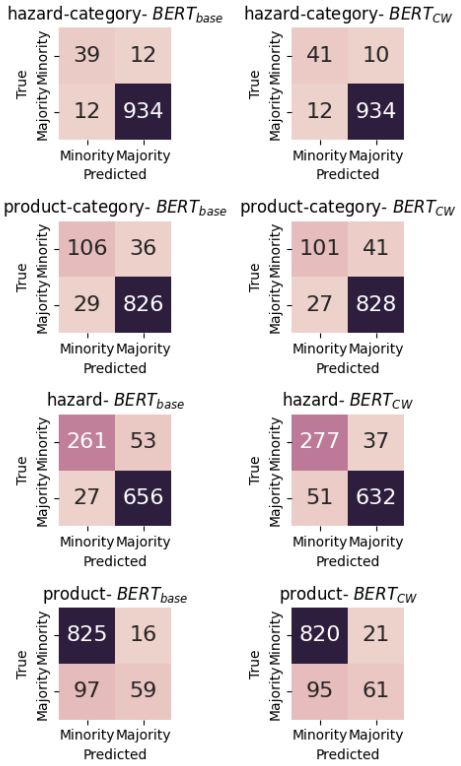

Figure 2: Confusion matrices comparing the performance of the $BERT_{base}$ and $BERT_{CW}$ models in the test set across the four categories showing the changes in the model's performance for minority and majority class predictions.

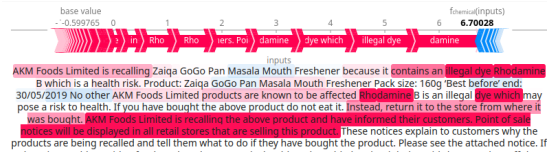
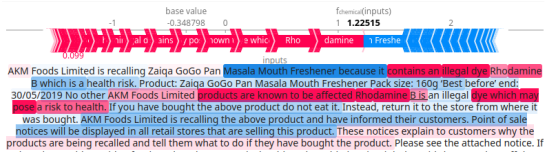
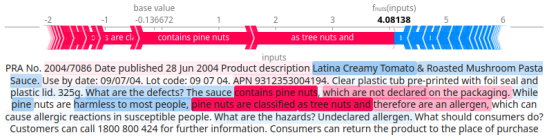


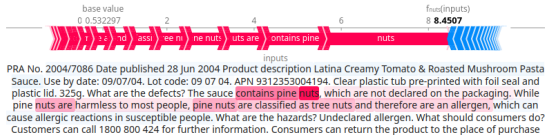
(a) Visualization of a correctly classified sample for `hazard-category` in baseline model for the true `chemical` class.



(b) Visualization of a wrongly classified sample for `hazard-category` in CW augmentation model for the true `chemical` class.



(c) Visualization of a wrongly classified sample for `hazard` in baseline model for the true `nuts` class.



(d) Visualization of a correctly classified sample for `hazard` in CW augmentation model for the true `nuts` class.

Figure 3: Visualizations of SHAP values for samples in the ground-truth classes of `hazard-category` and `hazard`, based on predictions from the $BERT_{base}$ and $BERT_{CW}$ models. Pink text indicates positive contributions toward predicting this class, while blue text indicates negative contributions. Text which does not contribute in each sample has been truncated.

6.3 Error Analysis - SHAP

We use SHapley Additive exPlanations (SHAP)[6] to further analyze BERT's prediction behavior. Figures 3a and 3b illustrate the SHAP values for a sample that was correctly classified with $BERT_{base}$, but was misclassified with $BERT_{CW}$ in the `hazard-category`, visualizing the contributions for the correct `chemical` class. Figures 3c and 3d show the SHAP values for a sample misclassified with $BERT_{base}$ but correctly classified with $BERT_{CW}$ in `hazard`, visualizing the contributions for the correct `nuts` class. For the `hazard-category`, the $BERT_{base}$ correctly identifies features such as 'illegal dye' (in pink color), while the CW augmentation has more negative (blue) contributions that push the model's prediction away from the correct class. For the `hazard` category, although both models focus on significant terms like 'pine nuts', the baseline model focuses on negative contributions like 'Latina Creamy Tomato' resulting in a misclassification which may imply that the model associates these features incorrectly with different hazards. This misclassification pattern could serve as a basis for future investigation, further exploring and explaining the model's predictions to improve its performance and reliability.

7 Limitations

While multiple experiments have been conducted, some limitations could be addressed in future studies. The dataset used was exclusively in English, and the augmentation techniques applied were limited to word-level adjustments. Future research could explore more sophisticated augmentation methods, such as LLMs, to generate new samples and verify their quality. Incorporating datasets in other languages could provide insight into the effectiveness of augmentation techniques. Further investigation could also focus on optimizing the number of augmented samples for minority classes to enhance classification performance, especially for food hazard classification, where reliable models are required to ensure safety. Lastly, to enhance even further the classifiers' performance, more complex architectures such as ensemble or hierarchical approaches could be used to compare their effectiveness on augmentation in the food hazard classification task.

8 Conclusion

We showed that word-level text augmentation can enhance multi-class classification in minority classes. We used various machine learning and transformer models on the SemEval-2025 Task 9 to assess the effects of these augmentations. Leveraging the `text` field, we discovered that transformers tend to outperform ML. Augmentation techniques showed a slight increase of F_1-macro scores, but this effect was not consistent across all augmentations. Comparing $BERT_{base}$ with each augmentation technique, a statistical significant improvement was found for fine-grained categories, which indicates that augmenting minority classes can improve the performance of transformers for these classes.

A Dataset and Experiments Details

A.1 Dataset Details

In this section, tables and figures related to the statistics of the provided dataset are presented. Table 11 shows some sample titles and text from the dataset along with their annotated classes. Table 10 presents the number and the names of the annotated classes. Figure 4 and Figure 5 show the distributions of hazard and product classes in coarse and fine-grained categories indicating the long-tail distributions that follow, while Figure 6 presents the distribution of occurrences in the dataset per country and year. Table 4 displays the site domain that the samples have been sourced along their number of samples.

A.2 Preprocessing Dataset Details

The `html.parser` was leveraged using the BeautifulSoup[7] package to remove the HTML content from the data. The regular expression that was used to remove the special characters is the following:

```
'[\t\n\r\u200b]|//| '
```

A.3 System Configurations Details

The experiments were run on different machines using Python version 3.10.16. For the fine-tuning and training of transformer models, NVIDIA A100 80GB and NVIDIA GeForce RTX 3070 Ti were utilized. For reproducibility, we used $seed = 2025$ as a seed number by employing it in PyTorch, NumPy, and Random packages. To run the BERT model two extra times and calculate the statistical significance, we used $seed = 2024$ and 2026. Moreover, the package versions and their respective URLs that were leveraged can be found in Table 5.

A.4 Transformer Models Details

In this section, we explain the encoder-only transformer models' details and architectures we used in the experiments. For BERT (Devlin et al., 2019), the `bert-base-uncased`[8] is used which consists of 110M parameters, 12 encoder layers, a hidden state size of 768, a feed-forward hidden state of 3072, and 12 attention heads, serving as

[7] https://www.crummy.com/software/BeautifulSoup/bs4/doc/

[8] https://huggingface.co/google-bert/bert-base-uncased

a foundational pre-trained transformer model. For RoBERTa (Liu et al., 2019), the `roberta-base`[9] (case-sensitive) is leveraged and has 125M parameters, structured with 12 encoder layers, a 768-dimensional hidden state, a 3072-dimensional feed-forward network, and 12 attention heads, which is trained on a large corpus leveraging dynamic masking. For DistilBERT (Sanh et al., 2020), the `distilbert-base-uncased`[10] is utilized, which is a lighter BERT variant having 66M parameters and 6 encoder layers while maintaining similar hidden state size and attention heads with BERT. For the ModernBERT (Warner et al., 2024), we used the `ModernBERT-base` [11] (case-sensitive), which contains 149M parameters, 22 encoder layers, hidden state of 768, an intermedia size of 1152, and 12 attention heads. It is trained on 2 trillion tokens, extending the token length to 8192 and incorporating other architectural enhancements to make it faster, lighter, and with better performance than other BERT variants.

A.5 Text Augmentation Details

In Algorithm 1, the function for creating new samples using augmentation is presented. Starting from the inputs of the function, it accepts: a threshold τ which is the number of samples that a class could contain to be a minority class, the number of samples to add S per minority class, a class counts C that contains the number of samples per class, an augmentation function F that accepts the sample and the number of samples to create, the original training dataset D and the $category$ (e.g. `hazard`) that we want to augment its classes. The function begins with finding the minority classes by getting the classes with samples less than the given threshold. Then, for each minority class, the respective samples are collected and the number of samples that need to be augmented for each sample is calculated by dividing the total samples over the number of samples of the specific class rounding down the result to the nearest integer. For each sample, then the augmentation function is applied and creates new samples, except for the last sample which is augmented for the remaining number of samples needed. The new samples are inserted into the original training dataset and the function returns the augmented set.

Algorithm 1 Function of creating samples for classification with augmentation

Require: Threshold of class number of samples τ, Total samples to add S, Class counts C, Augmentation function F , Original training dataset D, Category to augment cat

function CREATE_AUGMENTED_SAMPLES(τ, S, C, F, D, cat)
  $minority\_classes \leftarrow \{c \mid C[c] < \tau\}$
  $a\_s \leftarrow \emptyset$ ▷ augmented_samples
  for c in $minority\_classes$ **do**
    $samples \leftarrow \{d \in D \mid d[cat] = c\}$
    $N \leftarrow \left\lfloor \frac{S}{|\text{samples}|} \right\rfloor$
    for $sample$ in $samples$ **do**
      if is the last $sample$ **then**
        $N \leftarrow S - [N * (|samples| - 1)]$
      end if
      $new\_samples \leftarrow F(sample, N)$
      $a\_s \leftarrow new\_samples \cup \{a\_s\}$
    end for
  end for
  $augmented\_set \leftarrow D \cup a\_s$
  return $augmented\_set$
end function

A.6 Dataset Classes Statistics

In Table 6, a comparison between the classes' statistics before and after applying augmentation per category is presented. For `hazard-category` and `product-category`, the number of samples that have been created are 200 for classes that have under 200 samples. For `hazard` and `product`, the number of samples that have been added are 100 and 50, respectively, for classes that have under 100 samples.

A.7 F_1 Macro Evaluation Metric

For both subtasks, the evaluation metric given by the organizers was the F_1-macro score on the predicted and the annotated classes. The rankings are based on the hazard classes, meaning that if predictions for both hazard and product are correct, it will get a 1.0 score, while if the hazard predictions are correct but for product are wrong, it will score 0.5. The accurate scoring function can be seen in Algorithm 2.

A.8 Hyperparameters Details

To tune the hyperparameters, the Optuna optimization framework was employed, optimizing based on F_1-macro scores. For the ML models, the TF-IDF vectorizer parameters, such as min_{df}, max_df etc., were optimized, along with specific parameters for each model, such as max_iter for

Table 6: Comparison between the initial and after augmentation classes' statistics per category (`hazard-category`, `product-category`, `hazard`, `product`) in the training dataset.

Algorithm 2 Function for computing score for each subtask.

Require: hazard true ht, product true pt, hazard predictions hp, product predictions pp

function COMPUTE_SCORE(ht, pt, hp, pp)
  $F_1\_hazards \leftarrow F_1\text{-macro}(ht, hp)$
  $cm \leftarrow (hp == ht)$ ▷ correct_mask
  $F_1\_products \leftarrow F_1\text{-macro}(pt[cm], pp[ccm])$
  return $\frac{1}{2}(F_1\_hazards + F_1\_products)$
end function

SVM and LR, and $alpha$ for NB. The utilized hyperparameters for each model, category, and field are presented in Tables 12 to 17. When the SpaCy tokenizer[12] is used, English stopwords from SpaCy are also removed from the given text. Balanced class weight was used in SVM, LR, RF, and DT models.

For the transformer models, $batch\_size$, $epochs$, and $lr\_scheduler$ were optimized across all model variants over 10 trials. For all models, the learning rate was set at $5.0\text{e}{-5}$, and the maximum token length that the tokenizer can generate was set at 128, as no significant differences in performance with higher maximum token length were observed. In Tables 18 to 21, the utilized hyperparameters for each model, category, and field are listed.

The search space for each hyperparameter used during the tuning can be found in Table 7.

$epochs$	{3, 5, 10}
$lr\_scheduler$	{lin, cos, cosRestarts}

Table 7: Search space for each hyperparameter used in Optuna optimization trials for ML and transformer models. For learning rate schedulers: cos (cosine annealing), cosRestarts (cosine annealing with restarts), and lin (linear).

B More Results and Explainability Analysis

B.1 Results using title

In Table 8, we present the experimental results on the test set using the `title` field for both ML and transformer models. As with the results using `text`, transformer models overall outperformed the ML models, although they were lower than using `text`. The best models per category are: $BERT_{RW}$ for `hazard-category` (0.670), $RoBERTa_{RW}$ for `product-category` (0.736), $DistilBERT_{SR}$ for `hazard` (0.503), and RF_{base} for `product` (0.287). Among the ML models, SVM, LR, and RF demonstrated competitive performance across the categories, similar to the performance observed using only the `text` field. While there was variability between the baseline and augmented models, a slight, consistent increase was observed in `product-category` and `hazard` when using transformer models.

B.2 Statistical Significance Experiments

The mean F_1-macro scores for the BERT model experiments (both baseline and augmented versions, each run three times) are presented in Table 9.

B.3 Official Submitted Models

Since only one submission was allowed during the evaluation phase, the predictions of the models that

Model	hazard-category	product-category	hazard	product	ST1	ST2

Table 8: F_1-macro scores in the official test set given by the organizers utilizing the `title` field per category and subtasks scores (ST1 and ST2) rounding up to 3 decimals. With bold, we indicate the higher score per column.

Model	hazard-category	product-category	hazard	product
$BERT_{base}$	0.757	0.769	0.594	0.186
$BERT_{CW}$	0.768	0.756	0.658	0.284
$BERT_{RW}$	0.751	0.752	0.662	0.256
$BERT_{SR}$	0.771	0.75	0.652	0.189

Table 9: Mean F_1-macro scores per category for each $BERT_{base}$ and with augmentation models running three times using as random seed numbers: 2024, 2025, and 2026.

were submitted and were found to have the best F_1-macro scores on the development set for each category are: $RoBERTa_{base}$ for `hazard-category` with 0.880 F_1-macro score, $RoBERTa_{RW}$ for `product-category` with 0.750 F_1-macro score, $BERT_{CW}$ for `hazard` with 0.682 F_1-macro score, $BERT_{RW}$ for `product` with 0.260 F_1-macro score (all trained in `text` field). Then, these models were trained in both train and dev sets and provided their predictions on the test set. When submitting this combination of models, an ST1 score of 0.761 and an ST2 score of 0.4529 were achieved, which are our official leaderboard scores.

Category	Number of Classes	Names of Classes
Hazard Category	10	'allergens', 'biological', 'foreign bodies', 'fraud', 'chemical', 'other hazard', 'packaging defect', 'organoleptic aspects', 'food additives and flavourings', 'migration'
Product Category	22	'meat, egg and dairy products', 'cereals and bakery products', 'fruits and vegetables', 'prepared dishes and snacks', 'seafood', 'soups, broths, sauces and condiments', 'nuts, nut products and seeds','ices and desserts','cocoa and cocoa preparations', 'coffee and tea','confectionery','non-alcoholic beverages','dietetic foods', 'food supplements', 'fortified foods','herbs and spices','alcoholic beverages','other food product / mixed','pet feed','fats and oils','food additives and flavourings','honey and royal jelly','food contact materials', 'feed materials', 'sugars and syrups'
Hazard	128	'listeria monocytogenes','salmonella','milk and products thereof','escherichia coli','peanuts and products thereof' ... 'dioxins','staphylococcal enterotoxin','dairy products','sulfamethazine unauthorised','paralytic shellfish poisoning (psp) toxins'
Product	1068	'ice cream', 'chicken based products', 'cakes', 'ready to eat - cook meals', 'cookies' ... 'breakfast cereals and products therefor', 'dried lilies', 'chilled pork ribs', 'tortilla chips cheese', 'ramen noodles'

Table 10: Names and number of total classes of the four annotated categories. For `hazard` and `product`, some classes are ommited. For `product`, the total number of classes along with the test data is 1,142.

{liang, hflin}@dlut.edu.cn

Abstract

This paper describes our system developed for SemEval-2025 Task 1 : Advancing Multimodal Idiomaticity Representation. This task focuses on ranking images based on the relevance of their visual content and descriptive text to the specific meaning of a given noun compound. Leveraging parameter-efficient fine-tuning of the BLIP-2 model and external knowledge injected through the DeepSeek, our method enables effective ranking of images based on semantic relevance to noun compounds. Specifically, we fine-tune BLIP-2 with LoRA on the provided training dataset to generate descriptive captions for candidate images. The generated captions are then integrated with the original image descriptions using a large language model to create a unified textual representation, which, along with the target noun compound and its sentential context, serves as input for the DeepSeek. Our system achieves a classification accuracy of 0.73 on the English dataset and 0.85 on the Portuguese dataset.

1 Introduction

In SemEval-2025 Task 1 Subtask A (Pickard et al., 2025), participants are challenged to rank images based on their relevance to a given noun compound (NC) within a specific sentential context. This task aims to address the limitations of current large language models, which, compared to humans, often struggle with figurative expressions such as idioms (Tayyar Madabushi et al., 2021; Chakrabarty et al., 2022; Phelps et al., 2024). Building on the premise that human understanding of idioms relies on multisensory interactions with the real world (Lakoff and Johnson, 1980), Subtask A leverages visual representations to encourage the development of models that can better capture the semantic meaning of idioms, a crucial aspect of natural language understanding.

To address this challenge, we propose a system that leverages image-to-text techniques for data augmentation and utilizes advanced large language models to improve classification accuracy by combining parameter-efficient fine-tuning of a multimodal model with external knowledge injection.

We employ LoRA to fine-tune the BLIP-2 model (Li et al., 2023), a pre-trained multimodal model that excels at vision-language tasks, in order to generate descriptive captions for candidate images. BLIP-2 leverages a frozen image encoder and a learned query transformer to efficiently bridge the gap between visual and textual representations, making it well-suited for capturing the interplay between images and idiomatic expressions.

With the recent surge in popularity of DeepSeek, we utilized it for text integration and relevance analysis in the later stages of our experiments.The generated captions are then combined with the original image descriptions using DeepSeek to produce comprehensive and richly detailed textual representations, which are input to the DeepSeek API for inference in order to rank the images based on their contextual relevance to the target noun compound. By combining visual grounding with the reasoning capabilities of a large language model, our system aims to enhance idiomaticity representation and understanding, while also demonstrating the potential of multimodal models for this task.

Our experimental results on the SemEval-2025 Task 1 Subtask A dataset demonstrate that our system achieves promising ranking performance, obtaining high accuracy scores on both the English (0.73) and Portuguese (0.85) datasets. These findings highlight the potential of leveraging multimodal models for visually grounded language understanding and contribute to the development of more robust and context-aware techniques for idiomaticity representation.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 931–936

2 Background

2.1 Dataset Description

The dataset used in the experiment is divided into two parts, English and Portuguese. The English part contains 70 data and the Portuguese part contains 32 data. Each data is composed of: a compound word, a sentence using the compound word, the meaning type of the compound word in the sentence, five comic pictures associated with the compound word, and a text description of each picture.

2.2 Related Work

With the rapid development of machine learning, how to make machines learn to understand colloquialisms has become a very interesting topic. In recent years, many works have used various methods to explore this direction, such as synonym knowledge enhancing (Long et al., 2020), multi-granularity reasoning (Dai et al., 2023), and multi-semantic contrasting (Wu et al., 2024).

The superior ability of large language models has brought new possibilities for the development of colloquialism understanding. Some works (Donthi et al., 2024) have been thinking about how to enhance the understanding ability of large language models for colloquialisms while taking advantage of the basic reasoning ability of models. At the same time, many works (Khoshnevisan, 2019) are also exploring whether multimodal information and models can enhance the understanding ability of colloquialisms. The series of studies shows that the use of multimodal large models for colloquialism understanding tasks is worthy of in-depth exploration, and can provide more fresh ideas for the improvement of this task.

3 System Overview

Our system aims to enhance ranking accuracy by transforming the multimodal task into a purely text-based one, leveraging image-to-text models in the initial stage. Given that current large language models (LLMs) exhibit a comparatively limited capacity for image understanding compared to their proficiency in processing textual data, we strategically employ BLIP-2 for initial data augmentation. This allows us to transform the images into text, thereby enabling the use of more sophisticated LLMs for downstream processing and ultimately achieving superior ranking outcomes.Following this rationale, our system is structured into two primary components: Data Augmentation and Relevance Assessment. The overall architecture of the system is illustrated in Figure 1.

3.1 Data Augmentation

In this task, we employ BLIP-2 for data reprocessing to achieve the goal of data augmentation.

3.1.1 Fine-tuning

In this stage, we extracted all image-text pairs from the provided training and development datasets. To enhance the quality of image descriptions, we fine-tuned the BLIP-2 model using LoRA on these extracted pairs. Additionally, to assess the impact of dataset size on performance, we conducted a comparative experiment by randomly selecting 100 image-text pairs and fine-tuning a separate BLIP-2 model on this smaller subset. This allowed us to evaluate the effectiveness of our data augmentation strategy and explore the trade-off between dataset size and model accuracy.

Our results indicate that the BLIP-2 model fine-tuned on the smaller 100-pair dataset, while maintaining adherence to accurate image content descriptions, exhibited a greater capacity for generating creative and detailed textual descriptions compared to the model fine-tuned on the full dataset.

3.1.2 Caption Integration

A naive approach of simply concatenating the BLIP-2 generated image descriptions with the original captions often resulted in redundancy and logical inconsistencies, thereby hindering effective downstream relevance ranking. To address these limitations, we opted to leverage a large language model (LLM) for text integration.

Specifically, we employed the DeepSeek API, prompting it with carefully designed instructions to synthesize the two textual sources into a coherent and concise description. These instructions were carefully crafted, assigning DeepSeek the role of a "master of textual integration and reasoning." Beyond ensuring information completeness and logical coherence, the instructions also encouraged DeepSeek to infer symbolic meanings from the descriptive details. This strategic prompting aimed to enrich the integrated text with novel insights, ultimately enhancing the performance of downstream relevance assessment. This approach ensured that the resulting textual representation was not merely a concatenation of information, but rather a logi-

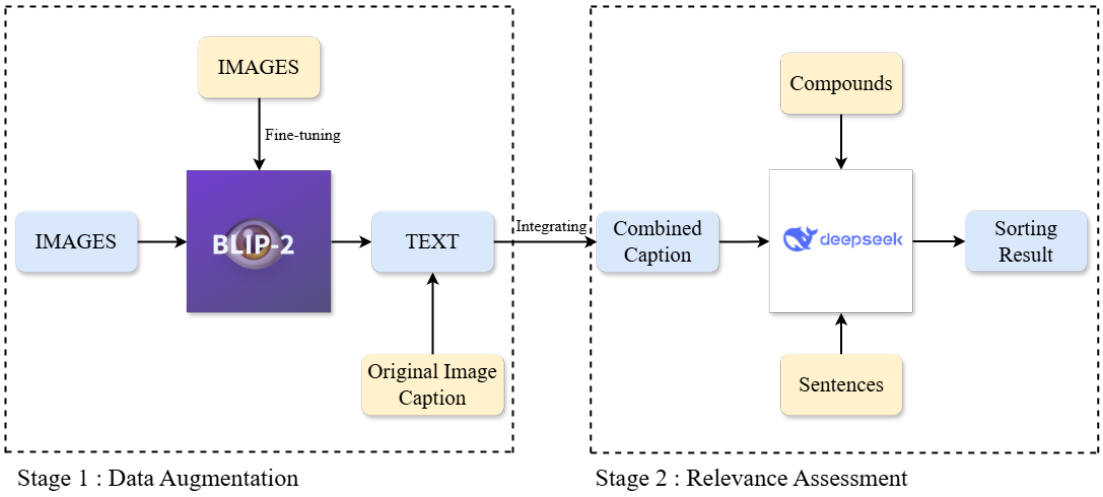

Figure 1: The overall architecture of our proposed system.

cally consistent and semantically rich summary, facilitating improved comprehension by subsequent ranking models.

3.2 Relevance Assessment

In the second component of our system, we explored two distinct approaches to achieve effective relevance ranking. The first approach involved direct utilization of a large language model (LLM) API, prompting the model with carefully crafted queries to elicit a ranking based on contextual relevance. The second approach focused on training a smaller, resource-efficient LLM, such as Llama 3.1 or Qwen 2.5, through fine-tuning on the generated textual data, which was obtained in the previous steps. This allowed us to compare the effectiveness of a zero-shot approach leveraging a powerful LLM API with a fine-tuning approach using a more specialized and resource-conscious model.

3.2.1 Direct API calls

For the relevance assessment component, we again utilized the DeepSeek API to analyze the degree of relatedness between the generated image descriptions and the target compound phrases. In this context, DeepSeek was prompted with meticulous instructions, assuming the role of an "image relevance ranking expert." These instructions directed DeepSeek to consider both the intrinsic meaning of the compound phrase and its nuanced interpretation within the provided sentential context. Furthermore, DeepSeek was explicitly instructed to account for any potential idiomatic or homophonic meanings of the compound, while providing a detailed rationale for the resulting image ranking. This deliberate approach ensured a thorough and context-aware evaluation of image relevance, moving beyond simple keyword matching to incorporate a deeper understanding of semantic relationships.

To generate relevance rankings, we formatted the compound phrase, the corresponding sentence, the five integrated descriptions, and the names of each image from the newly created dataset into a structured input for the DeepSeek API. This input, combined with the aforementioned instructions, enabled DeepSeek to produce both a ranked list of images and a detailed rationale outlining its reasoning process. This output was then used for subsequent evaluation.

3.2.2 Fine-tuning LLMs

In addition to leveraging the DeepSeek API, we explored a second strategy for relevance assessment: fine-tuning smaller, more resource-efficient large language models (LLMs) on the generated textual data. This approach involved training both Llama-3.1-8B and Qwen2.5-7B models on a dataset comprising the combined image descriptions (synthesized as previously described), the corresponding compound phrase, and the sentence providing contextual information. The objective of this fine-tuning process was to directly instill within these models the ability to discern and rank images based on their relevance to the target compound phrase.

While this fine-tuning approach offered the advantage of creating specialized models with potentially lower inference costs compared to relying on an external API, our experimental results indicated a clear performance gap compared to the

DeepSeek API-based ranking. Specifically, the models fine-tuned on Llama-3.1-8B and Qwen2.5-7B, while demonstrating some ability to capture semantic relationships, struggled to achieve the same level of accuracy and coherence in image ranking as the DeepSeek API, particularly in nuanced cases requiring a deeper understanding of idiomatic meanings. This suggests that, for this specific task and dataset, the reasoning capabilities and broader knowledge base inherent in larger, externally hosted LLMs offer a distinct advantage over the knowledge and skills that can be acquired through fine-tuning smaller models.

Despite the reduced performance, we believe that exploring fine-tuning approaches remains valuable. Further research could investigate techniques such as more extensive fine-tuning, the incorporation of more diverse training data, or the use of specialized loss functions to better optimize smaller models for this challenging relevance ranking task.

4 Experimental setup

4.1 DeepSeek API-based Ranking

To leverage the DeepSeek API for relevance ranking, we designed a meticulous prompt that combined the task instruction, the target noun compound, the contextual sentence, and the generated image descriptions. The prompt was structured to explicitly guide the LLM to assess the semantic similarity between the images and the compound, while considering both literal and figurative interpretations of the compound within the given context. Furthermore, the prompt requested a clear and detailed rationale for the model's ranking decision, allowing for a qualitative analysis of the model's reasoning process.

We accessed the DeepSeek API through the OpenAI Python library, configuring the API client with our unique API key and the appropriate base URL. The model parameter was set to "deepseek-reasoner" directing the API to utilize DeepSeek's general-purpose conversational model. For each data instance, the meticulously crafted prompt was packaged into a message with the "user" role and sent to the DeepSeek API. The resulting JSON response, containing the ranked list of images and the associated rationale, was then parsed to extract the predicted ranking.

4.2 Fine-tuning LLAMA and Qwen

For our fine-tuning experiments, we employed the Llama-Factory framework [1], a user-friendly and efficient tool for adapting large language models. Llama-Factory provides a streamlined interface for managing the fine-tuning process, encompassing data loading, model configuration, and training loop management. This framework facilitated experimentation with diverse hyperparameters and training strategies while ensuring consistent and reproducible results. We leveraged this framework to fine-tune both Llama-3.1-8B and Qwen2.5-7B.

Prior to fine-tuning, the BLIP-2 generated textual descriptions were combined with the original image descriptions as described previously to create a more comprehensive data format. We structured this data into a JSON file with a distinct instruction format that incorporated task descriptions. The fine-tuning process was conducted using optimized parameters saved within the model directory. Subsequently, we utilized the fine-tuned Llama-3.1-8B and Qwen2.5-7B models directly for inference, generating ranking predictions via their respective APIs. These predictions were then used for evaluation.

4.3 Evaluation Method

We employed the officially provided CodaBench website [2] for accuracy evaluation.

5 Results

The results of our experiments demonstrate a significant performance disparity between the two relevance ranking approaches. Specifically, the ranking accuracy achieved by directly utilizing the DeepSeek-R1 API substantially outperformed that of the Llama-3.1-8B and Qwen2.5-7B models after fine-tuning. The ranking accuracy of both methods on the given dataset is summarized in Table 1. This suggests that, for the task of visually grounded noun compound ranking, the inherent reasoning capabilities and extensive knowledge base of large, externally hosted LLMs offer a distinct advantage over models that have been fine-tuned on a limited dataset.

Furthermore, we observed that the DeepSeek API, when provided with the textually augmented

data, generated more accurate relevance rankings compared to both the original image-text data and the results obtained without any data augmentation. This indicates that our data augmentation strategy, which leverages image-to-text generation to enrich the textual representation of images, effectively enhances the ability of LLMs to discern nuanced semantic relationships and perform robust relevance assessments.

This observation highlights the challenge of effectively transferring knowledge acquired through fine-tuning to complex tasks that require nuanced semantic understanding. While the fine-tuned models demonstrated some capacity for capturing relationships between images and text, they appear to have struggled to generalize to the complexities of idiomatic expressions and the subtle contextual cues required for accurate relevance assessment. This underscores the importance of leveraging the vast pre-existing knowledge and sophisticated inference mechanisms embodied in advanced LLM APIs for tasks demanding a high degree of semantic understanding and reasoning.

6 Conclusion

In this work, we successfully addressed the challenge of visually grounded idiom understanding and ranking by combining data augmentation with fine-tuned BLIP-2 and leveraging the DeepSeek-R1 API. Our experimental results demonstrated that this synergistic approach yields high accuracy in ranking images according to their relevance to idiomatic expressions. Furthermore, our investigation of alternative strategies illuminated the performance gap between fine-tuning smaller parameter models and directly utilizing large language model APIs for this complex task.

Future research will focus on exploring further possibilities for multimodal idiom understanding. Key areas of investigation include enhancing the direct comprehension capabilities of multimodal LLMs for both image and text information, and exploring the use of text-to-image generation techniques to facilitate more effective text-based ranking approaches.

A Appendix

Table 2 gives the prompts used during experimentation.

phase	Prompt
integrative phase	You are now a master of image information integration, and I need you to help me integrate two descriptions of the same image. It is required that no key or detailed information be omitted, and at the same time, you can think and speculate on the content or scene present in the image, such as expressing emotions or possible metaphors.
sort phase	You are now an excellent expert in matching graphic and textual information and sorting relevance. Please help me complete an image sorting task. Below, I will provide you with a phrase (compound), a sentence that uses this phrase (sentence), the type of meaning of the phrase in the sentence (sentence_type), as well as the names of five images and their respective descriptive texts(image_caption). Please evaluate the relevance of these five images to the phrase I have given based on their descriptive texts, and perform a sorting task, requiring them to be sorted in descending order of relevance, with the most relevant ones written at the beginning. When evaluating relevance, you can refer to the meanings of the phrases I provided in the sentence to better understand their true meanings. Please carefully analyze and perform the sorting task. Sort the images by their names, with output formats similar to ['35234427395. png ',' 53378381715. png ',' 39938261459. png ',' 7485253662. png ',' 54879908369. png ']

Abstract

The DataBench shared task in the SemEval-2025 competition aims to tackle the problem of question answering (QA) from tabular data. Given the diversity of the structure of tables, there are different approaches to retrieving the answer. Although Retrieval-Augmented Generation is a viable solution, extracting relevant information from tables remains a significant challenge. In addition, the table can be prohibitively large for direct integration into the LLM context. In this paper, we address QA over tabular data first by identifying relevant columns that might contain the answers, then the LLM generates answers by providing the context of the relevant columns, and finally, the LLM refines its answers. This approach secured us 7th place in the DataBench lite category.

1 Introduction

Question Answering (QA) is a long-standing challenge in artificial intelligence, with numerous variations and applications. QA systems are extensively used in a variety of real-world scenarios, such as virtual assistants and chatbots for customer support. They serve as powerful tools for extracting relevant information from large and diverse datasets.

A crucial challenge arises when the required information is not just embedded in natural language but also stored in structured formats, such as tabular data. The primary challenge in tabular QA stems from the need to bridge the gap between structured data representation and natural language understanding. While substantial progress has been made in developing models that handle either natural language or structured data independently, effectively integrating both remains an open research problem.

Traditional retrieval methods struggle to select relevant table segments, and large language models (LLMs) can be inefficient when tasked with processing extensive tabular data directly. To advance research in this area, the DataBench shared task (Os'es Grijalba et al., 2025) was introduced, focusing on answering questions from tabular datasets. In particular, the shared task proposes to answer the question on the DataBench (Grijalba et al., 2024) datasets and a smaller DataBench lite version (a reduced version of each dataset from the original DataBench). In this paper, we focus primarily on a lite subtask. Our approach incorporates several key strategies inspired by existing methodologies. First, we observe that all the questions can be answered using information from only three relevant columns. We leverage column augmented generation (CAG), a technique that dynamically selects relevant columns based on LLM-generated hints and helps retain only the most relevant columns. CAG addresses multiple challenges simultaneously by filtering out irrelevant columns, reducing noise, and significantly shrinking the table size, which enhances model efficiency. We then explore the effect of several prompting techniques: 1) iterative self-refinement employs a feedback loop where the model iteratively refines its own responses; 2) self-consistency answer selection improves the reliability of stochastic LLM generations by aggregating multiple generated answers; 3) Chain-of-thought (CoT) allows the model to produce intermediate reasoning steps, which increases its reasoning capabilities.

By systematically analyzing the impact of each individual modification, we investigate how these techniques can be effectively combined to make our best performing solution. Our submission utilizes only open-source and still achieves competitive results: we rank 7th out of 35 teams on the DataBench lite leaderboard. Our findings highlight the potential of combining structured data processing techniques with robust QA methodologies to improve tabular QA capabilities.

Our main contributions are threefold:

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 937–952

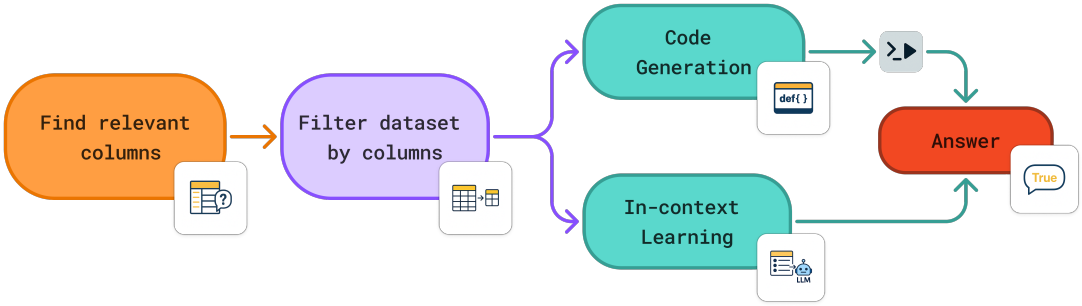

Figure 1: An illustration of CAG pipeline. Step 1) Extract column relevant to the question based on their names, see Appendix A. Step 2) Remove all irrelevant columns from the tables in dataset. Step 3) Code generation: Insert column names and descriptions, question in the prompt and generate code (see Appendix A), then execute it; In-context learning: Insert filtered tables, column descriptions and question in the prompt and generate an answer, see Appendix A. Reasoning prompting techniques, see Section 5.2, are applied along with the Step 3.

- **Column Augmented Generation** We enhance context retrieval by dynamically selecting relevant table segments using LLM-generated column hints, improving the quality of retrieved evidence.
- **Reasoning Prompts** We systematically experiment with different reasoning strategies to enhance LLM reasoning capabilities and identify the most effective prompting techniques.
- **Reasoning Scaling** We analyze how different levels of reasoning complexity influence performance, demonstrating that increased reasoning depth can significantly improve tabular QA accuracy.

2 Related Work

Prior work in table-based question answering can be broadly categorized into two main paradigms: **Text-to-Code** and **Retrieval-Augmented Generation** .

Text-to-Code methods translate natural language queries into executable code, typically SQL. Recent advances in this area have been driven by two key factors. First, improvements in pre-trained language models have led to richer semantic representations of queries and table content (Konovalov and Tumunbayarova, 2018). Second, a deeper understanding of the role that table structure plays in query interpretation has informed more accurate model architectures (Li et al., 2023).

Within this paradigm, several sub-approaches have emerged. Schema-aware parsing models, such as TAPAS (Herzig et al., 2020), T5-SQL (Arcadinho et al., 2022), TAPEX (Liu et al., 2022), and OmniTab (Jiang et al., 2022), explicitly encode schema information (e.g., column names and data types) to guide SQL generation. Another line of work uses intermediate logical forms, as in DIN-SQL (Pourreza and Rafiei, 2023), which first parse questions into structured operations before converting them to SQL, increasing the robustness of the model. Extensions to text-to-code approaches include systems like text2pandas (Venturi, 2023), which generate executable `pandas` code. These methods offer more flexible data manipulation and are especially useful for non-standard or heterogeneous table formats.

Retrieval-Augmented Generation approaches condition the model output on evidence retrieved from the knowledge base (table) (Belikova et al., 2024). These methods enhance the grounding of generated answers and improve performance on complex queries.

Several retrieval strategies have been proposed within the RAG framework. Aushev et al. (2025) proposed to combine retrieval with techniques to enhance LLM attention on the retrieved context rather than on its own knowledge. Table segment retrieval, as used in TableRAG (Chen et al., 2024), identifies relevant portions of the table for conditioning, helping models focus on the most informative regions. Row-column retrieval methods, including ITR (Lin et al., 2023) and TAP4LLM (Sui et al., 2024), further improve scalability by selectively encoding and retrieving key rows and columns.

In TableRAG (Chen et al., 2024), schema retrieval is used to identify relevant table columns by constructing structured representations of each column (including name, type, min/max values, and most frequent values). Given a query, a lan-

guage model generates a list of candidate columns, and retrieval is performed using vector search (e.g., FAISS), keyword search (BM25), or hybrid search strategies combining both. Embeddings from the *BAAI/bge-large-en-v1.5* model (Xiao et al., 2023) are used for vectorization. Similarly, TAP4LLM (Sui et al., 2024) introduces Table Sampling, where each column is embedded and the top-k columns are retrieved based on their semantic proximity to the query, again using FAISS. To enhance retrieval, keyword-based and hybrid search strategies are also explored.

ReasTAP (Zhao et al., 2022) demonstrates that high-level reasoning over tables can be incorporated during pre-training without requiring task-specific architectures. Although these methods reduce input length and improve focus, they often incur additional computational costs and may struggle with degraded embedding quality on longer sequences.

Finally, hybrid approaches combine retrieval with execution or synthesis mechanisms. For example, ReAcTable (Zhang et al., 2024) integrates context retrieval with program synthesis and iterative refinement, bridging the text-to-SQL and RAG paradigms. H-STAR (Abhyankar et al., 2024) further extends this idea by employing dynamic hybrid prompting, adapting between structured and unstructured strategies depending on the complexity of the query. These systems highlight the potential of combining multiple paradigms to balance efficiency, scalability, and accuracy.

Recent progress, particularly inspired by TableRAG (Chen et al., 2024), underscores the importance of selectively retrieving and conditioning on relevant table segments. Such methods have shown strong performance gains, especially on complex or noisy tables. However, their effectiveness remains closely tied to the precision of the retrieval component — inaccuracies at this stage can significantly degrade downstream performance.

The approaches to develop a QA system based on the tabular data can be further enhanced to be based on knowledge graphs (Sakhovskiy et al., 2024).

3 Dataset

The DataBench dataset consists of 65 publicly available datasets, with 3 269 975 rows and 1615 columns in total, and 1300 questions in 5 domains. The dataset is split into three sections: training (comprising 988 questions), testing (featuring 522 questions and 517 questions after changes), and development (consisting of 320 questions) (Grijalba et al., 2024). DataBench Lite is obtained by shortening the table for each question in the DataBench dataset so that 20 columns and 20 rows remain. Examples of multi-column questions (requiring more than two columns to generate a correct answer) are provided in the Appendix C.

Column types presented in DataBench:

- Boolean: Valid answers include True/False, Y/N, Yes/No (all case insensitive).
- Category: A value of a cell (or a substring of a cell) in the dataset.
- Number: A numerical value from a cell in the dataset that may represent a computed statistic (e.g., average, maximum, minimum).
- List[category]: A list containing a fixed number of categories. The expected format is: "['cat', 'dog']". Pay attention to the wording of the question to determine if uniqueness is required or if repeated values are allowed.
- List[number]: Similar to List[category], but with numbers as its elements.

4 Evaluation

Participants must answer questions using only the provided dataset, including development and training sets, without external data. The accuracy scores for DataBench and DataBench lite are ranked separately. An automated evaluation framework[1] streamlines the process, allowing customization of prompt building, model calling, and result evaluation, while supporting batch processing and standardized response handling.

The default evaluation function compares submissions against the truth set, featuring:

- Null: Treats null-like values as equivalent.
- Boolean: Normalizes inputs and checks against true/false lists.
- Category/String: Strips and compares strings, with date parsing for format variations.
- Number: The values are rounded to two decimal places for tolerance.

bge-large-en-v1.5 + BM25	20.15	62.29	30.46
TableRAG			
Llama-3.3-70B-Instruct			
bge-large-en-v1.5	16.41	32.70	21.85
BM25	26.96	27.92	27.43
bge-large-en-v1.5 + BM25	22.28	50.84	30.98

Table 1: The micro-averaged results for detecting the required columns to form the answer to the question (on the dev dataset). For the Table Sampling method, we consider k=3 based on the considerations given in the section D.

- List[Category]: Normalizes and checks set equivalence (order-agnostic).
- List[Number]: Normalizes, rounds, and ensures order-agnostic equivalence.

In addition, the organizers decided to manually review the results of the top scores to ensure fairness and accuracy in determining the winner.

5 System Overview

5.1 Column Augmented Generation

The Column Augmented Generation (CAG) approach is a two-step method inspired by Retrieval-Augmented Generation techniques. Since large tables cannot be easily incorporated into an LLM's context due to size constraints, the first step in our pipeline involves identifying the most relevant columns needed to answer a given question (see Appendix A for the relevant prompt). This column selection process is treated as a multi-label classification task, evaluated using micro-averaged precision, recall, and F1 score (see Table 1). The selected column names are then validated for format compliance, and if necessary, the generated response is refined or corrected.

Once the relevant columns are identified, the second step involves prompting the LLM again, this time with the extracted column data included as context. This ensures that the model focuses only on the most relevant information when generating an answer. The CAG approach aligns closely with techniques used in TableRAG (Chen et al., 2024), improving both passage quality and model efficiency by dynamically narrowing the input scope.

5.2 Reasoning Prompting Techniques

In addition to the CAG technique, we incorporated advanced prompt engineering methods to enhance reasoning abilities, specifically Chain-of-Thought (CoT) (Wei et al., 2022), Self-Consistency (Wang et al., 2023), and Self-Refine (Madaan et al., 2023), see all prompts in Appendix B. These techniques can be applied independently or in combination with CAG to improve its effectiveness.

The Self-Consistency method involves calling the model multiple times and aggregating the results using a majority vote to determine the most frequent answer. We experimented with different numbers of model calls, such as 3, 5, and 10, to assess its impact, see Figure 3.

The Chain-of-Thought technique encourages step-by-step reasoning by instructing the model to break down its thought process. This approach improves the focus of the model on intermediate reasoning steps while also increasing token generation. To implement this, we used few-shot prompting with explicit CoT examples. Additionally, we explored the combination of CoT and Self-Consistency to further refine the reasoning process.

Finally, we tried applying Self-Refine as a post-generation technique. The model was instructed to evaluate its own responses, providing feedback on correctness and answer format. This feedback was then used to guide subsequent answers, leading to iterative improvements.

In our code generation method, we generated Python code (which yielded better results than SQL) and then executed it. If the code generated an error, the self-refine method was applied with the exception given to the prompt. Chain-of-Thought and self-consistency were also integrated to improve the effectiveness. However, we achieved better results on DataBench lite using the Table-to-text method with the Chain-of-Thought and self-consistency.

6 Experimental Setup

For our experimental setup we used two open LMs: (1) `Llama-3.1-8B-Instruct`[2] is a language

[2] https://hf.co/meta-llama/Llama-3.1-8B-Instruct

Model	EM
Python Code Generation	
CodeLlama-7B*	30.3
CodeLlama-13B*	33.1
Llama-3.1-8B-Instruct	45.98
+ CAG	51.15 (+5.17)
Llama-3.3-70B-Instruct	70.5
+ CAG	65.51 (-4.99)
In-Context Learning	
Llama-2-7B*	14.8
Llama-2-13B*	20.7
Llama-3.1-8B-Instruct	27.78
+ CAG	37.93 (+10.15)
Llama-3.3-70B-Instruct	49.81
+ CAG	64.37 (+14.56)
DeepSeek-R1-32B	77.78
+ CAG	83.52 (+5.74)

Table 2: Results on the DataBench Lite test set. EM denotes the Exact Match (see Section 4); "*" denotes baselines provided by the competition organizers, see (Grijalba et al., 2024). +CAG indicates the use of our proposed CAG method. Our approach consistently outperforms baselines.

Model	EM
Llama-3.3-70B-Instruct	49.81
+CAG	64.37 (+14.56)
+CAG+Ref	69.36 (+19.55)
+CAG+CoT	81.03 (+31.22)
+CAG+CoT+Ref(1)	77.59 (+27.78)
+CAG+CoT+Cons(10)	**81.99** (+32.18)

Table 3: Results on the DataBench Lite test set. This table demonstrates the impact of various prompting techniques on the overall performance, applied in in-context learning settings. The techniques include: CAG (Column-Augmented Generation), CoT (Chain-of-Thought instruction included in the prompt), Ref (Self-Refine prompt), and Cons (Self-Consistency answer selection). For further details on how these prompting methods were implemented, refer to Section 5.2 and Appendix B.

model with 8 billion parameters and is optimized for conversational applications, supporting a contextual length of up to 128 thousand tokens; (2) `Llama-3.3-70B-Instruct`[3] is a large language model with 70 billion parameters and is optimized for conversational applications, supporting a contextual length of up to 128 thousand tokens (Touvron et al., 2023). In addition, we evaluate our CAG approach on DeepSeek-R1-32B[4] that has shown advanced reasoning abilities over the LMs of a comparable number of parameters (DeepSeek-AI, 2025). All LMs were evaluated for `temperature = 0.7`. The `BAAI/bge-large-en-v1.5`[5] was also used as an embedding model.

7 Results and Discussion

Our main results on the DataBench lite test split are summarized in Table 2.

7.1 Required Columns Generation

The findings confirm that the 70B model consistently outperforms the smaller 8B model across all settings. This is evident in the first step of the CAG pipeline, where LLMs identify relevant columns, as shown in Table 1. The 70B Llama achieves a micro-average F1 score of 90.95%, significantly outperforming the 8B models.

We also evaluated retrieval-based baselines. In TableRAG, the best results were achieved with the bge-large-en-v1.5 embeddings combined with BM25 retrieval, reaching an F1 score of 30.98%. In Table Sampling (from TAP4LLM), the best result was obtained with the bge-large-en-v1.5 model, achieving an F1 score of 34.82%. On the DataBench Lite dataset, Table Sampling outperformed TableRAG but still showed lower performance compared to CAG. This could be due to the fact that TableRAG and Table Sampling approaches typically perform better on large tables, while DataBench Lite consists of relatively small tables (20 rows and 20 columns) (Table 1). For Table Sampling, we found that the optimal number of retrieved columns is $k = 3$, as detailed in Appendix D.

7.2 Column Augmented Generation

Table 2 further demonstrates that the CAG technique significantly improves performance across all prompting strategies that do not require code execution, producing an absolute percentage increase of 10.1 and 12.6 for the 8B and 70B models, respectively. When combined with Chain-of-Thought, performance improves even further, with

[3] https://hf.co/meta-llama/Llama-3.3-70B-Instruct

[4] https://hf.co/deepseek-ai/DeepSeek-R1-Distill-Qwen-32B

[5] https://hf.co/BAAI/bge-large-en-v1.5

percentage gains of 26.8 and 19.5 over the baseline prompt.

7.3 Reasoning Prompting Techniques

Reasoning-based prompting techniques, including CoT, self-refinement, and self-consistency, contribute to additional accuracy gains when combined with CAG, see Table 3.

By aggregating multiple responses through self-consistency, we aimed to mitigate the randomization effect of suboptimal prompts. This approach proved effective, boosting EM scores by 0.96 absolute percent when compared to the CAG+CoT approach. Experiments with different numbers of reasoning paths indicate a stable increase in EM scores up to 10 paths, see Figure 3. Beyond this, setting up to 40 paths for the 8B model resulted in only a marginal gain, so due to the high computational cost, we opted to settle on 10 paths.

Self-refinement enables the model to verify and correct its responses, improving its reliability, particularly. However, while refinement techniques improved accuracy through self-correction, pure CoT performed better. CoT may have confused the model by already including iterative refinements, making added steps redundant.

DeepSeek-R1-32B, which performs extended reasoning before generating an answer, emerged as a strong alternative to traditional prompting techniques. It achieved an EM of 77.78%, which increased to 83.52 with CAG—the highest result obtained. Increasing test-time compute, whether through the progressive combination of prompting techniques (CAG $\rightarrow$ CAG+CoT $\rightarrow$ CAG+CoT+self-consistency) or through the use of reasoning models, consistently led to improved results. These findings highlight the benefits of test-time compute scaling for tabular QA.

Conclusion

In this work we applied the CAG approach for SemEval-2025 Task 8: TabularQA competition. The CAG is a two-step approach in which we first use an LLM to identify columns relevant to the question. The LLM then generates an answer based on the content of these columns. Using the CAG approach, we outperformed all of the baselines mentioned. In addition, we applied reasoning prompt engineering techniques to further improve the generated answers. Moreover, we revealed that CAG based on `DeepSeek-R1-32B` outperformed all sizes of Llamas, which confirms the superiority of the reasoning language models for TabularQA.

The CAG approach can be used independently or integrated within an NLP framework such as DeepPavlov (Savkin et al., 2024).

Limitations

Our experiments were limited by time and computational resources, which prevented us from fully optimizing the suggested prompting techniques. Wang et al. (2023) noted that increasing the number of reasoning paths could further improve performance. Additionally, we did not compute scores for the combination of self-refine and self-consistency prompting, as the computational cost of such an approach would have been prohibitively high. The `DeepSeek-R1-32B` model also presented challenges, as it generated extensive reasoning traces, often exceeding 16 000 tokens for even simple prompts, making it impractical to test additional prompting techniques within our resource constraints. Furthermore, we were unable to evaluate all potentially valuable open-source LLMs and did not test any models. Since we primarily focused on no-code solutions, we did not explore code-generation-specific optimizations in detail, though all the described approaches can be easily transferred to code generation.

A CAG Baseline Prompts

Prompt for extracting relevant columns

Given a table contains columns with names <*list of column names*>, I want to answer a question: <*question*>.

Please select a few column names from the list <*list of column names*>, the values of which will help answer the question.

Please provide a list of column names in the list format without any additional explanations.

Example of output: ["column name1", "column name2", "column name3"]

Baseline in-context learning prompt

You are a data analysis assistant. Given a table with the following **columns**: <*list of retrieved column names*>, and the **table data**: <*table as string*>, answer the following **question**: <*question*>. Your task is to analyze the table and provide a concise answer to the question. The answer must strictly adhere to one of the following formats, depending on the question:

1. **Boolean**: True or False
2. **Category**: A single category as a Python string (e.g., "category_name")
3. **Number**: A single number (e.g., 42)
4. **List[Category]**: A list of strings (e.g., ['category_1', 'category_2'])
5. **List[Number]**: A list of numbers (e.g., [1, 2, 3])

Rules:
- Do not include any additional text, comments, or explanations.

Examples:
Question 1: <*question*>
Answer 1: <*answer*>
. . .
Now, provide the answer to the following question: <*question*>

Baseline code generation prompt

 # Examples:
Example 1:
Question: <*question*>
Answer: <*answer*>
Example 2: . . .
—

 # Instructions:
Implement the following function in one line.
Answer with the function only with no additional explanations.
The function must return one of these types: **bool, int, str, list[int], or list[str].**

 # Formatting rules:
1) Answer with the function only. **No comments, no additional explanations.**

2) Your answer should start with: **def answer**
3) The function should be implemented **in one line**

 # Your task: complete the following function in one line. It should give the answer to: {question}
def answer(df: pd.DataFrame):
  df.columns = {list_columns}
  return

B Reasoning Prompting Techniques

In-context learning prompt with Chain-of-Thought

Example 1:
Table columns: <*list of column names*>
Question: <*question*>
Answer: <*answer*>

Example 2: . . .
—

You are a data analysis assistant. You are given a table and a question. Answer the question based only on the information in the table. The answer must be in one of the 5 following formats:
- **Boolean** (True or False) if the question requires a yes/no answer.
Example: [ANSWER] True
- **Number** if the question requires a numerical response.
Example: [ANSWER] 15
- **Category** (a string) if the question requires a categorical response.
Example: [ANSWER] London
- **List[Category]**: A list of strings.
Example: [ANSWER] ['San Francisco', 'New York', 'Wuhan', 'Bangalore']
- **List[Number]**: A list of numbers.
Example: [ANSWER] [1, 2, 3, 4, 5]

Rules:
- Start the answer with: "Let's think step by step". Then give your reasoning to your answer.
- Finish your answer with [ANSWER] and give the final answer.
- [ANSWER] part should contain only one of the following types: boolean, number, category, list[category], list[number]
- Don't give any additional text, comments or explanation in the [ANSWER] part.

Table: <*table as string*>
Table columns: <*list of column names*>
Question: <*question*>
Answer:
Let's think step by step.

Self-Refine Step 1: Prompt for extracting relevant columns

You are an AI assistant specialized in data analysis.
Given a table with the following columns: <*list of column names*>
Task: Select the most relevant columns that are necessary to answer the following question:**"question"**

Step-by-step reasoning:

1. Identify the key concepts in the question.
2. Match these concepts to the relevant columns in the table.
3. If multiple columns could provide similar information, select the **most informative** ones.
4. Ensure that the chosen columns are **minimal yet sufficient**.

Example:
Question: "What is the average salary of employees in the IT department?"

- **Step 1:** Key concepts → "average salary", "IT department"
- **Step 2:** Relevant columns → ["Salary", "Department"]
- **Step 3:** "Salary" contains numerical salary data; "Department" helps filter IT employees
- **Step 4:** Selected columns → ["Salary", "Department"]

IMPORTANT:

- Your step-by-step reasoning **MUST NOT** exceed 5 sentences.
- Your final JSON **MUST** be included within the response.
- If you fail to comply, your response will be discarded as invalid.

Your Task:

Perform the same step-by-step reasoning for the given question and return the final selected columns in **strict JSON format**.

Example Outputs:
Example 1 (if the question is about employee age):
json
["Age"]

Example 2 (if the question is about employee salary growth):
json
["Salary", "YearsAtCompany", "PercentSalaryHike"]

Example 3 (if the question is about employee job satisfaction and department):
json
["Department", "JobSatisfaction"]

CRITICAL REQUIREMENTS:

- You **MUST** return your response in two parts:
    1. **Your step-by-step reasoning.**

2. **The final validated response in STRICT JSON FORMAT.**

- The JSON response **must be the last thing in your answer** and formatted correctly.

Now, provide your response in the exact same JSON format.

Self-Refine Step2: Prompt for validating the retrieved columns

You have selected the following columns to answer the question: <*question*>

Selected columns: <*list of retrieved column names*>
Your previous reasoning was: <*list of column names*>
Full list of available columns in the dataset: <*list of column names*>

Validation Task

- If the selection is **correct and minimal**, return **"VALID"**.
- If the selection is **incorrect, incomplete, or redundant**, return the corrected column list in **strict JSON format**.
- If additional columns are **necessary**, add them.
- If some columns are **not needed**, remove them.

New Validation Rules

- You **must** justify any change in column selection.
- If the selection is **"VALID"**, explain **why**.
- If changes are needed, return **only** the corrected column list in JSON format.

IMPORTANT:

- Your step-by-step reasoning **MUST NOT** exceed 5 sentences.
- Your final JSON **MUST** be included within the response.
- If you fail to comply, your response will be discarded as invalid.

Example Outputs (JSON format)

If the selected columns are correct and minimal:
json
"VALID"

If some columns are incorrect or missing:
json
["Department", "EmployeeCount"]

If unnecessary columns are included:
json
["Age"]

CRITICAL REQUIREMENTS

- You **MUST** return your response in two parts:
  1. **Your step-by-step reasoning.**
  2. **The final validated response in STRICT JSON FORMAT.**
- The JSON response **must be the last thing in your answer** and formatted correctly.

Now, validate the selected columns and return your response in the correct JSON format.

Self-Refine Step 3: Prompt for generating an answer

You are a data analysis assistant. Given the following table: <*retrieved columns*>

Your previous reasoning was: <*response*>

Step-by-step reasoning before answering:

1. Identify the key data points in the table that are needed to answer the question.
2. Analyze how these data points interact with each other.
3. Perform any necessary calculations or logical deductions.
4. Formulate the final answer based on these steps.

IMPORTANT:

- Your step-by-step reasoning **MUST NOT** exceed 5 sentences.
- Your final JSON **MUST** be included within the response.
- If you fail to comply, your response will be discarded as invalid.

<*question*>

Answer format (strict JSON):

- Boolean: {"answer": true}
- Category: {"answer": "category_name"}
- Number: {"answer": 42}
- List of Categories: {"answer": ["category_1", "category_2"]}
- List of Numbers: {"answer": [1, 2, 3]}

CRITICAL REQUIREMENTS:

- You **MUST** return your response in two parts:
  1. **Your step-by-step reasoning.**
  2. **The final validated response in STRICT JSON FORMAT.**
- The JSON response **must be the last thing in your answer** and formatted correctly.

Now, provide the answer.

Self-Refine Step 4: Prompt for validating a generated answer

You have the following **table**: <*table as string*>
Given question: <*question*>
Proposed answer: <*answer*>
Your previous reasoning was: <*response*>

Validation Task

1. Check whether the provided answer is logically correct based on the table data.
2. If it is incorrect or incomplete, identify the error.
3. Provide the corrected answer if needed, using **strict JSON format**.
4. If the original answer is correct, return **"VALID"** (as a JSON string).

CRITICAL REQUIREMENTS

- The response **MUST BE STRICTLY IN JSON FORMAT** with **NO explanations, no additional text, and no reasoning**.
- **DO NOT** include **"Reasoning"** or **"Validation"** steps in the output.
- **ONLY return one of the following:**
  - **"VALID"** (as a JSON string)
  - A corrected JSON answer in the exact same format as the proposed answer.

IMPORTANT:

- Your step-by-step reasoning **MUST NOT** exceed 5 sentences.
- Your final JSON **MUST** be included within the response.
- If you fail to comply, your response will be discarded as invalid.

Example Outputs

If the answer is correct: "VALID"
If the answer needs correction: {"answer": 42}

DO NOT RETURN outputs like:

- "The answer is correct. Here is my reasoning..."
- "After analysis, I found a mistake. The correct answer is: ..."

Now, validate the answer and provide the response in the correct format.

C Multi-hop Questions

Examples of questions from the Data Bench dataset that strictly require more than two columns to answer (for our dataset, three columns).

Multi-hop questions

Q: Which 6 Pokémon from the second generation have the highest attack stats?
Columns used: ['generation', 'attack', 'name']

Q: Is the profession with the highest Openness the same as the profession with the highest Conscientousness?
Columns used: ['Profession', 'Openness', 'Conscientousness']

Q: Does the profession with the lowest Emotional_Range also have the lowest level of Conversation?
Columns used: ['Profession', 'Emotional_Range', 'Conversation']

Q: What is the average Extraversion level for the profession with the highest number of records (n)?
Columns used: ['Profession', 'Extraversion', 'n']

Q: Has the author with the highest number of followers ever been verified?
Columns used: ['author_id<gx:category>', 'user_followers_count<gx:number>', 'user_verified<gx:boolean>']

Q: Is the author who has the most favourites also the one with the most retweets?
Columns used: ['author_id<gx:category>', 'user_favourites_count<gx:number>', 'retweets<gx:number>']

Q: Is the most mentioned user also the most retweeted mentioned user?
Columns used: ['author_id<gx:category>', 'mention_names<gx:list[category]>', 'retweets<gx:number>']

Q: Does the author with the most retweets also have the most replies?
Columns used: ['author_id<gx:category>', 'retweets<gx:number>', 'replies<gx:number>']

D Table Sampling: Optimal k

The Figure 2 shows the F1 metric for the three approaches. It can be seen that for our table of 20 columns, it will be optimal to search for the top 3 most suitable columns. The results are also presented in the Table 1.

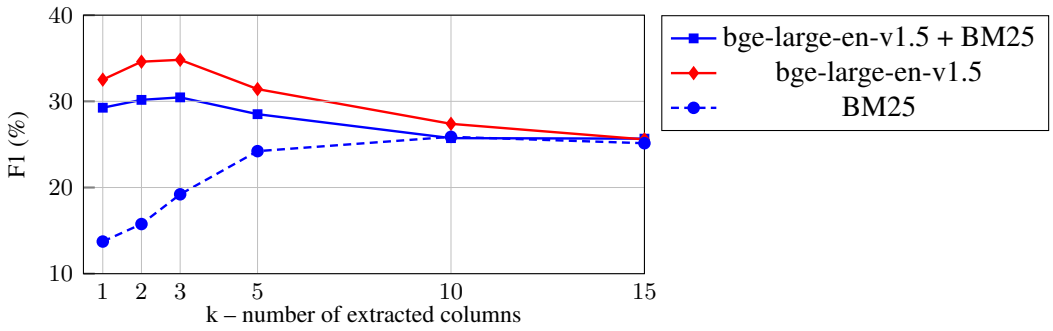

Figure 2: F1 scores for the "Table Sampling" column extraction method using different vector representations, shown for various values of the hyperparameter k (number of columns extracted).

E Analysis of Prompting Techniques

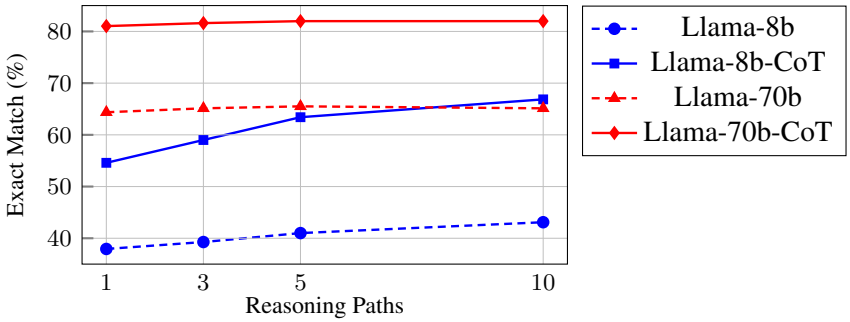

Figure 3: Self-Consistency results for DataBench lite test set. Exact Match is a metric with custom comparison function presented by competitions authors, see Section 4. Reasoning Paths means the number of times the model was called to generate an answer, see Section 5.2. CoT denotes Chain-of-Thought.

NBF at SemEval-2025 Task 5: Light-Burst Attention Enhanced System for Multilingual Subject Recommendation

Baharul Islam*, **Nasim Ahmad**†, **Ferdous Ahmed Barbhuiya***, **Kuntal Dey***
*IIIT Guwahati †Dibrugarh University
{baharul.islam22b,ferdous,kuntal.dey}@iiitg.ac.in, nasimahmad4117@gmail.com

Abstract

We present our system submission for SemEval 2025 Task 5, which focuses on cross-lingual subject classification in the English and German academic domains. Our approach leverages bilingual data during training, employing negative sampling and a margin-based retrieval objective. We demonstrate that a dimension-as-token self-attention mechanism designed with significantly reduced internal dimensions can effectively encode sentence embeddings for subject retrieval. In quantitative evaluation, our system achieved an average recall rate of 32.24% in the general quantitative setting (all subjects), 43.16% and 31.53% of the general qualitative evaluation methods with minimal GPU usage, highlighting their competitive performance. Our results demonstrate that our approach is effective in capturing relevant subject information under resource constraints, although there is still room for improvement.

1 Introduction

Automated subject classification of scholarly articles is of growing importance for digital repositories, allowing more efficient data retrieval, recommendation, and systematic reviews (Devlin et al., 2019). At **SemEval-2025 Task 5** (D'Souza et al., 2025), participants must predict *subject codes* for articles in two languages (English and German).

Previous SemEval tasks on concept or subject classification have used both classical machine learning and deep approaches (Agirre et al., 2014). Large pre-trained models (e.g., GPT-based (Brown et al., 2020) or other generative approaches) could be powerful but are often computationally heavy. We instead adopt a *dimension-as-token* approach, refining base embeddings from Sentence Transformers (Reimers and Gurevych, 2019) via an ultra-light attention transform.

By participating in **SemEval-2025 Task 5**, we discovered that our parameter-efficient, dimension-as-token self-attention approach can effectively handle both English and German data, achieving moderate recall rates of 32. 24% in the overall quantitative setting (all subjects), 43. 16% in Case 1 and 31. 53% in Case 2 of Overall Qualitative evaluation methods with minimal GPU usage. Despite challenges such as near-synonymous subject labels and sparse domain terms, our system still secured the **9th** position in both quantitative (all subjects) and qualitative evaluations. These findings highlight the potential of cross-lingual pipelines and public code for fragmented training and inference, even under resource-constrained conditions.

2 Task Description

The LLMs4Subjects shared task (D'Souza et al., 2025) challenges participants to develop LLM-based systems for automated subject tagging in a national technical library. In this task, systems must assign one or more subject codes to each article, drawing from an extensive GND (German National Library, 2025) subjects taxonomy. Participants are provided with a human-readable version of the taxonomy along with a bilingual data set (English / German) from TIBKAT (TIB - Leibniz Information Centre for Science and Technology, 2025) that includes various record types such as `article`, `book`, `conference`, `report`, and `thesis`.

2.1 Dataset Description

The **LLMs4Subjects** corpus combines two complementary resources that are released together for SemEval 2025 Task 5:

a) **GND subject taxonomy:** machine-readable export of more than 200000 controlled subject descriptors[1]. Each entry provides a persistent identifier, the preferred German label, optional alternative labels, and explicit *broader*, *narrower*, and *related* relations.

[1]'GND Sachbegriff' in the German National Library authority file

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 953–958
July 31 - August 1, 2025

b) **TIBKAT technical records:** 123589 bibliographic records (title + abstract) drawn from the open access catalog of the German National Library of Science and Technology. The corpus is bilingual (52 % German, 48 % English) and covers five record types: *article*, *book*, *conference*, *report*, and *thesis*. We follow the official split with 81937 documents for training, 13666 for development, and 27986 for blind testing; gold GND labels are provided for the first two splits only.

3 Proposed System

Our method has two well-defined stages. First, we create fixed embeddings for every data. Second, we train a small neural module that makes the embeddings of the articles match the embeddings of the GND subjects.

All subject labels (originally in German) are translated into English. We then use pre-trained Sentence-Transformer models to encode both subjects and articles. For articles, we join the title and abstract before encoding. Each subject and each article are now represented by a single 768-dimensional vector. These embeddings serve as input to our high-capacity transformation model, which is designed to enhance the semantic alignment between article embeddings and subject embeddings.

- **Dimension-as-Token Projection and Reshaping:** We treat every number in the 768-long vector as its own 'token'. A lightweight Burst-Attention layer with 16 hidden units and two heads lets these tokens exchange information.
- **Feed-Forward MLP:** The attention output passes through a three-layer feed-forward network with dropout. The result is the final vector of aligned articles.

Together, these components transform initial embeddings into a space where articles are more closely aligned with their relevant subjects, thus improving the effectiveness of subject retrieval.

Training procedure. During training only article vectors go through the alignment module(transformation module). For each article, we also retrieve its gold subject vectors and average them. The loss function moves the aligned article vector closer to this average and further away from a few randomly chosen, incorrect subject vectors. The subject vectors themselves remain fixed.

Inference procedure. At test time the alignment module is frozen. A new article is embedded, passed through the module, and compared using cosine similarity to the stored subject vectors. The k subjects with the smallest distance are returned as recommendations.

Design motivation. Leaving the large pretrained transformer models untouched avoids costly fine-tuning and keeps subject and article vectors consistent. The tiny alignment module is enough to correct systematic differences between the two sets of vectors while adding very little computation.

Figure 1 illustrates the complete system architecture. It begins by extracting embeddings for both the subject corpus and article texts, followed by a training module that applies the transformation block and computes a margin-based loss. After training, the resulting model is saved for inference, where articles are matched against subject embeddings to retrieve the most relevant subjects.

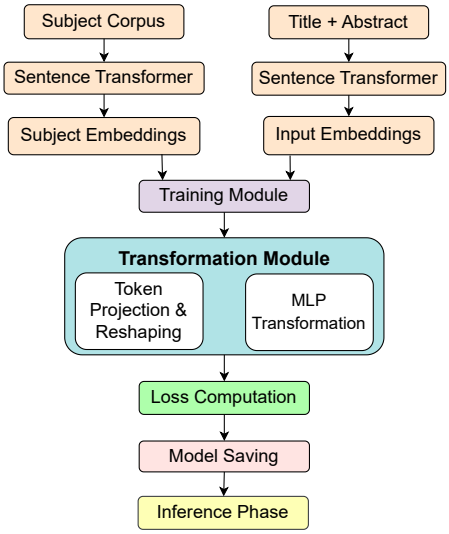

Figure 1: System Architecture. The model processes subject and article embeddings through a transformation module (Token Projection & Reshaping + MLP) and optimizes via margin-based loss

3.1 Data Preprocessing

In this stage, we convert all subject names and article texts into fixed-size vectors using off-the-shelf sentence-transformer models. These vectors form the inputs to our alignment module.

Subject corpus We begin with the GND subject list. Each entry has a unique *code* and a

German-language *Name* (Subject Name). We translate every name into English using the Helsinki-NLP/opus-mt-de-en model (Tiedemann and Thottingal, 2020). Next, we embed each translated name with a Sentence-Transformer. Concretely, for the ith subject name n_i we compute

$$\mathbf{s}_i = ST(n_i) \in \mathbb{R}^d, \quad d = 768. \tag{1}$$

Collecting all N subject vectors yields the subject matrix

$$\mathbf{S} = \begin{bmatrix} \mathbf{s}_1 \\ \mathbf{s}_2 \\ \vdots \\ \mathbf{s}_N \end{bmatrix} \in \mathbb{R}^{N \times d}. \tag{2}$$

Article corpus For the training data, each sample comprises a *title*, an *abstract*, and a set of gold-standard (correct) subject labels. We concatenate the title t_j and abstract a_j into a single text x_j, and compute its embedding as

$$\mathbf{m}_j = ST(x_j) \in \mathbb{R}^d. \tag{3}$$

For each training sample j, every gold subject name s_{jl} (with $l = 1, 2, \ldots, k_j$) is embedded, and the resulting embeddings are averaged to obtain a single representative embedding:

$$\mathbf{g}_j = \frac{1}{k_j} \sum_{l=1}^{k_j} ST(s_{jl}) \in \mathbb{R}^d. \tag{4}$$

Thus, the training document embeddings and the corresponding gold subject embeddings are aggregated into the matrices:

$$\mathbf{M} = \begin{bmatrix} \mathbf{m}_1 \\ \mathbf{m}_2 \\ \vdots \\ \mathbf{m}_M \end{bmatrix} \in \mathbb{R}^{M \times d}, \quad \mathbf{G} = \begin{bmatrix} \mathbf{g}_1 \\ \mathbf{g}_2 \\ \vdots \\ \mathbf{g}_M \end{bmatrix} \in \mathbb{R}^{M \times d}. \tag{5}$$

Embedding models For English text we use **all-mpnet-base-v2** (Reimers and Gurevych, 2019). For German text we use **T-Systems-onsite/german-roberta-sentence-transformer-v2** (T-Systems-onsite, 2022). Both models produce 768-dimensional outputs.

3.2 Dimension-as-Token Projection and Reshaping

To enhance expressiveness, we reinterpret each dimension of an article embedding $\mathbf{m}$ as an individual "token". Starting with an embedding $\mathbf{m}$ of shape (batch_size B, d), we first reshape it to a tensor of shape (d, B, 1). This operation enables us to treat each scalar dimension as a separate token, which is then projected to a hidden representation of size 16 (denoted as *model_dim*). Next, we apply a Burst Attention (Sun et al., 2024) encoder across these d tokens to capture their interdependencies. Finally, the tokens are projected back to a single scalar and reshaped to recover an embedding of the original dimension d. The forward pass is expressed as:

$$\begin{aligned} \tilde{\mathbf{x}} &= \text{Reshape}(\mathbf{m}) \in \mathbb{R}^{d \times B \times 1}, \\ \mathbf{X}_0 &= \text{Linear}_{\text{in}}(\tilde{\mathbf{x}}) \in \mathbb{R}^{d \times B \times \text{model\_dim}}, \\ \mathbf{X}_L &= \text{BurstAttnEnc}(\mathbf{X}_0), \\ \mathbf{X}_{\text{out}} &= \text{Linear}_{\text{out}}(\mathbf{X}_L) \in \mathbb{R}^{d \times 1}, \\ \mathbf{x}_{\text{attn}} &= \text{Reshape}^{-1}(\mathbf{X}_{\text{out}}) \in \mathbb{R}^d. \end{aligned} \tag{6}$$

Within the *BurstAttnEnc*, a Burst Attention(Sun et al., 2024) layer is used. Initially, layer normalization is applied to the input, after which multi-head self-attention is computed using 2 attention heads, each with a per-head dimension of 8. A dropout of 0.03 is applied to the attention output before it is passed to a feedforward network. This network expands the hidden representation to 64 dimensions, applies a ReLU activation, and includes another dropout of 0.03, with residual connections added throughout to ensure stable learning. The Burst Attention encoder is defined as:

$$\begin{aligned} \mathbf{X}^{(0)} &= \mathbf{X}_0, \\ \mathbf{Z}^{(l-1)} &= \text{LayerNorm}(\mathbf{X}^{(l-1)}), \\ \tilde{\mathbf{X}}^{(l)}_{\text{attn}} &= \text{MultiHead}(\mathbf{Z}^{(l-1)}), \\ \mathbf{Y}^{(l)} &= \mathbf{X}^{(l-1)} + \text{Dropout}(\tilde{\mathbf{X}}^{(l)}_{\text{attn}}), \\ \mathbf{U}^{(l)} &= \text{LayerNorm}(\mathbf{Y}^{(l)}), \\ \tilde{\mathbf{X}}^{(l)}_{\text{ff}} &= W_2 \cdot \text{ReLU}(W_1 \cdot \mathbf{U}^{(l)} + b_1) + b_2, \\ \mathbf{X}^{(l)} &= \mathbf{Y}^{(l)} + \text{Dropout}(\tilde{\mathbf{X}}^{(l)}_{\text{ff}}). \end{aligned} \tag{7}$$

Here, the weight matrices $W_1 \in \mathbb{R}^{16 \times 64}$ and $W_2 \in \mathbb{R}^{64 \times 16}$ are learnable parameters within the feed-forward sub-module.

3.3 Feed-Forward MLP

Subsequent to obtaining the intermediate representation $\mathbf{x}_{\text{attn}}$ from the burst-attention block, we further refine the embedding using a Feed-Forward Multi-Layer Perceptron (MLP). This MLP is composed of three linear layers with ReLU activations

and incorporates a dropout of 0.03 at each stage to reduce the risk of overfitting. The purpose of the MLP is to transform the intermediate representation back into the original embedding space, thus producing the final transformed embedding $\mathbf{z}$. This process is mathematically described as:

$$\begin{aligned}\mathbf{h}_1 &= \text{ReLU}(\text{Dropout}(W_1^{\text{MLP}}\mathbf{x}_{\text{attn}} + b_1^{\text{MLP}})),\\ \mathbf{h}_2 &= \text{ReLU}(\text{Dropout}(W_2^{\text{MLP}}\mathbf{h}_1 + b_2^{\text{MLP}})),\\ \mathbf{z} &= W_3^{\text{MLP}}\mathbf{h}_2 + b_3^{\text{MLP}}.\end{aligned} \tag{8}$$

In this formulation, $\mathbf{h}_1$ and $\mathbf{h}_2$ represent the outputs of the first and second hidden layers, respectively, and $\mathbf{z}$ is the output of the final layer. The weight matrices $W_1^{\text{MLP}} \in \mathbb{R}^{d\times 256}$, $W_2^{\text{MLP}} \in \mathbb{R}^{256\times 256}$, and $W_3^{\text{MLP}} \in \mathbb{R}^{256\times d}$, along with their corresponding biases b_1^{MLP}, b_2^{MLP}, and b_3^{MLP}, are learned during training.

Finally, the overall transformation function, denoted as $\text{transform}()$, is defined as the composition of the above operations, and for an input $\mathbf{m}$ it is computed as:

$$\begin{aligned}\text{transform}(\mathbf{m}) = \text{MLP}\Big(&\text{BurstAttnEnc}\big(\\ &\text{Linear}_{\text{in}}(\text{Reshape}(\mathbf{m}))\big)\Big),\end{aligned} \tag{9}$$

which outputs $\mathbf{z} \in \mathbb{R}^d$. This architecture is designed to capture the complex interdimensional relationships present in the initial embeddings, ultimately yielding a more robust and semantically aligned representation.

4 Training and Inference

During training, we learn only the small transformation block, keeping the Sentence-Transformer weights and the subject matrix $\mathbf{S}$ fixed. For each article j, with its raw embedding $\mathbf{m}_j$ we apply the learned transform to obtain the anchor embedding $\mathbf{a}_j = \text{transform}(\mathbf{m}_j) \in \mathbb{R}^d$. Let the averaged gold-subject embedding be $\mathbf{p}_j$, and let $\mathbf{n}_{j1}, \ldots, \mathbf{n}_{jk}$ denote k negative subject embeddings sampled from $\mathbf{S}$. Using cosine distance $d(\mathbf{x}, \mathbf{y}) = 1 - \frac{\mathbf{x}\mathbf{y}}{\|\mathbf{x}\|\,\|\mathbf{y}\|}$, we define the margin-based loss for article j as

$$\mathcal{L}_j = \sum_{i=1}^{k} \max\Big\{0,\ \alpha + d(\mathbf{a}_j, \mathbf{p}_j) - d(\mathbf{a}_j, \mathbf{n}_{ji})\Big\}, \tag{10}$$

$\alpha = 0.2$, Minimizing $\mathcal{L}_j$ brings the transformed article closer to its correct subjects while pushing it away from the incorrect ones.

We train for 20 epochs with batch size 4, using the AdamW optimizer and a cosine annealing scheduler. In each batch, only the embeddings of the article, their positives and the sampled negatives are passed through $\text{transform}(\cdot)$; the embeddings of the subject remain frozen.

Inference At inference time, we first transform and cache all GND subject embeddings as $\mathbf{S}' = \text{transform}(\mathbf{S})$, so that each row $\mathbf{s}'$ is the aligned vector for one subject. For a new article (title and abstract), we compute its embedding $\mathbf{m} = ST(\text{title}\|\text{abstract})$ using a Sentence-Transformer, then apply the trained mapping to obtain $\mathbf{a} = \text{transform}(\mathbf{m})$. Next, we measure the cosine-distance between $\mathbf{a}$ and each precomputed subject vector $\mathbf{s}'$: $d(\mathbf{a}, \mathbf{s}') = 1 - \frac{\mathbf{a}\cdot\mathbf{s}'}{\|\mathbf{a}\|\,\|\mathbf{s}'\|} \quad \forall\, \mathbf{s}' \in \mathbf{S}'$. Finally, we sort all subjects by increasing distance and return the k codes with the smallest values.

5 Experimental Setup

Our experiments were carried out on a bilingual data set partitioned into training, development and test sets for both English and German articles. The training set was used for margin-based optimization, the development set for intermediate performance monitoring, and the test set was reserved for official SemEval evaluation.

The embedding dimension is set to 768, and our model is configured with a hidden dimension (`model_dim`) of 16, 2 attention heads, a single Burst Attention layer, an MLP hidden dimension of 256, and a dropout rate of 0.03. The training employs a batch size of 4 and utilizes 15 negative samples per anchor-positive pair over 20 epochs.

We apply a margin-based loss with a margin of 0.2, optimizing the model using the AdamW optimizer with a learning rate of 1×10^{-4} (without weight decay) and a cosine annealing learning rate scheduler ($T_{max} = 20$, $\eta_{\min} = 1 \times 10^{-6}$). All experiments were executed on Google Colab L4 GPUs under Python 3.9, using PyTorch 1.13.1, SentenceTransformers 2.2.2, pandas 1.5.3, numpy 1.23.5, and tqdm 4.64.1. Evaluation measures included Precision@k, Recall@k, and F1@k across multiple cutoffs, along with average recall, as reported in Section 6.

6 Results

We report the performance of our system on the official test segment as well as on two qualitative

evaluation subsets. For evaluation, we use Precision @ k (P @ k), Recall @ k (R @ k), and F1 @ k. Precision @ k is defined as the number of relevant items in the top k predictions divided by Total number of items in k, Recall @ k is defined as the number of relevant items in the top k predictions divided by the total number of relevant items. The Fβ-score is computed as

$$F_\beta = \frac{(1+\beta^2) \times \text{Precision @ k} \times \text{Recall @ k}}{\beta^2 \times \text{Precision @ k} + \text{Recall @ k}} \quad (11)$$

and in our experiments we set $\beta = 1$ to obtain the F1@k score.

Quantitative Results Evaluation 1 of the shared task compared systems in a fully automatic setting in the blind TIBKAT test corpus. Participants submitted the *top–50* GND subject codes for every English or German record, and the organisers calculated P @ k, R @ k, and F1 @ k for each $k \in \{5, 10, \ldots, 50\}$. Scores were released at three granularities: (i) language level (en vs. de), (ii) record–type level (five technical record types), and (iii) the combined language–record level. Systems were ranked by the *average Recall @ k* over all cut-offs, a criterion in which our **NBF** run placed **9th**.

Qualitative Results Evaluation 2 complemented the automatic leaderboard with a manual assessment by subject specialists from TIB. A stratified sample of 140 records—ten from each of fourteen discipline codes (arc, che, elt, fer, his, inf, lin, lit, mat, oek, phy, sow, tec, ver)—was drawn. For every record, librarians inspected the *top–20* subjects proposed by each system and labelled them `Y` (correct), `I` (irrelevant but technically admissible), or `N`/blank (incorrect). Two leaderboards were produced: **Case 1**, counting both `Y` and `I` as correct, and **Case 2**, counting only `Y`. These settings correspond exactly to Tables 2 and 3.

Table 1 summarizes the overall quantitative results on the all-subjects evaluation (official test set) at cutoffs $k \in \{5, 10, 15, \ldots, 50\}$. The model achieves an average recall of 32.24% across these cutoffs, although the precision remains relatively low. Based on these official metrics, our system ranked **9th** in the quantitative track.

To better understand our design choices, we conducted experiments on two different subsets of the test data. Table 2 shows the overall qualitative results for Case 1, a subset characterized by common and less ambiguous subject labels. On this subset, the model achieves higher Precision, Recall, and F1 (with averages of 39.54%, 43.16%, and 39.03%, respectively). In contrast, Table 3 presents overall Qualitative results for Case 2, which consists of articles with more specialized or challenging subject mappings, yielding lower average metrics (Precision = 19.00%, Recall = 31.53%, F1 = 22.40%). These analyses demonstrate that while our parameter-efficient approach is competitive overall, its performance is sensitive to the complexity of subject labels.

6.1 Error Analysis

Although our system shows potential in assigning subject labels, we found two main sources of error. First, the system struggles with synonym overlaps. For instance, near-synonymous labels such as *"Natural Language Processing"* and *"Compu-*

tational Linguistics" often appear together in the training data without sufficient distinction, causing the model to confuse these overlapping concepts and misclassify the subjects.

Second, errors frequently occur with sparse domain terms. Articles addressing highly specialized or infrequent topics tend to be mislabeled because the negative sampling does not adequately cover these less common domains. These challenges suggest that future work should focus on enhancing the model's ability to differentiate between similar subject labels and on improving the representation of niche topics in the training process.

7 Conclusion and Future Work

We presented our system, which employs a novel dimension-as-token self-attention mechanism (*Burst Attention*) on top of Sentence Transformers. Our experiments demonstrate that, even with an ultra-light hidden dimension (16) and a single attention layer, the approach is competitive in terms of recall, achieving average recall rates of 32.24%, 43.16% and 31.53% in the Overall Quantitative, Qualitative Case 1, and Qualitative Case 2 evaluations, respectively. These results indicate that our model is effective at capturing relevant subject information under resource constraints, although there is still room for improvement.

In future work, we plan to explore deeper stacking of Burst Attention layers, more advanced negative sampling strategies, and the incorporation of hierarchical subject ontologies for improved synonym disambiguation. Additionally, we intend to investigate the integration of multimodal features to further enhance system performance. These enhancements aim to further improve both the accuracy and robustness of our subject classification system.

Acknowledgments

We thank the organizers of the SemEval-2025 Task 5 (D'Souza et al., 2025) for the data and evaluation framework, as well as the PyTorch, Hugging Face and SentenceTransformers communities for their invaluable open-source tools.

QMUL at SemEval-2025 Task 11: Explicit Emotion Detection with EmoLex, Feature Engineering, and Threshold-Optimized Multi-Label Classification

Angeline Wang, Aditya Gupta, Iran R. Roman and Arkaitz Zubiaga

Abstract

SemEval 2025 Task 11 Track A explores the detection of multiple emotions in text samples. Our best model combined BERT (fine-tuned on an emotion dataset) predictions and engineered features with EmoLex words appended. Together, these were used as input to train a multi-layer perceptron. This achieved a final test set Macro F1 score of 0.56. Compared to only using BERT predictions, our system improves performance by 43.6%.

1 Introduction

SemEval 2025 Task 11 Track A is about determining what emotion most people will think is reflected in a short text snippet (Muhammad et al., 2025). This is about the perceived emotion by a reader, not about how someone is truly feeling. This is important because the individual's actual emotional state of being is difficult to define with absolute certainty (Van Woensel and Nevil, 2019; Wakefield, 2021).

The task consists in identifying the presence of five emotions, i.e. joy, sadness, fear, anger, and surprise. The main chellenges include varying lengths of texts, and imbalance of emotions. We approached this by stacking WordPiece tokenisation, preprocessing, EmoLex words and BERT predictions as features, which then we pass to MLPs. Upon quantitative evaluation on the development set, we found that using separate models for each emotion and dynamic thresholding based on each emotion was the most effective system. Our code is openly available[1].

2 Background and Related Work

Emotion analysis, a subfield of sentiment analysis, seeks to identify nuanced emotional states in text rather than broad polarity (Liu, 2012). Early work focused on lexicon-based methods, such as EmoLex (NRC Emotion Lexicon), which maps words to primary emotions and remains foundational for explicit emotion representation (Mohammad and Turney, 2013). While lexicons like EmoLex provide interpretability, their static nature struggles with contextual nuances. Mohammad and Kiritchenko (2018) showed emotion co-occurrence patterns (e.g., anger-disgust) to refine multi-label predictions, but their work relied on rigid lexicon counts rather than context-aware scoring.

The shift toward multi-label detection addresses the limitation of single-label classification, as text often expresses overlapping emotions (Wiebe et al., 2005). SemEval tasks have driven progress with top systems hybridizing lexicons and neural models. For example, Fersini et al. (2022) combined lexicon-derived features with BERT for multimodal classification, while Kumar et al. (2024) optimized thresholds for LLM-based emotion detection. Although weighted losses provide gains (Demszky et al., 2020), few studies address sensitivity—adjusting boundaries for imbalance.

Traditional approaches like CountVectorizer-based lexicon scoring (Mohammad et al., 2018) treat emotion-linked words equally, ignoring discriminative power. Recent advances in hybrid paradigms highlight the need for weighted lexical integration and threshold optimization. Our work bridges this by integrating EmoLex with BERT, using positive weight calculation to amplify discriminative terms (e.g., "devastated" for sadness) and emotion-specific threshold optimization to balance precision and recall—advancing methods from generic sentiment analysis (Liu, 2012) to nuanced multi-emotion detection.

3 Task and Dataset

3.1 SemEval 2025 Task 11 Track A

This year, the task involves the multi-class detection of five different perceived emotions, and we have chosen to explore English text only (Muham-

[1] http://github.com/angelinewang/semeval-task-11-track-a

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 959–964

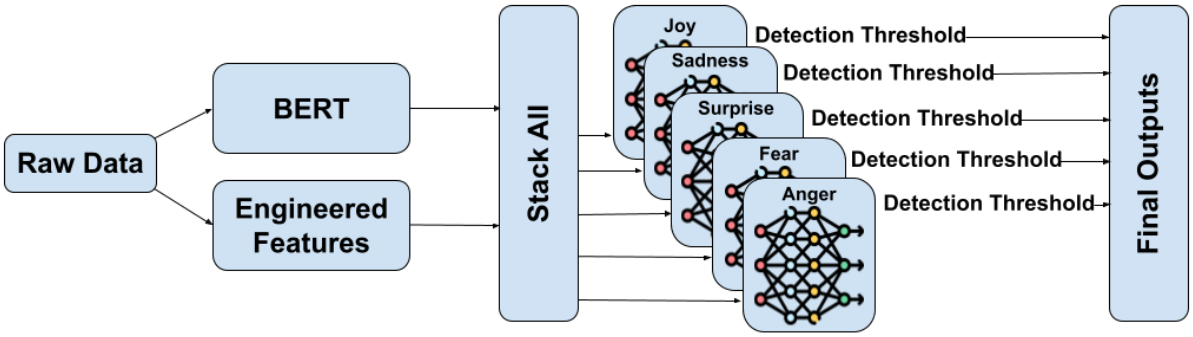

Figure 1: QMUL System Overview.

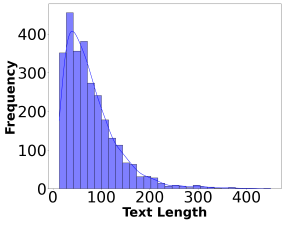
mad et al., 2025). This diverges from previous years' tasks, which focused on the speaker emotion (Kumar et al., 2024). This shift notably introduces cultural relativity due to annotators' diverse backgrounds, pragmatic ambiguity, and multi-perspective modeling (the need to predict majority perceptions rather than 'true' emotions).

3.2 Dataset

The dataset (Muhammad et al., 2025) includes 28 different languages, but we work only with English. Most of the data comes from social media posts (platforms such as Reddit, YouTube, Twitter, and Weibo). Some texts also include personal narratives, talks and speeches, which are anonymised. The data was human-annotated (through Amazon Mechanical Turk) by selection of all emotions applicable among five possible categories of perceived emotions: anger, sadness, fear, joy, and surprise. There was a total of 1222 annotators, and 5 to 30 annotators per sample. The training split has a size of 2,768, the development has 116, and the test set has 2,767.

The text length of the datasets follows a Zipfian Distribution as shown in the left panel of Figure 3. This is an important consideration due to the different context length constraints of different models.



Length	Train	Dev	Test
Avg	78	76	80
Min	13	9	5
Max	450	308	440
Range	437	299	435

Figure 3: Left: Training set distribution of text lengths. Right: Statistics of text lengths per split.

3.3 Exploratory Data Analysis

Visualising the emotion class distribution that the dataset is imbalanced and that there is significantly more instances of 'Fear' and significantly fewer percentage of text had the presence of the emotion class 'Anger' in the dataset, as seen in Figure 2a.

To understand the relation between different emotion categories, we computed a correlation matrix (Figure 2b), which quantifies the co-occurrence tendencies of emotions across text samples. This showed that almost all correlations are statistically significant, with a p-value less than 0.05, excluding 'Anger' and 'Surprise'. Interestingly, 'Joy' is the only emotion that is anti-correlated with all other emotions. This means that the presence of 'Joy' is strongly indicative of the lack of the other emotion classes. Therefore, detecting different emotions with specific sensitivities (i.e. with Emotion-specific detection thresholds) is motivated by these distribution and correlation patterns.

Furthermore, Figure 2c shows the conditional probability matrix of the training dataset, with P(X|Y), where X and Y are emotion labels. This is important to see bidirectional relations between emotions. For example, fear has a large, often unidirectional association with many classes. The association is unidirectional, as it can be seen that given 'Fear', 'Anger' does not co-occur nearly as often. In contrast, the association between 'Fear' and 'Sadness' is somewhat more bidirectional, as given 'Fear', 'Sadness' occurs 42.3% of the time (Mohammad and Kiritchenko, 2018). 'Fear' is also the class with the most data samples in the training dataset; so this could just speak to the imbalance of data. One of this dataset's main purpose is to capture overlapping emotions, so it is natural that we see these co-occurrences, small and big, between emotion classes.

Figure 2: Exploratory Data Analysis on Training Dataset.

4 System Overview

4.1 BERT Predictions as Features

As shown in Figure 1, we applied a pre-trained BERT (Savani, 2021; Devlin et al., 2018) model finetuned on an emotion dataset—dair-ai/emotion (Saravia et al., 2018) (this dataset included all five emotions under consideration, in addition to “love"). We chose to use the uncased version of BERT because it strips out accent markers and does not make distinctions between uppercase and lowercase letters. We used the model’s default tokenizer. And BERT was particularly useful for this task, as the texts are short in length (see Figure 3e). This means that BERT’s text length constraint does not interfere with its use for this case (Devlin et al., 2018).

We also chose to use the base variation of BERT because of our limited computational resources—Apple Mac laptops with M series chips—and the small size of the SemEval dataset (Muhammad et al., 2025).

We use BERT to obtain its class-wise emotion predictions for a given text d:

$$\mathbf{x}_{\text{bert}} = \text{BERT}(\text{Tokenize}(d)) \in \mathbb{R}^B, \qquad (1)$$

where $B = 5$ and $\mathbf{x}_{\text{bert}}$ contains the predicted probability distribution over 5 emotions.

4.2 Feature Engineering

In parallel to BERT predictions, the feature engineering pipeline includes: WordPiece tokeniser (with lowercasing, token for unknown words, separation token, padding token, classification token, mask token; tokens are further transformed into a numerical vector using CountVectorizer, which counts token frequencies), punctuation separation, stemming, lemmatization, bigram generation, and appending of matching EmoLex indicators.

After preprocessing, we check each token against the Emolex lexicon [2] to find ones that exists in EmoLex. This associates each token with one or more of the five target emotions. For each emotion class, a binary indicator is computed, and these five binary features are appended, yielding our "BoW representation". This step allows our model to learn from both contextual usage, through BERT, and explicit emotion associations, through EmoLex.

Therefore, document (i.e. a datapoint) d is represented as: $d \in \mathbb{R}^L$ where L = sequence length. This can be tokenized using the continuous bag of words CountVectorizer, thus yielding $\mathbf{x}_{\text{bow}} \in \mathcal{R}^V$, where V = vocabulary size (4,340 unique tokens).

4.3 Stacking All Features

Features from BERT predictions and feature engineering—capturing the full text contextual information—were stacked.

$$\mathbf{h}_0 = [\mathbf{x}_{\text{bow}} \| \mathbf{x}_{\text{bert}}] \in \mathbb{R}^D, \qquad (2)$$

where $x_{\text{bow}} \in \mathbb{R}^V$ is the BoW feature vector ($V = 4,340$) and $x_{\text{bert}} \in \mathbb{R}^B$ is the BERT output ($B = 5$, one per emotion class), yielding the final feature dimensionality of $D = V + B = 4,345$.

4.4 Emotion Detection MLPs

We used five multi-layer perceptron (MLP) classifiers, one for each emotion. Each MLP consists of a sequential arrangement of layers that process the stacked input of size D features in parallel.

The input layer reduces the dimensionality of the input to a lower dimensional space of 256, followed by batch normalisation and a ReLU activation. There are two subsequent projections. One

[2] EmoLex (Mohammad and Turney, 2013) maps frequent English words to explicitly emotion associations, providing interpretable signals.

that projects to a dimension of 128, and another one to a space of 64, hence further reducing dimensionality. Both of these projections also use batch normalisation and ReLU. The output layer condenses the features to a single output neuron that represents the probability of an emotion's presence, thus allowing for threshold-based detection. MLP learning is supervised using Binary Cross-Entropy Loss (Equations 3, 4).

$$L = \begin{cases} -w_p \text{BCE}(\hat{y}, y), & \text{if } y_p = 1 \\ 0, & \text{otherwise} \end{cases} \quad (3)$$

We add a *positive weight calculation* to handle class imbalance in the binary classification task. This modifies the loss function to penalise mistakes on the minority class more heavily:

$$w_p = \frac{\text{number of negative samples}}{\text{number of positive samples}} = \frac{N - \sum_i y_i}{\sum_i y_i} \quad (4)$$

where N is the total number of samples, $\sum_i y_i$ is the total number of positive samples (i.e., samples where $y_i = 1$). and $N - \sum_i y_i$ is the total number of negative samples (i.e., samples where $y_i = 0$).

4.5 Detection Threshold Selection

Emotion detection thresholds were selected based on the development set by optimising the F1 scores for each individual emotion. The thresholds found were used for the final predictions on the test set (Joy: 0.45, Sadness: 0.55, Surprise: 0.20, Fear: 0.50, Anger: 0.60). Our original motivation for looking for thresholds was due to the high imbalance in the proportion of data for each emotion, this can be seen in Figure 4a, which shows the final thresholds chosen with the proportion of the emotion data in the train set. The right panel of Figure 4b shows how each threshold impacts the Macro F1 score in the development set.

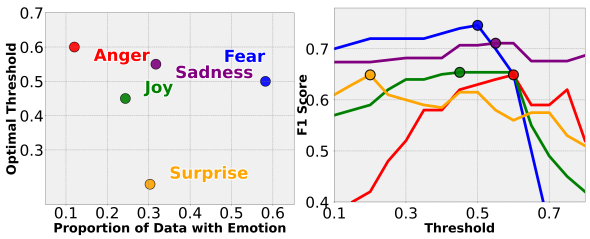

Figure 4: Left: Optimal thresholds for emotion detection aligned with the proportion of data for each emotion in the training set. Right: Variations in F1 score by detection threshold for each emotion. Colours in the left graph correspond to the right graph.

5 Experimental Setup

Input features. We assessed performance with three different variations of input features: (i) with inputs that consisted of BERT prediction logits only, (ii) with BERT predictions stacked on top of the engineered features, and (iii) with the addition of EmoLex words appended to the text that went into engineered features.

Classifier configurations. For each of the three variations above, we evaluate three dfiferent configurations of MLP classifiers: (i) a single MLP with a threshold of 0.5, (ii) a different MLP for the detection of each emotion, with a threshold of 0.5, and (iii) due to the imbalance of emotion data (Figure 2a), we assessed whether it might be useful to set differing detection thresholds for each emotion on top of just emotion-specific MLPs. These configurations help us evaluate the extent to which having different classifiers for each emotion helps.

Hyperparameters. All experiments used Adam (lr=$1e^{-3}$, weight decay=$1e^{-4}$), batch size 32, dropout (0.3/0.2), and a learning rate scheduler (patience=5, factor=0.5). This means that the learning rate is cut in half if there is no improvement of Macro F1 on the validation set for 5 epochs. Training was done for 400 epochs, with an early stopping mechanism with a patience of 10 epochs.

Evaluation. Performance was measured using the Macro F1 score.

	Dev	Test
Single MLP (0.5 Thrs)		
BERT	0.6080	0.5418
BERT+Feat ENG	0.6114	0.5624
BERT+Feat ENG+EmoLex	0.6075	**0.5638**

BERT+Feat ENG	0.6816	0.5542
BERT+Feat ENG+EmoLex	0.6433	*0.5558*

Table 1: Comparison of Macro F1 performance scores.

6 Results

For experiments with a single MLP and a 0.5 emotion detection threshold across all emotions, using

only BERT predictions as input features achieved a Macro F1 score of 0.6080 on the development set and 0.5418 on the test set. Using stacked engineered features on top of BERT predictions achieved an improvement leading to a Macro F1 of 0.6114 on the development set and 0.5624 on the test set. The addition was EmoLex words to the engineered features led to a drop in Macro F1 on the development set with a score of 0.6075, but an increase in test set performance to 0.5638—this ended up being our best model over all others on test set.

The variant with emotion-specific MLPs (but still with 0.5 detection thresholds), using only BERT predictions as input led to a model with a Macro F1 of 0.6162 on the development set (beating the performance of all preceding models) and 0.5434 on the test set. Stacking engineered features further increased the Macro F1 on the development set to 0.6476, and led to the a test set performance of 0.5457. Appending EmoLex words to the engineered features further increased the Macro F1 on the development set to 0.6491, and led to a test set performance of 0.5538.

Finally, using emotion-specific detection thresholds for each emotion-specific MLPs, when using BERT predictions as input, the development set performance continued to increase to 0.6568, but test set performance went down to 0.5364. Using engineered features in addition to BERT predictions led to an increase in development set performance with Macro F1 of 0.6816, with test set performance hovering at 0.5542. Finally, appending the EmoLex words to the engineered features led to a dip in development set Macro F1 performance to 0.6433, with a corresponding test set performance of 0.5558.

In general, we see that engineered features (without EmoLex words) always improved the performance on both the development and test set for all variations. On the test set, adding EmoLex words also consistently improved the performance of our models across all variations. On the other hand, EmoLex words resulted in a decrease in development set Macro F1 performance with emotion-specific MLPs and emotion-specific detection thresholds. It seems that EmoLex either does not create an impact or creates a slight negative impact when looking at development set performance. This shows that EmoLex words were non-specific to the validation set but allowed for better generalisability to unseen test data, which presumably included more of these words, and were perhaps indicative of classifications, which was maybe not the case for the smaller validation set. It is worth remembering that the test set is more than 20 times bigger than the development set. Thus, the size of the test set makes it more complex, challenging and thorough than the validation set, hence the generalisation of best models based on development set performance is not good.

Class-wise performance correlated with label frequency: the majority class (Fear) had the highest F1, while the rarest (Anger) showed lower recall (sparse training data). Joy performed well (moderate frequency), likely aided by anti-correlation with other emotions. Threshold optimisation partially addressed imbalance, but minority classes still lagged due to limited training data.

In summary, the results (Table 1) show that, in the development set, the best model included emotion-specific MLPs, emotion-specific thresholds, BERT, engineered features and EmoLex words. However, the best-performing model on the test set was BERT with the engineered features, EmoLex words, a single MLP and a 0.5 detection threshold for all emotions. This model ended up generalising the best, and other models that performed well on the development set tended to suffer heavily from domain shift when evaluated on the test set.

7 Conclusion

Our best model combined BERT predictions and engineered features (including EmoLex), which were used as input to an MLP. The detection was optimal using a 0.5 threshold, achieving a test Macro F1 of 0.564. This configuration generalized better than emotion-specific MLPs, likely due to capturing inter-class correlations. Key challenges included dataset label imbalance (e.g., dominance of "Fear") and performance drops between validation and test sets. Future work should explore synthetic data generation for minority emotions and newer BERT variants. This approach advances multi-hot emotion detection, with applications in opinion analysis and targeted sentiment modeling.

8 Ethical Considerations

Our investigation focuses solely on English text, and there may be bias for the contexts and emotions shown in the training data. The dataset may not be representative of all populations, with potential

biases in emotion detection for underrepresented groups. When using the model, it is important to consider the data used is anonymised and handled in compliance with privacy regulations. Emotion detection also has the potential for misuse for surveillance or manipulation. Further steps should be taken to prevent any biases identified during the evaluation process.

Abstract

We present Team INSALyon2's agentic approach to SemEval-2025 Task 10 Subtask 2, focusing on multi-label classification of narratives in news articles. Our system employs specialized Large Language Model agents for binary classification of individual narrative labels, with a meta-agent aggregating these decisions into final multi-label predictions. Using AutoGen to orchestrate GPT-based agents without fine-tuning, our approach effectively handles the two-level taxonomy classification challenge. Experiments on the English subset demonstrate competitive performance (*F1 macro coarse = 0.513, F1 sample = 0.406*), securing third place in the competition and showing the effectiveness of zero-shot agentic approaches for complex classification tasks.

1 Introduction

The rapid spread of online news and user-generated content has increased exposure to deceptive narratives and manipulation attempts. Major crisis events, such as geopolitical conflicts and climate change discussions, are particularly susceptible to the dissemination of disinformation. To support research in identifying and analyzing these narratives, Subtask 2 (`Task`) of the SemEval-2025 Task 10 (Piskorski et al., 2025) focuses on narrative classification, aiming to automatically categorize news articles into predefined narratives and subnarratives.

The goal is to assign multiple subnarrative labels from a two-level taxonomy to news articles. To address this problem, traditional machine learning techniques such as *binary relevance* (training separate classifiers for each label ignoring potential correlations between labels) (Zhang et al., 2018), *classifier chains* (a sequence of classifiers where predictions are based on previous classifications and original features) (Li et al., 2024; Weng et al., 2020; Senge et al., 2019), and *label powerset* methods (treating each unique label combination as a single class thus transforming the multi-label problem into a multi-class problem) (Shan et al., 2018; Morales-Hernandez et al., 2022; Nazmi et al., 2018) have been explored in the state-of-the-art. More recently, deep learning models leveraging *transformer architectures*, such as BERT (Devlin et al., 2019) and its multilingual variants (mBERT, XLM-RoBERTa (Conneau et al., 2020), camemBERT (Martin et al., 2020)), have proven effective in capturing contextual nuances in text classification. Such models are typically fine-tuned on specific datasets to enhance their performance (Chen et al., 2023; Wu et al., 2023; Yu et al., 2019). Besides, strategies like *hierarchical classification models* (Sadat and Caragea, 2022; Vens et al., 2008; Daisey and Brown, 2020) and *graph-based methods* (Gong et al., 2020; Peng et al., 2021; Deng et al., 2024; Ye et al., 2021; Vu et al., 2022) have been employed to account for label dependencies within structured taxonomies like the one used in the challenge.

In the `Task`, participants get plain-text news articles in multiple languages (Bulgarian, English, Hindi, Portuguese, and Russian). They are sourced from web portals, including alternative media platforms identified by fact-checkers as potentially spreading misinformation. The documents are annotated with a two-level taxonomy of narrative labels (Stefanovitch et al., 2025). The goal is to develop systems assigning the appropriate narrative and subnarrative labels to each article. Performance is evaluated on coarse (*narrative*) and fine (*subnarrative*) levels and as the official measure the sample-averaged $F1$ score[1] is used. It measures how accurately predicted labels ($narrative\_x$: $subnarrative\_x$) match the ground truth.

To solve this task, we introduce an agentic approach[2] where each Large Language Model (LLM)

[2] https://github.com/NourJadiri/narrative-extraction

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 965–980

agent handles a binary classification task for a single label. These binary decisions are then aggregated using another meta-agent to form the final multi-label output. Our method leverages the specialization of individual agents while combining their strengths to improve overall classification performance. On the English language, our approach has achieved $F1\_macro\_coarse = 0.513$ and $F1\_sample = 0.406$, securing third place.

2 Problem Definition

The `Task` is structured as a multi-label, multi-class text classification problem, where each article must be assigned one or more narrative labels from a two-level taxonomy. The first level consists of broader narratives, while the second level contains more specific subnarratives (e.g. see Table 1). This hierarchical classification presents a unique challenge, as models must correctly identify both levels of categorization while handling cases where articles may belong to multiple narratives. Two top-level narratives are: *Climate Change* (CC) and *Ukraine-Russia War* (URW). We have applied our approach to English texts only. Overview statistics of the data are given in Table 2. A full two-level narrative taxonomy is given in Appendix A.

3 Related work

To address a multi-label multi-class document classification problem, several techniques have been proposed in the state-of-the-art such as traditional machine learning (Bag of Words), deep learning approaches (Word embeddings, CNNs) or even transformer based approaches (BERT model family). Given the advancements in LLM capabilities for various NLP challenges, we propose to incorporate them into our approach. LLMs can serve as zero-shot classifiers, enabling text classification without explicit training on task-specific datasets. Few-shot learning, a prompting method where models are given minimal examples, further enhances their adaptability and performance (Guo et al., 2024; Wang et al., 2024). However, while LLMs demonstrate high accuracy in text classification, their performance can vary based on the task and dataset. Fine-tuning strategies, such as enhanced discriminative fine-tuning, can significantly improve their performance, especially in non-generative text classification tasks (venkata and Gudala, 2024). The final methodological choice involved determining whether to employ a single model specialized in multi-label classification (Lee et al., 2024) or to utilize multiple binary classifiers, followed by an aggregation of their outputs. While a single multi-label classifier might capture label dependencies, addressing issues like class imbalance more effectively (Law and Ghosh, 2021), having multiple binary classifiers presents a modular and flexible framework optimizing individual classifiers per class pair, potentially enhancing overall classification performance (Kang et al., 2015). Techniques such as Error-Correcting Output Coding (ECOC) improve generalization by leveraging relationships between classifiers (Liu et al., 2016). Additionally, in certain scenarios, binary classifiers, particularly when used with ensemble methods (e.g., one-vs-one, one-vs-all), can achieve superior performance compared to traditional multi-class classifiers (Galar et al., 2011). Thus, in the context of LLM-based zero-shot classification, using multiple binary classifiers aligns well with the inherent strengths of LLMs.

4 System architecture

We propose to adopt an agentic framework, where each agent functions as a specialized binary classifier. A general overview of our architecture is given in Figure 1. Each agent is responsible for detecting whether a given text belongs to a specific narrative or subnarrative. We based this decision on the growing ecosystem of LLM-based agent frameworks, such as AutoGen (Microsoft, 2024), CrewAI (CrewAI, 2024), Swarm (OpenAI, 2024), and SMOLAgent (Face, 2024), which provide mechanisms for structuring LLMs into specialized roles. Our classification system is structured around `AutoGen` (Microsoft, 2024), an agent-based framework to coordinate multiple LLM agents. In this setup, each agent processes input independently and returns a binary decision, with some agents dedicated to higher-level narratives and others focused on finer subnarrative distinctions. We provide the prompts for different kinds of agents in Appendix B. An example of the functioning of our approach is provided in Appendix C.

Group Chat Mechanics The system is organized as a group chat consisting of the user proxy agent, the manager agent, and multiple narrative (and subnarrative) agents. The manager agent limits each narrative agent to a single query per classification task, mitigating the risk of extended conversational history that could lead to context length issues in

Table 1: Annotation example of Subtask 2

article_id	narratives	subnarratives
EN_CC_200046.txt	CC: Climate change is beneficial	CC: Climate change is beneficial: CO2 is beneficial

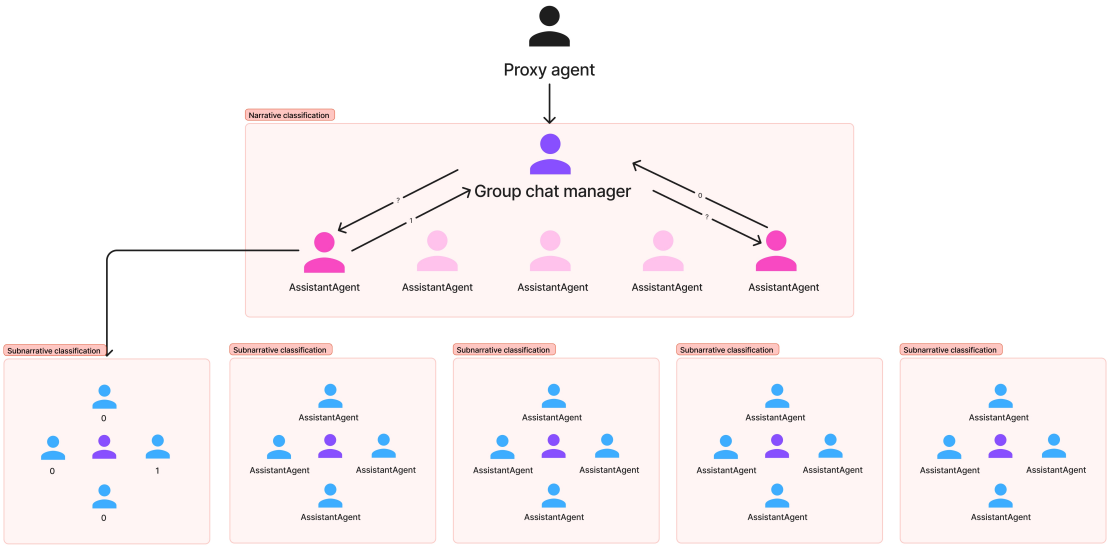

Figure 1: The user proxy agent forwards the input text to the first classification layer (Narrative Level). At this stage, the group chat manager acts as a high-level classifier, identifying potential narratives and dispatching the text to the relevant assistant agents. Once the primary classification is complete, a finer classification is performed using sub-narrative agents corresponding to the extracted narratives.

Table 2: General statistics of English subset

	CC	URW	Total
# articles TRAIN	176	223	399
# articles DEV	24	17	41
# articles TEST	48	53	101
# narratives	10	11	22 (+ *Other*)
# subnarratives	41	49	91 (+ *Other*)

LLM-based systems. The user proxy agent initiates the group chat for each new text sample by providing the manager agent with the document to be classified. The manager then selects up to six narrative agents, requesting a binary decision from each. Once all relevant agents have responded, the manager collects the answers and produces a multi-label classification output for the text.

Narrative level classification Each narrative agent is created with a system prompt that defines the narrative in question, using the taxonomy file given by the organizers and instructs the agent to respond with either `1` (if the text is clearly related to the assigned narrative) or `0` (if not). Additionally, each agent provides a short description, introducing itself and specifying the narrative it detects. It is presented to the manager agent within the group chat when the session is initiated. Moreover, LLM agents tend to give many false positives due to the semantic similarity of the classes. This is why we specified explicitly that the agent classifies negatively a text that is slightly ambiguous.

```
"Only answer with 1 if there are
EXPLICIT and CLEAR mentions of
the narrative in the text. Some
text will be ambiguous so if you
are slightly unsure, answer 0."
```

"Other" Class for Narrative Classification If all the queried narrative agents return a negative response (0), the text is automatically assigned to the "Other" class, indicating that it does not correspond to any predefined narrative. In such cases, subnarrative classification is bypassed, and the subnarrative is also set to "Other" by default.

Subnarrative level classification Once the high-level narratives are assigned, the classification pro-

cess moves to a finer level of granularity. For each identified narrative, a smaller group chat is created, consisting of subnarrative agents associated with that narrative (the taxonomy file given in the competition is used). Unlike the previous classification step, where the manager agent orchestrates the classification in a structured query-response pattern, subnarrative classification follows a round-robin approach. Each subnarrative agent independently classifies the text within its specialized scope.

"Other" Class for Subnarrative Classification Subnarrative classification presents additional challenges, as a text may belong to a broad narrative but not fit into any of its predefined subnarratives. To address this, we introduce a specialized classifier responsible for detecting such cases. This agent operates using a modified classification prompt:

```
"Statements that are related to
the narrative _, defined as _,
but are not related to any of
these subnarratives: _
```

Manager and User Proxy Agents A manager agent orchestrates the overall classification process. Upon receiving an input text, its task is to identify which narratives could be relevant and to query the corresponding specialized agents. Meanwhile, a user proxy agent acts as the interface between the user and the group chat, giving the text to be classified and collecting responses.

Implementation Considerations Practically, the `allowed_transitions` configuration in the group chat prevents agents from re-triggering themselves, guaranteeing that each agent delivers one context-sensitive classification per session. After every classification, the user proxy agent is reset to avoid any leftover conversational context from impacting future tasks. This structure ensures that the roles are clearly distinct: the manager agent manages high-level classification coordination, and each narrative agent makes a specific binary decision.

5 Experimental Setup

5.1 Dataset

The dataset consists of **399** English news articles, provided as a tab-separated file with three columns: *file ID, narrative(s), and subnarrative(s)*. Each article is labeled with one or more **narratives** and their corresponding **subnarratives**, except for instances classified under the special "Other" category, which signifies that the text does not belong to any predefined category.

Since our approach is **zero-shot**, no training is performed. Instead, the dataset is used exclusively for **evaluation**, where the model classifies texts based on predefined prompts without prior task-specific fine-tuning.

The dataset underwent preprocessing to structure the classification task as follows:

- **Taxonomy Parsing:** Narrative and subnarrative labels were extracted from a hierarchical taxonomy stored in JSON format.
- **Content Extraction:** The article text was retrieved based on file IDs.
- **Binary Labeling:** A binary label was created for each possible narrative and subnarrative.

5.2 Evaluation Metrics

Since this is a **multi-label, multi-class classification** problem, we evaluate model performance using the **sample-averaged F1 score**. The official evaluation consists of two modes:

- **Full Narrative-Subnarrative Matching:** An F1 score is computed per document by comparing its predicted narrative-subnarrative labels to the gold labels. A prediction is considered correct only if both the narrative and its corresponding subnarrative are accurate.
- **Narrative-Only Matching:** The subnarrative labels are ignored, and performance is evaluated solely based on whether the correct narratives were assigned.

5.3 Model Configuration

The following models were utilized:

- **GPT-4o/GPT-4o-mini:** Used as the primary classification agent for narrative and subnarrative labeling. A **temperature of 0** was set to ensure deterministic responses.
- **GPT-4o Mini:** Used as a **user proxy agent** to relay text to classification agents, chosen for cost efficiency.
- **Zero-Shot/Few-Shot Setup:** Agents classify text based on carefully designed prompts. No fine-tuning was performed.

5.4 Computational Environment

Experiments were conducted on a machine equipped with: **Processor:** Core 9 Ultra (22 CPU at 2.5Ghz), **RAM:** 32 GB, **GPU:** NVIDIA RTX 4070 (8 GB VRAM). However, all LLM inference was performed via API calls to remote servers. The local machine was used primarily to orchestrate API requests, pre-process input text, and handle classification results.

5.5 Baseline Comparison

To establish a lower-bound reference, a fully random classifier was used as a baseline. This model assigns narratives and subnarratives at random, providing a benchmark to ensure participating systems meaningfully outperform chance-level predictions.

6 Results

The main results are reported in Table 3. As it can be seen, the performance results are consistent among DEV and TEST set. Judging on the DEV set, we can state that 16 out of 22 narratives have prevalence <10%, indicating a highly imbalanced dataset. Distributions of narratives and subnarratives in the TRAIN and DEV datasets are given in Appendix E. They are highly skewed demonstrating the class imbalance. Thus, the top-3 most frequent *URW* narratives are: *URW: Discrediting Ukraine*, *Discrediting the West, Diplomacy*, and *URW: Praise of Russia*, while the top-3 *Climate Change* narratives are: *CC: Amplifying Climate Fears*, *CC: Criticism of institutions and authorities*, and *CC: Criticism of climate policies*.

On the DEV set, the *Climate Change* narratives generally have been predicted with higher recall than *URW*. Among the best performing narratives, we can list: "*CC: Climate change is beneficial*", "*URW: Discrediting Ukraine*", and "*URW: Blaming the war on others rather than the invader*". In contrast, 9 narratives (41% of total) have zero true positives (TP=0), meaning the model failed to identify any positive instances of these narratives: 3 CC narratives (e.g., "*Amplifying Climate Fears*"), and 6 URW narratives (e.g., "*Russia is the Victim*").

We may also note the high false positive rate for "*CC: Criticism of climate policies*", "*CC: Criticism of institutions and authorities*" and *CC: Criticism of climate movement* and misclassification of similar narratives. Thus, confusion occurred between related categories such as "*CC: Criticism of climate policies*" and "*CC: Criticism of institutions and authorities*" indicating limitations in distinguishing subtle semantic differences. Providing more detailed agent prompts focusing on discriminative features between similar categories can be explored for potential improvement. We provide confusion matrices for narratives and subnarratives on the DEV set in Appendix D. The issues such as class imbalance and the narratives with $TP = 0$ should be addressed in future work.

Another error pattern that can be observed is due to hierarchical error propagation. Errors at the narrative level invariably propagated to the subnarrative level, highlighting the importance of high-quality initial classification.

Although our primary focus was on English texts, after the official challenge, we conducted additional experiments on Portuguese and Russian subsets to address the multilingual nature of the original task. To do so, we translated all texts into English using the DeepL translation model (DeepL GmbH, 2023) to ensure consistency across linguistic sources. No further pre-processing or data augmentation was applied. The results are given in Table 4. The performance drop in non-English languages can be attributed to several factors such as cultural and contextual nuances that may not transfer across languages or translation issues resulting in the loss of semantics. To improve multilingual performance, future work could explore using truly multilingual models like XLM-RoBERTa (Conneau et al., 2019) instead of GPT or creating language-specific agent prompts rather than translated versions. Another option could be incorporating few-shot examples in target languages.

7 Discussion

Our agent-based classification framework offers several advantages, including ease of implementation, scalability, and model flexibility. Its modular design enables parallelization, making it suitable for large-scale classification tasks. Additionally, the approach is model-agnostic, meaning it can be used with any model that exposes an API.

Despite these strengths, the system faces several limitations. The system's primary limitation is *latency*, as classification depends on multiple API calls, leading to slow processing times. This bottleneck is particularly problematic in real-time applications or large-scale datasets. Future improvements could include local model inference to reduce dependence on external APIs and caching

Table 3: Results on Dev and Test sets for English

model	dataset	rank	$F1\_macro\_coarse$	$F1\_std\_coarse$	$F1\_sample$	$F1\_std\_sample$
INSALyon2	DEV		0.537	0.356	0.492	0.383
INSALyon2	TEST	3	0.513	0.378	0.406	0.382
baseline	TEST	26	0.030	0.127	0.013	0.070

Table 4: Results on Test set for Russian (RU) and Portuguese (PO)

langauge	model	dataset	rank	$F1\_macro\_coarse$	$F1\_std\_coarse$	$F1\_sample$	$F1\_std\_sample$
PO	INSALyon2	TEST	12	0.285	0.360	0.173	0.252
PO	baseline	TEST	16	0.037	0.14	0.014	0.070
RU	INSALyon2	TEST	12	0.247	0.341	0.137	0.271
RU	baseline	TEST	17	0.065	0.213	0.008	0.064

mechanisms to optimize efficiency. Combining our zero-shot approach with fine-tuned components could balance flexibility with performance in a computationally efficient manner.

The framework's effectiveness diminishes notably in *non-English languages*, limiting its applicability in truly multilingual settings without significant adaptation. Developing language-specific agent configurations with culturally adapted prompts and examples could improve performance across languages. Another directions could be a use of multilingual models like XLM-RoBERTa instead of GPT. In this case, an adjustment of the architecture will be required.

The binary decision approach sometimes fails to capture *implicit narrative elements* that require reading between the lines or understanding cultural context.

Despite these limitations, the framework remains robust by incorporating a structured two-step classification process and an "*Other*" class to handle ambiguous inputs. Future work could explore context-aware classification and cross-agent communication to further improve accuracy and efficiency. Adding capabilities for agents to justify their decisions would enhance system transparency and facilitate targeted improvements.

8 Conclusion

This paper introduced an agentic framework for multi-label multi-class text classification, leveraging specialized LLM agents to handle narratives and subnarratives. Despite hardware constraints preventing local fine-tuning and cost limitations linked to advanced API-based models, the proposed approach demonstrated competitive performance, achieving third place in Subtask 2 of SemEval-2025 Task 10. Future work could explore more sophisticated reasoning models and expanded fine-tuning strategies, potentially enhancing classification accuracy while balancing the practical trade-offs between computational resources and model complexity.

A Narrative Taxonomy

Tables 5 and 6 provide a two-level taxonomy used in the study.

B Agent Prompts

In this Appendix, we provide the prompts used for different kinds of agents.

B.1 Subnarrative Agent Prompt

```
"You are a classification model trained to do binary classification by detecting whether a given text is related to a specific subnarrative or not.
You have been trained to recognize the subnarrative: SUBNARRATIVE.
This subnarrative is defined as: SUBNARRATIVE_DEFINITION.
Here are some examples of statements related to this subnarrative: SUBNARRATIVE_EXAMPLES.
If the text is related to the subnarrative, please respond with '1'. Otherwise, respond with '0'. Do not try to make sentences, just respond with '1' or '0'.
You are ONLY allowed to answer with '1' or '0' and NOTHING else.
Only answer with 1 if there are explicit and clear mentions of the subnarrative in the text.
If you are slightly unsure, classify as 0."
```

In the above prompt `SUBNARRATIVE` is the name of the subnarrative in question, `SUBNARRATIVE_DEFINITION` is the definition from the guidelines (Stefanovitch et al., 2025), and `SUBNARRATIVE_EXAMPLES` are the examples of the documents representing a given subnarrative. Both the definition and the examples are extracted from the taxonomy document given for the competition.

B.2 Narrative Agent Prompt

```
"You are a classification model trained to do binary classification by detecting
```

Table 5: Narrative taxonomy: CC

Narrative	Subnarrative
Amplifying Climate Fears	Amplifying existing fears of global warming Doomsday scenarios for humans Earth will be uninhabitable soon Other Whatever we do it is already too late
Climate change is beneficial	CO2 is beneficial
Controversy about green technologies	Other Renewable energy is costly Renewable energy is dangerous Renewable energy is unreliable
Criticism of climate movement	Ad hominem attacks on key activists Climate movement is alarmist Climate movement is corrupt Other
Criticism of climate policies	Climate policies are ineffective Climate policies are only for profit Climate policies have negative impact on the economy Other
Criticism of institutions and authorities	Criticism of international entities Criticism of national governments Criticism of political organizations and figures Criticism of the EU Other
Downplaying climate change	CO2 concentrations are too small to have an impact Climate cycles are natural Human activities do not impact climate change Humans and nature will adapt to the changes Ice is not melting Other Temperature increase does not have significant impact Weather suggests the trend is global cooling
Green policies are geopolitical instruments	Green activities are a form of neo-colonialism Other
Hidden plots by secret schemes of powerful groups	Blaming global elites Climate agenda has hidden motives Other
Questioning the measurements and science	Data shows no temperature increase Greenhouse effect/carbon dioxide do not drive climate change Methodologies/metrics used are unreliable/faulty Other Scientific community is unreliable

Table 6: Narrative taxonomy: URW

Narrative	Subnarrative
Amplifying war-related fears	By continuing the war we risk WWIII NATO should/will directly intervene Other Russia will also attack other countries There is a real possibility that nuclear weapons will be employed
Blaming the war on others rather than the invader	Other The West are the aggressors Ukraine is the aggressor
Discrediting Ukraine	Discrediting Ukrainian government and officials and policies Discrediting Ukrainian military Discrediting Ukrainian nation and society Other Rewriting Ukraine's history Situation in Ukraine is hopeless Ukraine is a hub for criminal activities Ukraine is a puppet of the West Ukraine is associated with nazism
Discrediting the West, Diplomacy	Diplomacy does/will not work Other The EU is divided The West does not care about Ukraine, only about its interests The West is overreacting The West is weak West is tired of Ukraine
Distrust towards Media	Other Ukrainian media cannot be trusted Western media is an instrument of propaganda
Hidden plots by secret schemes of powerful groups	Other
Negative Consequences for the West	Other Sanctions imposed by Western countries will backfire The conflict will increase the Ukrainian refugee flows to Europe
Overpraising the West	NATO will destroy Russia Other The West belongs in the right side of history The West has the strongest international support
Praise of Russia	Other Praise of Russian President Vladimir Putin Praise of Russian military might Russia has international support from a number of countries and people Russia is a guarantor of peace and prosperity Russian invasion has strong national support
Russia is the Victim	Other Russia actions in Ukraine are only self-defence The West is russophobic UA is anti-RU extremists
Speculating war outcomes	Other Russian army is collapsing Russian army will lose all the occupied territories Ukrainian army is collapsing

Team INSAntive at SemEval-2025 Task 10: Hierarchical Text Classification using BERT

Yutong Wang **Diana Nurbakova** **Sylvie Calabretto**
INSA Lyon, CNRS, Universite Claude Bernard Lyon 1, LIRIS, UMR5205,
69621 Villeurbanne, France
{fistname.lastname}@insa-lyon.fr

Abstract

We propose a BERT-based hierarchical text classification framework to address the challenges of training multi-level multi-class text classification task. As part of the SemEval-2025 Task 10 challenge (Subtask 2), the framework performs fine-grained text classification by training dedicated sub-category classifiers for each top-level category. Experimental results demonstrate the feasibility of the proposed approach for such a task.

1 Introduction

With the rapid development of Natural Language Processing (NLP), extracting narratives from online news has attracted widespread attention in both academia and industry (Piskorski and Yangarber, 2013). A deep understanding of how entities are presented in news articles and the identification of underlying narratives are crucial for media analysis, misinformation detection, and socio-political research (Vosoughi et al., 2018).

This study focuses on the cross-lingual, multi-label, and multi-category document classification task, which involves automatically identifying and assigning narrative labels and sub-narrative labels to news articles based on a two-level narrative labeling system within a specific domain. Specifically, each article may contain one or more narrative labels, with each narrative further subdivided into sub-narrative labels. The main objective of this study is to accurately assign all applicable narrative labels and their corresponding sub-narrative labels to each article. The task covers five languages (Bulgarian, English, Hindi, Portuguese, and Russian) and aims to evaluate narrative classification performance under cross-lingual conditions.

SemEval-2025 Task 10 (Piskorski et al., 2025; Stefanovitch et al., 2025) focused on multilingual characterization and narrative extraction from online news, divided into three independent subtasks. We participated in the Subtask 2 on the narrative classification. In this task, our model achieved a mid-to-upper range ranking on the final leaderboard, outperforming the baseline systems while still leaving room for further improvement.

Our approach combines large-scale pre-trained language models, a hierarchical classification strategy, and entity framing analysis to automatically identify and classify narratives across different languages and topics, providing a solution for narrative extraction from multilingual news texts.

In this study, we first perform translation-based data augmentation on the raw text data to ensure label consistency and accuracy across multiple languages. We then fine-tune a Transformer-based language model on the augmented dataset. To identify sub-narrative labels, we train separate classification models for each sub-narrative label and combine these models into an ensemble model. After completing the narrative label classification, we calculate the probability distribution of each sub-narrative label under its corresponding main narrative label and select the sub-narrative label with the highest probability as the classification result.

2 Background

Narrative classification is of great importance for extracting and identifying narrative structures from various types of texts, and it plays a crucial role in fields such as computational linguistics, NLP, and information retrieval (IR). In recent years, researchers have shifted their focus from traditional personal narratives (Langellier, 1989) to more diverse text types, especially informational texts (e.g., news reports, meeting minutes, and case analyses), and have made significant progress in developing computational methods for identifying narratives.

Classical narrative theory was initially proposed

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 981–988

by Labov and Waletzky (Labov and Waletzky). Building on this work, Swanson et al. (Swanson et al., 2014) manually annotated texts related to personal stories, categorizing clauses into three narrative types (orientation, evaluation, and action) and developed corresponding feature-based models. This endeavor laid an important foundation for subsequent research in narrative classification.

As the demand for automatic recognition of narrative structures continues to grow, there has been increasing interest in integrating narrative theory with machine learning models, aiming at achieving more efficient and accurate narrative classification across a variety of text types. Saldias and Roy (Saldias and Roy, 2020) employed convolutional neural networks (CNNs) to classify sentences in personal-story texts, automatically labeling each sentence according to the three narrative types proposed by Swanson et al. Meanwhile, Levi et al. (Levi et al., 2022) introduced NEAT (Narrative Elements AnnoTation), which uses multiple supervised learning models to distinguish highly interrelated narrative categories. Hatavara et al. (Hatavara et al., 2024) further developed a rule-based and computational approach to systematically extract narratives from parliamentary records and oral history interviews, demonstrating its feasibility on large datasets.

Recent surveys have provided comprehensive overviews of current methods and challenges in narrative extraction (Santana et al., 2023; Norambuena et al., 2023). Meanwhile, large-scale pre-trained language models, especially BERT (Devlin et al., 2019) with their pre-training on bidirectional language models (Rogers et al., 2020), are capable of better understanding contextual information within sentences and have thus been widely applied to narrative classification tasks (Gao et al., 2019; Hu et al., 2022; Purificato and Navigli, 2023). However, challenges still persist due to data scarcity and the inherent complexity of narrative structures, motivating researchers to explore the use of large language models (LLMs) for data augmentation (Conneau et al., 2020). Although both GPT (OpenAI et al., 2023) and BERT are large-scale pre-trained language models, GPT, as a generative model, has the ability to produce coherent and contextually relevant text. Thus, it offers novel solutions to address data insufficiency, particularly in the generation of high-quality narrative texts (Bartalesi et al., 2024) and translating narrative records (Hendy et al., 2023).

3 System overview

3.1 Framework Overview

Due to the limited volume of available training data and the large number of label categories, directly training deep learning models often fails to produce satisfactory results. To address this issue, this study proposes a multistage text translation and classification framework designed to efficiently handle multilingual texts and convert them into a standardized format suitable for deep learning model training. It comprises the following key steps:

(1) *Data Augmentation via Text Translation*: First, all articles written in languages other than the target language are translated into the required training language to ensure data consistency. For articles that exceed a certain length, a segmented translation strategy is employed to overcome API limitations while preserving textual integrity and readability.

(2) *Narrative Classification*: After translation, a global classification step is performed to assign articles to specific themes or categories based on their overall content. This step utilizes a pre-trained Transformer model (e.g., BERT) combined with supervised learning to optimize the classification process.

(3) *Sub-narrative Classification*: Next, texts under the same narrative label are further classified into subcategories to capture fine-grained semantic information. A hierarchical classification method is adopted to allow the model to recognize various narrative structures, thereby improving classification accuracy.

This framework offers several advantages: (1) Automation: It enables an end-to-end automated process from multilingual translation to classification, minimizing manual intervention and improving data-processing efficiency. (2) Adaptability: It supports multilingual inputs and can be adapted for various text classification tasks. (3) Computational Resource Optimization: The framework improves computational efficiency through segmented translation, dynamic model loading, parallel processing, and other optimization strategies.

3.2 Text Translation Framework

This study employs an automated text translation framework designed to batch-process and translate lengthy articles, ensuring the textual content

is comprehensively and efficiently converted into the target language. Built on OpenAI's GPT-4o, the system adopts a segmented translation strategy to address the challenges posed by extremely long texts. The framework consists of the following key steps: (1) *Segmentation and Preprocessing*: Long documents are divided into smaller segments to circumvent API length limitations. This segmentation method retains readability and allows for efficient parallel processing. (2) *Machine Translation Integration*: Each segment is translated into the target language using a LLM. This step ensures linguistic uniformity, which is crucial for downstream tasks such as classification and semantic analysis. (3) *Data Standardization*: The translated text is converted into a standardized format suitable for subsequent model training, facilitating organized data storage and retrieval.

Given a collection of source language text files, some of which may exceed the maximum output length supported by the OpenAI API (4,096 tokens), we propose a segmentation-based translation approach to address this limitation. This approach involves three main steps for each original text: (1) **Text Segmentation**: The input text is divided into smaller segments to ensure each falls within the API's token limit. (2) **API-based Translation**: Each segment is translated individually using the OpenAI translation API. (3) **Translation Merging**: All translated segments are then concatenated to reconstruct the complete translated text.

For texts exceeding the length limit, this process ensures translation segment by segment and reassemblage into a coherent full translation. By integrating segmentation, translation, and standardized output, this framework produces high-quality multilingual data for further classification and semantic analysis. Its modular design also enables flexible adaptation to different languages, domains, and model architectures, thus enhancing scalability and robustness in multilingual NLP pipelines.

3.3 Multi-label Text Classification

After augmenting the training articles via text translation, this study employs a BERT-based multi-label text classification framework. Specifically, for text data containing multiple narrative labels, a pre-trained Transformer model (`BERT-base-uncased` (Devlin et al., 2019)) is used for text representation learning. We then train on the augmented text corpus. The objective of this task is to perform multi-label classification on the input text, where each article can belong to multiple categories.

Given a dataset $D = \{(x_i, Y_i)\}_{i=1}^{N}$, where x_i represents the text and $Y_i \subseteq C$ denotes the set of labels assigned to that text (C is the set of all possible classes). The goal is to train a model F such that, for an input text x_i, it predicts the most appropriate set of class labels: $\hat{Y}_i = F(x_i) = \{\hat{y}_i^1, \hat{y}_i^2, \ldots, \hat{y}_i^m\}, \quad \hat{y}_i^j \in \{0, 1\},$, where $\hat{y}_i^j$ indicates the probability that x_i belongs to class c_j. The model architecture is given by: $F(x) = \text{Sigmoid}(\text{BERT}(x))$,, where: **BERT** acts as the backbone network, outputting logits that serve as class prediction scores, **Sigmoid** converts the logits into class probabilities: $p(y_i) = \frac{1}{1+e^{-z_i}}$,, where z_i is the prediction score for class i. We optimize the Binary Cross-Entropy loss: $L = -\sum_{i=1}^{m} [y_i \log p(y_i) + (1 - y_i) \log(1 - p(y_i))]$,, where m denotes the total number of classes, y_i is the ground truth label for class i, and $p(y_i)$ is the model-predicted probability for that class.

3.4 Sub-narrative Label Classification

For sub-narrative labels, we use a BERT-based hierarchical text classification framework designed to perform multi-level classification. In this task, each text is first categorized into one or more top-level labels, and then further subdivided into sub-labels associated with each top-level category. To improve classification accuracy and generalization, a dedicated sub-label classifier is trained separately for each top-level label.

For each top-level category c_j, we train a dedicated subcategory classifier. The number of neurons in its output layer is equal to the number of subcategories under c_j. Formally, we denote this classifier as: $M_j = \text{BERT}_\theta + \text{FC}(h, |C_j^{\text{sub}}|)$,, where BERT_θ represents the BERT model parameterized by θ, $\text{FC}(h, |C_j^{\text{sub}}|)$ is a fully connected layer that takes the hidden representation h as input and outputs a vector of length $|C_j^{\text{sub}}|$.

Given a text dataset $D = \{(x_i, y_i)\}_{i=1}^{N}$, where x_i represents the text and y_i represents the corresponding class label, let the set of top-level categories be denoted by: $C_{\text{top}} = \{c_1, c_2, \ldots, c_m\}$, and let the set of subcategories associated with a specific top-level category c_j be denoted by: $C_j^{\text{sub}} = \{s_j^1, s_j^2, \ldots, s_j^n\}$. The goal is to learn a function F such that, given a known top-level category c_j, it can predict the subcategory label for a text x_i as follows: $\hat{s}_i = F(x_i \mid c_j)$.

4 Experimental Setup

Dataset Description. The SemEval-2025 Task 10 Subtask 2 dataset consists of news articles in five different languages: English (EN), Portuguese (PO), Russian (RU), Bulgarian (BU), and Hindi (HI). Each article is annotated with one or more narrative labels from a predefined set of 21 top-level narratives, and each narrative is further associated with one or more sub-narratives from a total of 91 possible sub-narratives.

For our experiments, we used the multilingual corpus with varying document distributions across languages (see Figures 1-2). Prior to data augmentation, the training set contained 399 EN articles, 400 PO articles, 133 RU articles, 401 BU articles, and 366 HI articles. The development set consisted of 41 EN articles, 35 PO articles, 32 RU articles, 35 BU articles, and 35 HI articles. Our test set included 101 EN articles, 100 PO articles, 60 RU articles, 100 BU articles, and 99 HI articles.

The dataset exhibits significant class imbalance at both narrative and sub-narrative levels, as shown in Figures1 and 2. Some narratives like "*Criticism of Institutions and Authorities*" and "*Discrediting Ukraine*" appear frequently, while others like "*Climate Change is Beneficial*" and "*Controversy about green technologies*" are rarely represented. This imbalance presents a challenge for classification models, particularly in identifying and correctly classifying minority classes.

To address the imbalance in training data across languages, particularly the limited number of RU articles, we implemented a translation-based data augmentation strategy. After augmentation, each language in the training set contained 1,699 articles, creating a balanced training corpus across all five languages. This augmentation approach enabled our model to learn more robust cross-lingual patterns and improved overall performance, especially for languages with fewer original training samples.

Implementation Details. We implemented our model using PyTorch (1.10.0) and the Hugging Face Transformers library (4.16.2). For the text translation framework, we employed OpenAI's GPT-4o via the official API. Documents were segmented into chunks of approximately 1,000 tokens to stay within API limits while maintaining context coherence. For our augmentation process, we translated non-English articles to English and vice versa to ensure balanced representation across languages.

We set the following hyperparameter values for BERT-based multi-label classification model: (a) pre-trained model: `bert-base-uncased`, (b) maximum sequence length: 128 tokens, (c) batch size: 8 (narrative classifier) / 3 (sub-narrative classifiers), (d) learning rate: 2e-5 with AdamW optimizer, (e) weight decay: 0.01, (f) training epochs: 30 (early stopping with patience of 5) for narrative classifier / 3 for sub-narrative classifiers, (g) dropout rate: 0.1, (h) classification threshold: 0.2 (optimized on validation set) for narrative classifier.

To validate the effectiveness of our data augmentation approach, we conducted experiments both with and without the augmented data. The results demonstrate significant performance improvements when using the augmented dataset, particularly for languages with fewer original training samples like Russian (see Table 3).

The training process for the narrative and sub-narrative classifiers was structured as follows. We first trained the top-level narrative classifier on the full augmented dataset of 1,699 articles per language. For each narrative category, we filtered the dataset to include only articles with that narrative label. We then trained a dedicated sub-narrative classifier for each narrative category using a single-label classification approach with LabelEncoder. During inference, we first predicted the narrative labels using the top-level classifier, then employed the corresponding sub-narrative classifiers to predict the fine-grained labels.

For the sub-narrative classification, we organized articles by their top-level narrative labels and trained separate BERT-based models for each top-level category. Unlike the multi-label approach used for narrative classification, each sub-narrative classifier was trained as a standard single-label classification model using cross-entropy loss. This approach was chosen due to the hierarchical nature of the labels and to reduce complexity in the sub-narrative prediction task.

All sub-narrative models were saved with their corresponding tokenizer and label encoder to enable efficient inference. During prediction, once the top-level narrative was identified, the corresponding sub-narrative model was loaded to predict the specific sub-category. This hierarchical approach allowed us to effectively handle the large number of potential sub-narratives while maintaining computational efficiency.

To address the class imbalance issue in the top-level narrative classification, we implemented class weighting in the loss function, where weights were

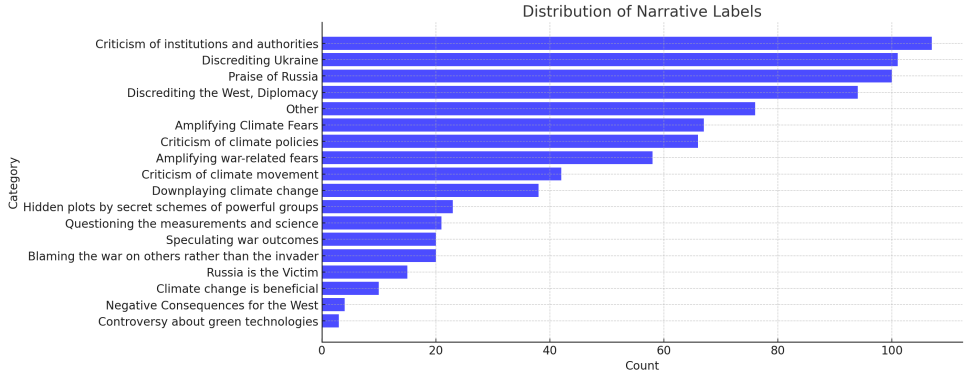

Figure 1: Distribution Narrative Labels

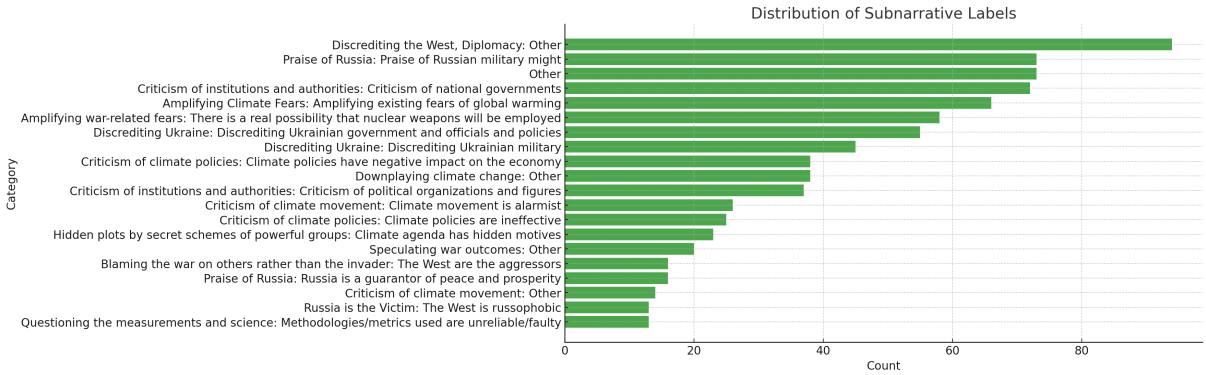

Figure 2: Distribution Subnarrative Labels

inversely proportional to class frequencies in the training set. This approach improved the model's ability to identify minority classes without significantly degrading performance on majority classes.

Evaluation Metrics. Following the official SemEval-2025 Task 10 evaluation criteria, we measured our model's performance using the following metrics: (a) **F1 Macro**: The unweighted mean of F1 scores for each class, giving equal importance to all classes regardless of their frequency. This metric is particularly important for evaluating performance on imbalanced datasets, as it prevents the model from being overly biased toward majority classes. (b) **F1 Samples**: The F1 score calculated for each instance and then averaged, which accounts for the multi-label nature of the task. This metric provides insights into the model's ability to correctly predict all relevant labels for each document.

Additionally, we report the standard deviation (St.Dev) for both metrics to analyze the stability of our model's performance across different classes and samples. A lower standard deviation indicates more consistent performance across all categories, which is desirable for robust classification systems.

5 Results and Analysis

In this study, we performed multilevel classification on text data in different languages and computed the F1 Macro Coarse and F1 Samples metrics to evaluate the model's classification performance across different language datasets. The experimental results are presented in Table 3, where F1 Macro Coarse measures the overall balance of classification performance between categories, and F1 Samples focuses on the performance of the model in individual samples.

Table 1: F1 Scores on Test set

Lang	F1 Macro	F1 St.Dev	F1 Sample	F1 St.Dev Smp
EN	0.443	0.380	0.281	0.352
PO	0.491	0.275	0.245	0.204
RU	**0.554**	**0.328**	**0.323**	**0.342**
BU	0.523	0.366	0.324	0.360
HI	0.365	0.440	0.365	0.414

To further validate the effectiveness of the proposed model, we conducted a systematic comparison with baseline methods on different language-specific datasets. As presented in Table 3, our

model consistently outperforms the baseline across all evaluated languages. The F1 Macro and F1 Sample scores demonstrate substantial improvements, reflecting both better overall classification balance and stronger sample-level performance.

Table 2: F1 Scores Comparison with Baseline Models

	Baseline		**Proposed Model**	
	F1 Macro	F1 Sample	F1 Macro	F1 Sample
EN	0.030	0.013	**0.443**	**0.281**
PO	0.037	0.014	**0.491**	**0.245**
RU	0.065	0.008	**0.554**	**0.323**
BU	0.040	0.039	**0.523**	**0.324**
HI	0.081	0.000	**0.365**	**0.365**

The comparative analysis reveals remarkable improvements over the baseline models. For English (EN), our model achieves an F1 Macro score of 0.443 compared to the baseline's 0.030, representing a 14.8× improvement. Similarly, Portuguese (PO) shows a 13.3× improvement, Russian (RU) an 8.5× improvement, Bulgarian (BU) a 13.1× improvement, and Hindi (HI) a 4.5× improvement in F1 Macro scores. The most dramatic improvement is observed in the F1 Sample metric for Hindi, where our model achieves 0.365 compared to the baseline's 0.000, indicating the baseline completely failed to correctly classify individual samples in this challenging language.

Table 3: F1 Macro Coarse Comparison

Lang	No Augmentation	With Augmentation
EN	0.329	**0.443**
PO	0.220	**0.491**
RU	0.224	**0.554**
BU	0.188	**0.523**
HI	0.301	**0.365**

Our model performs best on the Russian (RU) dataset, reaching an F1 Macro Coarse of 0.554 and an F1 Samples of 0.323, suggesting relatively high accuracy both at the global category level and for individual samples. In contrast, when applied to the Hindi (HI) dataset, it exhibits the lowest classification performance, with an F1 Macro Coarse of only 0.365, implying that this language poses a greater classification challenge—potentially due to data quality or linguistic factors. Meanwhile, Portuguese (PO) and Bulgarian (BU) show comparable results at 0.491 and 0.523, respectively, indicating relatively stable model generalization for these languages. Regarding the standard deviation (St. Dev.), Hindi's F1 St.Dev. Coarse is as high as 0.440, with an F1 St.Dev. Samples of 0.414, suggesting large variability in its classification performance—likely stemming from data imbalance or label inconsistencies. In contrast, Portuguese has an F1 St.Dev. Coarse of only 0.275, implying more stable classification outcomes, making it suitable for more fine-grained text classification tasks. The distribution of classification results is not uniform: a few high-frequency categories (e.g., "*Criticism of Institutions and Authorities*", "*Slandering Ukraine*," "*Praise for Russia*") occupy a relatively large portion of the corpus, whereas other categories (e.g., "*Questioning Scientific Measurements and Indicators*", "*Climate Change is Beneficial*") have significantly fewer samples. This imbalance not only reflects real-world differences in the frequency with which various narratives appear but also potentially affects the model's discriminatory power: when high-frequency categories dominate the dataset, the model tends to learn their features more effectively, while its ability to recognize low-frequency categories weakens accordingly.

6 Conclusion

In the multi-label setting, the framework integrates a BERT-based text classification method, using automated data processing, optimized training workflows, and memory management strategies. Our proposed framework additionally provides a range of functional modules (segmentation, automated translation, and standardized output) that facilitate the generation of high-quality multilingual data for subsequent classification and semantic analysis. Experimental results show that our method performs well in handling large-scale, multilingual text data and achieves high accuracy in hierarchical classification tasks. Future research directions include: (1) further optimizing parallel processing strategies to improve overall training efficiency; (2) enhancing the accuracy of sub-category classification; and (3) exploring more powerful multilingual pre-trained models to strengthen system robustness and generalization capabilities.

MSA at SemEval-2025 Task 3: High Quality Weak Labeling and LLM Ensemble Verification for Multilingual Hallucination Detection

Baraa Hikal, Ahmed Nasreldin, Ali Hamdi
Faculty of Computer Science, MSA University, Egypt
{baraa.moaweya, ahmed.nasreldin, ahamdi}@msa.edu.eg

Abstract

This paper describes our submission for SemEval-2025 Task 3: Mu-SHROOM, the Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes (Vázquez et al., 2025). The task involves detecting hallucinated spans in text generated by instruction-tuned Large Language Models (LLMs) across multiple languages. Our approach combines task-specific prompt engineering with an LLM ensemble verification mechanism, where a primary model extracts hallucination spans and three independent LLMs adjudicate their validity through probability-based voting. This framework simulates the human annotation workflow used in the shared task validation and test data. Additionally, fuzzy matching refines span alignment. Our system ranked 1st in Arabic and Basque, 2nd in German, Swedish, and Finnish, and 3rd in Czech, Farsi, and French.

1 Introduction

Large Language Models (LLMs) are highly effective in generating text; however, they sometimes produce hallucinations—misleading content that is not properly grounded in the input data (Huang et al., 2025). Identifying these spans is essential for improving the reliability of LLM-generated outputs in translation, summarization, and conversational AI (Alaharju, 2024). SemEval-2025 Task 3: Mu-SHROOM tackles this challenge by presenting a multilingual benchmark for detecting character-level hallucinations across multiple languages. The task involves detecting hallucinated spans in instruction-tuned LLM outputs, presenting challenges in language diversity, annotation consistency, and accurate span localization. (Sriramanan et al., 2025)

To tackle this challenge, our system utilizes a hybrid approach that integrates task-specific prompt engineering for weak label generation with an LLM ensemble verification mechanism (Hikal et al., 2025). Our methodology follows a multi-step adjudication process in which a primary LLM identifies hallucination spans, and three independent LLMs subsequently verify their validity through a probability-based voting mechanism (Kang et al., 2024b). Additionally, we apply fuzzy matching techniques to improve the alignment of hallucination spans with ground truth annotations, thereby enhancing detection accuracy (Chaudhuri et al., 2003).

By participating in this task, we gained insights into language-specific hallucination challenges and the strengths and limitations of LLM-based verification. Certain LLMs demonstrated closer alignment with human annotations, while hallucination patterns varied significantly, particularly in morphologically rich languages where annotation ambiguity was higher (Abdelrahman, 2024). Our results indicate that ensemble verification and span refinement substantially improve hallucination detection, offering a robust approach for mitigating LLM hallucinations in multilingual settings.[1]

2 Related Work

Hallucination detection in Large Language Models (LLMs) has been studied in machine translation, text summarization, and conversational AI (Ji et al., 2023). Earlier approaches primarily relied on sentence-level classification, whereas recent research has transitioned to span-level detection for greater precision (Joshi et al., 2020). Self-consistency verification and knowledge-grounded approaches have improved hallucination identification, but many depend on external data, limiting their applicability in multilingual settings. (Mehta et al., 2024)

Multilingual NLP models struggle with hallucinations, especially in low-resource languages

[1] https://github.com/baraahekal/mu-shroom

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 989–995

where confidence scores are unreliable (Kang et al., 2024a). Morphologically rich languages introduce additional challenges due to intricate annotation inconsistencies (Tsarfaty et al., 2013). Prior work on translation-based verification has attempted to address this, but these approaches are ineffective in zero-shot scenarios (Nie, 2022).

Ensemble verification methods enhance detection accuracy by utilizing multiple models. Approaches such as multi-agent verification and cross-model adjudication have proven effective in assessing LLM outputs (Liu and Wang, 2024). Our system expands on these approaches by integrating weak label generation with an ensemble verification pipeline, while also utilizing fuzzy matching to improve span alignment. Unlike previous methods that rely on single-model hallucination detection, our approach leverages an ensemble of LLMs for adjudication, reducing model bias and improving hallucination span refinement via fuzzy matching.

3 System Overview

Our hallucination detection approach integrates task-specific prompt engineering, an LLM ensemble verification mechanism, and post-processing refinements. The system is composed of three key components: fine-tuned prompt construction, hallucination span verification through LLM ensembles, and post-processing with fuzzy matching. An overview of the full pipeline is illustrated in Figure 1.

3.1 Prompt Engineering for Weak Label Generation

We analyzed the validation dataset to extract annotator instructions and identify patterns, enabling the construction of a fine-grained prompt with few-shot examples. Iterative refinement improved extraction accuracy. Detailed prompt in Appendix A.

3.2 Selection of State-of-the-Art LLMs

Building on the insights from the Vectara LLM Report, we chose Gemini-2.0-Flash-Exp, Qwen-2.5-Max (Yang et al., 2024), GPT-4o (OpenAI, 2024), and DeepSeek-V3 (Liang and et al., 2024) as our primary models for hallucination detection. These models were selected for their strong factual accuracy and reliable generation capabilities, ensuring consistent performance across multiple languages. Figure 2 illustrates the model rankings from the report.

3.3 LLM Ensemble Verification Mechanism

Our hallucination detection pipeline utilizes a multi-stage ensemble verification process. With four selected LLMs—Gemini-2.0-Flash-Exp, Qwen-2.5-Max, GPT-4o, and DeepSeek-V3—we systematically rotate through different configurations, where one model identifies hallucinated spans while the other three act as adjudicators. This setup is inspired by the Mu-SHROOM annotation process, where multiple human annotators reviewed and adjudicated hallucination spans in the validation and test datasets. By simulating this human adjudication process with LLMs, we aim to improve label consistency and mitigate annotation biases.

Span Extractor Model (SEM) A primary LLM identifies hallucinated spans by analyzing question-answer pairs. Given a question Q and an answer A, the span extractor outputs candidate hallucination spans $S = \{s_1, s_2, \ldots, s_k\}$:

$$S = \text{LLM}_{\text{extract}}(Q, A, \text{prompt})$$

Voting Adjudicator Models (VAMs) The three remaining LLMs act as adjudicators, independently assessing each span $s_i \in S$ and assigning a hallucination probability score:

$$p_{ij} = M_j(s_i, Q), \quad p_{ij} \in [0, 1]$$

where M_j represents an adjudicator LLM.

Iterative Model Rotation: This process is repeated for all possible combinations of the four models, ensuring that each model serves as the span extractor exactly once, while the other three act as adjudicators. Given four models, this results in a total of four unique verification runs.

Consensus-Based Labeling (CBL): The final hallucination probability for each span is determined by aggregating the probabilities across all verification runs:

$$p_i = \frac{1}{N} \sum_{j=1}^{N} p_{ij}$$

where $N = 3$ is the number of adjudicator models per run. The final hallucination label is assigned using a majority voting scheme across all runs. A span is classified as hallucinated if:

$$p_i \geq 0.7$$

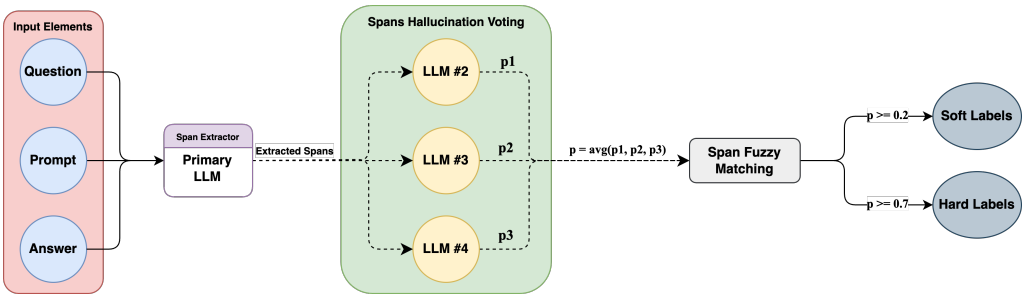

Figure 1: Overview of our hallucination detection pipeline.

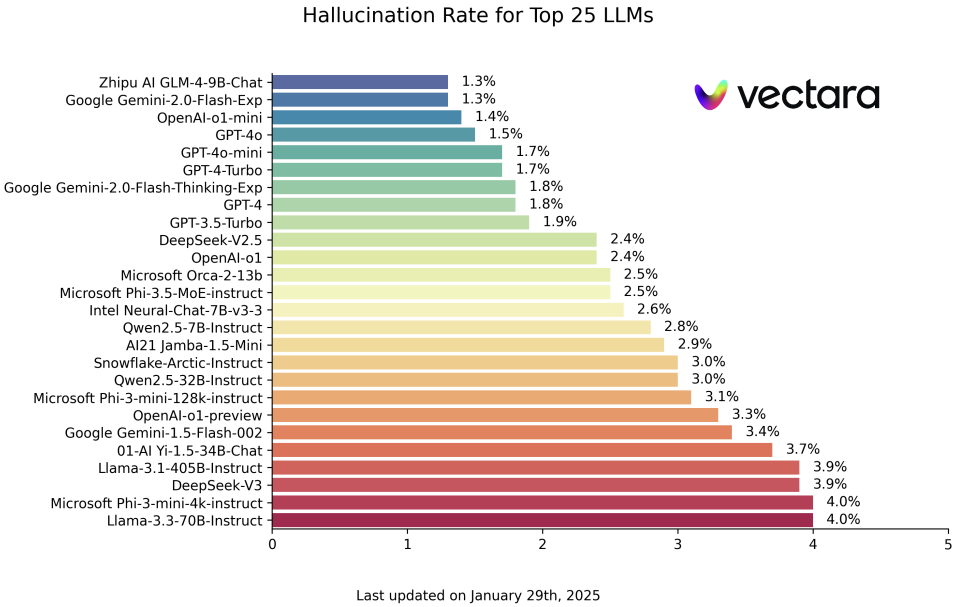

Figure 2: Performance rankings of LLMs according to the Vectara Hallucination Leaderboard (Vectara, 2024).

The threshold $\tau = 0.7$ was chosen based on empirical observations on the validation set. During tuning, we found that lower thresholds (e.g., 0.5) tended to produce too many false positives by labeling uncertain spans as hallucinations, while higher thresholds (e.g., 0.8) missed subtle hallucinations annotated by human reviewers. A threshold of 0.7 offered the best trade-off between precision and recall, and its behavior closely matched the annotation patterns observed in the Mu-SHROOM validation data (Vázquez et al., 2025).

This iterative model selection ensures robustness by reducing individual model biases and leveraging diverse perspectives from different LLMs.

3.4 Post-Processing with Fuzzy Matching

LLMs frequently introduce minor inconsistencies in span extraction, such as variations in capitalization, extra spaces, or incomplete word boundaries. To minimize these errors, we use fuzzy matching with a similarity threshold of 0.9 (partial ratio). The similarity score between a predicted span s_i and a ground truth span g_j is given by:

$$\text{Similarity}(s_i, g_j) = 1 - \frac{\text{Lev}(s_i, g_j)}{\max(|s_i|, |g_j|)}$$

where $\text{Lev}(s_i, g_j)$ is the Levenshtein distance. If $\text{Similarity}(s_i, g_j) \geq 0.9$, the span is considered correctly aligned.

3.5 Algorithm Implementation

Our pipeline follows a multi-stage verification process where a primary LLM extracts candidate hallucination spans, and three adjudicator models verify them using probability-based voting. Fuzzy matching refines span alignment, improving precision. This ensemble approach mitigates model bias and enhances robustness.

Algorithm 1 in Appendix B outlines the full process.

Lang	Question	Answer
English	What did Petra van Staveren win a gold medal for?	Petra van Stoveren won a silver medal in the 2008 Summer Olympics in Beijing, China.
French	En quelle année Childebert IV est-il devenu roi des Francs?	Childebert IV est devenu roi des Francs en 743, après la mort de son père, Charles Martel. Il a régné jusqu'à sa mort en 751.
German	Wie viele Zuschauer haben Platz im Gillette Stadium in Foxborough?	Das Gilette Stadium ist mit einer Kapazität von rund 50.000 Zuschauern das größte Stadion in der NFL.
Arabic	أين تقع إسبيرانس؟	إسبيرانس توجد في جنوب أفريقيا، بالتحديد في ولاية نايلدز في منطقة الكاليفورنيا الجنوبية. هي معروفة بمنطقة الجبال والطبيعة الخلابة.
Arabic	بأي يد كانت تلعب كيكو موريجامي؟	كيكوك موريجامي كانت تقود بالقدم اليمنى.

4 Experiments and Results

4.1 Dataset

Our system was evaluated on the Mu-SHROOM dataset from SemEval-2025 Task 3. We leveraged only the validation and test sets, using the validation set for prompt refinement and the test set for final evaluation. Unlike traditional supervised approaches, we did not use the training set for model learning. Instead, we employed prompt-based weak labeling and an ensemble verification mechanism (Smith et al., 2024). The test set contained unlabeled examples, and final system evaluation was conducted by the task organizers.

Figure 3 presents dataset examples in different languages, highlighting hallucinated spans.

4.2 Evaluation Metrics

We evaluated our system using the official Mu-SHROOM metrics:

- **Intersection-over-Union (IoU)**: Measures the overlap between predicted and gold hallucinated spans (Rezatofighi et al., 2019).
- **Probability Correlation (Corr)**: Evaluates the correlation between predicted hallucination probabilities and human annotations (Sheugh and Alizadeh, 2015).

The IoU score for a predicted span s_p and a ground truth span s_g is computed as:

$$\text{IoU} = \frac{|s_p \cap s_g|}{|s_p \cup s_g|}$$

where $|s_p \cap s_g|$ represents the overlapping characters, and $|s_p \cup s_g|$ is the total number of unique characters in both spans.

4.3 Results

As each of the four LLMs alternates as the span extractor while the others act as adjudicators, we report results for each combination. The tables [1,2,3,4] show performance across languages.

Lang	IoU Score	Probability Corr

Table 5: Best performance per language, with span extractor and final rank.

Our system outperformed other methods in Arabic and Basque, where annotation consistency was higher. However, performance dropped in English, likely due to increased annotation variability—English had up to 12 different annotators per sample (Vázquez et al., 2025) leading to inconsistencies.

4.4 Discussion

Our system effectively detects hallucinated spans across multiple languages by using ensemble verification to reduce model bias and fuzzy matching to refine span alignment. However, challenges remain—especially in dealing with annotation inconsistencies and ambiguous hallucinations, which tend to be more common in morphologically complex languages.

A key finding is that different LLMs vary in their alignment with human annotations, indicating that task-specific fine-tuning or alternative verification strategies could further improve detection accuracy. Additionally, improving span refinement techniques beyond fuzzy matching may reduce boundary mismatches and improve character-level precision.

5 Conclusion

We presented our system for *SemEval-2025 Task 3: Mu-SHROOM*, focusing on hallucinated span detection in LLM-generated text across multiple languages. Our approach combines prompt-engineered weak label generation with an LLM ensemble verification mechanism, demonstrating strong performance in multilingual hallucination detection.

Our results confirm the effectiveness of ensemble-based adjudication, ranking among the top systems in several languages. However, challenges such as annotation variability and morphological complexity highlight areas for further refinement.

Future work could focus on integrating external knowledge for hallucination verification, fine-tuning LLMs to better align with human annotations, and refining span localization techniques to enhance character-level precision. These improvements could further advance hallucination detection in multilingual NLP systems.

A Appendix: Instruction Prompt template for Extraction and Annotation

Question & Answer Pair

i) Question: `model-input`

ii) Answer: `model-output-text`

Task Description

`You are a professional annotator and {entry[lang]} linguistic expert. Your job is to detect and extract hallucination spans from the provided answer compared to the question.`

Exact Span Matching

`Extract spans word-for-word and character-for-character exactly as they appear in the answer. Ensure perfect alignment, including punctuation, capitalization, and spacing. If a span is partially supported, only extract the unsupported portion. Preserve original numeral formats: Persian/Arabic numerals must remain in their native script.`

Minimal Spans

`Select the smallest possible spans that, when removed, completely eliminate the hallucination. Prioritize precision: Avoid extracting entire sentences if a shorter phrase accurately captures the hallucination. Ensure the extracted span exclusively contains hallucinated content without removing valid information.`

Hallucination Definition

`Any phrase, entity, number, or fact that is not supported by the question. Any exaggeration or overly specific detail absent in the question. Incorrect names, locations, numbers, dates, or causes. In yes/no questions, unsupported answers (e.g., "Yes", "No") and speculative details.`

Soft and Hard Labels

`Assign probabilities [0.0 - 1.0] for soft labels based on hallucination confidence. Include spans with` ≥ 0.7 `probability in hard labels.`

B Appendix: Our Proposed Framework

Algorithm 1 Hallucination Detection Pipeline

Require: Question Q, Answer A, LLM ensemble $\{M_1, M_2, M_3\}$, threshold $\tau = 0.7$
Ensure: Set of hallucinated spans S^*

$S \leftarrow \text{LLM}_{\text{extract}}(A, Q, \text{prompt})$
for each $s_i \in S$ **do**
  Compute hallucination scores:
    $p_{ij} = M_j(s_i, Q), \quad \forall M_j$
  Compute final probability:
    $p_i = \frac{1}{N} \sum_{j=1}^{N} p_{ij}$
  if $p_i \geq \tau$ **then**
    Add hallucinated span to refined set:
      $S' \leftarrow S' \cup \{s_i\}$
  end if
end for
Apply fuzzy matching for span refinement:
  $S^* \leftarrow \text{FuzzyMatch}(S', \text{Ground Truth}, 0.9)$
Return S^*

SRCB at SemEval-2025 Task 9: LLM Finetuning Approach based on External Attention Mechanism in The Food Hazard Detection

Abstract

This paper reports on the performance of SRCB's system in SemEval-2025 Task 9: The Food Hazard Detection Challenge. We develop a system in the form of a pipeline consisting of two parts: 1. Candidate Recall Module, which selects the most probable correct labels from a large number of labels based on the BERT model; 2. LLM Prediction Module, which is used to generate the final prediction based on Large Language Models(LLM). Additionally, to address the issue of long prompts caused by an excessive number of labels, we propose a model architecture using the external attention mechanism to reduce resource consumption and improve performance. Our submission achieves the first place with the macro-F1 score of 54.73 on Sub-Task 2 and the third place with the macro-F1 score of 80.39 on Sub-Task 1. Our system is released at https://github.com/Doraxgui/Document_Attention.

1 Introduction

SemEval is a series of international research workshops aimed at advancing the field of natural language processing(NLP), with a particular focus on semantic analysis techniques and the creation of high-quality annotated datasets to address various complex challenges in natural language semantics. Each year, the workshop organizes a series of shared tasks, offering a platform for the presentation and comparative evaluation of computational semantic analysis systems developed by different teams. The Food Hazard Detection Task (Randl et al., 2025) comprises two sub-tasks: Sub-Task 1 focuses on classifying the type of hazard and product, while Sub-Task 2 aims to classify the exact hazard and product.

The challenges of this task include: 1) a heavily imbalanced class distribution, and 2) a large number of labels: 10 types of hazards and 22 types of products in Sub-Task 1, and 128 exact hazards and 1,142 exact products in Sub-Task 2. Constructing prompts with such a large number of labels for LLM-based response generation leads to high resource consumption and degraded performance.

For challenge 1, our proposed solution employs Large Language Models(LLMs). As LLMs demonstrate strong performance on data augmentation (Cai et al., 2023), particularly for imbalanced data. Therefore, we use LLM, specifically Qwen2.5-72B-Instruct (Yang et al., 2024), to perform data augmentation and deal with the imbalanced class distribution. For labels with limited training samples, we prompt the LLM to generate new samples based on the content of these samples, the semantic meaning of the label, and the text format of a randomly selected training sample. For challenge 2, we propose a novel model architecture named the **External Attention Mechanism**, which is used to combine input embeddings with label embeddings to inject label information into the input, as opposed to the conventional approach of concatenating label information in text form and relying on the self-attention mechanism. This innovative structure treats input and labels as two separate parts, reducing the length of prompts and leading to significant resource savings and performance improvements.

Our system is a pipeline consisting of two parts: **Candidate Recall Module** and **LLM Prediction Module**. The Candidate Recall Module is mainly composed of a BERT model with a classifier added at the top, which is used to filter all labels and keep those candidate labels which have high probability of correctness. The purpose of this module is to reduce the number of all candidate labels and help subsequent modules reduce error options and improve performance. The LLM Prediction Module first obtains the hidden states of the input and the hidden states of all labels, and then aligns them through the **External Attention**

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 996–1003

Mechanism (alternatively called Label Attention Module) to generate a new representation. Finally, the system uses this new representation to predict hazards and products in the form of Next Token Prediction task. The purpose of this module is to allow the hidden states of the input to calculate the attention mechanism with labels **externally**, rather than splicing labels directly into the input in the form of text and using Self-Attention Mechanism of LLM. In this way, the length of the LLM's input prompts can be significantly reduced. Moreover, in the External Attention Mechanism, all labels are treated equally, and the potential impact of the labels' order will not be introduced, as the hidden states of labels are calculated in parallel.

2 Background

The Food Hazard Detection Corpus, introduced in (Randl et al., 2025), includes the professional manually labeled titles and full texts on food recall collected from official food agency websites, and the language is English. Figure 1 shows an example of training data, our analysis reveals that relying solely on the title or text results in incomplete information extraction. Therefore, we combine both features to enhance the performance of the models.

(Edwards and Camacho-Collados, 2024) states that optimizing the top-layer classifier is ineffective for imbalanced class distribution. (Radford et al., 2019) introduces that the text generation mode based on Autoregressive LLM can be used as a better alternative method. (Plaza-del Arco et al., 2023) claims that LLM can adapt to different tasks without a large number of training samples due to their ability of understanding natural language instructions. Based on these studies, we focus mainly on LLM instruction tuning in our system, finetuning LLM to predict hazards and products.

3 Data

3.1 Data Processing

Our system concatenates the title and text into a single text format, followed by data cleaning. The cleaning process includes handling spaces and line breaks, removing duplicate natural segments, and converting characters into lowercase. Additionally, the system truncates the cleaned data to a specified maximum token length. For the Candidate Recall Module, the maximum token length is set to 512, while for the LLM Prediction Module, it is set to 1,024 (more than 90% of the training data tokens fall within this limit).

3.2 Data Augmentation

To address the class imbalance problem, we refer to the oversampling technique (Gosain and Sardana, 2017). For labels with fewer than 50 training samples (a threshold defined by ourselves), we use LLM, specifically the Qwen2.5-72B-Instruct, for data augmentation. Given a sample, we instruct the LLM to generate a new sample by combining the meaning of the given sample, the label of the given sample, and the writing style of a randomly selected sample from the training data. An example of our data augmentation is provided in A. Compared to repeated oversampling, this method is better aligned with the overall data distribution and enhances diversity.

4 System Description

For each classification task (including the classification of 1.type of hazard, 2.type of product, 3.exact hazard, 4.exact product), we use a unified pipeline consisting of two modules: **Candidate Recall Module** and **LLM Prediction Module**.

4.1 Candidate Recall Module

Our preliminary classification experiments with RoBERTa-base (Liu et al., 2019) indicate that while the macro-F1 score of the model is suboptimal, it achieves an impressive Recall score of over 95 for each label. This suggests that, given a sample, the BERT-like model will predict some candidate labels. These candidate labels: 1.always contain the gold label; 2.are much less than all labels, especially for Sub-Task 2, thereby mitigating the challenges posed by the large number of labels. In order to make full use of this feature, we add the Candidate Recall Module to the front of the LLM Prediction Module.

In the Candidate Recall Module, we adopt the one-vs-all approach (Galar et al., 2011), constructing a binary classifier on the top of BERT(Kenton and Toutanova, 2019) architecture for each label to predict the probability of a sample belonging to that label. For instance, we construct 128 classifiers for Sub-Task 2's exact hazards and 1,142 classifiers for Sub-Task 2's exact products. In our system, labels predicted by the classifier with a probability greater than 50% will be considered as

Input	title	Recall Notification: FSIS-024-94
	text	··· Product: SMOKED CHICKEN SAUSAGE ··· Problem: BACTERIA...
Sub-Task 1 output	hazard-category	biological
	product-category	meat, egg and dairy products
Sub-Task 2 output	hazard	listeria monocytogenes
	product	smoked sausage

Figure 1: Data sample

candidate labels. During training, negative samples are randomly selected from other labels in the training data. The Candidate Recall Module outputs a set of candidate labels. Compared to considering all labels, this approach significantly reduces the label space while maintaining a high probability of including gold labels.

4.2 LLM Prediction Module

In the LLM Prediction Module, candidate labels are incorporated into the processed data in the form of text. And our system needs to select a LLM as **Reference LLM** and another LLM as **Target LLM**. Reference LLM is used to process all labels, and Target LLM is used to be finetuned to process the input and generate the final prediction.

As depicted in Figure 2, the LLM Prediction Module is comprised of two modules: **Label Embedding Generation Module** and **Label Attention Module**. The Label Embedding Generation Module is used to generate the embeddings for all labels using Reference LLM, which can be considered as using Reference LLM to understand and generate the meaning of all labels. The Label Attention Module is designed to integrate the embeddings of processed data generated by Target LLM and the embeddings of all labels generated by Reference LLM. This module aligns the embeddings from Target LLM with those from Reference LLM, injecting all label information into the embeddings derived from Target LLM.

Due to the large number of labels, constructing prompts as a multiple choice task, where the LLM selects an option from a list candidate labels, is infeasible. Instead, we use External Attention Mechanism (alternatively called Label Attention Model) to combine the information of all labels while keeping the prompts concise, and we formulate the task as a Next Token Prediction task, where the LLM directly generates the label content. After instruction tuning, LLM can generate responses that can be parsed simply and mapped to those labels. Moreover, our designed structure is more suitable for traditional Next Token Prediction task, rather than the classification task.

4.2.1 Label Embedding Generation Module

Reference LLM generates embeddings (these embeddings are the hidden states which are used to map the entire LLM token vocabulary) for each token in all labels, which will be precomputed and stored to avoid real-time computation. The dimension of the hidden states (embeddings) would be (Length, Size), where **Length** is the number of tokens in the label, and **Size** is the size of hidden states. The hidden states of all labels are concatenated to form the ***Reference***, with dimensions (Number, MaxLength, Size), where **Number** is the total number of labels, **MaxLength** is the maximum token count across all labels, and **Size** is the size of hidden states. Zero-padding is applied for labels with fewer than MaxLength tokens.

For instance, for the exact hazards classification of Sub-Task 2, there are 128 labels, assuming that there are 5 tokens in each label. Input all the content of labels into Reference LLM and it will generate the ***Reference*** with the dimension of (128, 5, Size), where **Size** is the size of the hidden states. ***Reference*** will be stored locally for further calling, it contains hidden states (embeddings) of all tokens for all labels in one classification task.

The parameters of Reference LLM are frozen and the Reference LLM does not participate in training or inference, only the ***Reference*** will. And we choose Qwen2.5-14B-Base (Yang et al., 2024) as the Reference LLM.

This module aims to generate the understanding for all labels, which is stored as ***Reference***.

4.2.2 Label Attention Module

Given the processed data added with candidate labels, Target LLM generates its embeddings (the hidden states which are used to map the entire LLM token vocabulary), named as ***Query***. The dimension of ***Query*** is (QueryLength, Size), where

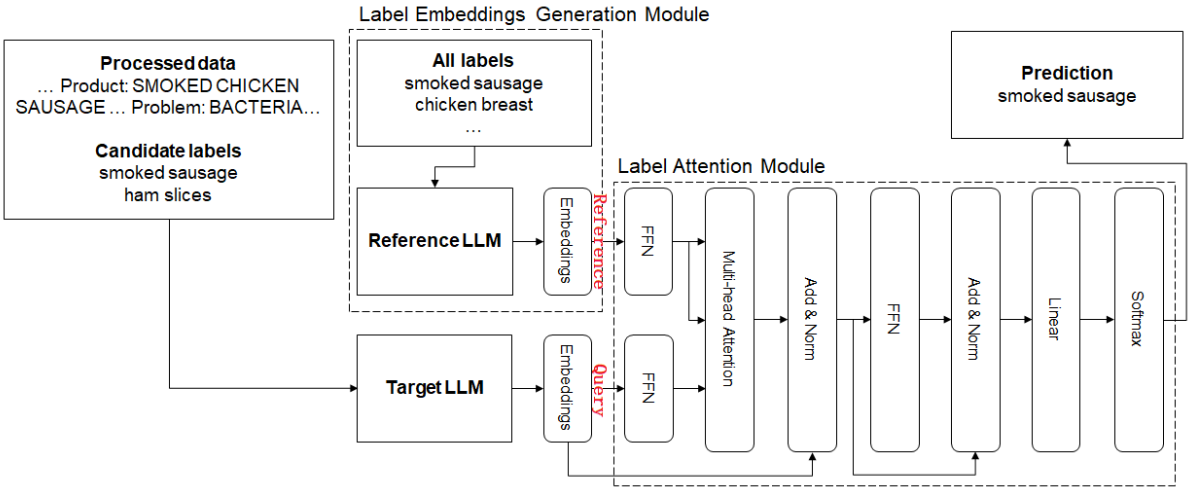

Figure 2: LLM Prediction Module

the **QueryLength** is the number of tokens in the processed data and **Size** is the size of hidden states.

For instance, if one processed data has 100 tokens, the dimension of ***Query*** would be (100, Size), where **Size** is the size of hidden states.

The parameters of Target LLM and the parameters in Label Attention Module need to be trained in training process. We choose Qwen2.5-14B-Base as the Target LLM (the same as the Reference LLM).

For alignment between ***Query*** and ***Reference***, we refer to the classic attention mechanism (Vaswani et al., 2017), treating ***Query*** as queries (Q) and ***Reference*** as keys (K) and values (V). We add a feedforward neural network (FFN) to each of them. In multi-head attention part, we set the number of attention heads to 12 and use the classic algorithm of attention mechanism as follow:

$$attention = Softmax(\frac{QK^T}{\sqrt{d_k}})V \qquad (1)$$

where **Q** is the result of FFN on ***Query*** and **K**, **V** are the results of FFN on ***Reference***. d_k is the dimension of **K**.

The output of multi-head attention exhibits significant deviation from the original Target LLM embeddings, which hinders model convergence if used directly in subsequent computations. Consequently, to reduce the burden of model training, we incorporate the embedding generated by Target LLM (***Query***) into the output of multi-head attention via a residual connection (He et al., 2016), followed by layer normalization (Ba et al., 2016) (the add&norm block). This approach consistently demonstrates significant performance improvements. Next, we simulate the structure of the Attention Mechanism from Transformers by incorporating an FFN, a residual connection followed by layer normalization. The Label Attention Module will output a new hidden state that has the same dimension with ***Query***.

During finetuning, we define the task objective as Next Token Prediction using the new hidden state of the output, rather than directly linear classification because text generation, through its inherent semantic understanding, can more effectively mitigate the impact of imbalanced class distribution. Specifically, when constructing the processed data, we add its gold label to the end of the data in the form of text. Because of the unidirectional attention mechanism of the decoder structure of LLM, it will not influence the calculation of External Attention Mechanism mentioned before. We add a linear layer to map the result embeddings combined by ***Query*** and ***Reference*** into the vocabulary space of LLM to predict the tokens of the gold label. When finetuning with the task objective of Next Token Prediction, we mask whole processed data except for the tokens of gold label we added at the end of the data, aiming to finetune the model only on the label prediction.

Furthermore, the Label Attention Module can resolve with the influence caused by the sequence of options. For instance, *prompt: Which one is better, A or B?* and *prompt: Which one is better, B or A?* generally have different answers, because of the inherent mechanism of LLM. However, the Label Attention Module addresses this is-

sue through matrix calculation. Unlike traditional approaches that rely on position embeddings, the matrix-based mechanism in the Label Attention Module does not involve explicit positional information, which treats each option fairly.

5 Experimental Setup

5.1 Data Splitting

For the Candidate Recall Module, we employ a 5-fold cross-validation, using 4 folds for training and the remaining fold for validation. For the LLM Prediction Module, due to the computing resource requirements (e.g. GPU memory and training time), we directly use the entire training dataset for training and the actual validation set for evaluation. Unlike smaller models such as BERT, LLM is less prone to overfitting during text generation tasks, which justifies this approach.

5.2 Hyperparameters

For the Candidate Recall Module, we select RoBERTa-base and DeBERTaV3-base (He et al., 2021) as base models. The learning rate is set to 1e-5 and the batch size is set to 4 with 4 negative samples. We use the AdamW optimizer and employ early stopping to prevent overfitting. For the LLM Prediction Module, we select Qwen2.5-14B-Base as the base model. The learning rate is set to 7e-6 and the effective batch size is 64 (achieved through gradient accumulation). We use the AdamW optimizer and train for 3 epochs.

5.3 Evaluation Measures

For Sub-Task 1, the measure is the average macro-F1 score of the type of hazard and product, which focuses more on the part of hazard. For Sub-Task 2, the measure calculates the average macro-F1 score of the exact of hazard and product, which also focuses on the part of hazard. In our system, the Candidate Recall Module is evaluated using the Recall score, which measures the ability to recall gold candidate label, counting whether the gold label is among the predicted candidate labels. The LLM Prediction Module is evaluated using the macro-F1 score for both hazard and product.

6 Results

6.1 Experiment Results

Candidate Recall Module The validation results on the cross-validation set are illustrated in Table 1, it indicates the average score of 5-fold cross-validation.

Both RoBERTa-base and DeBERTaV3-base achieve high Recall scores, exceeding 95, with DeBERTaV3-base slightly outperforming RoBERTa-base.

LLM Prediction Module The validation results on the actual validation set are illustrated in Table 2. All methods involve LLM predicting labels through text generation, differing in prompt construction and model structure. Method LLM inputs processed data without any labels into LLM. Method LLM+AL constructs prompts with processed data and all candidate labels. Method LLM+FL uses processed data and filtered candidate labels from Candidate Recall Module. Method LLM+FL+LPM incorporates LLM Prediction Module with processed data and filtered candidate labels.

Each value represents the macro-F1 score for each classification task, and the time column indicates the time consumption in hours. The reason why different methods show huge different time consumption is that some methods do not need a lot of memory, thus we increase their batch size and decrease their gradient accumulation during training. Memory consumption **mainly** depends on the length of prompt, therefore only the time consumption of Sub-Task 2 is evaluated (total amount of time consumption on exact hazard and exact product), as the time consumption of Sub-Task 1 is approximately the same.

Compared to LLM and LLM+AL, LLM+FL shows improvements in most tasks. With LPM, LLM+FL+LPM further enhances performance. Both using all labels, the time consumption of LLM+FL+LPM reduces compared to LLM+AL.

6.2 Test Results

We employ the majority voting approach for model ensemble, the differences between candidate models include adjustments to the LLM Prediction Module's structure, variations in the types of LLM and changes in Candidate Recall Module's models, and so on.

Our system achieves the highest macro-F1 score for Sub-Task 2 and a high score for Sub-Task 1. Table 2 details our result on the test set, showing performance consistent with the validation set except for the type of hazard, indicating potential overfitting.

	Sub-Task 1		Sub-Task 2	
PLM	type of hazard	type of product	exact hazard	exact product
RoBERTa-base	97.89	95.71	98.23	96.40
DeBERTaV3-base	**98.70**	**96.67**	**98.80**	**97.46**

Table 1: The recall scores on average validation (5-folds) set. PLM indicates Pretrained Language Model

Validation	Sub-Task 1		Sub-Task 2		
Method	type of hazard	type of product	exact hazard	exact product	time
LLM	80.47	75.19	68.52	38.14	**2**
LLM + AL	83.82	74.50	64.97	38.11	9
LLM + FL	82.44	81.78	67.64	39.64	4

6.3 Further Work

Several areas warrant further exploration and improvement: a) Optimizing the embedding generation method in the Label Embedding Generation Module. b) Using a different or larger Reference LLM in the LLM Prediction Module, with varying FFN sizes for mapping. c) Exploring the full use of the Label Attention Module by increasing the number of attention layers or adjusting the structure, and so on. In the future, we plan to explore and improve the LLM Prediction Module to achieve a more robust and efficient structure.

7 Conclusion

In this work, we propose a system consisting of the Candidate Recall Module and the Label Prediction Module. We identify that the primary cause of high training time consumption is the long prompt. To address this, we design the Candidate Recall Module to reduce the length of prompt in terms of system structure. And we design the Label Prediction Module to further minimize the impact of the prompt length using the External Attention Mechanism in terms of algorithm. Additionally, the Label Prediction Module also addresses the problem of the option sequence. With the help of other techniques like data augmentation and pipeline optimization, our system achieves the highest score for Sub-Task 2, and a competitive score for Sub-Task 1. For future work, we plan to explore advanced architectures to optimize the LLM Prediction Module.

8 Limitation

The LLM Prediction Module enhances performance and speed, but increases storage consumption. The results of the Label Embedding Generation Module are either generated in real time using the Reference LLM or pregenerated offline and stored locally, both imposing memory or storage burdens. Additionally, the LLM Prediction Module takes more time to train.

Abstract

The emotion recognition task has become increasingly popular as it has a wide range of applications in many fields, such as mental health, product management, and population mood state monitoring. SemEval 2025 Task 11 Track A framed the emotion recognition problem as a multi-label classification task. This paper presents our proposed system submissions in the following languages: English, Algerian and Moroccan Arabic, Brazilian and Mozambican Portuguese, German, Spanish, Nigerian-Pidgin, Russian, and Swedish. Here, we compare the emotion-detecting abilities of generative and discriminative pre-trained language models, exploring multiple approaches, including curriculum learning, in-context learning, and instruction and few-shot fine-tuning. We also propose an extended architecture method with a feature fusion technique enriched with emotion scores and a self-attention mechanism. We find that BERT-based models fine-tuned on data of a corresponding language achieve the best results across multiple languages for multi-label text-based emotion classification, outperforming both baseline and generative models.

1 Introduction

The task of emotion recognition involves identifying emotions in text or speech. Track A of SemEval 2025 Task 11 (Muhammad et al., 2025b) focuses on multi-label emotion recognition in social media texts across several languages. Following the definition of the universal emotions introduced by Ekman (1992), the task involves classifying the texts for the following six basic emotions: Anger, Disgust, Fear, Joy, Sadness, and Surprise. In this paper, we present our work submitted to the shared task for the following languages: English, Algerian and Moroccan Arabic, Brazilian and Mozambican Portuguese, German, Spanish, Nigerian-Pidgin, Russian, and Swedish.

Large language models (LLMs) have achieved remarkable results on a wide range of applications (Chang et al., 2024). As these models become increasingly integrated into real-world settings covering diverse domains, LLMs are expected to exhibit human-like behaviour for proficient social interactions. This served as a motivation to include LLMs in our investigated approaches, comparing their performance to discriminative pre-trained language models (PLMs). Accordingly, our approaches fall under two main tasks, *Classification* and *Generation*, as we work with both discriminative and generative PLMs. We explore a wide range of techniques, including zero- and few-shot prompting, as well as fine-tuning and few-shot fine-tuning. We also propose a novel approach to extending the BERT architecture with feature fusion and self-attention, incorporating token-level emotion scores statistically calculated on the train set.

In our conducted experiments, non-causal models demonstrated superiority over causal ones. We also observed that imbalanced data has a high impact on a model's performance, notably biasing outcomes toward the detection of 'Fear' in the English setup. Our code is available online.[1]

2 Related Work

Emotion Recognition. Strapparava and Mihalcea (2007) and Mohammad et al. (2018) addressed emotion recognition in the SemEval challenges, tackling tasks such as affective text exploration, bridging emotional and sentiment aspects, and inferring speakers' emotions from tweets. More recently, Zhang et al. (2023) examined an architecture with discourse- and speaker-aware modules within graph attention networks, which outperformed the state-of-the-art (SOTA) in the task of Emotion Recognition in Conversations.

Nag et al. (2023) explored several deep learning

[1] https://github.com/profii/semeval25_task11

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1004–1014

techniques to address different emotional intelligence (EI) tasks, including emotion recognition. Zhao et al. (2024) tackled the issue of catastrophic forgetting in LLMs, which was previously reported by Luo et al. (2023) when integrating EI.

PLMs have proven to be highly effective on various NLP benchmarks (Sun et al., 2019; Devlin et al., 2019; OpenAI, 2023; Nikishina et al., 2023; Chowdhery et al., 2023; Demidova et al., 2024; etc.). With respect to the current task, we considered the following approaches:

Fine-tuning. Recent advances have been made in fine-tuning approaches by adapting PLMs with minimal parameter updates. For example, PEFT (Ding et al., 2023) and LoRA (Hu et al., 2022) techniques significantly reduce the computational requirements while maintaining high performance.

In-Context Learning. Zero- and few-shot ICL offer the advantage of not modifying the model parameters. Dong et al. (2024)'s survey provides a taxonomy of ICL that demonstrates various ways to apply pre-trained language models in NLP tasks. Brown et al. (2020) highlight the effectiveness of few-shot ICL reaching SOTA performance.

Few-shot Fine-tuning. Mosbach et al. (2023) presented a method of few-shot fine-tuning that is between ICL and full fine-tuning. Their approach involves using a small number of labelled examples in the input during the fine-tuning stage (resembling few-shot learning).

Feature Fusion with Self-Attention. The feature fusion (FF) method implies a combination of multiple feature representations, such as embeddings. Recent works (Yang et al., 2020, 2024) showed implementations of FF under self-attention that enhanced model performance in Named Entity Recognition. Santoso et al. (2021) explored the combination of self-attention and word-level features that improve Speech Emotion Recognition.

3 Methodology

In this section, we describe the system overview by examining both groups of approaches for classification and generation tasks in detail.

3.1 Data

The organizers of the SemEval 2025 Task 11 (Muhammad et al., 2025a) provided 28 datasets across different languages, taking as resources news, social media, annotated speeches, translations from literature, and examples written by natives and augmented with machine-generated content. To simplify the annotation process, the authors chose the following six labels: Anger, Disgust, Fear, Joy, Sadness, and Surprise. They did not include Disgust in the English dataset due to the insufficient number of class elements. In our work, we only use the training dataset from Muhammad et al. (2025a) to train our models, while the development set is used for evaluation. Table 4 in Appendix A.1 provides an analysis of the task's datasets. As further training data, we also considered GoEmotions (Demszky et al., 2020) and MELD (Poria et al., 2019), but early experiments showed that they did not offer any improvement, which we believe is because their annotations represent speakers' emotions instead of perceived ones.

As one utterance can evoke several emotions, we analyzed all emotion combinations occurring in the data. We provide further analysis for English in Appendix A.1.2, showing emotions co-occurrence.

Preprocessing. The informal nature of the social media domain presents noisy content such as hashtags, mentions, emojis, elongated words, informal abbreviations, and various punctuation styles. While these elements can help in the expression of emotions, they can also complicate the tokenization process. We believe that preprocessing can help improve the consistency of textual representations for emotion classification. To clean our data, we perform the following preprocessing steps: standardizing similar emojis to a set of basic Ekman emotions (Anger: ':@', Fear: 'D:', Joy: ':)', Sadness: ':(', Surprise: ':o', Neutral: ':|'), as well as removing elements such as URLs, user mentions and hashtags[2]. We evaluated the effectiveness of these steps across a subset of the languages, revealing a benefit to English only.

3.2 Models

We explore the use of non-causal and causal PLMs, thus organizing our approaches into two main categories: Classification and Generative.

3.2.1 Baselines

In the monolingual setup, organizers of Muhammad et al. (2025a) experimented with chain-of-thought prompting on various LLMs (Qwen2.5-

[2]The preprocessing script is provided in the GitHub repository: https://github.com/profii/semeval25_task11

72B, Dolly-v2-12B, Llama-3.3-70B, Mixtral-8x7B, and DeepSeek-R1-70B) and fine-tuning on multilingual language models (LaBSE, RemBERT, XLM-R, mBERT, and mDeBERTa).

3.2.2 Classification Models

We utilize RoBERTa-large for the English setup (Liu et al., 2019) and XLM-RoBERTa-large for the other languages (Conneau et al., 2020). These models are optimized for contextual relationship understanding and include an attention mechanism, making them suitable for text classification tasks.

Fine-tuning. We fine-tune non-causal models, where the hyper-parameter values are specified in Appendix A.2.1.

Curriculum Learning. Curriculum Learning is a fine-tuning approach designed to improve model performance by starting with easier examples and progressively introducing more complex ones. We apply this strategy by beginning with neutral utterances, followed by examples containing only one emotion, and gradually increasing the complexity to sentences having multiple emotions.

Feature Fusion with Self-Attention. Motivated by the work of Santoso et al. (2021), we integrate emotional features to enhance the model's ability to capture nuanced emotional contexts and assign dynamic weights. This extension recognizes that different tokens hold various levels of emotional relevance. We apply two transformations to the model architecture during fine-tuning: additional two layers (self-attention and linear classifier) and the token-level feature fusion with emotion scores, as shown in Figure 1. The self-attention layer takes as input token-level emotion-weighted embeddings that are concatenated to the embeddings produced by the previous layer. The emotion-weighted embedding is equal to the number of emotion classes, where each element contains an emotion score, representing a probability of that emotion being associated with that input token. In order to calculate the emotion scores, we first tokenize the sentences in the training data using the relevant non-causal model for each language. For each token, the emotion score is based on the number of occurrences of that token (e.g. 'tears') in sentences with a certain emotion label (e.g. Fear, Sadness), divided by the total occurrences of this token across all emotions.[3]

[3]Our emotion score is calculated on the training data.

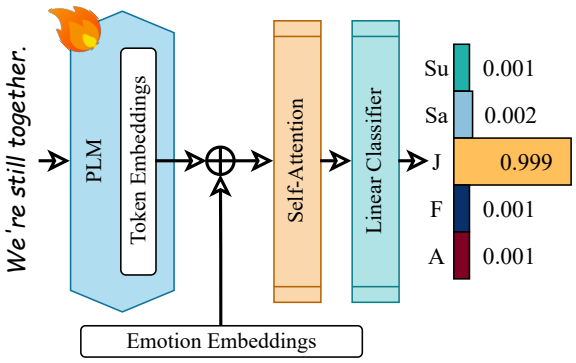

Figure 1: Scheme of the Feature Fusion with Self-Attention (FFSA) approach, where $\oplus$ denotes the concatenation operator and *A, F, J, Sa*, and *Su* represent Anger, Fear, Joy, Sadness and Surprise, respectively.

Figure 2 provides an example of an emotion score mapping.

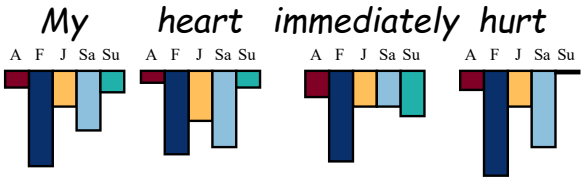

Figure 2: Example of Emotion Score mapping, where *A, F, J, Sa*, and *Su* represent Anger, Fear, Joy, Sadness and Surprise, respectively.

3.2.3 Generative Models

We utilize the following LLMs: Meta-Llama-3-8B-Instruct (Llama-3) (Grattafiori et al., 2024), GPT-4o-mini (OpenAI, 2024), and Qwen2.5-32B-Instruct (Qwen2.5) (Qwen, 2025). Our choice of causal models is based on preliminary experiments that we conducted, where these LLMs outperformed others.[4] The superiority of these models has also been confirmed by Wang et al. (2023), where they demonstrated both high EI and strong performance on general tasks.

We explore the use of in-context learning and fine-tuning. For both approaches, the inference part consists of generating output and deducing the emotion. Table 7 in Appendix A.2.2 demonstrates the hyper-parameters for the inference mode, where we opted for less creative and more consistent responses. As generative models can provide

[4]We also experimented with Mistral-7B-v0.1, Qwen2.5-14B-Instruct, Phi-3-medium-4k-instruct, Meta-Llama-3-8B, deepseek-ai/deepseek-llm-7b-chat, Gemma-2-9b, Llama-3.1-8B-Instruct, and Vicuna-7b-v1.5.

Language	Model	BERT-F1	XLM-F1	Llama-F1
English	RoBERTa-large	**78.9**	76.5	73.0
Algerian Arabic	MarBERT	**58.5**	46.8	39.3
Moroccan Arabic	bert-base-arabic-camelbert-msa	**56.3**	51.9	34.4
Brazilian Portuguese	bert-base-portuguese-cased-large	53.1	**53.4**	37.9
Mozambican Portuguese	bert-base-portuguese-cased-large	**54.8**	52.0	32.0
German	gbert-large	68.2	**69.9**	42.2
Nigerian-Pidgin	-	-	**58.0**	34.5
Russian	RuBERT-large	83.9	**85.4**	49.9
Spanish	RoBERTa-BNE-base	77.0	**77.2**	54.5
Swedish	bert-base-swedish-cased	**50.8**	23.5	37.3

Table 1: Best results on the **development set**, showing the F1-Macro scores for BERT-based language-specific models (*BERT-F1*), XLM-R (*XLM-F1*), and Llama-3-8B-Instruct (*Llama-F1*). Best models are bolded.

final responses outside of the given set of emotions, we apply a post-processing step to map the model output to the six Ekman emotions, using the GoEmotions mapping (Demszky et al., 2020) provided in Table 8 in Appendix A.3.

In-Context Learning. In the context of limited GPU memory, 8-bit quantization with bitsandbytes[5] allowed us to experiment with multiple prompt templates. In Appendix A.4, we demonstrate the two most effective prompts for English that we subsequently use throughout all our ICL experiments, as well as the examples we used for few-shot learning.[6]

Instruction Fine-tuning. We perform instruction fine-tuning on Llama-3. Due to computational limitations, experiments are conducted with 4-bit quantization and the LoRA adapter. Fine-tuning hyper-parameters are also specified in Appendix A.2.2. To achieve higher performance, we additionally implemented few-shot fine-tuning.

3.3 Evaluation Metrics

We report macro-averaged F1 score, which is the main metric used for evaluation by the shared task organizers (Muhammad et al., 2025a). F1-Macro is defined as the (unweighted) average of F1 scores calculated separately for each label.

4 Results

For discriminative models, we use BERT-based language-specific models as well as XLM-R, covering fine-tuning, FFSA, and CL across all languages. For generative models, we conduct preliminary experiments on the English language, where the best setup was found to be using Llama-3 along with prompt#1 (see Appendix A.4). In Table 2, we present the best results across different generative models for English. Due to resources constraints for experimenting with other languages, we apply this best-performing setting across all languages. Table 1 presents the best results for language-specific BERT models, XLM-R, and Llama-3 on the development set for each language. In Appendix A.5, we elaborate on experimental results on the English setup.

Model	Prompt #	F1-Macro
Llama-3	1	**73.0**
GPT-4o-mini	2	69.8
Qwen2.5	2	69.1

Table 2: Best results on Prompting for the English development set, where *Llama-3* is Meta-Llama-3-8B-Instruct, *Qwen2.5* - Qwen/Qwen2.5-32B-Instruct.

In Table 3, we present the results on the test set. We demonstrate a comparison between our results, the best scores from Muhammad et al. (2025a), and the highest F1-Macro in competition across different languages.

Our results show that discriminative models outperformed Llama-3 across all languages. Among discriminative models, we find that XLM-R is more consistent across multiple languages except for Arabic and Swedish, considering the difference between XLM-R and language-specific BERTs.

5 Discussion

In order to further understand our experiment results on the English development set, we analysed confusion matrices of models with fine-tuning and Feature Fusion with Self-Attention (FFSA) approaches (see Figures 7a and 7b in Appendix A.6.1). We observed that both models are overfitting by choosing 'Fear' in most of the con-

[5] https://huggingface.co/docs/bitsandbytes/

[6] For all prompt-related experiments, the model was prompted in English with a language-specific example.

Language	Model	Approach	Baseline*	F1-Macro†	BEST‡	Δ
Russian	XLM-R-large	Fine-tuning	83.8	**88.7**	90.9	2.2
Mozambican Portuguese	portuguese-large	Curriculum learning	45.9	**50.7**	54.8	4.1
Moroccan Arabic	camelbert-msa	Fine-tuning	52.8	**57.8**	62.9	5.1
English	RoBERTa-large	FFSA	70.8	**76.2**	82.3	6.1
Spanish	XLM-R-large	Fine-tuning	77.4	**77.8**	84.9	7.1
Swedish	swedish	Curriculum learning	52.0	**55.3**	62.6	7.3
Nigerian-Pidgin	XLM-R-large	Fine-tuning	55.5	**60.0**	67.4	7.4
German	gbert-large	Fine-tuning	64.2	**66.0**	74.0	8.0
Algerian Arabic	MarBERT	Fine-tuning	55.8	**57.9**	66.9	9.0
Brazilian Portuguese	portuguese-large	FFSA	51.6	**54.7**	68.3	13.6

Table 3: We report the best results we achieve on the **test set** across languages. We present the best result of baselines from Muhammad et al. (2025a) ($\star$), our results ($\dagger$), the highest F1-Macro in competition ($\ddagger$), and the difference between the best in competition and our score (Δ). We use the following abbreviations: *FFSA* for feature fusion with self-attention approach, *camelbert-msa* for bert-base-arabic-camelbert-msa, *portuguese-large* for bert-base-portuguese-cased-large, and *swedish* for bert-base-swedish-cased.

fusion cases, possibly due to imbalanced data (see also Figure 4 in Appendix A.1.3). Regarding FFSA, the additional self-attention layer appears to improve the distinction between Anger, Fear and Joy. Additionally, the dataset samples demonstrate that the fine-tuned RoBERTa model does not effectively distinguish Sadness and Surprise emotions from others, interpreting them as Anger or Fear and Fear or Joy, respectively, due to ambiguous cases.

Moreover, a comparison of these two approaches on F1, Recall, and Precision scores with Statistical Significance (Berg-Kirkpatrick et al., 2012) shows a 0.84 P-value, which means that the difference in the performance of these two models is not statistically significant. However, the FFSA technique does not require much additional high computational power, allowing this method to be applied efficiently in the English setup.

We believe multiple factors could be affecting the performance of models across languages, including data imbalance, sentence length and dataset size. Mozambican Portuguese and Algerian Arabic demonstrate the lowest results, likely due to being low-resource languages with relatively small datasets. In contrast, for Nigerian-Pidgin, despite typically being a low-resource language, Nigerian-Pidgin XLM-R performs relatively well. We believe this could be due to being well-resourced in this set-up (see Table 4), as well as the prevalence of English in the language. In terms of sentence length, Brazilian Portuguese and Swedish contain longer sentences (on average and at their maximum lengths), complicating input processing. As for German, its linguistic similarities to English suggest strong model performance. However, we believe models might struggle with longer dependencies and complex sentence structures due to relatively long sentences.

Regarding error analysis for RoBERTa, Expected Calibration Error (ECE) of the approaches of both fine-tuning and fine-tuning with Curriculum Learning and Data Preprocessing have 8.7% and 8.5% ECE, respectively. This indicates that these models are well-calibrated but still have miscalibration. As for the Feature Fusion with Self-Attention approach, the model is on a threshold with 10.3% ECE, meaning the model's confidence levels might be overconfident or underconfident, compared to actual outcomes. Comparing selected predictions of those models in Figures 8-10 in Appendix A.6.2 show that fine-tuned RoBERTa demonstrates some overconfidence with a high probability of incorrect labels, particularly when it comes to Fear, possibly related to a data imbalance.

6 Conclusion

This paper presents our contribution to the SemEval-2025's multi-label text-based emotion recognition task. In our work, we compare the emotion-detecting abilities of causal and non-causal models along with investigating multiple techniques such as curriculum learning, instruction and few-shot fine-tuning, as well as feature fusion with emotion scores (FFSA). Fine-tuned language-specific BERT-based models and XLM-RoBERTa-large gave the best results across multiple languages, outperforming baseline and generative models. For future work, we believe an interesting direction would be using data augmentation to address the lack of perceived emotion detection datasets. Additionally, we can explore improving the FFSA method using emotion lexicons.

Limitations

We acknowledge that our study on generative models for non-English languages is limited by basing some decisions solely on the English setup and applying them to other languages. Ideally, further studies should be conducted to identify the best experimental setup for each language. As for the test phase, we compared the two best approaches from the development phase on the test set for each selected language to report the final results. Another limitation is that emotion scores were computed only on training data samples, which may not fully capture real-world emotion dependencies.

Ethics Statement

As emotion recognition models heavily depend on the training data, biases presented in the datasets can be represented in the fine-tuned model version. Moreover, the possibility of misuse remains a significant concern, as the models could be used for manipulative purposes, such as generating targeted emotional responses or influencing public sentiment. We also acknowledge the computational resources required to work with LLMs, such as Llama-3, making it less accessible for lower-resource environments.

A Appendix

A.1 Data

A.1.1 Cross-lingual analysis

Table 4 provides analytical information across selected languages, indicating small sizes of datasets and extraordinal cases with long sentences (especially in Brazilian Portuguese and Swedish data). This may influence a model's performance due to the limited input size of a model.

Language	Size	L_{max}	L_{mean}
English	2768	450	78
Algerian Arabic	901	274	76
Moroccan Arabic	1608	444	77
German	2603	856	219
Nigerian-Pidgin	3728	279	111
Brazilian Portuguese	2226	2665	114
Mozambican Portuguese	1546	147	65
Russian	2679	609	62
Spanish	1996	191	53
Swedish	1187	3476	196

Table 4: Analytical information of training data among all selected languages. We present the number of samples per language (*Size*), as well as the sentence lengths in terms of the number of characters, showing the mean and max values across languages.

A.1.2 Emotional Combinations

The heat map in Figure 3 of such combinations distinctly illustrates co-occurrence rates for English training data. Some pairs of emotions occur more frequently than others, as indicated by their higher probability. This may reflect real-life tendencies, where the most commonly expressed emotions appear more often.

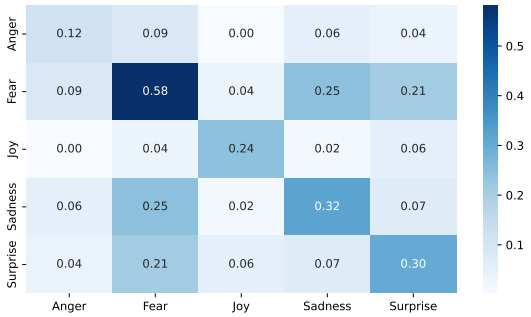

Figure 3: Heat map of pairwise probabilities for English train set.

English utterances with Neutral and Joy-only emotions, combinations of (Fear with Sadness), (Fear with Surprise), and (Fear with both Sadness and Surprise) demonstrate strong correlations.

A.1.3 Emotion Distribution

In addition, Figure 4, which shows the emotion distribution, confirms that the overall low probabilities of combinations involving Anger and Joy illustrate data imbalance. This may reflect emotional states that commonly co-occur in social media texts.

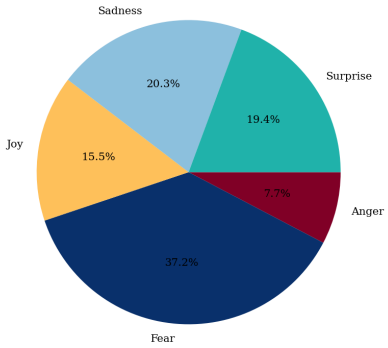

Figure 4: Emotion distribution in English Train dataset.

A.2 Hyper-parameters

A.2.1 Non-causal Models

Table 5 presents the tested hyper-parameter ranges. During experiments, we found the most optimal set of these hyper-parameters based on model performance. Figure 5 demonstrates the process of finding the optimal epoch number, as well as experiments with the HuggingFace Trainer[7], which outperformed our custom training function.

Hyper-parameter	From	To	Optimal
Epochs	1	20	10
Batch size	8	32	32
Learning rate	1e-6	3e-5	2e-5
Weight decay	1e-6	5e-6	1e-6

Table 5: Range of tuned hyper-parameters for RoBERTa-large in English setup.

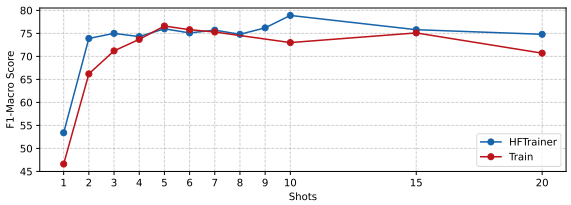

Figure 5: The plot of F1-Macro score results over the number of epochs of RoBERTa-large on the English development set using the custom training function (*Train*) and HuggingFace Trainer (*HFTrainer*).

[7] https://huggingface.co/docs/transformers/trainer

A.2.2 Causal Models

In Table 6, the demonstrated LoRA hyper-parameters allow us to regularize reducing memory usage by freezing most model weights and adapting all linear layers in a model.

Hyper-parameter	Value
LoRA α	16
dropout	0.1
r	64
bias	'none'
target modules	"all-linear"

Table 6: LoRA hyper-parameters for fine-tuning Llama-3-8B-Instruct in English setup.

During the inference process, we use certain generation parameters, shown in Table 7, for both fine-tuning and in-context learning approaches to control the model output. These parameters reduce creativity to ensure the model generates consistent responses while maintaining emotional context.

Parameter	Value
max_new_tokens	50
do_sample	True
temperature	0.1
top_p	0.6

Table 7: Parameters for the inference of Llama-3-8B-Instruct in English setup.

A.3 Postprocessing

To align emotions from the model's responses according to the basic six emotions, we use emotion mapping from Table 8. For the English setting, we map Disgust to Fear emotion.

Emotion	Variations
Anger	Anger, Annoyance, Disapproval
Disgust	Disgust
Fear	Fear, Nervousness
Joy	Joy, Amusement, Approval, Excitement, Gratitude, Love, Optimism, Relief, Pride, Admiration, Desire, Caring
Sadness	Sadness, Disappointment, Embarrassment, Grief, Remorse
Surprise	Surprise, Realization, Confusion, Curiosity

Table 8: Emotion mapping from Demszky et al. (2020).

A.4 In-Context Learning.

As shown in Figure 6, our prompt templates have an instruction format where we utilize special tokens for structuring. Also, we used complex and diverse examples from the training dataset presented in Table 9 in a few-shot setup.

#	Utterance	Labels
1	*"The cop tells him to have a nice day and walks away."*	Anger, Joy, Surprise
2	*"About 2 weeks ago I thought I pulled a muscle in my calf."*	Fear, Sadness
3	*"I got to babysit my grandson but my back hurt the next day."*	Joy, Sadness

Table 9: Selected representative samples for few-shot learning from the English Train dataset.

A.5 English Deep-dive Experiments

In Table 10, we provide results on all approaches in the English setup conducted using RoBERTa-large and Llama-3, where RoBERTa with a combination of fine-tuning and curriculum learning on preprocessed data shows the highest 81 F1-score.

Model	Approach	F1-Macro
RoBERTa	Preprocessing + CL	**81.0**
RoBERTa	FFSA	80.4
RoBERTa	CL	79.9
RoBERTa	Preprocessing	79.0
RoBERTa	Fine-tune	78.9
Llama-3	Prompt	73.0
Llama-3	Few-shot fine-tune	68.5
Llama-3	Instruction fine-tune	64.3

Table 10: Best results on the English development set, where *RoBERTa* - RoBERTa-large, *Llama-3* is Meta-Llama-3-8B-Instruct, *FFSA* - feature fusion with self-attention, *CL* - curriculum learning.

We found that preprocessing steps benefit the RoBERTa, which is optimized for clean and structured input such as Wikipedia[8] and BookCorpus (Zhu et al., 2015). In contrast, Llama-3 did not show better results on the preprocessed data compared to the original dataset. As a decoder, Llama-3 appears to be more robust to raw text variations because they are trained to handle natural instances.

A.6 Result Analysis

A.6.1 Confusion Matrices

For the English dataset, Figures 7a and 7b demonstrate confusion matrices of the two effective approaches, such as fine-tuning and feature fusion with self-attention. They represent a comparison between predicted and true labels, indicating a low

Abstract

The widespread deployment of large language models (LLMs) across diverse domains has underscored the critical need to ensure the credibility and accuracy of their generated content, particularly in the presence of hallucinations. These hallucinations can severely compromise both the practical performance of models and the security of their applications. In response to this issue, SemEval-2025 Task 3 Mu-SHROOM: Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes introduces a more granular task for hallucination detection. This task seeks to identify hallucinations in text, accurately locate hallucinated segments, and assess their credibility. In this paper, we present a three-stage method for fine-grained hallucination detection and localization. First, we transform the text into a triplet representation, facilitating more precise hallucination analysis. Next, we leverage a large language model to generate fact-reference texts that correspond to the triplets. Finally, we employ a fact alignment strategy to identify and localize hallucinated segments by evaluating the semantic consistency between the extracted triplets and the generated reference texts. We evaluate our method on the unlabelled test set across all languages in Task 3, demonstrating strong detection performance and validating its effectiveness in multilingual contexts.

1 Introduction

LLMs have gained widespread application across various fields due to their exceptional performance, making them a core technology of significant interest. However, their reliance on vast training data and probabilistic inference mechanisms makes them prone to generating factually incorrect, misleading, or unsubstantiated content, leading to the phenomenon of "hallucination" (Bai et al., 2024). Hallucinations not only reduce the reliability and practicality of model-generated content but also pose safety and trust issues in real-world applications, ultimately affecting their effectiveness in critical domains. Therefore, accurately detecting and locating hallucinated information has become a key research challenge.

Existing research on hallucination detection has explored different granularity levels, including response-level detection (Zhou et al., 2020), which determines whether an entire output contains hallucinations; sentence-level detection (Mishra et al., 2024), which analyzes whether an individual sentence includes false information; and phrase-level detection (Min et al., 2023), which identifies hallucinations at a finer semantic unit. Although these methods have made progress in hallucination identification, most still struggle to accurately predict the exact location of hallucinations, particularly in multilingual settings. To bridge this gap, SemEval-2025 Task 3 Mu-SHROOM (Vázquez et al., 2025), introduces a more fine-grained hallucination detection and localization task, aiming to advance research on hallucination detection and localization across 14 languages.

For this task, we proposes a **three-stage method** for hallucination detection and localization in a passage. First, the method converts passages into multiple triple representations to enable more fine-grained hallucination detection. Next, for each extracted triple, the method generates fact-based reference text. Finally, by comparing the semantic similarity between the original triples and the generated fact-based references, the method identifies hallucinated triples, precisely locates the hallucinated segments, and formats the output according to the task requirements. The proposed method integrates fine-grained semantic analysis and fact-alignment strategies, allowing not only the identification of hallucinated information in passages but also the precise localization of hallucinations. In

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1015–1022

the SemEval-2025 Task 3 competition, the method was tested on the unlabeled test sets for all languages and achieved corresponding detection results.

2 Related Work

2.1 Response-Level Detection

Existing response-level hallucination detection methods evaluate generated text as a whole to assess its factual consistency but face limitations in fine-grained hallucination identification and localization. For instance, TruthfulQA (Lin et al., 2021) evaluates the overall truthfulness of model-generated text and finds that larger models are more prone to generating misleading hallucinations, highlighting that increasing model size alone does not enhance truthfulness. HaluEval (Li et al., 2023) employs fine-grained annotations and a "sampling-filtering" mechanism to construct high-quality hallucination datasets, revealing distinct hallucination patterns of LLMs across different tasks. However, a major drawback of these methods lies in their inability to precisely locate hallucinated content. In SemEval-2025 Task 3 Mu-SHROOM, hallucination detection requires not only identifying hallucinations but also predicting their exact locations. Response-level detection methods, however, can only determine the overall factual consistency of a text without providing character-level annotations. Moreover, existing approaches struggle with generalization in multilingual and multimodal settings, making cross-lingual hallucination detection particularly challenging.

2.2 Sentence-Level Detection

Unlike response-level detection, sentence-level hallucination detection evaluates the truthfulness of generated text on a per-sentence basis to enable more fine-grained hallucination identification and enhance local factual consistency. For example, (Manakul et al., 2023) identify potential hallucinations by comparing multiple sampled responses to the same query and measuring their consistency. (Deng et al., 2024) propose PFME (Progressive Fine-Grained Model Editor), which integrates real-time fact retrieval with fine-grained editing to detect and correct hallucinations at the sentence level, improving both truthfulness and reliability. However, despite offering finer-grained analysis than response-level methods, sentence-level approaches remain limited by their reliance on evaluating entire sentences rather than precisely locating hallucinated segments. These methods often depend on inter-sentence consistency or external fact alignment but fail to pinpoint the exact position of hallucinations within a sentence.

2.3 Phrase-Level Detection

Advancing beyond sentence-level methods, phrase-level hallucination detection decomposes sentences into clause-level factual assertions, enabling more precise hallucination identification and correction while improving the detection of multiple hallucinations within a single sentence. For instance, FActScore (Min et al., 2023) evaluates the factual consistency of long-form text generation by segmenting generated text into a series of atomic facts and extracting phrases as claim units. It then calculates the proportion of claims supported by reliable knowledge sources to enhance evaluation accuracy. Additionally, (Chern et al., 2023) integrate tool-augmented methods with a fine-grained claim extraction mechanism, partitioning generated text into atomic content units (ACUs) to detect factual errors with greater precision. Although phrase-level methods offer finer granularity than sentence-level approaches, their primary limitation lies in weak localization capabilities. Most methods rely on claim unit segmentation and fact comparison but struggle to precisely align hallucinated content with specific entities or relations in the text.

Compared to existing response-level, sentence-level, and phrase-level hallucination detection methods, the proposed three-stage fine-grained detection and localization approach offers significant advantages in detection granularity and localization accuracy. Response-level methods assess the overall factual consistency of text but fail to precisely locate hallucinations, making them inadequate for SemEval-2025 Task 3 Mu-SHROOM, which requires character-level annotation. Sentence-level methods evaluate hallucinations on a per-sentence basis but still analyze entire sentences, making it difficult to identify the exact part of the sentence where hallucinations occur. Phrase-level methods, such as FActScore and ACUs, decompose sentences into claim units but rely on clause segmentation and fact comparison, which limits their ability to accurately align hallucinated content with specific entities or relations in the text.

The proposed method extracts triples to parse text into more granular subject-verb-object structures, integrating fact comparison and semantic

consistency computation to enable hallucination detection at the clause, phrase, and even word level. This approach ensures precise hallucination localization and outputs results in a structured format. Compared to existing methods, it demonstrates superior detection accuracy, localization capability, multilingual adaptability, and interpretability, making it better suited to meet the fine-grained hallucination detection and localization requirements of SemEval-2025 Task 3.

3 Task Description and Datasets

In Mu-SHROOM Task 3, the organizers introduce a task aimed at predicting the locations of hallucinated segments in text generated by LLMs. This task focuses on identifying hallucinations in LLM outputs across multiple languages, including Modern Standard Arabic, Basque, Catalan, Mandarin Chinese, Czech, English, Farsi, Finnish, French, German, Hindi, Italian, Spanish, and Swedish.

The dataset consists of a sample set, a validation set, and an unlabeled training set. The sample set includes model-generated question-answer pairs, soft labels, and hard labels. Soft labels indicate potential hallucinated spans along with their probability distributions, while hard labels specify the exact boundaries of hallucinated segments within the generated text. Compared to the sample set, the validation set provides additional tokenized outputs and logit values for each generated token. The unlabeled training set contains only model-generated question-answer pairs without hallucination annotations.

4 Methodology

We proposed a **three-stage method**, as illustrated in Figure 1. In the first stage, we applies the technique from RefChecker (Hu et al., 2024) to extract multiple triples from each user-provided passage. In the second stage, a high-performing language model generates references for each extracted triple based on stored knowledge. In the third stage, the method compares the generated references with the original triples to assess their semantic similarity, determine whether hallucinations are present, and perform hallucination localization and structured output formatting.

4.1 Triplet Generation

A triple serves as a structured representation of knowledge, fundamentally consisting of an ordered

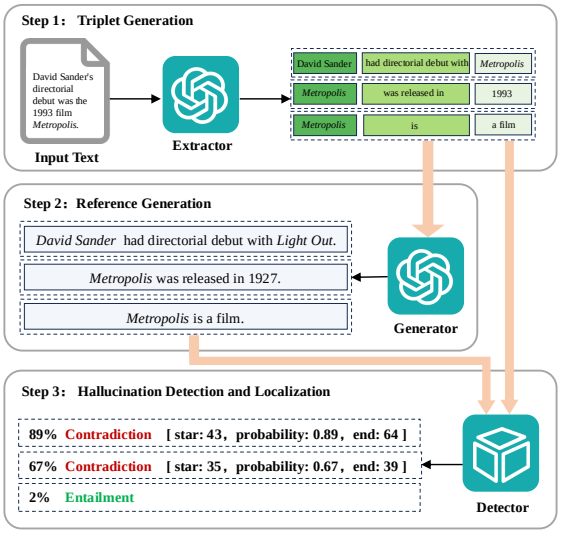

Figure 1: The overview of the three-stage hallucination detection process.

list with three elements: the subject, predicate, and object extracted from a sentence. The subject represents an entity and serves as the core component of a sentence, indicating the entity being described. The predicate expresses the relationship or attribute between the subject and object, typically consisting of a verb or verb phrase that conveys the subject's actions, state, or characteristics. The object functions as the target of the predicate and can represent an entity. Together, the subject, predicate, and object form a complete semantic expression.

A triple extracts the subject, predicate, and object from a sentence and structures them into a formal representation, enabling more effective identification of core information within the text. The triple generation module processes each input passage under evaluation and extracts one or more triples from it.Specifically, the triple generation module employs high-capability language models, such as GPT-4 (Achiam et al., 2023) and DeepSeek (Guo et al., 2025), to process passages in batches and convert them into one or more triples. The extracted triples encompass all key factual relationships present in the passage. The prompt used is included in the Appendix.

4.2 Reference Generation

The reference generation module constructs references based on the content of the passage under evaluation. Specifically, the reference generation module constructs prompts based on the subject-predicate-object triples extracted by the triple generation module and utilizes an advanced language

model with internet access, such as GPT-4 (Achiam et al., 2023) or DeepSeek (Guo et al., 2025), to generate the corresponding references. The prompt used is included in the Appendix. In our design, the language model evaluates the accuracy of the triples by leveraging both internet-accessed information and its internal knowledge, generating corresponding reference text accordingly. To ensure the accuracy of hallucination detection, the generated reference text must precisely and correctly describe the content of the triples under evaluation.

Therefore, we impose constraints on the format of the generated reference text, allowing only two predefined structures:(1)If the content described by the triple aligns with factual information, the module directly converts the triple into a grammatically correct declarative sentence as the reference text. (2)If the triple contains inaccuracies or contradictions, the module retrieves factual information through the language model's internet access and reconstructs a factually accurate declarative sentence using the subject, predicate, and the correct object from the triple. Experimental results indicate that constraining the reference text format improves hallucination detection performance compared to an unconstrained approach.

4.3 Hallucination Detection and Localization

The hallucination detection and localization module utilizes the FacebookAI/roberta-large language model (Trinh and Le, 2018) to assess the semantic similarity between triples and the reference. Specifically, the model processes the input text in batches and applies softmax normalization to compute the probability distribution of relation matching, quantifying the semantic consistency between triples and the reference text. The essence of this task lies in multi-class classification, where the results of semantic similarity comparison are categorized into Entailment, Neutral, and Contradiction. If the text under evaluation contains hallucinations, a semantic discrepancy should exist between the triple and the corresponding reference, leading to a higher probability of being classified as Contradiction. Subsequently, the probability of being classified as Contradiction is used as the soft label, and samples with a predicted Contradiction probability greater than 0.5 are identified as containing hallucinations. Once hallucinated samples are determined, hallucination localization is conducted. Hallucination localization process focuses on the triples marked as hallucinations, identifying the position of their objects within the original passage and converting the results into a structured output format. In a sentence, the subject is typically a stable entity, the predicate expresses the relationship between the subject and the object, and the object is an entity or concept determined under the constraints of the given subject and predicate. In natural language, once the subject and predicate are established, the selection of the object usually belongs to an open set. When predicting the object entity, overgeneralization or erroneous associations may occur, leading to hallucinations. To facilitate hallucination localization, this module primarily focuses on identifying the position of hallucinated objects within a sentence while preventing errors caused by multiple occurrences of the same object. Finally, after determining the precise location for the hard label output, the module integrates the soft label value to generate a structured output, producing the final task-formatted result.

5 Experiments & Results

5.1 Implementation

Our method primarily employs API calls to interact with the large model and obtain its feedback. Specifically, during both the triple generation and reference generation steps, the GPT-4o model is accessed via API calls to generate triples and corresponding references. The hallucination detection module utilizes a locally deployed FacebookAI/roberta-large language model. To ensure efficient execution of experiments, all computations run in a GPU-accelerated environment. Specifically, NVIDIA RTX 4090 GPUs provides computational acceleration, while FP16 mixed-precision computation optimizes processing efficiency. All experiments run in the Ubuntu 22.04 operating system environment, with Python dependencies including Transformers[1], PyTorch[2], and related deep learning frameworks. To ensure stable API calls, the batch processing approach manages request execution, while appropriate rate limits prevent exceeding the API threshold and maintain experimental integrity.

5.2 Metrics

Our experiment employs two metrics, **Intersection-over-Union (IoU)** and **Spearman Correlation**

[1] https://github.com/huggingface/transformers
[2] https://github.com/pytorch/pytorch

(Cor), to assess the effectiveness of our method in hallucination detection.

IoU measures the ratio of the intersection to the union between the predicted hallucinated content and the ground truth hallucinated content, providing a quantitative evaluation of the overlap between the predicted and actual hallucination regions. Equation 1 presents the formula for IoU, where P denotes the hallucinated content predicted by the model, and G represents the ground truth hallucinated content identified through manual annotation.

$$\text{IoU} = \frac{|P \cap G|}{|P \cup G|} \tag{1}$$

Spearman correlation quantifies the rank correlation between the predicted probability scores of hallucination and the manually assigned scores, serving as a measure of consistency between the model's hallucination predictions and human evaluations. Equation 2 defines the Spearman correlation, where $\mathbf{p} = [p_1, p_2, \ldots, p_n]$ represents the sequence of hallucination probabilities predicted by the model, with p_i denoting the probability of hallucination at the i-th character. Similarly, $\mathbf{g} = [g_1, g_2, \ldots, g_n]$ denotes the sequence of hallucination proportions from human annotations, where g_i indicates the probability that the i-th character is annotated as hallucinated. The term d_i represents the rank difference between the predicted probability p_i and the human-annotated probability g_i after sorting. The variable n denotes the length of the text.

$$\rho = 1 - \frac{6 \sum_{i=1}^{n} d_i^2}{n(n^2 - 1)} \tag{2}$$

5.3 Results and Analysis

Our method is evaluated on the unlabeled test sets provided by the organizers across all languages, achieving a certain level of detection performance. Table 1 below presents the results of our approach on test sets for each language.

Our method offers advantages by incorporating triple generation, factual alignment, and semantic similarity computation, enabling precise detection and localization of hallucinated segments. Compared to traditional binary classification approaches and certain hallucination detection methods based on entire passages, our method enhances interpretability and achieves more fine-grained hallucination detection.

Language	IoU	Cor
AR	0.2722	0.4477
CA	0.4644	0.5432
CS	0.3060	0.2695
DE	0.3400	0.4066
EN	0.4025	0.4781
ES	0.3447	0.3104
EU	0.2916	0.3989
FA	0.1661	0.3946
FI	0.2459	0.3366
FR	0.2286	0.2873
HI	0.0613	0.5586
IT	0.3967	0.4991
SV	0.3080	0.3655
ZH	0.1913	0.3047

Table 1: Performance of our proposed method on different language test sets.

The experimental results reveal significant performance differences across languages in terms of IoU and Cor metrics. Specifically, the model achieves the best performance on the Catalan test set, with an IoU of 0.4644 and a Cor of 0.5432. On test sets for languages such as English and Italian, the IoU and Cor values remain stable at approximately 0.4 and 0.5, respectively, indicating strong generalization capability across these languages. However, on test sets for languages such as Farsi and Chinese, the IoU value falls below 0.2, which may be attributed to weaker generalization or higher linguistic complexity. Therefore, it may be worth considering the use of XLM-RoBERTa model specifically for these languages in the future.

6 Conclusion

This study proposes a three-stage approach for hallucination detection and localization, consisting of triple generation, reference text generation, and hallucination detection and localization. The method enables fine-grained identification of hallucinated content in text generated by large language models. Experimental results indicate that the method achieves good hallucination detection performance in languages such as English, but its detection accuracy decreases in some low-resource languages and those with complex syntactic structures and data.

A Prompts Used in the Method

The following presents the prompts used in this study for the triple generation and reference generation.

Prompt

Given an input text, please extract a KG from the text and represent the KG with triples formatted with ("subject", "predicate", "object"), each triplet in a line. Please note that this is an EXTRACTION task, so DO NOT care about whether the content of the candidate answer is factual or not, just extract the triplets from it. Importantly, ensure that the extracted KG does not contain overlapping or redundant information. Each piece of information should be represented in the KG only once, and you should avoid creating triplets that are simply the inverse of another triplet. For example, if you extract the triplet ("John", "owns", "Car"), do not also include ("Car", "owned by", "John") as it represents the same information in reverse. The language you generated should be the same as the language of the user input text.

Clarification on redundancy: First, Do not create triplets that reverse the subject and object to state the same fact. Next, Ensure each fact is represented uniquely in the simplest form, and avoid creating multiple triplets that convey the same information.

Here are some in-context examples:

Input:

Optimus (or Tesla Bot) is a robotic humanoid under development by Tesla, Inc. It was announced at the company's Artificial Intelligence (AI) Day event on August 19, 2021.

KG:

("Optimus", "is", "robotic humanoid")

("Optimus", "under development by", "Tesla, Inc.")

("Optimus", "also known as", "Tesla Bot")

("Tesla, Inc.", "announced", "Optimus")

("Announcement of Optimus", "occurred at", "Artificial Intelligence (AI) Day event")

("Artificial Intelligence (AI) Day event", "held on", "August 19, 2021")

("Artificial Intelligence (AI) Day event", "organized by", "Tesla, Inc.")

Input:

The song "Here Comes the Boom" was originally released by American rock band Nelly in 2002 for the soundtrack of the film "The Longest Yard."

KG:

("The song 'Here Comes the Boom'", "originally released by", "American rock band Nelly")

("The song 'Here Comes the Boom'", "released in", "2002")

("The song 'Here Comes the Boom'", "featured in", "soundtrack of the film 'The Longest Yard'")

("American rock band Nelly", "released", "The song 'Here Comes the Boom'")

("The Longest Yard", "had soundtrack featuring", "The song 'Here Comes the Boom'")

Now generate the KG for the provided input text:

Input:

{input_text}

KG:

Figure 2: Prompt of triplet generation.

Prompt

System Prompt : **You are a knowledgeable intelligent information retrieval assistant dedicated to providing users with accurate and valuable answers. For user inquiries, you will rely on your existing knowledge to respond and conduct searches when necessary to offer the most up-to-date and comprehensive information. Users may input statements that could be either correct or incorrect, and you need to provide supporting references or sources for the user's input without outputting any irrelevant content. Note that the language provided by the user may not be English, and you should respond in the language provided by the user.**

User Prompt :

Subject: {subject}, Predicate: {predicate}, Object : {object}. This statement may be correct or incorrect. If the statement is correct, repeat the statement in the format: subject + predicate + object. If the statement is incorrect, do not provide any reasons; simply output the correct statement by keeping the subject and predicate while replacing the object with the correct one. Do not provide any additional content, explanations, or reasons. You also do not need to indicate whether the statement is correct.

Example 1:

User input: Subject: A, Predicate: is, Object: B.

If the statement is correct, you should response: A is B.

If the statement is incorrect, you should response: A is C (where C is the correct answer for subject A and predicate "is").

Example 2:

User input: Subject: A, Predicate: contains, Object: B.

If the statement is correct, you should response: A contains B.

If the statement is incorrect, you should response: A contains C (where C is the correct answer for subject A and predicate "contains").'" + "Note that the language provided by the user may not be English, and you should respond in the language provided by the user.

Abstract

Bridging the gap in text-based emotion detection has received significant attention due to the diverse ways in which emotions are explicitly conveyed in written text. Digital communication platforms often present complex emotional expressions which are a challenge to conventional analysis methods. This paper presents a two-track approach to address these challenges in English: Track 1 (Multi-label Emotion Detection) and Track 2 (Emotion Intensity) are described. The method primarily revolves around sophisticated textual mining techniques and fine-tuning transformer-based language models to generate powerful semantic features. A multi-label classification approach is applied on Track 1 for capturing common emotional states, and regression models are used on Track 2 to estimate emotion strengths. The developed system achieved competitive rankings of 31 and 17 in both tracks, highlighting the promise of the approaches used to improve the precision and robustness of text-based emotion detection.

1 Introduction

Text-based emotion recognition has become one of the core elements of contemporary natural language processing, which has changed the way we perceive and use digital communication. Today's social media and instant messaging culture often allows people to communicate their nuanced, often unacknowledged, emotional states through the written word. This rich tapestry of affective expression not only influences personal interactions but also drives applications in customer service, mental health monitoring, and social analytics. Nevertheless, conventional sentiment analysis methods usually lack the depth of human emotion spectrum and nuances.

Track 1 is concerned with Multi-label Emotion Detection and Track 2 is concerned with Emotion Intensity estimation.

Track 1 promotes the creation of models able to detect shared emotional states in a text, accommodating the complex dimension of human affect. Simultaneously, Track 2 asks the researchers to measure the fine nuances in the intensity of emotion, beyond dichotomizing between emotion intensities, to provide a more nuanced description of affective expression. Taken together, these tasks strive for the current state-of-the-art by encouraging novel solutions that can cope with the complexity and richness of real-world textual emotions.

This paper is structured as follows: Section 2 surveys the relevant related works in textual emotion detection and sentiment analysis, discussing both historical trends and recent progress. Section 3 gives a detailed explanation/ task description such as the dataset and the evaluation metrics. Section 4 consists of the adopted methodology, highlighting the preprocessing techniques, model architectures, and training procedures. Section 5 presents the experimental results along with a comparative analysis of the approaches used. Section 6 discusses the error analysis, to identify potential areas for improvement. Finally, Section 7, the conclusion section, contains a summary of key findings and insights into future research directions.

By addressing these challenges, the gap between conventional sentiment analysis methods and the complex, multidimensional nature of human emotion is bridged. Through advanced textual analysis and innovative modeling techniques, the aim is to enhance the reliability and depth of emotion detection systems, ultimately contributing to more empathetic and effective digital communication platforms. The code for the tasks is available on GitHub at this repository.

2 Related Work

Emotion analysis on textual data has been extensively researched in Natural Language Processing

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1023–1027

(NLP) with applications from multi-label emotion classification to intensity regression of emotions. Conventional methods were based on lexicon-based approaches, in which words were assigned to pre-defined emotional categories in terms of resources like the NRC Emotion Lexicon (Mohammad and Turney, 2013). While these approaches provided useful insights, they lacked contextual understanding and struggled with complex linguistic patterns.

Multi-label emotion classification is to assign multiple emotion labels to a text. Early ML-based approaches have been applied to TF-IDF and n-gram features with Support Vector Machines (SVMs) and Random Forests (Strapparava and Mihalcea, 2008), respectively. Nevertheless, the traditional methods have been surpassed by deep learning methods like Long Short-Time Memory (LSTM) networks and Convolutional Neural Networks (CNNs) (Felbo et al., 2017). The introduction of the transformers, especially BERT (Devlin et al., 2019) and Roberta (Liu et al., 2019), has improved multi-label classification considerably by exploiting the contextual embeddings. Recent works have optimized thresholding techniques, such as adaptive thresholding (Pérez-Rosas et al., 2020) and focal loss, to handle label imbalances in multi-label classification.

Emotion intensity prediction (i.e., how much of an emotional expression is there in a given text) has been addressed from both lexicon-based and deep-learning points of view. Early works relied on affective lexicons such as the NRC Affect Intensity Lexicon (Mohammad, 2018) to assign predefined intensity scores. Nevertheless, those approaches could not learn the dynamic emotion expression in real-world text. Recurrent neural networks (RNNs) and BiLSTMs have been applied to model sequential dependencies in text, improving intensity prediction (Baziotis et al., 2018). Transformer-based architectures (e.g., BERT, Roberta) have also significantly helped this domain by training models to perform regression by tuning the model parameters for regression tasks using loss functions such as Mean Squared Error (MSE) or Huber Loss (Goel et al., 2021).

In this paper, we focus both on the multi-label emotion classification and the emotion intensity regression, both using transformer-based models. The classification problem is approached as a multi-label problem, using Binary Cross-Entropy with Logits (BCEWithLogitsLoss) and threshold-tuning methods to enhance emotion detection. In the regression task, the model is trained to predict the intensity of emotion by MSE loss, with the goal of optimal fine-grained emotion strength detection. By integrating recent advancements in transformers and loss function optimization, this work aims to enhance both the classification and regression aspects of emotion analysis in textual data.

3 Task Description

We focus on two related yet distinct tasks aimed at analyzing the emotional content in text: Multi-label Emotion Detection and Emotion Intensity Prediction. Both tasks contribute to a deeper understanding of affective computing, particularly in the context of social media, dialogues, and opinionated text. The dataset is due to the efforts of (Muhammad et al., 2025) and (Belay et al., 2025).

3.1 Track A: Multi-label Emotion Detection

The goal of this task is to classify a given text snippet into multiple perceived emotions. Specifically, for a given text, we determine whether each of the following six emotions applies: joy, sadness, fear, anger, surprise, or disgust. Since emotions are not mutually exclusive, a text may exhibit multiple emotions simultaneously. The model outputs a binary decision for each emotion: 1 if the emotion is present, 0 otherwise.

3.2 Track B: Emotion Intensity Prediction

This task extends the analysis by predicting the intensity of a given emotion in a target text. Given a text and a specified target emotion (one of joy, sadness, fear, anger, surprise, or disgust), the model predicts the emotion's intensity on a four-point ordinal scale: 0 (no emotion), 1 (low intensity), 2 (moderate intensity), and 3 (high intensity).

4 Methodology

This paper aims at two fundamental tasks of emotion analysis: emotion classification with multiple labels and regression of emotion intensity. We adopt transformer-based models, i.e., fine-tuned BERT and RoBERTa models, to better solve both tasks. The methodology is composed of data preprocessing, model structure, training approach, and evaluation metrics.

4.1 Data Preprocessing

The dataset is preprocessed by removing special characters, URLs and redundant whitespaces. By

keeping stopwords to maintain the context integrity, the Byte-Pair Encoding (BPE) tokenizer is applied for tokenization. For multi-label classification, labels are one-hot encoded to enable discrete probability assignment to each emotion. On the other hand, for regression, the intensities of the emotion are normalized in the range of [0,1] so that they scale consistently and train stably (Mohammad, 2018). In addition, to address data sparsity, lowercasing and lemmatization are used as text normalization techniques and padding is performed to a fixed size so that the batches are uniform.

4.2 Model Architecture

In the field of multi-label classification, we adopt a pre-trained transformer model (RoBERTa) which utilizes multiple self-attention layers and can capture the inherent contextual dependencies within the whole textual information. The transformer encoder is applied to the input text that has been tokenized by Byte-Pair Encoding (BPE). The output from the last hidden layer is fed into a fully connected dense layer and each neuron represents an emotion label. As an instance may have several emotions at the same time, sigmoid activation is applied to each of the output neurons separately to produce probability scores for each of the labels. A threshold (e.g., 0.5) is applied to classify whether an emotion exists. Binary Cross-Entropy with Logits Loss (BCEWithLogitsLoss) is employed for training as it aims to optimize predictions for each emotion category rather than assume mutual exclusivity.

For emotion intensity regression, the same architecture based on RoBERTa is employed as a feature extractor but instead of having a dense layer with multiple outputs and sigmoid activation, we make the last layer consist of a single neuron for each emotion class with linear activation. This setup allows the model to predict continuous intensity values rather than categorical labels. To minimize errors in continuous predictions, the Mean Squared Error (MSE) loss function is used, as it penalizes large deviations and ensures smoother optimization (Goel et al., 2021). Additionally, we introduce a dropout layer before the final output to reduce overfitting by randomly deactivating neurons during training, improving the model's generalization ability. We use a single model with five neurons in the final layer, where each neuron corresponds to one emotion, enabling the classification of all emotion classes.

In both tasks, the last transformer layer's hidden states are first passed through a pooling mechanism (CLS token embedding or mean pooling) before being input to the final output layer. This is done to ensure that the most important features are extracted and used effectively. Layer normalization and weight decay regularization are also used to stabilize training and avoid overfitting.

4.3 Training Strategy

Fine-tuning is performed with the AdamW optimizer and a learning rate of 2e-5, and a linear scheduler with warm-up stages to avoid extreme weight changes in the early training stages. In the case of classification, threshold tuning after training is applied to refine decision boundaries in order to solve the multi-label assignment (Pérez-Rosas et al., 2020). Models are trained using batch sizes of 16 and 32 for classification and regression, respectively, in an attempt to maximize GPU memory use.

For multi-label classification, the sigmoid-activated logits are thresholded at an evolving value, learned from validation set analysis, to achieve the best performance trade-off in terms of precision-recall. Training is carried out for 10-15 epochs with early stopping using a validation loss based criterion to prevent overfitting. To regularize updates and improve convergence, in particular for very large batch training, the gradient accumulation method is employed.

In emotion intensity regression, The RoBERTa model is fine-grainedly trained using the MSE loss function. The dropout probability is fixed to 0.1 to further regularize learning and prevent overfitting. The dynamic learning rate scheduler is adaptive to provide the convergence. Model checkpoints are saved at the highest validation performance, guaranteeing that the final evaluation be performed on the most optimized state.

4.4 Evaluation Metrics

For classification (Track A), evaluation is conducted using F1-Score to assess label co-occurrence and retrieval effectiveness. We achieved a macro F1-score of 0.75. In the regression task (Track B), Pearson correlation is employed to measure the strength of linear associations (Strapparava and Mihalcea, 2008). In the second track we achieved a Pearson correlation of 0.75. The detailed results for Track A, and Track B are shown in Figure 1 and Figure 2 respectively.

Language	Emotion	Score
English	Macro F1	0.75
	Micro F1	0.7749
	Anger	0.6625
	Fear	0.8365
	Joy	0.7674
	Sadness	0.766
	Surprise	0.7175

Figure 1: F1-Score for track-A

Language	Emotion	Score
English	Anger	0.7169
	Fear	0.7727
	Joy	0.7815
	Sadness	0.7868
	Surprise	0.6959
	Average Pearson r	**0.7508**

Figure 2: Pearson correlation for track-B

5 Error Analysis and Results

In Track A, emotion classification with a multi-class classification method, the model obtained a Macro F1 of 0.75. While this reflects a good overall performance, scores across emotions significantly differ. The best-performing class was Fear (F1 = 0.8365), while the worst was Anger (F1 = 0.6625). This discrepancy indicates that the model has trouble separating Anger from other emotions, perhaps due to similar linguistic patterns with emotions like sadness or frustration. The class imbalance could also have affected the performance of some emotions. The Micro F1 score of 0.7749 reflects that the model performed better in classifying instances that occur frequently but struggled with less frequent or ambiguous emotional expressions.

For Track B, a multi-label regression task for emotion intensity prediction, the model achieved an average Pearson correlation of 0.7508, indicating a strong relationship between predicted and actual emotion intensities. However, the correlation varied across emotions, with Sadness (0.7868) and Joy (0.7815) being predicted more accurately than Surprise (0.6959). The lower correlation for Surprise suggests that the model found it challenging to predict its intensity, likely because of the subtlety of this emotion and context dependence. Another possible source of inaccuracy is the occurrence of co-occurring emotions within the text, which would give rise to underestimation or overestimation of certain intensities. One could make further enhancements by using more emotion-specific contextual embeddings or treating ambiguous instances better using contrastive learning mechanisms.

6 Conclusion

Track A and Track B results demonstrate strong performance in classification and regression tasks. In Track A, the model achieved a Macro F1 score of 0.75, which indicates a well-balanced performance across all emotion categories. The Micro F1 score of 0.7749 suggests that the model handles overall classification instances effectively. The model in Track B achieved a mean Pearson correlation value of 0.7508, indicating very high correspondence between predicted and ground truth emotion intensity. The figures indicate the model's power in both the classification of discrete emotion and prediction of continuous intensity and its strength in dealing with sensitive emotional expressions from the text.

Abstract

In this paper, we describe our official system of the Firefly team for two main tasks in the SemEval-2025 Task 8: Question-Answering over Tabular Data. Our solution employs large language models (LLMs) to translate natural language queries into executable code, specifically Python and SQL, which are then used to generate answers categorized into five predefined types. Our empirical evaluation highlights the superiority of Python code generation over SQL for this challenge. Besides, the experimental results show that our system has achieved competitive performance in two subtasks. In Subtask I: Databench QA, where we rank the Top 9 across datasets of any size. Besides, our solution achieved competitive results and ranked 5^{th} place in Subtask II: Databench QA Lite, where datasets are restricted to a maximum of 20 rows.

1 Introduction

The Shared Task 8 (Os'es Grijalba et al., 2025) aims at building Question-Answering (QA) systems for tabular data using the DataBench benchmark (Grijalba et al., 2024), which contains 65 real-world tabular datasets from different domains, allow to assess distinct sort of questions related to each data type. This shared task has two main tasks, including DataBench QA and DataBench Lite QA. The DataBench QA subtask requires developing a system that answers questions using datasets of any size. The DataBench Lite QA subtask used the sampled version of each dataset with a maximum of 20 rows per tabular dataset (DataBench Lite). The dataset involves questions with answers and their type (including boolean, number, category, list[number], and list[category]), name of specific columns used and their types, along with the associated dataset name. The system developed by the participants will need to provide an answer which would then be compared with a gold standard.

In this paper, we propose a system that uses large language models (LLMs) to solve Shared Task 8. Our system is based on the GPT models and a structured query generation approach by producing either SQL queries or Python code to answer questions on tabular data. The generated SQL or Python code is executed on the dataset, and refines the output to produce the final response.

The rest of the paper is organized as follows. Section 2 provides the related work. The system description is presented in Section 3, followed by evaluation results in Section 1. The experimental setup and conclusion is discussed in Section 4 and Section 6, respectively.

2 Related Work

Question-Answering over Tabular Data (QAoTD) has garnered significant interest due to its broad applications in structured data retrieval and decision support systems. Existing approaches can be broadly categorized into rule-based methods, transformer-based architectures, and code-generation techniques, each addressing different challenges associated with querying tabular data.

Building on previous research, Vakulenko and Savenkov (2017) proposed a system that enables non-technical users to query open datasets using natural language. Their approach extends an existing chat-bot interface for metadata-based search by incorporating content-based retrieval from tables, allowing users to pose queries and obtain answers directly from structured data. Compared to earlier deep learning-based models, such as Sun et al. (2016), which focus on cross-table search, and Yin et al. (2016), which explore learning aggregation operations, this system offers a more lightweight and user-friendly

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1028–1033

solution, reducing computational overhead while enhancing usability for open data exploration.

To improve numerical reasoning and compositional query execution, Zhou et al. (2022) introduced UniRPG, a program synthesis approach designed for discrete reasoning over both tables and text. Their method leverages a neural programmer to generate executable programs, ensuring syntactic correctness and improving reliability in arithmetic computations. Prior research, such as Cao et al. (2023), explored converting natural language questions into executable Python programs, enabling flexible table processing and API integration. While these approaches enhance structured reasoning, they remain sensitive to execution errors and struggle to generalize to unseen table schemas.

More recently, advances in large-scale pre-trained language models have significantly impacted table-based question answering. Deng et al. (2024) conducted a study assessing the table reasoning capabilities of large language models (LLMs) and multimodal LLMs, analyzing their performance across different prompting techniques and table formats. Their findings, published in the Findings of ACL 2024, indicate that while LLMs exhibit strong generalization abilities, they often face challenges in numerical reasoning and logical consistency. Compared to earlier table-based QA models such as TAPAS (Herzig et al., 2020), which leverage weak supervision for table parsing or TAPEX (Liu et al., 2022), which achieves table pre-training by learning a neural SQL executor on a synthetic corpus, LLMs offer greater flexibility but remain prone to hallucinations when dealing with structured information.

3 System Description

3.1 Approach

The diagram in Figure 1 illustrates our approach for Subtask I and Subtask II. The system is composed of five main components: Pre-processing, Select Relevant Columns, Generate Code, Execute Generated Code and Fixing, and Generate Answer. Pre-processing involves normalizing raw input data to improve consistency and quality. The system then using GPT models to identify relevant columns and extract sample data to aid code generation. In the Generate Code stage, relevant dataset attributes and query context are provided to the model to generate executable code. This process follows one of two strategies: generating Python code for direct data manipulation or SQL queries for structured database retrieval. The generated code is then executed in the Execute Generated Code and Fixing stage to extract the necessary information from the dataset. Finally, in the Generate Answer stage, the extracted results are transformed to align with one of five predefined answer types. The detailed structure of the system is described in the following.

Pre-processing Dataset: Pre-processing is one of the essential components in building an effective Question-Answering system for tabular data. In this task, we apply a standardized pre-processing step that focuses on normalizing null values to ensure consistency across different datasets.

Select Relevant Columns: As illustrated in Figure 1, we leverage the power of GPT models through designed structured prompts to identify relevant columns for answering a given question. To achieve this, we first provide the model with the full set of column names and the input question. Specifically, given a dataset with M columns $C = \{c_1, c_2, ..., c_M\}$ and an input question Q, we construct a structured prompt that presents both the column metadata and the question to the language model. The model then processes this input and predicts a subset of relevant columns $C_{\text{rel}} \subseteq C$ that are most likely to contain the necessary information for answering Q.
Once the relevant columns are selected, we proceed to extract sample data from these columns to provide additional context for subsequent stages. The extracted sample data serves as a representative subset of the information within the selected columns, helping to enhance the accuracy of code generation in the later steps. By leveraging the contextual understanding of large language models, our approach ensures that both the selected columns and the extracted sample data are semantically aligned with the question, thereby structuring the information effectively for downstream processing.

Generate Code: Given the input question, the selected relevant columns from the *Select*

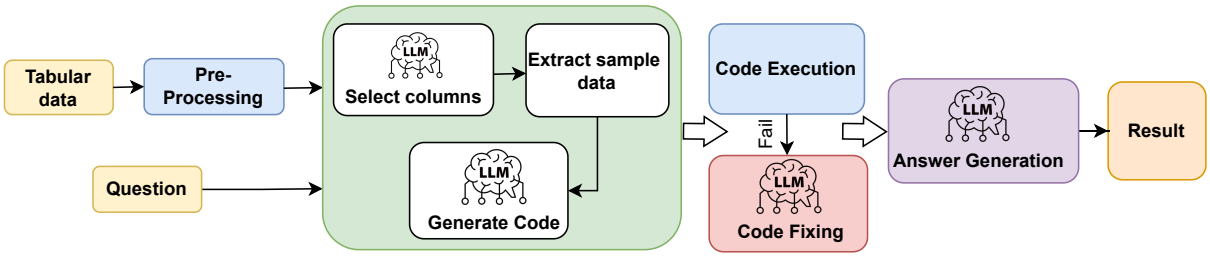

Figure 1: Pipeline for Question-Answering over Tabular Data Using Large Language Models.

Relevant Columns step, and sample data from these columns, we generate executable code to retrieve the answer. We formulate a structured prompt that encapsulates the extracted column names, representative data samples from each selected column, and additional context information—specifically, the table name for SQL-based generation or the CSV path for Python-based generation. Based on this input, we employ two distinct code generation strategies: one for generating Python code and another for generating SQL code. Figure 2 illustrates two examples of code generation. The first example shows Python code, while the second demonstrates SQL code. We designed specific prompts to guide the model behavior (Appendix A.1). This approach ensures adaptability in handling different types of data retrieval and computation tasks efficiently.

Execute Generated Code and Fixing: *For Python-generated code*, we execute the generated script directly on the provided CSV dataset. The script is designed to process the extracted columns, perform necessary computations, and return the relevant answer. Execution is handled within a controlled environment to ensure correctness and prevent unintended operations. The output of this execution serves as the extracted answer to the input question. *For SQL-generated code*, we first convert the CSV file into a structured database format using SQLite. The extracted columns and sample data are loaded into an SQLite database, where the generated SQL query is executed. This ensures efficient and structured querying over tabular data. The result of the SQL query is then returned as the answer to the question.

To maintain execution reliability, we implement an error-handling mechanism that detects and addresses failures occurring in either execution method. However, execution may encounter errors such as syntax errors or invalid operations. To handle these issues, the system implements a two-step fixing strategy: first, capturing the exact error message along with the code snippet; second, feeding these into the large language model using an error-correction prompt. The model then predicts a corrected version of the code, which is re-executed iteratively until successful or a maximum retry limit is reached. This iterative refinement process enhances robustness and adaptability, ensuring more accurate and reliable extraction of answers while minimizing execution failures.

Generate Answer: The result from the *Execute Generated Code* step is processed to align with the expected answer type. Based on the question's context and extracted data, the output is transformed into one of the predefined types: *Boolean, Number, Category, List[Number], or List[Category]*. This ensures consistency and accuracy in answering different types of questions while preserving the structure of the extracted information.

3.2 Large Language Models

We utilized two models from the GPT family of large language models (Kalyan, 2023) in this work.

- **GPT-4o**: GPT-4o is an autoregressive omni-model developed by OpenAI (OpenAI et al., 2023), capable of handling complex reasoning tasks and generating high-quality text responses efficiently.
- **GPT-3.5-turbo**: GPT-3.5-turbo, also developed by OpenAI, is an advanced version of GPT-3.5 with improved performance in understanding natural language and text generation.

4 Experimental Setup

Data and Preprocessing: We utilized the official development set for system development. As the

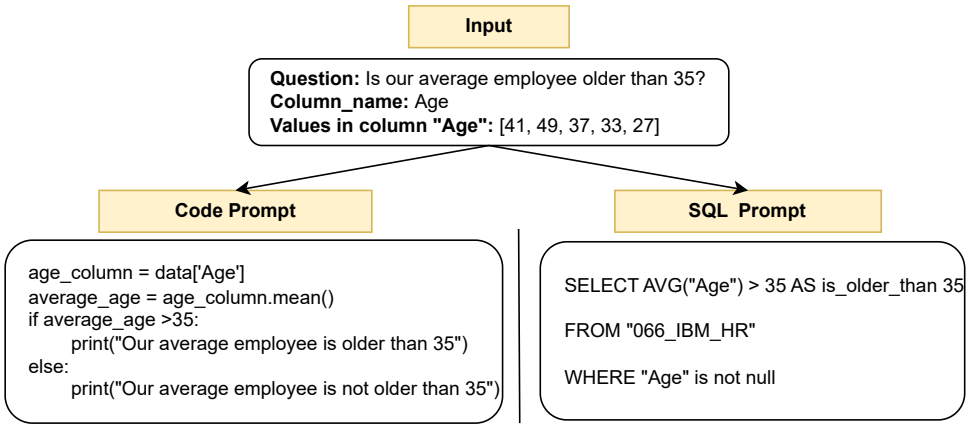

Figure 2: Examples of Generated Python and SQL Code.

competition rules stipulated, no additional data was used during the system development process.

Evaluation Metrics: The evaluation metric for two Subtasks is Accuracy Score between submission and test gold set. These evaluation metrics were provided by the task organizers and are available on GitHub.

Configuration Settings: We use the OpenAI API to access two large language models for setting up our experiments.

5 Results and Discussion

In this section, we present the official results of our final submission model for two tasks and the accuracy results split by question type for each task in the Task 8 Shared Task competition. We also compare results with the results from the five top teams for each task.

Subtask I: DataBench QA Table 1 presents the performances of our system. Table 2 shows the performances of our system compared with the five top teams on Task I. The official results on CondaBench show that we achieved an accuracy of 86.40% on the test set (Top 9).

Subtask II: DataBench Lite QA Table 1 presents the results of our submission on Subtask II. Table 3 presents the performances of our system compared with five top teams based on the final rankings. According to the official results on CondaBench, we ranked 5^{th} with an accuracy of 86.21% on the test set of this subtask.

Table 1 presents the experimental results obtained using the official evaluation function provided by the organizers on GitHub. These results highlight the performance of different approaches across various question types. Experimental results show that the Python-based approach with GPT-4o achieves the highest accuracy, with 79.69% on DataBench QA and 81.99% on DataBench Lite QA. The model performs particularly well on Boolean (96.90% and 95.35%) and Category (87.84%) questions. The SQL-based approach also demonstrates stable performance, especially for Category questions (90.54% in both tasks). Overall, GPT-4o outperforms GPT-3.5-turbo across all metrics, highlighting its superior ability to handle complex queries.

However, the system struggles with list-type questions (list[category] and list[number]), achieving only 47.22% and 55.56% accuracy with Python GPT-4o. Additionally, GPT-3.5-turbo performs significantly worse in Python-based queries, particularly for Category questions (35.14% and 45.95%). The main cause of low performance in these types of questions is errors in applying conditional filters that remove important data or retain unwanted values. Moreover, errors in duplicate processing can remove essential data, leading to inaccurate or incomplete results. The accuracy across different question types remains uneven, showing that improvements in list extraction and numerical reasoning are needed to enhance overall performance.

Subtask	Method	boolean	category	number	list[category]	list[number]	Average
Subtask I	GPT-3.5-turbo (SQL)	59.69	59.46	52.56	41.67	58.24	54.79
	GPT-4o (SQL)	73.64	90.54	73.72	59.72	81.32	75.48
	GPT-3.5-turbo (Python)	72.09	35.14	66.03	43.06	58.24	58.62
	GPT-4o (Python)	96.90	87.84	77.56	47.22	78.02	**79.69**
Subtask II	GPT-3.5-turbo (SQL)	66.67	70.27	58.33	50.00	61.54	61.49
	GPT-4o (SQL)	85.27	90.54	80.13	55.56	79.12	79.31
	GPT-3.5-turbo (Python)	72.09	45.95	73.72	50.00	75.82	66.48
	GPT-4o (Python)	95.35	87.84	80.77	55.56	81.32	**81.99**

6 Conclusion

In this paper, we presented a system for Question-Answering on tabular data in the SemEval-2025 Task 8. Our approach leverages large language models to generate column descriptions, select relevant columns, and produce executable code to derive final answers. The system efficiently processes diverse tabular datasets and generates accurate responses without requiring additional training data. Our experiments demonstrate competitive performance across different datasets in DataBench. For future work, we plan to enhance our system's ability to handle more complex table structures and improve its accuracy in missing or ambiguous data. Additionally, exploring better prompting strategies for large language models could further optimize system performance.

A Appendix

A.1 Prompt Engineering

Prompt Design for Python Code Generation.

Write a Python script to extract data related to the question: `{question}`
Do not write anything except the python code.

Follow the instruction below:
1. Reads the CSV file from path `{csv_file_path}`
2. The columns used in the data are `{relevant_col}`.
3. The columns information are `{relevant_info}`, this includes column name and several different values extracted from that column (which may or may not be the entire value in the column).
4. Just print the complete answer sentence based on the answer of the last question and the question.

Prompt Design for SQL Code Generation.

Write an SQL script to extract data related to the question: `{question}`
Follow the instruction below:
1. Need to keep the table name in `" "`
2. If any column name matches a reserved keyword in SQLite (e.g: Transaction,...), ensure it is wrapped in double quotes (`" "`) to avoid syntax errors.
3. Do not use `DISTINCT` unless the question explicitly requires unique values, such as when it contains terms like "different value", "unique", or "distinct".
4. Use `ORDER BY column DESC` when sorting in descending order. Use `ORDER BY column ASC` when sorting in ascending order.
5. Only provide the SQL query; do not include any explanations or additional text.
Now write an SQL query to answer the question: `{question}` based on the table name `{table_name}`, the columns used `{relevant_col}`, and several different values extracted from those columns `{relevant_info}`.

Abstract

The Multilingual shared-task on Hallucinations and Related Observable Overgeneration Mistakes in the SemEval-2025 competition aims to detect hallucination spans in the outputs of instruction-tuned LLMs in a multilingual context. In this paper, we address the detection of span hallucinations by applying an ensemble of approaches. In particular, we synthesized a dataset and fine-tuned LLM to detect hallucination spans. In addition, we combined this approach with a white-box method based on uncertainty quantification techniques. Using our combined pipeline, we achieved 3rd place in detecting span hallucinations in Arabic, Catalan, Finnish, Italian, and ranked within the top ten for the rest of the languages.

1 Introduction

In recent years, there have been significant advancements in Natural Language Generation (NLG) models, mainly due to transformer-based architectures such as GPT (Radford et al., 2019). Nevertheless, the field faces two related challenges: the first is the propensity for current neural systems to create incorrect, yet coherent outputs, and the second is the inefficiency of current metrics in prioritizing accuracy over fluency. This leads to a phenomenon known as "hallucination", where NLG models generate cohere but inaccurate outputs that are difficult to automatically identify (Ji et al., 2023).

The shared-task on Multilingual Hallucinations and Related Observable Overgeneration Mistakes (Mu-SHROOM, Vázquez et al. (2025)) has been suggested to address this challenge. In particular, the Mu-SHROOM task aims to detect hallucination spans in the outputs of instruction-tuned LLMs in a multilingual context models (Arabic, Basque, Catalan, Chinese, Czech, English, Farsi, Finnish, French, German, Hindi, Italian, Spanish, and Swedish).[1]

[1]https://helsinki-nlp.github.io/shroom/

Mu-SHROOM is the continuation of the competitions in hallucination detection, the first being SHROOM. Its goal was to detect hallucinations and overgeneration errors within various generation tasks, such as machine translation, paraphrasing, and definition modeling (Maksimov et al., 2024; Rykov et al., 2024).

To address the Mu-SHROOM challenge, we developed an ensemble of approaches. First, we fine-tuned LLM on synthetic span-level hallucination detection data. Then, we combined this approach with white-box methods based on uncertainty quantification (UQ) techniques. Using our combined pipeline, we achieved 3rd place in detecting span hallucinations in Arabic, Catalan, Finnish, Italian, and ranked within the top ten for the rest of the languages.

Our contribution could be summarized as follows:

- We demonstrate a pipeline for synthetic data generation without any human annotation for span-level hallucination detection.
- We propose training an additional lightweight model that leverages multiple white-box UQ methods, demonstrating effectiveness without relying on any external information.
- We demonstrate that combining both the white-box and black-box methods can further enhance performance.

2 Related Work

2.1 Black-box

Within the scope of black-box approaches for hallucination detection, FactScore (Min et al., 2023) is a well-known approach. It first extracts atomic facts from the model's response and compares them to a retrieved context using an additional LLM. This process yields a fact-verification score that indi-

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1034–1045

cates whether the claims are supported by the retrieved context.

Several approaches exist for the detection of word-level hallucinations, among which RAGTruth (Niu et al., 2024) is a widely recognized pipeline for this task. Initially, the developed dataset and its corresponding benchmark were designed to evaluate LLMs within a retrieval-augmented generation (RAG) pipeline for various tasks, such as summarization, question-answering, and others. However, it could be easily adapted for the fact-checking task. The dataset was created using human annotation of LLM responses to capture hallucinations.

Furthermore, the task of hallucination detection can naturally be extended to hallucination editing. For example, the FAVA (Mishra et al., 2024) model is specifically trained for word-level hallucination detection and editing tasks according to the introduced hallucination taxonomy. To collect training data, the authors asked LLM to insert errors from the introduced taxonomy into the responses.

Despite their advantages, both RAGTruth and FAVA are limited in their applicability, as they are designed only for English-language tasks.

2.2 White-box

White-box approaches leverage internal generation signals, such as token-level probability distributions or hidden states, to detect hallucination of LLMs. For instance, Token Probability and Token Entropy (Fomicheva et al., 2020) utilize the probability distribution of each token. Belikova et al. (2024) demonstrated that token maximum probability and margin probability can be successfully used to enhance the trustworthiness of the RAG pipeline over knowledge bases. Moskvoretskii et al. (2025) showed that UQ scores can be used to develop adaptive RAG pipeline that outperforms the vanilla RAG in both performance and computational efficiency. Krayko et al. (2025) applied UQ scores, particularly mean token entropy and mean token probability, for the continuous evaluation of the RAG pipeline. Fadeeva et al. (2023) introduced the Claim Conditioned Probability (CCP) method, which evaluates the consistency of the several most probable token candidates.

These methods, while simple and effective for various tasks, exhibit several limitations in hallucination detection across multiple models. The distribution of UQ scores can differ between models. Furthermore, UQ scores are often poorly calibrated (Kadavath et al., 2022), which requires the use of an additional trainable model to normalize these values.

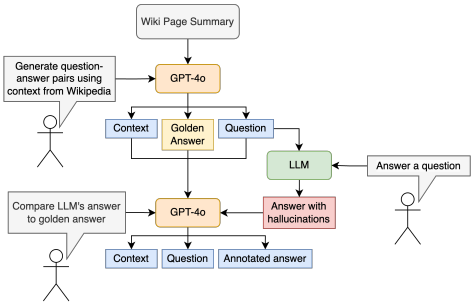

Figure 1: Synthetic data collection procedure. The detailed process is described in Section 3.

Studies have shown that hidden states (Azaria and Mitchell, 2023; CH-Wang et al., 2024; Vazhentsev et al., 2025) and attention matrices (Chuang et al., 2024; Vazhentsev et al., 2024) of LLMs contain significant information on the truthfulness of model output. These works suggest training auxiliary models to predict uncertainty using these features.

Various methods require multiple stochastic samples from LLMs to quantify uncertainty based on the consistency of generated answers (Manakul et al., 2023; Lin et al., 2023; Duan et al., 2024; Vashurin et al., 2025). Although these approaches are effective in sequence-level tasks, none of these methods can be directly applied to token-level hallucination detection.

3 Multilingual Synthetic Dataset for Hallucination Detection

All of our approaches require additional data for fine-tuning and calibration. The exact scheme of synthetic data generation is shown in Figure 1.

To collect synthetic data, we first generate multilingual question-context-answer triplets based on contexts from Wikipedia. Generation was performed using GPT-4o for the exact prompt used to generate question-answer pairs. Next, we collect the hypotheses by passing the generated questions without any contexts to various LLMs. Finally, we ask GPT-4o to find all inconsistencies between the LLM answer and the golden answer. Any inconsistent information in the hypotheses that contradicts the golden answer is considered a hallucination. In total, synthetic dataset contains 52 271 samples after all filtering stages.

The generation of synthetic training data through

LLM has been successfully employed to address detoxification (Moskovskiy et al., 2024, 2025) and PII detection (Savkin et al., 2025).

4 System Overview

4.1 Black-box

Our black-box approach incorporates a retriever that provides additional context along with the question-answer pair to a fine-tuned multilingual LLM. The LLM then highlights the spans in the answer that contain hallucinations. The architecture of the black-box pipeline is shown in Figure 2 in Appendix D.

A fine-tuned LLM, by itself, provides only hard labels, as it simply inserts special tokens around the spans with hallucinations. Therefore, to obtain soft labels with probabilities for each span, we employ two strategies. The first method is a `logit`-based approach, which assigns the probability of the span based on the probability of the opening tag. The next method is a `sampling`-based approach that samples the annotations from the model several times and aggregates the predictions. The probability of a span is calculated as the normalized frequency of its occurrence across samples. In addition, the baseline approach confidently set probability of 1.0 for each predicted span.

4.2 White-box

Our white-box pipeline is designed to predict token-level hallucination probabilities by leveraging uncertainty scores. For a given generated text $\tilde{y}$ of a length N, for each token $t_i \in \tilde{y}$, $i = 1 \dots N$, the procedure consists of the following steps:

1. We construct a feature vector $\mathbf{x}_i$ by concatenating the uncertainty scores obtained using a sliding window centered at the position i. For a given window size k, the feature vector is defined as:

$$\mathbf{x}_i = \bigoplus_{m=0}^{M-1} \left[\mathbf{u}_{i-k}^{(m)}, \mathbf{u}_{i-k+1}^{(m)}, \dots, \mathbf{u}_{i+k}^{(m)} \right],$$

   where $\bigoplus$ denotes the concatenation operation, $\mathbf{u}_j^{(m)}$ represents the uncertainty score from method m for token j, and M – total number of UQ methods. In our experiments, we use Token Probability, Token Entropy, and CCP. For tokens outside the valid range (i.e., if $j < 0$ or $j > N$), we set $\mathbf{u}_j^{(m)} = 0$.

2. The target label $y_i \in [0, 1]$ is defined as the maximum hallucination probability across all spans covering the token. If token i does not belong to any hallucinated span, we set $y_i = 0$.

Finally, we train a lightweight calibration model $f(\cdot)$ to predict the hallucination probability for each token, given its feature $\mathbf{x}_i$. For the model $f(\cdot)$, we employ logistic regression (LR) and gradient boosting (GB). To convert the soft probability predictions into binary hard labels, we determine an optimal probability threshold using the validation set.

4.3 Merging

To take advantage of both approaches, we integrate predictions from the white-box and black-box methods. For each token, the final hallucination probability is calculated as a weighted average:

$$p_{\text{final}} = \alpha\, p_{\text{black box}} + \beta\, p_{\text{white box}},$$

where $p_{\text{black box}}$ and $p_{\text{white box}}$ represent the probabilities obtained using the black-box and white-box methods, respectively, with α and β being positive tunable parameters that satisfy $\alpha + \beta = 1$.

5 Experimental Setup

5.1 Baselines

For all baselines, we adopt the context obtained in the retrieval stage for the black-box method, described in Section 5.2. Thus, we evaluated the FAVA[2] model passing questions and answers from the validation and test subsets along with the retrieved contexts. This ensures FAVA and black-box are tested on identical input data. We did not perform any soft labeling for FAVA, therefore, we assign a probability of 1.0 for each span.

Furthermore, we train the ModernBERT[3] encoder on the binary token classification task using our synthetic data. The training parameters are presented in Appendix E.

For FactScore, we use retrieved contexts to verify each generated atomic fact. For each token, the soft label equals the frequency of it appearing in unsupported claims or equals zero for all tokens that appear in all claims or are present in the original input.

[2] https://hf.co/fava-uw/fava-model
[3] https://hf.co/answerdotai/ModernBERT-large

We also select different LLMs as baselines, including both open-source and proprietary ones: GPT-4o, Phi-4[4], and Qwen2.5-7B-it. In the prompt, we asked models to identify and highlight hallucinations in the text using the tags `[HAL]` and `[/HAL]`. The evaluation is performed with retrieved context in 3-shot mode, where, for each question-answer pair, we randomly sample three examples of correctly identified hallucinations from the language-specific validation set.

5.2 Black-box

Model fine-tuning: As an LLM for the black-box hallucination detection pipeline, we fully fine-tuned Qwen2.5-7B-Instruct[5] due to its strong multilingual capabilities. See Appendix F for more details on LLM selection. For highlighting hallucination spans, we add two special tokens `[HAL]` and `[/HAL]` to the model's tokenizer. We added the synthetic data along with FAVA and RAGTruth to the training dataset mixture. In total, the model was trained with 84 334 training samples. Details on dataset mixture and training hyperparameters are presented in the Appendix B.

Retrieval: To retrieve the contexts for hallucination detection, we used the DuckDuckGo API[6]. We simply passed the question as is and collected the top 20 pages from the search output. Next, we filtered only Wikipedia articles related to the question from the search output. Finally, we collected and merged all Wikipedia summaries for the questions.

Soft Labeling: We compare different soft-labeling strategies:

- `Base`: simply assign a probability of 1.0 to each selected span.
- `Logit`: extract the probability of the opening `[HAL]` token in a greedy decoding setup.
- `Temp`: perform temperature sampling and set `top_k`, `top_p`, `num_beams`, and a `temperature` parameters.
- `DBS`: perform Diverse Beam Search (Vijayakumar et al., 2016) sampling strategy and adjust `diversity_penalty`, `num_beams`, and a `num_beam_groups` parameters.

5.3 White-box

We use the implementation of uncertainty quantification methods from LM-Polygraph (Fadeeva et al., 2023; Vashurin et al., 2024). In our experiments, we consider two training strategies for the calibration model.

Model-specific training: For each language, a separate hallucination detection model was trained using bootstrap-validation with a 70/30 ratio for train/validation split.

Model-agnostic training: Data from all languages were combined and a single model was trained using K-fold cross-validation. This approach yielded a more stable training process due to reduced data variance.

Table 1: Main results. For black-box, we report two soft-labeling strategies: `Base`, without any specific soft-labeling, and `DBS`, which is based on the span frequency calculation in the Diverse Beam Search generation output. For white-box methods, LR refers to logistic regression, and GB refers to gradient boosting.

6 Results

6.1 Baselines

The results of baseline evaluation are shown in Table 1. The FAVA model performed with IoU score at the relatively low level of 26.49 on validation and 27.43 on test, which is significantly lower than the Black-box$_{\text{Base}}$ level with the same settings, without any soft labeling strategy. This shows that the FAVA taxonomy is probably not complete enough and does not observe many errors that LLMs generate. The FactScore$_{\text{GPT-4o}}$ shows relatively low performance, while the trained ModernBERT achieves an IoU score of 32.87 on the validation set and 33.35 on the test set.

When considering LLM-based methods, the GPT-4o and Phi-4 models that were used in 3-shot mode with randomly sampled examples show the best results compared to all the baselines.

6.2 Black-box

First, we perform ablation study of several LLMs to select the best performing model for hallucination detection in the Black-box pipeline (Table 7 in Appendix F). In contrast to results obtained in 1-shot setting, Qwen2.5-7B-it outperforms all other considered LLMs, even 14B Phi-4 model.

Next, we performed a soft-labeling hyperparameter ablation study (Table 5 in Appendix C). We found that the best IoU is observed with sampling 5 hypotheses using Diverse Beam Search along with a diversity penalty in the 1.0 level. Considering `Temp`, the best IoU is observed with sampling 5 hypotheses and temperature in 0.5.

Finally, we run `base` and `DBS` soft-labeling methods along with the fine-tuned Qwen2.5-7B-it on both the validation and test parts. On both validation and test, `DBS` is a best-performing soft-labeling strategy. Futhermore, this approach substantially outperforms all other methods described.

6.3 White-box

Detailed results of the white-box experiments across various languages and different training strategies are provided in Table 8 in Appendix G. Both the model-specific and model-agnostic approaches demonstrate improvements over the baseline methods. Notably, the model-agnostic approach outperforms the model-specific approach by 3% of IoU and by 11% of Cor, considering only the languages that are present in both the validation and test sets.

Additionally, the results indicate that a combination of all UQ methods yields robust improvements compared to using any single UQ method. Furthermore, the results with the GB model are slightly better that with the LR model. The final results, utilizing the model-agnostic approach trained on all UQ methods, are presented in Table 1.

6.4 Merging

In our work, we explore various approaches to combine the outputs of white-box and black-box methods. Specifically, we utilize logistic regression on predicted spans, gradient boosting with black-box predictions as features, and a simple weighted average approach.

Ultimately, the weighted average method, where the contribution of each method is controlled via parameters α and β, proved to be the most stable and effective fusion strategy. Our experiments revealed that the optimal values of α and β vary significantly across languages, and selecting them individually for each language leads to better results. To select the best hyperparameters, we perform a grid search on the validation set, selecting α and β that maximize IoU. A detailed breakdown of the results, including per-language optimal values, is provided in Table 2 in Appendix A.

7 Error Analysis

We conducted a detailed error analysis on a subset of English test examples to pinpoint the most common failures of our span-detection algorithms. We found that the vast majority of errors remain factual misclassifications. Notably, both the white-box and black-box methods tend to identify spans that are slightly longer. Although they still correctly cover the spans, they occasionally truncate entities – e.g. predicting "Ewald Klein in the 1930" instead of the distinct facts "chemist", "Ewald", "1930s" – a behavior more pronounced in the white-box method, which tends to select larger, statement-level spans over fine-grained annotations.

On the quantitative side, we measured in-accuracy in 14 languages (Table 9 in Appendix H), it evaluates whether the predicted answer includes the ground truth (Moskvoretskii et al., 2025). In many cases, the black-box method fully subsumes the expert spans – yielding higher in-accuracy but at the cost of over-segmentation. To mitigate both over- and under-segmentation, we experimented with two post-processing heuristics: (1) forcing inclusion or exclusion of partially labeled tokens and (2) stripping leading/trailing whitespace and punctuation from predicted spans. Fully including or excluding partially matched tokens uniformly reduced average IoU by 1.3% and 1.0% respectively, with no language benefiting. In contrast, applying only the punctuation cleanup heuristic increased IoU by 0.3% overall and by 2.2% for English (moving our English results from 9th to 6th place). These results demonstrate that simple span-boundary corrections can yield meaningful gains without retraining the core model.

Conclusion

We have shown that the lightweight white-box approach produces much better results that complicated baseline methods, even without relying on external knowledge.

The quality of our synthetic data generation

pipeline and the effectiveness of white-box approach is demonstrated by the high scores achieved by the merged method: our approach was ranked 3rd for four languages and within the top ten for the rest of the languages.

Limitations

Although synthetic data contains answers from LLMs of different sizes and architectures, only GPT-4o was used as a question-answer pairs generator and as a main annotator of hallucinations. This means that the annotation is probably not as objective as it could be if we used several proprietary models or even a group of crowdsourcers.

Since the uncertainty scores are poorly calibrated, we use supervised models in our white-box approach to both calibrate and combine several UQ methods. Consequently, the performance of this approach depends on the quality and size of the data available for training.

A Merging Experiments

The hyperparameters were selected using the following grid: α from 0.1 to 1.0 with a step of 0.015, $\beta = 1 - \alpha$, and threshold from 0.05 to 0.65 with a step of 0.03. For each language, we selected the hyperparameters that maximized the IoU on the validation set. If the objective was to maximize the product of IoU and Cor on validation, the average IoU on the test set slightly decreased (to 57.66%), but Cor significantly improved (up to 58.31%). Additionally, the experiments revealed that each language requires its own set of hyperparameters; otherwise, if hyperparameters are tuned to maximize the average metrics across all languages, the merging results are worse than those of a single black-box method.

Language	α	β	**threshold**	**val**		**test**

Table 2: Results of hyperparameter tuning for the weighted average of white-box and black-box results.

B Black-box Training Details

The black-box model is trained on a dataset mixture created by combining the synthetic data, FAVA and RAGTruth datasets. Details about each dataset are shown in Table 3.

Dataset	**# of training samples**
Synthetic data	52 271
FAVA	27 364
RAGTruth	4699
Total	84 334

Table 3: Training dataset mixture details.

LLMs training for the black-box approach was performed on a single 8xA100 node with DeepSpeed Stage 2 optimization. The global batch size was 32 samples. All models were trained in a fixed setup with 4 epochs and a linear learning rate scheduler. All details on custom hyperparameters are shown in Table 4.

Hyperparameter	**Value**
learning_rate	1e-5
num_train_epochs	4
lr_scheduler_type	linear
warmup_ratio	0.3
gradient_accumulation_steps	32
batch_size	1
deepspeed stage	2

Table 4: Black-box training hyperparameters, remaining hyperparameters follow HuggingFace Trainer defaults.

C Soft Labeling Details

The soft labeling methods ablation for the black-box approach on the validation subset is shown in Table 5.

The `DBS` approach strongly outperforms the baseline, `Logit`, and `Temp` methods. Sampling more hypotheses, 10 instead of 5, only slightly improves IoU when the diversity penalty is 0.5. However, this effect is not relevant when the diversity penalty is greater than 0.5. We found that the best IoU is observed with 5 hypotheses and $\alpha = 1.0$.

The `Temp` approach shows quite robust results. Scaling temperature and sampling more hypotheses negatively affects the results for this soft labeling approach. The best IoU for `Temp` is 49.19 with 5 hypotheses and a temperature level of 0.5. Baselines

Soft Labeling Method	**val**	
	IoU	Cor
Base	46.78	43.58
Logit	47.00	43.38
DBS $n = 5, \alpha = 0.5$	52.52	49.54
DBS $n = 5, \alpha = 0.75$	53.39	**50.74**
DBS $n = 5, \alpha = 1.0$	**53.43**	49.95
DBS $n = 10, \alpha = 0.5$	53.30	50.59
DBS $n = 10, \alpha = 0.75$	52.84	47.59
DBS $n = 10, \alpha = 1.0$	51.53	45.39
Temp $n = 5, t = 0.5$	49.19	47.01
Temp $n = 5, t = 1.0$	49.18	46.91
Temp $n = 5, t = 1.5$	49.18	47.11
Temp $n = 10, t = 0.5$	48.31	47.62
Temp $n = 10, t = 1.0$	48.14	47.61
Temp $n = 10, t = 1.5$	48.07	47.62

Table 5: Ablation on soft labeling methods for Black-box. n stands for `num_beams`, α for `diversity_penalty`, t for `temperature`.

D Black-box Pipeline Architecture

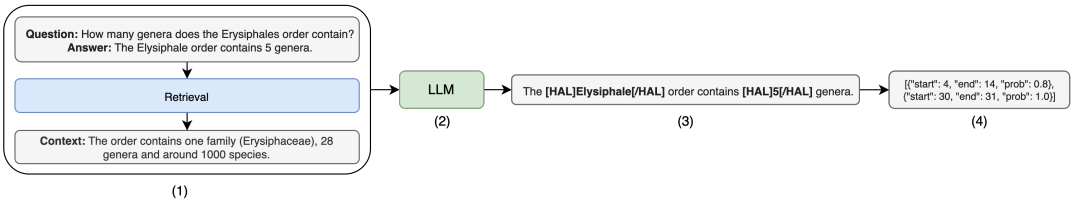

Figure 2: Black-box pipeline architecture. (1) Using the input question, we retrieve additional context and (2) pass it along with the question and answer to the fine-tuned LLM. (3) The model then detects and highlights hallucinations. (4) Finally, we post-process the LLM outputs and perform soft labeling to assign span probabilities.

E ModernBERT Training Details

As the black-box model, ModernBERT was trained on the full dataset mixture described in Appendix B. Training was performed on a single A100 40GB GPU. Details on the training hyperparameters are given in Table 6.

Hyperparameter	Value
learning_rate	1e-5
num_train_epochs	15
weight_decay	0.01
gradient_accumulation_steps	40
batch_size	1

Table 6: Encoder training hyperparameters.

F LLM Ablation

We used LLMs of different sizes and architectures for the black-box pipeline (Abdin et al., 2024; Yang et al., 2024). The results of our comparison are shown in Table 7. We used the Mu-SHROOM validation subset for ablation. We did not ablate different soft-labeling methods here as the goal of this ablation is to select the best base LLM for other ablations. Thus, according to our `Base` soft labeling approach, the probability of each span is assigned as 1.0. For each LLM, the training hyperparameters and the data set mixture were the same as described in the Appendix B.

We found that while Phi-4 and Qwen2.5-14B-Instruct are the largest models in our study, they are not the best performing LLMs in this setting. By averaging the IoU and Cor scores, Qwen2.5-7B-Instruct LLM outperforms all other models.

Although Qwen2.5-3B-it is the smallest model of the observed ones, it is only slightly inferior to larger models for French and Italian. For English and Swedish it even surpasses all observed checkpoints. Overall, its IoU score at the level of 37.89 is close to the IoU score of the best performing Qwen2.5-7B-it.

Also, the 14B model performs slightly better in Spanish, German, French, and Swedish, but yields significantly to the 7B model in Hindi and Finnish.

Phi-4 shows comparable performance to the 7B and 14B models for German and Swedish. For all other languages, including English, Phi-4 shows inferior performance.

G White-box Results

The detailed results with the white-box methods are presented in Table 8. These results indicate that model-agnostic training of the GB model, leveraging all UQ methods, achieves the best average results on both validation and test datasets.

Additionally, we explore the use of the features extracted from the attention matrices, as proposed by Vazhentsev et al. (2024). The LR model trained on these features demonstrate the best performance on several language, such as English and Finnish. However, it is important to note that the number of extracted features varies across models due to differences in the number of layers and attention heads. As a result, experiments with this approach are conducted using a model-specific strategy, considering only the languages presented in the validation set.

Abstract

This paper presents the method for the unlearning of sensitive information from large language models as applied in the SemEval 2025 Task 4 challenge. The unlearning pipeline consists of two phases. In phase I, the model is instructed to forget specific datasets, and in phase II, the model is stabilized using a retention dataset. Unlearning with these methods secured a final score of 0.420 with the 2nd honorary mention in the 7B parameter challenge and a score of 0.36 in the 13th position for the 1B parameter challenge. The paper presents a background study, a brief literature review, and a gap analysis, as well as the methodology employed in our work titled NeuroReset. The training methodology and evaluation metrics are also presented, and the trade-offs between unlearning efficiency and model performance are discussed. The contributions of the paper are systematic unlearning, a comparative analysis of unlearning methods, and an empirical analysis of model performance post-unlearning

1 Introduction

Large Language Models (LLMs) demonstrate excellent natural language understanding and language generation capabilities. They are trained on vast amounts of data. Curating the data to remove private or sensitive information is a labor-intensive task and is often overlooked. As a result, once an LLM is trained, it may contain sensitive or erroneous information that ideally should be deleted for ethical, privacy, or regulatory reasons (Liu, S, 2025). Unlearning in machine learning is an emerging area of interest, focusing on the selective removal of unwanted information while preserving the overall model integrity and generalization ability (Jia, Jinghan et al, 2024). The unlearning must guarantee that the information erased is not recoverable by model inversion attacks but, at the same time, allow the model to function on unrelated tasks (Doshi, 2024). The traditional unlearning methods, such as knowledge distillation and fine-tuning, have issues such as uncertain outputs post-unlearning and catastrophic forgetting, whereby the said models lose relevant knowledge alongside the ones they do not want to lose (Wang, 2024; Wang, 2024). This work describes a scalable unlearning paradigm using fine-tuned LLMs. LLM unlearning with multitask evaluations are also proposed in recent times (Ramakrishna, 2025 A).

We propose a two-phase unlearning framework comprising target-specific gradient-based forgetting and post-unlearning stabilization. Hence, it leads to effective removal of specified data while substantially reducing catastrophic forgetting of general knowledge. The system was evaluated on multi-tasking scenarios measuring unlearning efficacy and overall model performance post-unlearning.

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1046–1051

Primary contributions of this work are threefold:

1. Developed and implemented a Gradient-Based Sequential Unlearning Framework that employs an organized two-phase process for the targeted forgetting followed by stabilization thereby diminishing catastrophic forgetting.
2. Proposed a detailed Mathematical Design for Forget-Retain Balance that introduces an objective function to balance retention and forgetting, thereby providing a mechanism for control over the removal of unwanted/sensitive knowledge.
3. Proposed an unlearning method that is scalable and adaptable to Pre-Trained Language Models that enables the swift prototyping of large datasets for real-world applications.

1.1 Background

Rising deployment of LLM into almost every domain calls for the development of unlearning methods to erase the sensitive data without complete retraining of the model. The state of affairs necessitating unlearning is observed in the following contexts:

- Data Privacy Compliance: Laws and Regulations to govern removing sensitive data (Liu, S, 2025).
- Bias and Fairness: It's important to remove biased or unethical content so that responsible AI deployment is assured.
- Security Concerns: It addresses the mitigating attacks in which model inversion is done using sensitive information that is preserved (Zhang, 2024).

Various approaches proposed in the literature for LLM unlearning include forgetfulness through loss-adjustable unlearning, which offers an efficient removal of information without close retention of data and yet guarantees utility of the model (Wang, 2024). Name-aware unlearning enhances privacy safeguards against forgetting critical data without suffering considerable performance trade-offs (Liu, 2024). However, the above LLM unlearning benchmarks are vulnerable to slight tampering, and hence the desirability for sharper evaluation metrics (Thaker, 2024). δ-Unlearning is a scalable, black-box technique where logits are adjusted on a smaller model rather than a full model retraining (Huang, 2024). LLMs may shape model behaviour by discouraging undesirable impacts on weights rather than mitigating privacy leakage (Wang, 2024). Effective unlearning methods do the expected oblivion with minimized side-effects, particularly in some sensitive domains (Lynch, 2024). Robust unlearning frameworks should rather maintain model performance while ensuring the targeted removal of whatever information (Wang, 2025). Efficient unlearning techniques for large language models can enable privacy compliance, multi-task convenience, and controlled knowledge removal at very low additional computational costs (Blanco-Justicia, 2025). Unlearning can never be a panacea for content regulation concerning generative AI as things may be recalled from forgotten memory due to in-context learning and may need further filtering mechanisms (Shumailov, 2024). Unlearning would, therefore, serve as a sort of alignment strategy economical answer for RLHF because it will only need negative examples to be computationally efficient in responding to a harmful response, copyrighted material, and hallucinations within LLMs (Yao, 2023).

The proposed unlearning method called NeuroReset addresses some of the restrictive aspects of existing methods by enhancing computational efficiency and ensures controlled removal of knowledge. This method, unlike conventional retraining-heavy techniques [Wang, 2024; Blanco-Justicia, 2025; Yao, 2023], greatly reduces computational overhead, making the process selectively forget undesirable knowledge. This is achieved through the application of specific gradient updates followed by stabilization, which is carried out with conserved data. The methodology, having two stages, ensures that the privacy protection to mitigate the performance degradation, as outlined in earlier works: (Liu, 2024; Lynch, 2024; Wang, 2025). Additionally, the framework avoids the possible resurgence of forgotten knowledge (Shumailov, 2024) by reinforcing the desired behaviours through fine-tuning, thereby making it a more robust and scalable unlearning approach.

2 System Overview

2.1. Model Architecture

The pre-trained OLMo language models have been used in conjunction with the Transformers library of Hugging Face. The models utilized in the experiments are:

- 7B Parameter OLMo- a large-scale LLM which is further fine-tuned and subsequently unlearned using the dual-phase method (OLMo 7B).
- 1B Parameter OLMo- another smaller LLM evaluated the same way (OLMo 1B).
- 7B Parameter OLMo Tokenizer- the pre-defined tokenizer used for the tokenising of the 7B parameter OLMo LLM (OLMo 7B TK)
- 1B Parameter OLMo Tokenizer- the pre-defined tokenizer used for the tokenising of the 1B parameter OLMo LLM (OLMo 1B TK).

2.2. Unlearning Framework

The proposed system introduces a two-step unlearning mechanism as shown in Fig. 1.

1. Forget Phase: The model undergoes fine-tuning on a forget dataset to suppress specific information using gradient-directed schemes targeted toward unlearning. Adversarial training procedures are applied so that the unlearned information is hard to recover.
2. Retain Phase: To restore general knowledge and prevent the drift of the model, a stabilization phase is introduced in which only the specified content is unlearned while retaining other broader general knowledge.

Let M be a fine-tuned language model, D_f be a dataset for forgetting while D_r is a dataset for retaining. The aim here is to forget all that has been learned from D_f and keep with it such that it doesn't affect all the knowledge encoded in D_r. Suppose that the parameters of M are denoted by θ. It is desired to optimize those θ such that:

$$\theta^* = arg\min_{\theta} (1-\lambda)L_r(\theta) - \lambda L_f(\theta) \quad (1)$$

where:

- L_f (θ) is the loss function for forgetting the sensitive content.
- L_r(θ) is the loss function for the knowledge to be retained.
- λ: A trade-off hyperparameter, always between 0 and 1, determining the weight of forgetting versus retaining.

Equation (1) provides a generalized formulation for unlearning. In our implementation, this equation is operationalized in a sequential manner rather than as a joint optimization. This separation ensures independent controllability over each phase and enables clearer empirical analysis of their individual effects. The values of L_f and L_r in practice are weighted according to the percentage dictated by the choice of λ.

2.2.1 Forget Phase

2.2.1.1 Dataset Processing and Tokenization

The forget dataset D_f is first loaded and tokenized as per the given equation:

$$X_f = T(D_f) \quad (2)$$

Where T is the tokenizer used (OLMo Tokenizer) for mapping the textual input into their corresponding tokenized tensors.

The model is then updated using AdamW optimization:

$$\theta_{t+1} = \theta_t - \eta \frac{\widehat{m_t}}{\sqrt{\widehat{v_t}}+\epsilon} \quad (3)$$

$\widehat{m_t}$ and $\widehat{v_t}$ are biased corrected estimates for the first and second phases and η is the learning rate. ∈ is a small constant to prevent zero division.

2.2.2 Retain Phase

Dataset Processing

The retain dataset D_r is also tokenized is a similar process:

$$X_r = T(D_r) \quad (4)$$

Fine-tuning for Knowledge Retention

To mitigate the model's loss of generalization capability, the retain dataset is used for re-stabilization:

$$L_r(\theta) = \sum_{i=1}^{N} \mathcal{L}(N\left(X_r^{(i)};\theta\right), Y_r^{(i)}) \quad (5)$$

This helps restore performance on broader NLP tasks without reintroducing the forgotten content. Forget data is not reused in this phase. The phased separation is deliberate, providing operational

modularity and isolating unlearning effects before knowledge restoration.

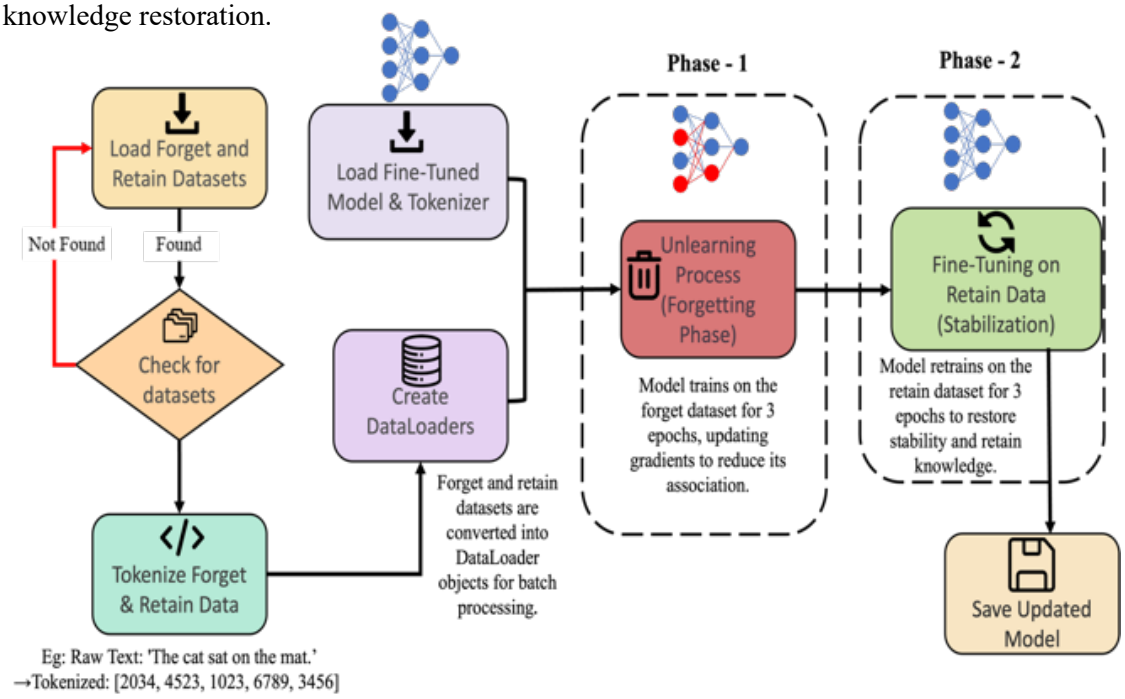

Figure 1: Proposed 2-step Unlearning Mechanism

2.2.3 Implementation

Tokenization involves receiving texts from the tokenizer of Hugging Face and transforming them to tensors compatible with the model. *Optimization* encompasses the AdamW optimizer to update the parameters. *Batch Processing* ensures smooth training through DataLoader.

This unlearning paradigm uses the principle of sequential fine-tuning to preserve information that is expected to be retained while being able to forget unwanted information and thereby maintain model performance.

3 Experimental Setup

3.1. Datasets

The experiment relied on datasets from SemEval - 2025 Task 4 (Ramakrishna et al, 2025 B) in both Parquet and JSONL formats. There are two datasets as follows:

- Forget Dataset: Contains sensitive information that must be unlearned by the model (Ramakrishna et al, 2025 B)
- Retain Dataset: A general knowledge dataset used to stabilize the model after unlearning (Ramakrishna et al, 2025 B)

3.2 Hyperparameters

The following hyperparameters were used in the experiment: Optimizer: AdamW, Learning Rate: 5e-5, Batch Size: 16, Epochs: 3 (Forget Phase) + 3 (Retain Phase)

In this work , λ is taken as 1 during the Forget Phase (to focus solely on unlearning) and 0 during the Retain Phase (to focus purely on knowledge restoration). However, in general, $\lambda \in [0,1]$can be adjusted to perform simultaneous forget-retain trade-offs or blended fine-tuning depending on desired outcomes.

3.3 Evaluation Metrics

To measure the competence of the used unlearning strategy, the following metrics were used:

- Task Aggregate Score: Overall performance across multiple NLP tasks can be measured.
- MIA Score (Membership Inference Attack): Lower values indicate stronger privacy and successful unlearning.
- MMLU Avg. (Massive Multitask Language Understanding): Evaluates the retention of general knowledge.

4 Results

Table 1: Evaluation of the NeuroReset Framework for 7B and 1B OLMo Models

Model	Final Score	Task Aggregate	MIA Score (↓)	MMLU Avg.
7B	0.420	0.152	0.876	0.232
1B	0.360	0.000	0.841	0.238

4.1 Key Findings

• **Privacy Assurance**: The models demonstrate reduced susceptibility to Membership Inference Attacks (MIA), with scores of 0.876 (7B) and 0.841 (1B). Lower scores indicate better protection of sensitive data, compared to a random model baseline of 1.0.

• **General Knowledge Trade-Off**: MMLU performance indicates a reduction in general knowledge retention, with accuracy dropping below the original baseline. This is an expected trade-off in aggressive unlearning strategies and highlights a key challenge for future work. A remedy for this would be utilizing more heterogenous/balanced dataset to achieve a score above benchmark matrix, enhancing the proposed architecture in the future.

• **Scalability**: The framework exhibits consistent behavior across model sizes, showing adaptability of the method.

• **λ Usage in This Experiment**: For interpretability and controlled experimentation, the system used discrete values of λ (1 for forget, 0 for retain). However, **λ can take any value between 0 and 1**, enabling future explorations of blended or weighted optimization strategies.

• As a part of the future scope the learnable hyperparameter λ can be used in the 3rd phase which would be the mixed phase – a combination of forget and retain in a supervised manner on the field/real-time implementation.

4.2 Discussion

The dual-phase unlearning methodology effectively removes sensitive content and supports model stability. However, the following limitations and challenges are acknowledged:

• **Privacy–Utility Trade-off**: A notable drop in MMLU performance (~23%) suggests that aggressive unlearning impairs generalization. Future research must optimize this balance.

• **Sequential vs. Joint Learning**: Though Equation (1) presents a joint formulation, our sequential approach was chosen to simplify training dynamics and avoid conflicting optimization gradients.

• **Evaluation Robustness**: While MIA scores show promise, further adversarial evaluation (e.g., data extraction or inversion tests) could strengthen privacy guarantees.

• **Compute Cost:** The two-phase fine-tuning increases training time and compute usage, warranting efficiency improvements.

5 Conclusion

This paper presents the NeuroReset framework employing the dual phase unlearning method for LLM unlearning. Sensitive information unlearning is a very challenging task, and one of the key parameters is the MIA score. Our proposed approach achieved the MIA score of 0.876 for 7B parameter and 0.841 for 1B parameters placing us in the top 15 teams in the SemEval challenge 2025. The approach presents some limitations, such as an inefficient retain phase and lack of support for multidomain and multilingual aspects. The presented work can be extended further to mitigate these challenges by further fine-tuning and experimentation. The long-term goal also includes assessing the effects on downstream applications.

Abstract

This paper introduces the participation of the QUST team in subtask 1 of SemEval-2025 Task 10. We evaluate various large language models (LLMs) based on instruction tuning (IT) on subtask 1. Specifically, we first analyze the data statistics, suggesting that the imbalance of label distribution made it difficult for LLMs to be fine-tuned. Subsequently, a voting mechanism is utilized on the predictions of the top-3 models to derive the final submission results. The team participated in all language tracks, achieving 1st place in Hindi (HI), 2nd in Russian (RU), 3rd in Portuguese (PT), 6th in Bulgarian (BG), and 7th in English (EN) on the official test set. We release our system code at: https://github.com/warmth27/SemEval2025_Task10

1 Introduction

SemEval-2025 Task 10 encourages participants to develop algorithms for multilingual recognition and extraction of narrative tasks from online news (Piskorski et al., 2025; Stefanovitch et al., 2025). We participated in subtask 1 (Entity Framing), which aims to assign fine-grained role labels, covering three main types (protagonists, antagonists, and innocent) to named entities (NEs) mentioned in news articles, based on a predefined fine-grained role classification system (Mahmoud et al., 2025). This is a multi-label multi-class text-span classification task.

During this process, we face several challenges:

- **Complexity of languages:** Compared to widely spoken languages like English, smaller languages such as Bulgarian lack high-quality pre-trained language models, which significantly heighten the complexity of model architecture design.
- **Data scarcity:** Insufficient training data has resulted in suboptimal fine-tuning outcomes for the large language models (LLMs). Performance is also weaker for languages with smaller datasets.

In subtask 1, we first conduct a quick evaluation by comparing our model with the baseline model. Inspired by Xu et al. (2024) and Zhang et al. (2023), we apply instruction tuning (IT) to several LLMs on subtask 1. However, IT entails substantial training costs. We first fine-tuning the models in English, then apply it to other languages to minimize fine-tuning and evaluation time.

To enhance the model's performance and generalization ability, we adopt a hard voting based on ensemble learning (Jabbar, 2024), in which the top-3 selected models vote to determine the final prediction. Experimental results indicate that ensemble learning significantly enhances the model performance.

2 Related Work

2.1 Instruction tuning for LLMs

IT is a powerful technique that adjusts the input context to align with specific instructions, updating the parameters of LLMs in a supervised manner (Wang et al., 2024b; Jiang, 2023). Current studies frequently examine the efficacy of IT for LLMs. For instance, Qin et al. (2024) presents a comprehensive review of IT in LLMs, detailing the fine-tuning process with instruction pairs and evaluating the critical factors that influence the outcomes of IT. Wang et al. (2024a) emphasizes that in the IT process of LLMs, the quality of the dataset plays a more significant role than its quantity.

Similar to the aforementioned studies, in subtask 1, IT helps the model understand complex contextual information and accurately assign fine-grained roles to entities based on instructions. By applying customized IT, we can improve the model's

performance on complex tasks, particularly when large-scale labeled data is scarce, as this method effectively enhances the model's generalization ability.

2.2 Voting

Voting is an ensemble learning strategy that enhances overall performance by combining the predictions of several base models (Xu et al., 2024; Abro, 2021). The voting strategy we adopt is hard voting, in which the final result is determined by the majority vote based on the predicted class labels of the top-3 models. The most frequent class is chosen as the final outcome.

PT	1251	116	297
RU	722	86	214

Table 1: Statistics of each language

3 Experimental Setup

3.1 Data

The statistical distribution of each language dataset is presented in Table 1. It is evident that the data distribution is imbalanced across the five languages, especially for languages with fewer training samples (such as BG and EN), which could impact the model's generalization ability.

Additionally, we analyze the distribution of label counts, as shown in Figure 1. The results indicate that the majority of samples are single-labeled. Based on this observation, we design an experiment in which the task is treated as a single-label task to evaluate whether this approach can enhance the original results. The experimental results and analysis are presented in Section 4.1.

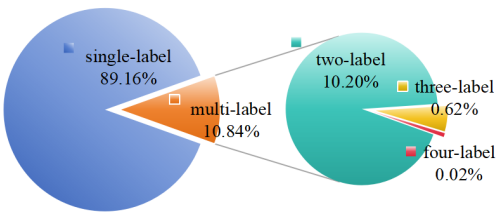

Figure 1: Distribution of the number of labels in the dataset.

3.2 Instruction strategy

Inspired by Wang et al. (2024b), we improve several versions based on their work. Ultimately, we find that this version of the instruction yields the best results. The example directive is: "*Given an article and an entity within that article. Analyze this article and the entity, and provide the fine-grained roles of the entity.*" This instruction emphasizes the requirement to assignone or more fine-grained roles to each entity, supporting a one-to-many label output.

3.3 Model configurations

Before identifying the final models, We first compared the performance of several baseline models from Hugging Face[1]. Considering the multilingual nature of the task, we primarily conduct experiments using the English dataset during the model comparison phase. The models involved in the evaluation include DeBERTa-v3-small (He et al., 2021), GLM4-9B-chat (GLM et al., 2024), Qwen2-7B-instruct (Yang et al., 2024), Qwen2.5-14B-instruct (Yang et al., 2024), Phi-3-small-128k-instruct (Phi-3-small) (Abdin et al., 2024a), Phi-3-medium-128k-instruct (Phi-3-medium) (Abdin et al., 2024a), and Phi-4 (Abdin et al., 2024b).

Given the variations in data size across languages, as well as considerations for training time and computational efficiency, we established two training schemes: 10 epochs and 20 epochs. The learning rate for the Qwen2-7B-instruct model is set to 1e-5, while for the other models, it is set to 1e-4. To avoid overfitting and enhance storage efficiency, we implement an epoch selection strategy, retaining only the model parameters that yield the best performance.

The final result utilizes an ensemble learning strategy, employing hard voting to combine the predictions of the top-3 selected models for each language, thereby enhancing the prediction accuracy of the final result.

4 Results

4.1 Single-label result

Since the majority of samples are single-labeled, we extract data containing only single labels from

[1]https://huggingface.co/

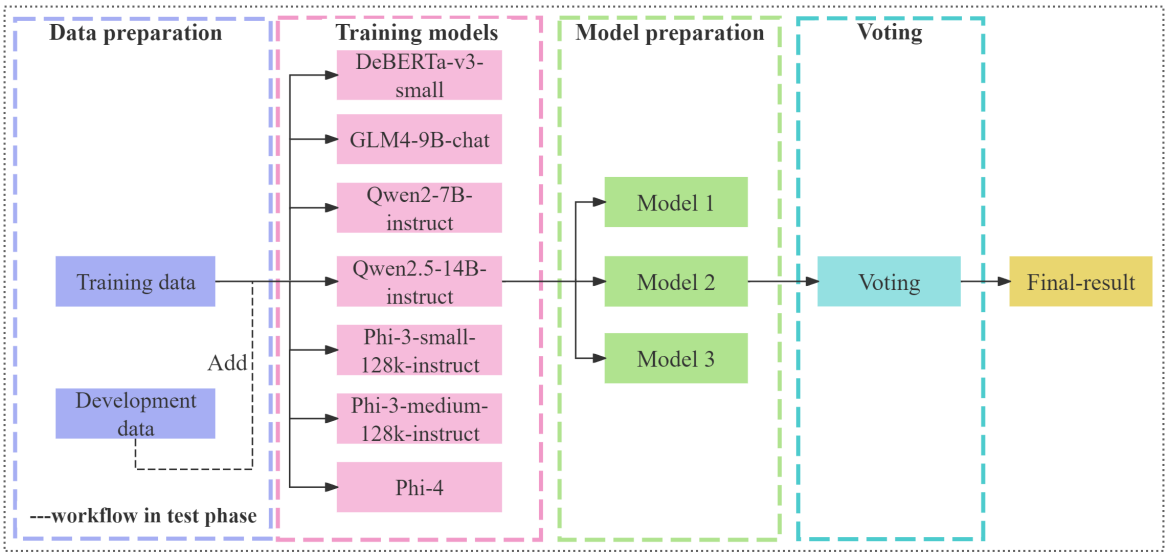

Figure 2: llustration of the overall workflow in this paper. "Model 1", "Model 2" and "Model 3" represent the top-3 best models of the performance employed.

Language	Model	Methods	Exact Match Ratio
EN	Phi-3-small-128k-instruct	Single-label	0.3736
		Multi-label	**0.3846**

Table 2: The result of Single-label Vs. Multi-label. **Bold** indicates the best result.

the English training dataset to treat this task as a single label task. As shown in Table 2, the score for the single-label task is 0.3736, whereas the score for the multi-label task is 0.3846. The result for the single-label task drops by only 2.86%. Although this approach does not improve model performance, the decline is minimal, suggesting a significant imbalance in the dataset.

4.2 Evaluation results

Our evaluation primarily relies on the official development data. The goal of our evaluation is to rapidly identify models and methods that perform well, and to compare the performance variations among different models. To enhance experimental efficiency, we focus primarily on evaluating the English dataset at this stage.

As shown in Table 3, all large language models except GLM4-9B-chat significantly outperform DeBERTa-v3-small, confirming that IT can effectively enhance the performance of LLMs on this task. Among these, GLM4-9B-chat yields the lowest result, possibly due to limited instruction comprehension, which leads to weaker generalization ability.

Phi-4 achieves the best performance among the single models, slightly outperforming Phi-3-medium and Phi-3-small, suggesting that larger-scale Phi-series models offer more stability on this task.

Voting strategy further enhances the final performance by 1.1% compared to the Phi-4, indicating that the voting strategy effectively integrates the advantages of the individual models. However, the improvement is limited, possibly due to similar predictions across models or the inherent performance ceiling of the task.

4.3 Official test results

Our approach participated in several language tracks, with Hindi ranked 1st, Russian ranked 2nd, Portuguese ranked 3rd, and Bulgarian and English ranked 6th and 7th, respectively, as shown in Table 4. Additionally, our approach significantly outperforms the baseline of subtask 1 across all languages, demonstrating the effectiveness of our approach. However, it is worth noting that our performance in English and Bulgarian is comparatively weaker, while the final test results for Hindi are better than the performance in the previous evaluation phase.

This unexpected phenomenon may be related to the scale of the training data. The training data for

Table 4: Official test results.**Bold** indicates the best result, and <u>Underline</u> indicates the second-best result.

English and Bulgarian is relatively limited, which may limit the model's generalization ability, while Hindi benefits from a richer dataset, allowing the model to better learn task patterns and perform more effectively in the test phase. Furthermore, Table 4 shows strong performance in Russian and Portuguese, further indicating that the scale of training data might be a key factor affecting model performance.

5 Conclusion

In summary, our team developed an effective approach for subtask 1 of SemEval-2025 Task 10. We first conduct instruction tuning on large language models on the English dataset and choose the models that perform best, then adapt them to other languages. In the final testing phase, to augment the training data, we incorporate the development data into the training set and select the top-performing model based on evaluation. Ultimately, hard voting successfully integrates the advantages of several models, thereby enhancing the prediction accuracy.

As the training data for English and Bulgarian is relatively limited and we have not yet employed data augmentation methods, future work will explore effective strategies to augment both the quantity and quality of data, thereby enhancing the model's capacity to comprehend texts from diverse languages and cultural backgrounds.

AGHNA at SemEval-2025 Task 11: Predicting Emotion and Its Intensity within a Text with EmoBERTa

Moh. Aghna Maysan Abyan
School of Electrical Engineering and Informatics
Institut Teknologi Bandung
Bandung, Indonesia
13521076@std.stei.itb.ac.id

Abstract

This paper presents our system that have been developed for SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection. The system is able to do two sub-tasks: Track A, related to detecting emotion(s) in a given text; Track B, related to calculate intensity of emotion(s) in a given text. The system will have EmoBERTa as the model baseline, despite some minor differences used in the system approach between these tracks. With the system designed above, Track A achieved a Macro-F1 Score of 0.7372, while Track B achieved Average Pearson r Score of 0.7618.

1 Introduction

SemEval-2025 is the 19th edition of SemEval. SemEval-2025 presents 11 different tasks, one of which is the task titled as "SemEval-2025 Task 11: Bridging the Gap in Text-Based Emotion Detection". This task focuses on text-based emotion recognition. In the repository provided, there are 3 sub-tasks that can be done, which will be referred to as "Tracks", namely:

- **Track A:** Multi-Label Emotion Detection
- **Track B:** Emotion Intensity
- **Track C:** Cross-lingual Emotion Detection

Due to time constraints, we were only able to build the system for two different tracks, that being Track A and Track B. For the English language, there are five available emotions: anger, fear, joy, sadness, and surprise. Track A focused on predicting emotions within a text by assigning label to each of the five emotions, with either 0 (no emotion detected) or 1 (emotion detected). Track B focused on predicting emotions within a text by assigning label to each of the five emotions, with either 0 (no emotion), 1 (low degree of emotion), 2 (moderate degree of emotion), or 3 (high degree of emotion).

There are several applications on Text-Based Emotion Detection (TBED) in the modern world. First, TBED can help to detect or diagnose a user's mental health through their posts on social media (Saffar et al., 2022). Second, integrating TBED into an AI system allows for better understanding and interaction between the AI or computers and humans (Machová et al., 2023). And the last example being its integration to business and finances allows data analysts to understand customer reviews more efficiently (Kusal et al., 2022).

In this paper, we propose a system named AGHNA (Automated Generalized Human-emotion detection with a Neural Approach). AGHNA utilizes EmoBERTa as the base model for both tasks mentioned before (Track A & Track B). EmoBERTa is a model developed or fine-tuned from RoBERTa to achieve better results specifically in Emotion Recognition in Conversation (ERC) tasks. EmoBERTa is able to generate better performance compared to other ERC models, such as DialogXL and CESTa (Kim & Vossen, 2021). To further enhance EmoBERTa's performance for both tasks, AGHNA incorporates several additional approaches to the system. These approaches are: Experimenting different feature extraction methods, applying optimization with AdamW, using Binary Cross Entropy (for Track A) and Mean Squared Error (for Track B), and other approaches that will be elaborated even further throughout the paper.

2 Related Works

Related work in the field of TBED has produced various new methods and approaches, but several aspects are still not perfect. The biggest challenge is the high computing resources required due to the complexity of the models being built and the large amount of data that must be trained before testing.

One of the related studies is a research on creating an annotated corpus for Bangla multi-label

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1057–1063

emotion detection (Banshal et al., 2023) by collecting data in the form of comments totaling 136,583 data taken from 11 different news stories on Facebook.

The implemented approach uses feature extraction methods such as tokenization and TF-IDF. After that, various methods were applied, using Machine Learning (ML) algorithm (Logistic Regression, Random Forest, Multinomial Naive Bayes, Support Vector Machine, and K-Nearest Neighbors), Deep Learning (DL) algorithm (LSTM, BiLSTM, and hybrid CNN-BiLSTM and CNN-LSTM), and transformer-based algorithms (BanglaBERT, mBERT, Bangla-Bert-Base, and Bangla-Electra). The results are as follows:

- The MNB algorithm achieved the best performance among ML algorithms with an accuracy of 82.64
- BiLSTM provided the best performance among DL algorithms with an accuracy value of 79.14
- Bangla-Bert-Base provided the best performance among transformer-based algorithms with an accuracy of 83.23

There are several advantages offered from the results of this research. These advantages include MONOVAB's contribution to providing a TBED in Bangla which was previously minimal, the use of various approaches (ML, DL, and Transformers) to obtain the most optimal results, as well as an annotation process using a context-based approach. However, there are also limitations in this research. First, the high complexity due to the implementation of various approaches requires high computing resources. Second, there are data that can't be adapted to the corpus because the data cannot be processed using a context-based approach, suggesting for a more suitable lexical-based approach.

Another related research discuss about emotion prediction in text and multi-turn conversations by Combining Advanced NLP, Transformers-based Networks, and Linguistic Methodologies (Singh et al., 2024) which was carried out based on tasks from "WASSA 2022 Shared Task: Predicting Empathy, Emotion and Personality in Reaction to News Stories" and "WASSA 2023 Shared Task: Empathy, Emotion and Personality Detection in Conversation and Reactions to News Articles", both of which are related to emotion prediction.

Split	WASSA 2022	WASSA 2023
Training	1,860	792
Test	525	136
Validation	270	208

Table 1: Data frequency for WASSA 2022 and WASSA 2023 datasets.

The dataset used comes from WASSA 2022 and WASSA 2023, with the statistics provided in the Table 1.

The approach taken in this research involves using a Feedforward Neural Network (FFNN) with ReLU activation and PyTorch, experimenting with various embedding models as input to the neural network, hyperparameter tuning, overcoming data imbalances, utilizing lexicon features, and an ensemble method using two SVR models to model the relationship between text features and emotions. The final results of the study showed an average score increase of 33.59% over the baseline for WASSA 2022 and 64.02% over the baseline for WASSA 2023.

There are several advantages obtained from the results of this research. These advantages include the use of transformers that are integrated with various linguistic features and ensemble methods that can mitigate bias by combining multiple predictions. However, there are also drawbacks in this research. The most noticeable drawback in this research is the high complexity of the model due to the combination of various approaches that requires high computational resources.

3 Dataset

This research will use the dataset provided by the organizers of this SemEval task. There will be an equal amount of data and texts given for both Track A and Track B in the English language, with the statistics provided in Table 2.

Split	# of rows
Train	1,860
Dev	525
Test	270

Table 2: Data frequency for SemEval-2025 Task 11 English dataset.

There are two stages of system development during the process: Development stage, where participants use the Dev data to make predictions; Testing

Emotion	# Emotion Frequency
Anger	333
Fear	1,611
Joy	674
Sadness	878
Surprise	839
Total	4,335
Avg. emotion frequency/text	1.566

Table 3: Emotion frequency for SemEval-2025 Task 11 English Train dataset.

stage, where participants use the Test data to make predictions.

Since the task involves a multi-label dataset, there are multiple instances where a sentence may have more than one detected emotion, either in the Train dataset or as the result of system's predictions. After a quick analysis, each emotion's frequency in the Train dataset are provided in Table 3.

There is a noticeable discrepancy in terms of emotion frequency within the given dataset. For example, the emotion fear appears in 1,611 different texts, whereas the emotion anger appears in only 333 different texts, approximately five times less than fear. This, in return, causes data imbalance and may lead into biases in the system's predictions.

4 Benchmark

The benchmark used for evaluating the performance of the proposed system in this research is based on the official baseline scores provided by the task organizers. These baseline scores are derived from the organizers' own research effors related to the task and serves as the reference for the evaluation of our system's final performance. The baseline system utilizes the RemBERT model, a model that can be used for multiple tasks including text classification, the main topic of this research. In detail, the baseline has a Macro-F1 Score of 0.7083 for Track A, and an Average Pearson Correlation Coefficient (r) Score of 0.6415 for Track B (Muhammad et al., 2025).

5 System Overview

Although several adjustments are required to handle Track A and Track B separately, it is important to note that, due to the similar nature of processing for both tracks (making predictions on given texts),

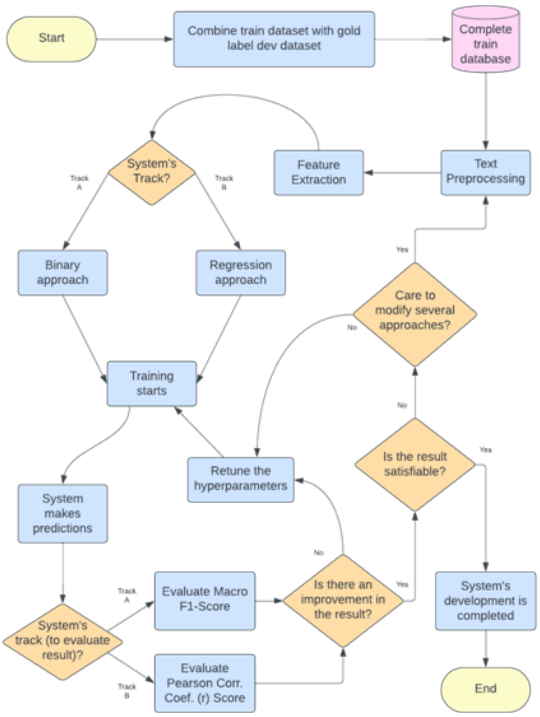

Figure 1: AGHNA's Architecture Design

the overall system design remains similar to that shown in Figure 1.

The system designed for this task will be based on EmoBERTa. Unlike most existing works on ERC that combine different kinds of neural network architectures, and therefore deemed too complex, EmoBERTa simply utilizes the existing RoBERTa model while encoding the speaker's information along with multiple utterances.

EmoBERTa demonstrated very good results when tested with MELD (Multimodal EmotionLines Dataset) and IEMOCAP (Interactive Emotional Dyadic Motion Capture) datasets outperforming several ERC models. On MELD, EmoBERTa achieved a weighted F1-Score of 65.61%, slightly better than the next model, COSMIC (Ghosal et al., 2020) with 65.21%. And, on IEMOCAP, EmoBERTa achieved a weighted F1-Score of 68.57%, slightly better than the next model, CESTa (Wang et al., 2020) with 67.1% (Kim & Vossen, 2021). After understanding the beneficial performance of EmoBERTa for this task, we aim to improve its performance by implementing additional methods into our final system. The additional methods will focused on hyperparameter tuning in several areas, such as the number of epoch, batch size, learning rate, etc.

5.1 Track A

Track A focuses on predicting whether if a specific emotion is present in a given text. Since this is a binary classification task, Binary Cross Entropy (BCE) loss function will be used to analyze the model's performance. For the preprocessing stage, we will utilize Term Frequency–Inverse Document Frequency (TF-IDF) as a method to calculate the importance of words in a text. TF-IDF analyzes several key terms in a document relative to the corpus.

Inside the main training process, focal loss will be utilized to handle class imbalance. To optimize model training, AdamW Optimizer will be used to maintain model stability and performance by decoupling weight decay, alongside learning rate schedulers to adjust the learning rate throughout the training process.

5.2 Track B

Track B focuses on predicting the intensity of an emotion in a given text. Unlike Track A that focuses on binary classification issues, Track B deals on regression classification, as the label may spanning in a real value between 0 and 3. Therefore, they system can't use BCE for this track. Instead, We will use Mean Squared Error (MSE) as the alternative loss function. MSE works similarly to BCE in calculating training errors but it is designed for regression tasks instead of binary tasks.

While the main approach for Track B is mostly similar to Track A, we also put an experimentation on new methods during our research for Track B. For example, in the preprocessing stage, we explored using TextBlob as it is provides more capabilities at feature extraction. We've also integrated attention mechanism to help the system focus more on specific/relevant parts of the text, improving accuracy. Lastly, to handle class imbalance, we also implemented data augmentation to the system, giving a more diverse training examples. Unfortunately, due to time constraints, we were unable to add these new approaches to Track A.

6 Result

For the training dataset, we combined 2,768 data from the provided training dataset with an additional 116 data from the Dev dataset. The Dev dataset were included because they had been assigned gold labels by the organizers, meaning they had been manually reviewed and correctly labeled. Giving a total number of 2,884 data prepared to be trained before the system starts to make predictions into the Test dataset.

During the training process, we conducted several experiments to fine-tune the system's performance. After analyzing the results, we identified and collected the optimal combination of hyperparameters that may yielded the best results for the system. The hyperparameters' values are provided in Table 4.

Hyperparameter	**Value**
seed	42
model	tae898/emoberta-large
max. sequence length	128
batch size	16

Table 4: Model Hyperparameters

To minimize the system's execution time, we opted to ran the system for both tracks using NVIDIA A100 GPU on Google Colab, as it is the fastest accelerator compared to other accelerators in Google Colab. After running the system for both tracks independently, we also run the system for two other different models with the intention of model comparison: BERT (bert-large-uncased) and RoBERTa (roberta-large). The system's final results/performance submitted to CodaBench for the SemEval competition, alongside comparisons to other models, are presented in Tables 5 and 6.

Emotion	F1-Score (%)
Anger	68.12
Fear	80.05
Joy	73.70
Sadness	74.10
Surprise	72.63
Macro-F1	**73.72**
Micro-F1	**75.19**

Table 5: System's final result for Track A (EmoBERTa only).

Emotion	emoberta-large	roberta-large	bert-large-uncased
Anger	72.15	69.18	67.21
Fear	77.14	76.22	74.54
Joy	80.41	77.83	77.00
Sadness	79.50	75.96	75.92
Surprise	71.72	68.90	66.46
Average	**76.18**	**73.62**	**72.23**

Table 6: System's final result for Track B between three different models (%).

For the purpose of ranking and evaluation from the organizers, Macro-F1's Score will be used as the main metric for Track A, while Average Pearson Correlation Coefficient (r)'s Score will be used for Track B.

In Track A, our system AGHNA achieved a Macro-F1 Score of 73.72%, placing 38th out of 97 participants, placing it within top 40% of all submissions. This result represents a small improvement of 4.08% over the baseline score of 70.83% provided by the task organizers. Meanwhile, for Track B, AGHNA achieved an Average Pearson Correlation Coefficient (r) Score of 76.18%, placing 11th out of 43 participants, placing it within top 26% of all submissions. This result represents a major improvement of 18.75% over the baseline score of 64.15% provided by the task organizers.

From Table 6, it can be seen that EmoBERTa (emoberta-large) outperforms BERT (bert-large-uncased) and RoBERTa (roberta-large) in Track B by an average margin of 2-4%. Unfortunately, we lost the experiment logs for Track A, and since the system was updated after the SemEval test phase ended, we are unable to re-run the models in their pre-update versions before the paper submission deadline, hence why we only showed the EmoBERTa-only result for Track A in Table 5. Nevertheless, we can confirm that EmoBERTa also outperforms both BERT and RoBERTa in the updated system, by combining approaches from Track B into Track A as shown in Table 7.

Data imbalance remains a significant challenge in Track A, provided by the notable difference in F1-Score between the emotions anger and fear. The gap between these two emotions is 11.93%, indicating several emotions are more accurately predicted than others. Such difference suggests the model struggles to generalize across every emotions in the dataset, most likely due to uneven distribution of emotions within the given dataset. Although with such problems faced in Track A, Track B doesn't seem to suffer as much, with the lowest and highest Pearson Correlation Coefficient (r) Score, performed by surprise and joy respectively, differs by only 8.69%. This statistics further highlight Track B's overall success while also giving a massive understanding the need of improvement for Track A.

Due to the time constraints given by the task organizers, our research was unable to implement several Track B's methods to Track A. Although, by how successful the result for Track B is compared to Track A, we have integrated several methods from Track B (such as the implementation of TextBlob) into Track A after the SemEval test phase ended, and we plan to add more features for both tracks in the future.

7 Conclusion

As seen in the results and ranking statistics from the previous chapter, AGHNA demonstrates strong capabilities in predicting emotions, both in binary

Emotion	emoberta-large	roberta-large	bert-large-uncased
Anger	62.55	63.75	56.21
Fear	84.70	84.06	82.91
Joy	78.48	75.82	76.07
Sadness	75.43	76.55	73.93
Surprise	72.81	70.71	68.84
Average	**74.79**	**74.18**	**71.59**

Table 7: Updated system's final result for Track A between three different models (%).

classification detection (Track A) and regression classification for intensity (Track B). This is evident from AGHNA's performance outperforming two baselines (one for each tracks) set by the organizers and achieved a top-half ranking in both tracks, including an almost top-quarter ranking in Track B.

Despite these results, there are still several room for improvements in both tracks, especially Track A. Therefore, we hope that in future research, we, or others interested in further improving the system, can develop way better solutions to bring another improvement for EmoBERTa's performance in emotion detection. Although improvements are desired for both tracks, we believe Track A warrants more in-depth analysis, as it shows bigger potential for improvement.

Acknowledgments

First, we would like to express our deepest gratitude to God, The One and Only, for granting us the strength, faith, and determination to complete this research. Secondly, we extend our appreciation to the organizer of this SemEval task for providing us the opportunity to develop an NLP-related system, applying our knowledge in this field of computation. Thirdly, we would like to express our thankfulness our supervisor, Dr. Fariska Zakhralativa Ruskanda, S.T., M.T., for her guidance and support throughout this research. And lastly, we want to thank our friends and families for supporting us during the period of research.

Abstract

Hallucinations are one of the major problems of LLMs, hindering their trustworthiness and deployment to wider use cases. However, most of the research on hallucinations focuses on English data, neglecting the multilingual nature of LLMs. This paper describes our submission to the "*SemEval-2025 Task-3 — Mu-SHROOM, the Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes*". We propose a two-part pipeline that combines retrieval-based fact verification against Wikipedia with a BERT-based system fine-tuned to identify common hallucination patterns. Our system achieves competitive results across all languages, reaching top-10 results in eight languages, including English. Moreover, it supports multiple languages beyond the fourteen covered by the shared task. This multilingual hallucination identifier can help to improve LLM outputs and their usefulness in the future.

1 Introduction

Hallucinations are unwanted parts in the LLM outputs that are either not aligned with the source document (intrinsic) or non-factual in terms of world knowledge (extrinsic) (Narayanan Venkit et al., 2024). These over-generations are a severe problem in NLP research, and their detection and mitigation are studied widely (Rashad et al., 2024; ul Islam et al., 2025). However, most hallucination research focuses on English data. Therefore, the "*SemEval-2025 Task-3 — Mu-SHROOM, the Multilingual Shared-task on Hallucinations and Related Observable Overgeneration Mistakes*" provides hallucination annotations in fourteen languages and asks the participants to create multilingual hallucination detectors (Vázquez et al., 2025). Their data comes from open-source instruction-tuned LLMs, generated in a QA setting, and humans annotated each token to determine whether it belongs to a hallucinated phrase. Each token receives two different labels: A binary hard label, obtained as a majority vote between the annotators, and a soft label $\in [0, 1]$ given by the proportion of annotators who labeled the token as a hallucination.

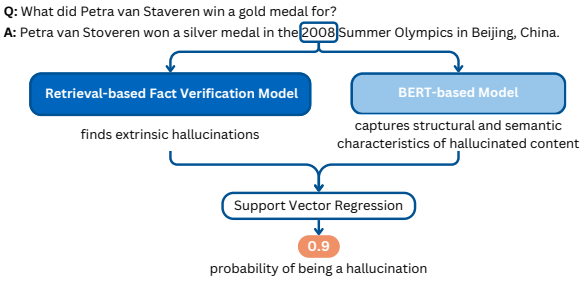

Figure 1: Given a question-answer pair, each token in the answer is evaluated for extrinsic hallucinations using a retrieval-based fact verification model, which compares the token against external knowledge. Simultaneously, the Bert-based Model captures structural and semantic characteristics of hallucinated content. The results from both models are then integrated using Support Vector Regression to estimate the final probability of each token being a hallucination.

In this paper, we present our contribution to the shared task: a **MultilIngual and Knowledge-Aware Non-factual hallucination Identifier (MiKaNi)**. Our system is model-agnostic and supports multiple languages beyond the fourteen covered in the shared task. It annotates hallucinations on a token level, providing fine-grained information about the correctness of atomic facts. To obtain these annotations, we propose a two-part pipeline (visible in Figure 1): The first part is an atomic fact-checker based on the retrieval of information from Wikipedia. The second part is a fine-tuned BERT model incorporating linguistic features. The predictions from the two parts are then combined using a Support-Vector Regression model. Our combined system achieves competitive scores across all languages (e.g., 8/44 in English, 2/33 in French).

*Equal contribution

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1064–1076

Our code and model weights are publicly available for further usage and development[1].

2 Background and related work

Many different approaches exist to detect hallucinations in generated texts (Narayanan Venkit et al., 2024). Some of them take information about the generating model into account, e.g., by analyzing attention weights or the model's logits (Sriramanan et al., 2024). While the logits of the last model layer were provided in this shared task, we created a model-agnostic detection mechanism that does not require any information about the underlying LLM.

Intrinsic hallucinations occur when the model outputs deviate from the source document. This is often the case in summarization or RAG-based tasks that provide long contexts for the model generations (Ravi et al., 2024). In contrast, in the MuSHROOM data, the model only receives a question that it has to answer based on its internal knowledge. Therefore, the main interest point of our hallucination identifier is to find extrinsic hallucinations. This entails a fact-checking or verification objective. The most popular way to check the facts in generated texts is to compare them against world knowledge covered in Wikipedia or knowledge graphs (Min et al., 2023). Thus, the first part of our system builds upon this, comparing the atomic facts against retrieved data from the English Wikipedia. Previous works solved this comparison by predicting the entailment (Rawte et al., 2024) or the edit operations that are necessary to transfer the retrieved information into the model generations (Mishra et al., 2024).

3 System overview

Our approach integrates the strengths of two complementary submodels, whose outputs are combined in a third model to generate the final hallucination prediction. The first submodel is designed to detect extrinsic hallucinations by retrieving relevant Wikipedia facts and using them to assess token-level hallucination probabilities. The second submodel is BERT-based and trained on token-level hallucination probability-annotated data. It focuses on identifying common hallucination patterns. The outputs of both submodels, along with additional extracted features, are fed into a Support Vector Regression (SVR) model, producing the final combined hallucination score. Details about this architecture are presented in Figure 1.

3.1 Retrieval-based Fact Verification Model (RFVM)

The RFVM is a multi-step pipeline detecting hallucinations in LLM outputs by leveraging Wikipedia as a factual reference source. Given a question-answer (QA) pair, the model extracts atomic facts from the answer, retrieves and ranks relevant Wikipedia passages, and ultimately uses the retrieved evidence to assess the factuality of each token in the answer. The model's architecture and the GPT-4o system prompts are presented in the Appendix in Figure 7 and Appendix B, respectively.

3.1.1 Pipeline Description

Atomic Fact Extraction The first step involves breaking down the LLM-generated answer into atomic facts. An atomic fact is a self-contained statement that can be independently verified as true or false (Min et al., 2023). We use GPT-4o to extract these facts in a few-shot setting.

Since the subsequent retrieval and ranking processes rely on English text, the atomic facts are translated into English during the fact extraction process.

Search Term Extraction Once atomic facts are obtained, we extract search terms that will be used to retrieve relevant Wikipedia articles. This is done via LLM-based prompting, where GPT-4o generates a set of search terms most relevant to each atomic fact. These search terms serve as the query inputs for Wikipedia-based fact retrieval.

Wikipedia Fact Retrieval This is built upon the "Retrieval-Augmented Evaluation Pipeline" by Lukas Ellinger (2024) and consists of three core steps: (1) search, (2) rank, and (3) select.

(1) Search The search phase is an iterative process in which each atomic fact and its associated search terms are processed. Each search term is queried using the Wikipedia API. If a Wikipedia page with an exact title match exists, the process continues with the next steps directly. If no exact match is found, Wikipedia's built-in suggestion mechanism is used to retrieve up to two alternative pages that may be relevant to the search term. To improve efficiency, searches are cached.

[1] Code on Github, You can also test the fact checker here!

(2) Sentence Ranking Once a Wikipedia page has been retrieved, its sentences are processed and ranked based on their relevance to the corresponding atomic fact. We first apply co-reference resolution to the entire page to ensure consistency at the sentence level. The text is then split into individual sentences, creating a structured content representation. Finally, each sentence is ranked using the BM25 retrieval algorithm.

(3) Evidence Selection The final step in the retrieval process selects the most relevant sentences based on one of two strategies:

- **Top-n Selection**: The top-n most relevant sentences, as determined by BM25 ranking, are selected.
- **Maximal Marginal Relevance (MMR) Selection**: Selects highly relevant sentences while ensuring diversity.

Fact Verification and Hallucination Prediction The output of the fact retrieval module is a structured list of dictionaries, where each entry consists of an atomic fact and its most relevant Wikipedia evidence.

This structured evidence, along with the original QA pair, is then passed to GPT-4o for hallucination detection. The process begins by splitting the generated answer into individual sentences. Each sentence is evaluated separately, with the full list of retrieved Wikipedia facts and the original question provided as context. GPT-4o estimates the probability of each token being hallucinated based on this evidence. To accelerate inference, sentence-level concurrency is employed, allowing multiple sentences to be processed in parallel.

Final Aggregation Once all individual hallucination predictions are obtained from the LLM, the results are aggregated into a single final hallucination probability distribution over the entire answer.

3.2 BERT-based Model (BM)

The BERT-based Model (BM) builds on a pre-trained BERT model (Devlin et al., 2019) to detect hallucinations in the generated text. The model processes a structured prompt containing an instruction, a question, and an answer, as illustrated in Figure 2.

First, the output embedding from BERT is extracted and concatenated with a part-of-speech

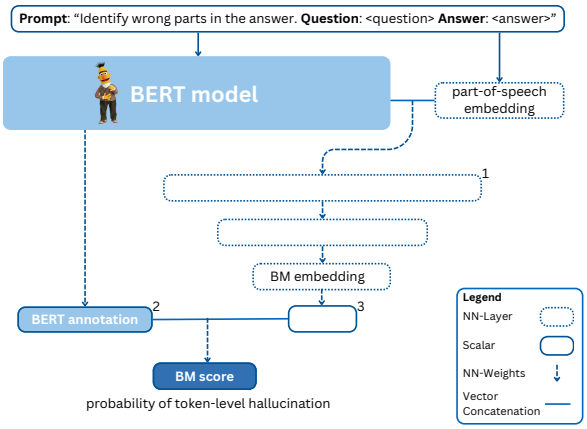

Figure 2: BERT-based Model architecture: BERT is prompted with the instruction, question, and answer. It is then enhanced with the answer's part-of-speech embedding and processed through several fully connected layers to obtain the final token hallucination score.

(POS) embedding. The POS embedding is generated using SpaCy (Honnibal et al., 2020), where each token in the answer is represented by a numerical POS tag. The combined BERT-POS representation is then passed through several linear layers (1), each with a ReLU activation function. The output of these layers produces an intermediate representation: the BM embedding. Additionally, the original BERT output is re-introduced into the model by processing it through a fully-connected layer to obtain a BERT annotation (2). This annotation is then concatenated with the processed BM embedding (3). The resulting representation is subsequently processed through a final fully connected layer, which computes the BM probability of a token being a hallucination (BM score).

3.3 Support Vector Regression model (SVRM)

The final hallucination score is determined using a Support Vector Regression model (Drucker et al., 1996) that combines various linguistic and contextual features. The ensemble of different models and features, like neural embeddings, fine-tuned models, or linguistic features, has shown good results in shared task submissions before (Liu et al., 2024; Anschütz and Groh, 2022). Thus, we opted for a similar combined approach. Our features include POS tags, question-answer entity matches, and outputs from previous models: the RFVM score, the BERT annotation, the BM score, and the BM embedding, as depicted in Figure 3.

The question-answer entity feature is a binary value assigned to each token in the answer, indicat-

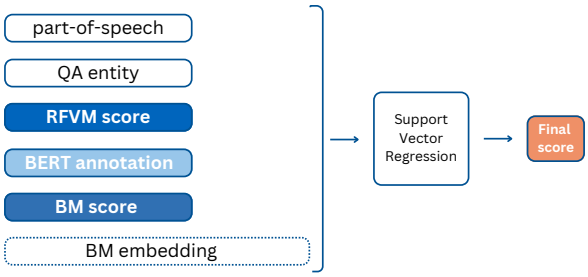

Figure 3: SVR Model architecture: POS embedding, QA entity, RFVM score, BERT annotation, BM score, and BM embedding are concatenated and processed as input for the Support Vector Regression.

ing if it is part of a named entity in the question. Named entity annotations are obtained using SpaCy or Stanza (Qi et al., 2020), and the identified entities are matched to BERT tokens.This feature helps to recall non-hallucinated tokens, as we found that many true hallucinations are named entities (see Figure 4 in the appendix).

All features are concatenated into a unified representation, which the SVR model uses to learn a regression function that predicts the final hallucination probability for each token.

3.4 Experimental setup

3.4.1 RFVM Setup

The RFVM model leverages GPT-4o as LLM for various prompting-based tasks. To maximize the model's performance, each step in the pipeline is guided by a carefully crafted system prompt along with a set of few-shot examples. The prompts are presented in Appendix B. Prompting is employed in three key stages: atomic fact extraction, search term generation, and final hallucination prediction.

System Prompt Structure The system prompts across all three stages follow a consistent structure. Each prompt begins with an introductory paragraph that provides contextual background on the task. This is followed by a section containing detailed task instructions, specifying the expected model behavior in a precise and structured manner. Finally, the prompt explicitly defines the expected input and output format, ensuring that the model generates responses in a structured and processable form.

Prompting for Atomic Fact Extraction For atomic fact extraction, the model is provided with a system prompt that includes a structured task description along with three illustrative examples. Two of these examples are in English, while one is in Spanish, preparing the model for multilingual inputs. These few-shot examples serve to clearly define the task of breaking down complex answers into simple, verifiable statements.

Prompting for Search Term Generation In the search term generation step, the system prompt includes two examples in English. During the atomic fact extraction, all facts are translated into English. Thus, at this stage, all input data is strictly in English to ensure consistency throughout the retrieval process. Since the quality of search terms directly impacts retrieval success, the prompt was iteratively improved using trial and error. Extracting search terms that lead to a valid Wikipedia page hit is a non-trivial task requiring precise guidance. The system prompt for this step contains 13 detailed instructional steps to ensure the generated search terms maximize retrieval accuracy.

Prompting for Hallucination Prediction For the final hallucination prediction step, a single English QA pair from the Mu-SHROOM validation set is used as an example. Including only one example is primarily driven by computational and cost-efficiency considerations. Despite this limitation, the example is carefully chosen to demonstrate the hallucination detection task.

Evidence Selection For evidence selection, we opted for MMR to ensure the diversity of search results while also maintaining the relevance of facts. As MMR parameters we use $\text{top}_n = 4$ and $\lambda = 0.7$ to balance relevance and diversity.

3.4.2 BM training

The BM was trained on a multilingual dataset that consists of Mu-SHROOM SemEval validation datasets for English, German, French, Finnish, Swedish, Italian, and Spanish (Vázquez et al., 2025). The dataset is divided into training, validation, and test sets, following an 80/10/10 split.

The training was conducted over 10 epochs, using separate learning rates for fine-tuning BERT ($5e{-}5$) and training the fully connected (FC) layers ($3e{-}4$). A batch size of 1 was used to account for the token-based processing. The learning rate for the FC layers was multiplied by a factor of 0.5 if no improvement was observed for three consecutive epochs. To preserve initial features, the first three layers of BERT were frozen during training.

We use Mean Squared Error (MSE) as our loss,

with triple weighting applied to labels where the hallucination probability was greater than zero. The loss was calculated and backpropagated for each token in the answer while the computational graph was retained. After processing all tokens, the prediction variance was calculated, scaled by a regularization rate of 0.9, and then backpropagated to penalize uniform outputs. After the initial training, the model was fine-tuned for three additional epochs with a lower regularization rate of 0.5 while keeping other hyperparameters unchanged.

3.4.3 SVR training

The regression model was trained on the soft labels, using all languages in the Mu-SHROOM training data. The dataset was divided into training and validation sets using a 90/10 split.

The SVR model was trained with a regularization parameter $C = 10$ to increase sensitivity to errors. Non-hallucination samples (with soft labels of 0) were weighted at 0.01, while all other samples were given a weight of 100. For POS tagging, SpaCy was used for all languages except Arabic, Hindi, Czech, Basque, and Persian, where Stanza was applied. Additionally, word spans were merged if the distance between words was less than three and the probability difference did not exceed 15%, with the higher hallucination probability being retained for the combined span.

4 Results

The Hallucinations were evaluated using intersection-over-union (IoU) for hard labels and Spearman correlation (Cor) for soft labels. IoU measures the overlap between hallucination spans, while Cor assesses the correlation between predicted and reference probabilities (Vázquez et al., 2025).

The submission results, including IoU and Cor scores along with the corresponding ranks, are presented in Table 1. The shared task organizers provided three baselines: a *neural baseline*, a *mark all* baseline that labels everything as hallucinations, and a *mark none* baseline. Our system outperformed these baselines in all languages except Chinese, where the mark-all baseline performed slightly better. This shows that our combined approach is successful. However, the performances vary across languages. This could be due to the underlying data, as the best-performing systems per language also show a great range of IoU scores (between 0.53 in Spanish and 0.79 in Italian). Another factor is the dependence on SpaCy and Stanza annotations, as their quality may decrease for certain languages. Nevertheless, our system shows a good generalization to unseen test-only languages like Catalan and Farsi.

Language	IoU ↑	Cor	Rank
Italian	0.6787	0.5388	12/31
French	0.6314	0.5157	2/33
Finnish	0.6267	0.5751	5/30
Catalan	0.5971	0.5551	7/24
Swedish	0.5886	0.3930	6/30
Hindi	0.5835	0.4964	12/27
German	0.5569	0.5088	10/31
Farsi	0.5465	0.4238	11/26
English	0.5249	0.5363	8/44
Basque	0.5237	0.4709	7/26
Arabic	0.4778	0.5114	14/32
Chinese	0.4735	0.4095	9/29
Czech	0.3874	0.3738	12/26
Spanish	0.3739	0.5027	14/35

Table 1: Results across languages, sorted by IoU scores. All languages, except Chinese, outperformed the baselines. Languages where our submission is in the top 10 of all submitted systems are bolded. Languages in *italic* are test-only languages without available training data.

Tables 2 and 3 provide test-set scores for our two subsystems separately. The BERT-based model tends to outperform the RFVM in most languages. However, the BM still benefits from further annotations in the RFVM results, resulting in higher scores for the ensembled models. A further analysis of language-specific behavior and a more qualitative analysis is provided in Appendix A.

5 Conclusion

In this paper, we present MiKaNi, a multilingual and knowledge-aware hallucination identification system that achieved competitive performance in the Mu-SHROOM shared task. Our system combines fact verification against external sources with a BERT-based system fine-tuned to detect common hallucination patterns. The system uses the same architecture for all languages and LLM outputs, making it strongly multilingual and model-agnostic, generalizing well on the unseen test set languages. The language capacities for further languages are only limited by the availability of SpaCy or Stanza annotations and their support in multilingual BERT. In future work, we will try to make the

model even more flexible by testing open-source fact verification models instead of relying on OpenAI's GPT-4o.

6 Limitations

Our Retrieval-based Fact Verification Model (RFVM) heavily relies on prompting GPT-4o to obtain the atomic facts and search terms and to perform the overall hallucination prediction. While this API is easy to use and GPT-4o generates high-quality responses, relying on closed-source models limits the reusability of our approach for other researchers, particularly those with limited financial resources. For future work, we plan to experiment with open-source and more lightweight models to reduce this barrier.

Another limitation of our pipeline is the high latency during inference due to the modular and sequential design. A QA pair has to be processed by our RFVM, including a retrieval process against the Wikipedia API and multiple calls to the OpenAI API. While the RFVM and the BM predictions can run in parallel, the SVRM depends on both outputs and, thus, has to wait for these results. During development, we focussed our efforts on a good performance in as many languages as possible. However, for deployment of our model in an LLM interface, the individual pipeline steps would have to be improved for efficiency.

Acknowledgments

The Retrieval-based Fact Verification Model (RFVM) was inspired by a Master's thesis by Lukas Ellinger (2024). We thank Lukas for sharing his code with us and for his continued support.

Some parts of this paper were written with the help of AI assistant tools in the form of ChatGPT. All AI-generated contents were thoroughly revised by the authors.

A Further analysis and discussion

Figures 4 and 5 illustrate the distribution of hallucinated words across part-of-speech categories and languages, respectively. Notably, Swedish exhibits the highest number of hallucinated words, while Spanish has the lowest. The majority of hallucinations occur in numbers, proper nouns, and nouns.

Spanish exhibits low IoU scores, ranking among the lowest-performing languages alongside Arabic. As shown in Table 2, both RFVM and BM performed poorly on Spanish, resulting in similarly low performance for SVRM, which recorded the lowest IoU scores among all languages. The underperformance of RFVM and BM may be due to the high word count in Spanish samples (see Figure 5), as both models struggle with long inputs. Additionally, BM achieved a lower IoU score than RFVM on Spanish (see Table 2), likely due to the very low hallucination content, as BM tends to overpredict hallucinations.

Chinese underperformed relative to the baseline, as both RFVM and BM struggle with long inputs. Chinese samples contain relatively long outputs, comparable to other languages (see Figure 5). RFVM, in particular, achieved the lowest IoU score on Chinese (see Table 2). This may also be attributed to the challenges of translating Chinese into English. Translation can introduce ambiguities, modify sentence structures, or obscure contextual meaning, making it more difficult for RFVM to retrieve precise matches from English Wikipedia.

On the Italian dataset, BM slightly outperformed SVRM. Since the Italian data does not exhibit significant deviations, and SVRM heavily relies on BM, this result may indicate the performance ceiling of both approaches. It also suggests the need to incorporate additional metrics into SVRM to improve its predictions.

Language	Ground truth	SVR prediction
Catalan	La pel·lícula Faster, Pussycat! Kill! Kill! no té narrador. És una pel·lícula muda, de manera que no hi ha veu en off explicant la història.	La pel·lícula Faster, Pussycat! Kill! Kill! no té narrador. És una pel·lícula muda, de manera que no hi ha veu en off explicant la història.
German	Die griechische Ägäis-Insel Angista gehört zu den Nördlichen Sporaden.	Die griechische Ägäis-Insel Angista gehört zu den Nördlichen Sporaden.
Swedish	År 2008 var det 1 357 600 invånare i Dourbies. Detta är en ökning med 10 000 invånare sedan 2007. Befolkningen ökade med 21,5% under de senaste 5 åren.	År 2008 var det 1 357 600 invånare i Dourbies. Detta är en ökning med 10 000 invånare sedan 2007. Befolkningen ökade med 21,5% under de senaste 5 åren.

Table 4: Randomly selected annotation examples. Hallucinations are highlighted in red. Our SVR model sometimes annotates too many tokens, but covers the right spans in general.

Overall, Tables 2 and 3 show that the ensemble SVRM model benefits from both models. For example, the German IoU scores of RFVM and BM are close to one another at 0.4907 and 0.4735, respectively. However, if the two models are combined in the SVRM, the score increases to 0.5569. A similar behavior can be seen in Basque, English, and Swedish.

To further analyze the shortcomings of our models, we investigate the mispredicted spans. Figure 6 shows the number of samples per model that have a perfect overlap of hallucination span annotations, a partial overlap, or no overlaps at all. The RFVM seems to strike a good balance between over-prediction, i.e., predicting too many false positives, and under-predictions that miss some spans. However, it is also the model with the most failures, mostly due to no annotations at all. Combining the predictions in the SVR model results in a higher rate of over-predictions, more perfect matches, and fewer failure cases. Some examples are shown in Table 4.

B GPT-4o system prompts

B.1 Atomic Fact Extraction System Prompt

```
You are a fact extractor. Your task is to split
the answer to a given question into atomic facts.
Atomic facts are concise, self-contained statements
that are free from ambiguity or dependency on
context beyond the statement itself. Each fact
should be clear, stand alone, and should not assume
any implicit understanding from other facts or
the question.

When performing the task, adhere to the following
 principles:

### Input:
The input will be a dictionary with the following
structure:
{
  "question": "The question providing context.",
   "answer": "The complex answer to be broken
              down into atomic facts."
}

### Output:
A valid JSON list of atomic facts, each as a
separate string. Example:
[
  {
    "fact": "Atomic fact 1.",
    "english_translation": "Atomic fact 1."
  },
  {
    "fact": "Atomic fact 2.",
    "english_translation": "Atomic fact 2."
  },
  {
    "fact": "Atomic fact 3.",
    "english_translation": "Atomic fact 3."
  }
]

### Guidelines:
1. Coreference Resolution:
 - Resolve pronouns (e.g., "he," "she," "it") to
    their specific referents.
 - Resolve demonstratives (e.g., "this," "that")
    to their explicit meaning.

2. Contextual Dependency:
 - Ensure each fact is self-contained and does not
    rely on the context of the question or other
    facts.

3. Logical Breakdown:
  - Split the information into the smallest
    meaningful units.
  - Maintain semantic accuracy and avoid
    splitting at inappropriate junctures
    (e.g., splitting compound phrases
    unnecessarily).
```

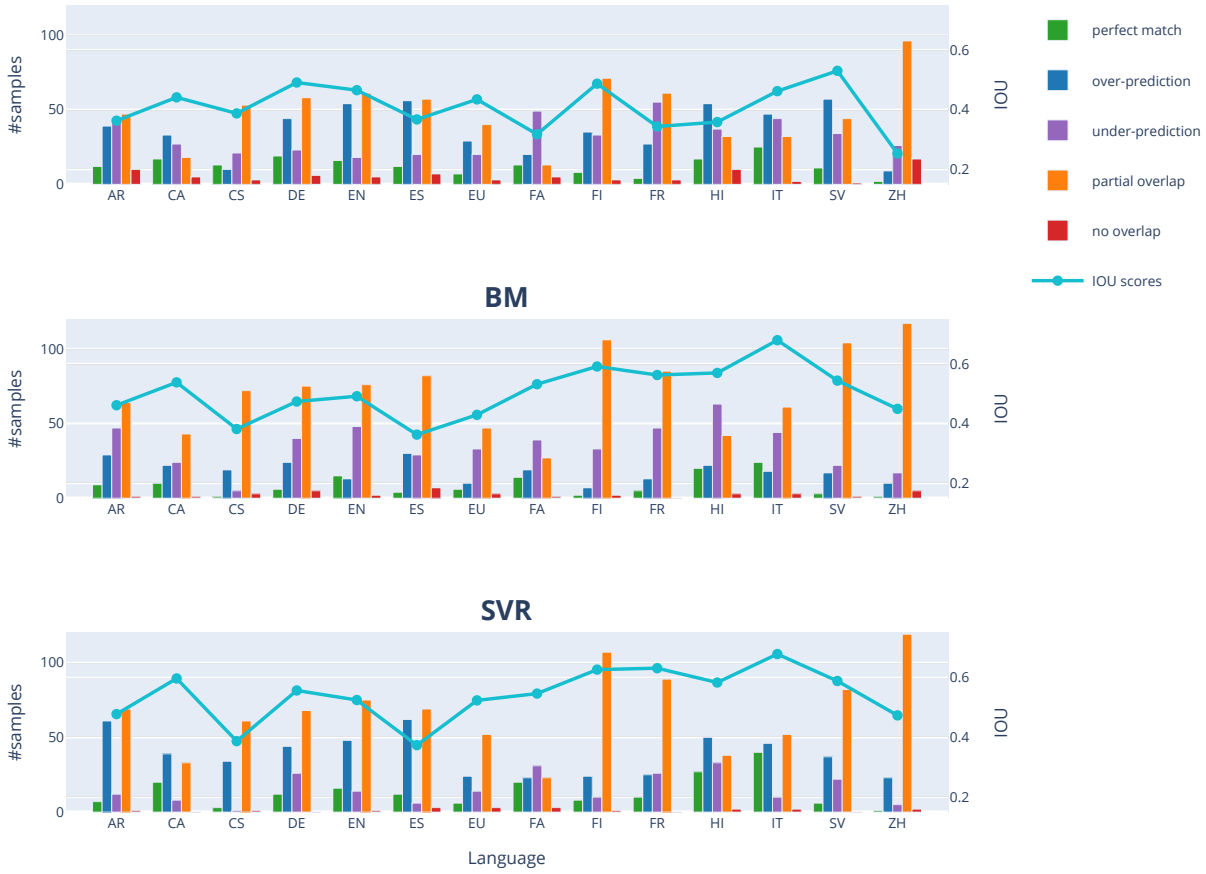

Figure 6: Caption

```
4. Precision and Completeness:
  - Include all relevant details from the answer.
   - Avoid redundancy between facts.

5. Avoid Negation:
  - Extract the fact as is and avoid introducing
     negation if the original fact does not use
     negation in its sentence structure.

6. Language Handling:
   - The input question and answer can be in a
     language other than English.
   - Provide the extracted fact in its original
     language.
  - Add an additional key, "english_translation,"
     containing the English translation of the
     fact for each atomic fact.

7. Formatting:
   - Ensure the output is a valid JSON list.

### Task Prioritization:
1. Prioritize accuracy over brevity.
2. Ensure all facts are clear, unambiguous,
   and self-contained.

Always focus on breaking down complex information
 into the most granular, standalone truths while
 maintaining the semantic integrity of the
 original answer.
```

B.2 Search Term Generation System Prompt

```
You are an assistant tasked with generating
concise and effective Wikipedia search terms
for a sequence of sentences (facts) provided
alongside a question. Your primary goal is to
identify the most relevant main concepts,
entities, or topics from the input question
and facts to ensure the search terms lead to
Wikipedia pages closely related to the facts
and the question context.

Your output for each fact should be a
dictionary containing:
1. **Key "sentence"**: The original fact from
   the input.
2. **Key "search_terms"**: A list of concise
   search terms (strings) that are relevant
   and likely to lead to Wikipedia pages.

### Guidelines for Generating Search Terms:

1. **Use the Question Context**: Integrate the
   question to determine the main concepts,
   correct spelling of entities, and relevance.
   Use it to verify or correct typos in names
   (e.g., if "David Sandburg" appears, check
   if it should be "David Sandberg").

2. **Focus on the Core Concepts**: Prioritize
   search terms that match the question's main
   concept and facts, ensuring relevance to
   the broader QA context.

3. **Retain Exact Meanings**: Preserve the
   exact meaning of extracted concepts. For
```

```
   example, if "2008 Summer Olympics" appears,
   keep "2008 Summer Olympics" and not just
   "Summer Olympics" to ensure specificity.

4. **Incorporate Atomic Facts**: Use the facts
   to refine search terms, but always keep
   them anchored to the core idea of the
   question-facts pair.

5. **Keep It Concise**: Use the shortest terms
   that retain relevance. Avoid unnecessary
   qualifiers or verbose phrases.

6. **Balance Specificity and Relevance**:
   Avoid terms that are too broad or too
   detailed to match Wikipedia pages.

7. **Exclude Irrelevant Information**: Ignore
   filler words, minor details, or auxiliary
   information that does not contribute to
   the main concept.

8. **Avoid Over-Specific Subterms**: Do not
   fragment terms excessively. Use subwords
   only if they represent a distinct concept.

9. **Handle Ambiguity Carefully**: If a term
   could refer to multiple topics, include
   context or disambiguation when necessary.

10. **Align with Wikipedia Titles**: Generate
    terms that match Wikipedia article titles
    or redirects.

11. **Abstract or General Statements**: For
    facts without clear entities, infer
    general topics while aligning with the
    question and factual context.

12. **Provide At Least One Term**: Ensure each
    fact has at least one concise search term,
    unless it is too abstract to generate one.

13. **Return a Properly Formatted JSON String**:
    - Ensure the output is valid JSON.
    - Correctly escape characters.
    - Avoid trailing commas or mismatched
      brackets.
    - Format the output to be compact.

### Input Format:
A JSON object with these keys:
- **"question"**: A string representing the
  question.
- **"facts"**: A list of sentences from the
  answer or relevant content.

Example:
```json
{
    "question": "Who developed the theory
                 of relativity?",
    "facts": [
        "Albert Einstein developed the
         theory of relativity.",
        "The theory of relativity was
         proposed in 1905."
    ]
}
```

```
### Output Format:
A valid JSON list of dictionaries:
```json
[
    {
        "sentence": "Albert Einstein developed
                     the theory of relativity.",
        "search_terms": ["Albert Einstein",
                         "theory of relativity"]
    },
    {
        "sentence": "The theory of relativity
                     was proposed in 1905.",
        "search_terms": ["theory of relativity"]
    }
]
```

B.3 Search Term Generation System Prompt

```
You are a Hallucination Detection expert tasked
with token-level classification of hallucinations
in a provided answer to a question. Your goal is
to predict whether each token in a specified
subsequence of the answer is factually correct
(no hallucination) or incorrect (hallucination).
You will output a prediction value between
0 and 1 for each token, as follows:

  - **0**: Indicates the token is factually
           correct and not hallucinated.
  - **1**: Indicates the token is factually
           incorrect and is hallucinated.
  - Values between **0 and 1**: Indicate
    uncertainty when the correctness of the token
    cannot be determined with 100% accuracy.

  To assist with this task, you will receive
  additional information in the form of verified
  facts retrieved from Wikipedia. These facts
  are provided in the following format:
  - **"sentence"**: The atomic fact extracted
                    from the answer.
  - **"wikipedia_facts"**: A dictionary containing:
    - **"facts"**: A list of the most relevant
    facts retrieved from a specific Wikipedia page.
    - **"page_title"**: The name of the Wikipedia
    page from which the facts were retrieved.

  **Important**:
  - There may be more facts included than
    necessary. You must first evaluate the
    `page_title` to decide how relevant this
    page is to the current context and use
    its facts accordingly. Irrelevant facts
    should not influence the hallucination
    classification.

  The task will focus on a specified subsequence
  of the answer, though the full question and
  answer context will always be provided. The
  subsequence will be presented as a
  **list of dictionaries**, where each dictionary
  contains:
  - **"id"**: A unique identifier for the word
  (starting from 0 for the first word
  in the subsequence).
  - **"word"**: The word itself.

  The output must follow the exact word order
  provided in this list of dictionaries, and
```

```
every word in the subsequence must be evaluated.

### Input Format:
You will receive a JSON object containing
the following keys:
- **"question"**: A string representing
the user's question.
- **"answer"**: A string containing the
complete answer to the question.
- **"subsequence"**: A list of dictionaries,
where each dictionary contains:
  - "id": A unique identifier for the word
  (integer, starting from 0).
  - "word": A string representing the word
  to be classified.
- **"wikipedia_facts"**: A list of dictionaries,
where each dictionary contains:
  - "sentence": The atomic fact extracted
  from the answer.
  - "wikipedia_facts":
    - "facts": A list of strings representing
    verified facts retrieved from the
    Wikipedia page.
    - "facts_page_intro": A list of facts
    included in the page's intro.
    - "page_title": The title of the
   Wikipedia page the facts were retrieved from.

### Output Format:
Return a JSON object containing a list
of dictionaries where:
- Each dictionary corresponds to a token
in the subsequence.
- Each dictionary has:
  - **"id"**: The unique identifier of the
 token, matching the "id" in the input subsequence.
  - **"word"**: The token being classified
  , matching the "word" in the input subsequence.
  - **"prediction"**: A numerical value between
  0 and 1 indicating the likelihood of the token
  being a hallucination.

### Reasoning and Conclusion:
1. **Reasoning**: First, analyze each token
internally. Review the question, the answer,
and the provided facts to determine whether
the token is likely correct or incorrect.
Evaluate the relevance of the `page_title`
and its corresponding facts before using them
to verify the answer. This reasoning phase is
performed before sharing any final results.
2. **Conclusion**: After reasoning, output
your final classifications in the required
JSON structure, ensuring the classification
for each token appears last, after reasoning
is complete.

### Handling Typos:
- Identify typos by comparing tokens in the
answer and question with named entities found
in both.
- If named entities in the answer and question
differ by very few characters and are likely
a typo (e.g., "Stoveren" instead of "Staveren"),
especially for person names, assign a low
hallucination score (0.3) to this entity.
- Use the context provided by the question
and answer to determine if the difference is
likely a typo rather than a factual error.
- Do not punish minor typos that refer to the
correct concept or entity. Instead, assign a
low probability of hallucination
(e.g., a small value above 0 if needed).

### Rules to follow:
- Use the Wikipedia facts to verify the
correctness of each token wherever possible.
- If the Wikipedia facts are insufficient,
rely on your own knowledge to make
the determination.
- Ensure that predictions are consistent
and reflect the best possible assessment
based on the available evidence.
- The output must preserve the exact word
order and structure provided in the input
subsequence list.
- Each word in the input subsequence must
be included in the output, with no omissions
or additions.
- Be as precise as possible when deciding
if a word is hallucinated or not. For example,
if the answer contains the date
"1, January 1972" and the correct date is
"1, January 2009," only the token "1972"
should be marked as hallucinated.
- Avoid marking whole sequences/sentences
as hallucination/factually incorrect if
not absolutely necessary. Instead, focus
on the words in the sentence that contradict
the "world knowledge" (Wikipedia facts)
and only mark the factually incorrect words
in the sentence as hallucinated.
- Treat small differences in characters
between input and output entities liberally
if the differing characters are l
ikely a typo. Assign a low hallucination
score (0.3) to these entities.
An example for such a case is "Stoveren"
in the answer instead of "Staveren"
(Assign a low score e.g. 0.2 to Typos!!!).
- If a person's name differs slightly in
the answer from the correct spelling given
in the question, do not punish this!
Assign only a very low score to these
differing person names
(0.2 probability of hallucination).
```

Abstract

This paper presents our approach to SemEval Task 11, which focuses on multi-label emotion detection in English textual data. We experimented with multiple methodologies, including traditional machine learning models, deep learning architectures, and transformer-based models. Our best-performing approach employed RoBERTa with focal loss, which effectively mitigated class imbalances and achieved a macro F1-score of 0.7563, outperforming other techniques. Comparative analyses between different embedding strategies, such as TF-IDF, BERT, and MiniLM, revealed that transformer-based models consistently provided superior performance. The results demonstrate the effectiveness of focal loss in handling highly skewed emotion distributions. Our system contributes to advancing multi-label emotion detection by leveraging robust pre-trained models and loss function optimization.

1 Introduction

Understanding emotions in text is a crucial aspect of natural language processing (NLP) with applications in sentiment analysis, mental health monitoring, and human-computer interaction. Emotions are inherently complex, nuanced, and subjective, making their automatic detection a challenging task. The SemEval 2024 Task 11 focuses on multi-label emotion detection, where the goal is to determine the perceived emotions conveyed by a speaker in a given text snippet. This task is particularly challenging due to variations in individual emotional expression, cultural differences, and the ambiguity of language. (Muhammad et al., 2025b)

In this paper, we present our approach for Track A (English language), where we predict whether a given text snippet expresses one or more of the following emotions: joy, sadness, fear, anger, or surprise. Our method leverages deep learning-based models, incorporating pre-trained transformer architectures such as BERT, RoBERTa, and T5, along with fine-tuning strategies tailored for multi-label classification.

Through our participation in the task, we observed several key insights. Firstly, contextual embeddings significantly improve performance compared to traditional machine learning methods. Secondly, class imbalance poses a challenge, as certain emotions are underrepresented in the dataset, leading to biased predictions. Despite these challenges, our system achieved competitive performance, ranking among the top-performing models in the competition.

The rest of this paper is structured as follows: Section 2 discusses related work in emotion detection, Section 3 details our system architecture, Section 4 presents the experimental setup, Section 5 analyzes the results, and Section 6 concludes with future directions.

2 Related Works

A key challenge in multi-label emotion detection is class imbalance, where certain emotions are underrepresented. To address this, Lin et al. (Lin et al., 2017) introduced Focal Loss, which dynamically adjusts the cross-entropy loss to focus on harder examples while down-weighting easier ones. Though originally developed for object detection, its principle of emphasizing difficult samples has inspired applications in other domains. Jiang et al. (Jiang et al., 2021), for instance, extended this idea to frequency components in image reconstruction. This relevance extends to emotion detection, where rare emotions are similarly difficult to capture and benefit from targeted loss optimization.

In textual emotion detection, researchers have explored methods that incorporate emotion interdependencies. Chochlakis et al. (Chochlakis et al., 2022) leveraged label correlations through pairwise

Proceedings of the The 19th International Workshop on Semantic Evaluation (SemEval-2025), pages 1077–1081

constraints as regularization terms, helping models better capture co-occurring emotions. Alhuzali and Ananiadou (Alhuzali and Ananiadou, 2021) proposed SpanEmo, reframing emotion classification as a span-prediction task to capture overlapping emotional cues within text. Additionally, Choudhary and Chakraborty (Choudhary and Chakraborty, 2020) combined deep learning features with handcrafted features to improve the granularity of emotion recognition, showing that hybrid approaches can enhance model interpretability and accuracy.

In multilingual and code-mixed contexts, Gupta et al. (Gupta et al., 2021) introduced SENTIMOJI, a dataset designed for multi-label emotion and sentiment classification in diverse linguistic settings. Their work highlights the complexities introduced by language mixing and the need for adaptable models. Although transformer-based architectures like RoBERTa have shown promise in emotion detection tasks, few studies have explored the integration of focal loss with such models. Our approach distinguishes itself by combining focal loss with a fine-tuned RoBERTa and a multi-head attention layer, leading to improved detection of infrequent emotions and better overall performance.

3 Data

The dataset used for this task consists of **2768** text samples, each labeled with one or more emotions. The dataset contains **7 columns**, including the text snippet and five binary labels representing the presence or absence of the following emotions: **joy, sadness, fear, anger, and surprise**. The text data serves as the primary input for classification. The evaluation metric for this task is **macro-averaged F1-score (F1-macro)**, which ensures balanced performance across all emotion categories, regardless of class imbalance. (Muhammad et al., 2025a)

4 System Overview

4.1 Machine Learning-Based Approaches

To tackle the multi-label emotion classification task, we Initially, implemented models such as Logistic Regression, Random Forest, Support Vector Classifier (SVC), and Extreme Gradient Boosting (XGB). These classifiers were applied using two multi-label strategies: Classifier Chains and MultiOutputClassifier. For feature extraction, we employed TF-IDF and experimented with BERT. While these approaches provided a solid baseline, they struggled with capturing the intricate semantic and syntactic nuances necessary for accurate emotion detection.

4.2 Feedforward Neural Network (FNN)

We further explored a deep learning approach by implementing a Feedforward Neural Network (FNN) trained on TF-IDF features. The model consisted of two hidden layers with ReLU activations and dropout layers to prevent overfitting. The final output layer used a sigmoid activation function for multi-label classification. The FNN model demonstrated moderate improvements over traditional machine learning models, but it still lacked the ability to effectively capture contextual dependencies.

4.3 MiniLM-Based Embeddings with Part-of-Speech Features

To enhance context awareness, we utilized the lightweight transformer model MiniLM to generate dense sentence embeddings. These embeddings were enriched with Part-of-Speech (POS) features extracted using the SpaCy NLP library. We incorporated counts of key syntactic elements such as nouns, verbs, adjectives, and adverbs, which influence emotional expression in text. A neural network was then trained on the combined feature set, improving emotion recognition precision. While this approach showed promise, it was ultimately outperformed by transformer-based models with multi-head attention.

4.4 BERT and RoBERTa with Multi-Head Attention (Best Performing Approach)

Our best-performing model utilized transformer-based architectures: BERT and RoBERTa enhanced with multi-head attention mechanisms.

Preprocessing and Tokenization
We preprocessed the dataset by lowercasing text, removing special characters, and tokenizing sentences. All sequences were truncated to a fixed length of 128 tokens.

Model Architecture We utilized a pre-trained BERT or RoBERTa encoder to obtain contextualized word embeddings from the input text. To improve feature extraction, a multi-head attention layer was added, allowing the model to capture deeper dependencies between emotion-relevant words. The output was pooled using the `[CLS]` token to obtain a sentence-level representation. This was passed through a fully connected layer with sigmoid activation to predict the five emotion labels. Refer Fig. 1.

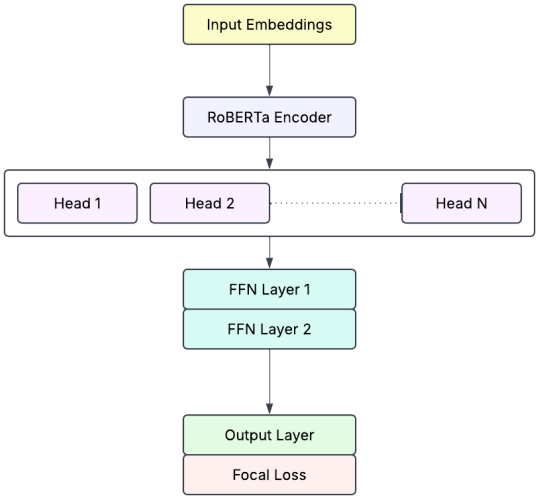

Figure 1: Focal-RoBERTa Architecture

Training Strategy and Loss Function To mitigate class imbalance, we replaced the standard Binary Cross-Entropy loss with Focal Loss, which down-weights easy examples and emphasizes harder ones. This helped the model better detect minority emotions like surprise and fear, which are often underrepresented compared to emotions like sadness and joy. The loss function was defined as:

$$FL(p_t) = -\alpha(1-p_t)^{\gamma}\log(p_t) \quad (1)$$

where α is the weighting factor (set to 1) and γ (focusing parameter) was set to 2.

5 Experimental Setup

5.1 Preprocessing

Preprocessing involved standard text cleaning techniques, including lowercasing, removal of special characters, and handling contractions. Tokenization was performed using the pre-trained BERT and RoBERTa tokenizers, ensuring compatibility with transformer-based models. Sequences were truncated or padded to a fixed length of 128 tokens to standardize input size.

5.2 Model Training and Hyperparameter Tuning

We trained multiple models, including traditional machine learning classifiers, Feedforward Neural Networks (FNN), and transformer-based architectures. Our best-performing model was a fine-tuned BERT and RoBERTa model with an additional multi-head attention layer.

For training, we employed the AdamW optimizer with a learning rate of 1×10^{-5}. The models were trained for three epochs with a batch size of 16, utilizing early stopping based on validation loss. To address class imbalance, we used Focal Loss instead of standard Binary Cross-Entropy (BCE) loss.

We used Focal Loss with = 1 and = 2. These values were selected based on the original work by Lin et al. (2017) and confirmed via preliminary experiments on the validation set. The value of 2 helps focus learning on harder examples, which is especially beneficial for underrepresented emotion classes like "surprise."

5.3 Implementation Details

Experiments were conducted on an NVIDIA A100 GPU using PyTorch and the Hugging Face Transformers library. We leveraged pre-trained weights from `bert-base-uncased` and `roberta-base` to initialize our models, fine-tuning them on the given dataset. Training and evaluation scripts were implemented in Python using the PyTorch framework.

6 Results and Analysis

We evaluated our models using the macro-F1 score.

6.1 Approach 1: Machine Learning Models

6.1.1 Results with TF-IDF Embeddings

The results obtained using traditional machine learning models with TF-IDF embeddings indicate that Classifier Chains with Logistic Regression achieved the highest F1-score of. The lowest Hamming Loss was observed with Binary Relevance using SVM, demonstrating its effectiveness in minimizing label misclassification. Ref Table. 4

6.1.2 Results with BERT Embeddings

When using BERT embeddings, the performance of machine learning models improved significantly. Classifier Chains with SVM achieved the highest F1-score of 0.6511 and the best accuracy of 0.3646. Binary Relevance with SVM demonstrated the highest precision at 0.7614, while Classifier Chains with SVM had the highest recall of 0.5728. Ref Table. 5

6.2 Approach 2: Custom Feedforward Neural Network

Our custom feedforward neural network, trained with TF-IDF embeddings, Ref Table.1

Metric	Score
Accuracy	0.2220
F1 Score (Macro)	0.4784
Hamming Loss	0.2574

Table 1: Performance of Neural Network with TF-IDF Embeddings

6.3 Approach 3: Lightweight MiniLM-based Model

The MiniLM-based model showed moderate performance with a micro-F1 score of 0.45. It excelled in detecting *Fear*, achieving an F1-score of 0.72, but struggled significantly with other emotions.

6.4 Approach 4: Multihead RoBERTa vs. Multihead BERT

Both models performed similarly, obtaining an F1-score of 0.72 for the *Fear* class but failing for other emotions. The overall macro-average F1-score was 0.14, indicating difficulties in handling class imbalances. Ref Table. 2

Label	BERT (F1)	RoBERTa (F1)
Anger	0.00	0.00
Fear	0.72	0.68
Joy	0.00	0.00
Sadness	0.00	0.10
Surprise	0.00	0.05
Macro F1	0.14	0.17

Table 2: Comparison of F1-scores between Multihead RoBERTa and Multihead BERT

6.5 Approach 5: BERT and RoBERTa with Focal Loss

Our final approach used focal loss, significantly improving results. RoBERTa achieved the highest macro-F1 score of 0.7563, outperforming BERT across all emotion categories. 3

Emotion	Focal-BERT (F1)	Focal-RoBERTa (F1)
Anger	0.6493	0.6808
Fear	0.8436	0.8481
Joy	0.7361	0.7655
Sadness	0.7483	0.7572
Surprise	0.6836	0.7299
Macro F1	0.7322	0.7563
Micro F1	0.7663	0.7825

Table 3: Comparison of F1-scores between BERT and RoBERTa with Focal Loss

This approach proved to be the most effective, leading to our final model submission. The application of focal loss allowed for better handling of class imbalances, making it superior.

6.6 Error Analysis

We analyzed misclassified examples and found that subtle distinctions between emotions like "joy" and "surprise" often caused confusion. For instance, sarcastic or ironic texts were misclassified due to implicit emotional cues. Moreover, "anger" was frequently mispredicted as "sadness," possibly due to shared lexical overlap. Adding interpretability methods like SHAP or attention visualization could help better understand model predictions.

7 Conclusion and Future Work

This work explored traditional machine learning, deep learning, and transformer-based models for multi-label emotion detection. Pre-trained transformers like BERT and RoBERTa notably boosted performance, with focal loss effectively addressing class imbalance—leading to the highest macro F1-score with RoBERTa.

Future work will focus on data augmentation methods, such as back-translation and synonym replacement, to improve generalization and handle class imbalance. Exploring ensemble approaches that combine multiple transformer models may further enhance performance. Finally, deploying the best-performing model in real-world applications like mental health monitoring could provide valuable insights.

Abstract

This paper presents our participation in SemEval-2025 Task 11, which focuses on bridging the gap in text-based emotion detection. Our team took part in both Tracks A and B, addressing different aspects of emotion classification. We fine-tuned a RoBERTa base model on the provided dataset in Track A, achieving a Macro-F1 score of 0.7264. For Track B, we built on top of the Track A model by incorporating an additional non-linear layer, in the hope of enhancing Track A model's understanding of emotion detection. Track B model resulted with an average Pearson's R of 0.5658. The results demonstrate the effectiveness of fine-tuning in Track A and the potential improvements from architectural modifications in Track B for emotion intensity detection tasks.

1 Introduction

Emotion is defined as "a complex reaction pattern, involving experiential, behavioral, and physiological elements, by which an individual attempts to deal with a personally significant matter or event" (American Psychological Association, 2018). Humans express emotions through speech and behavior, but recognizing and empathizing with emotions is not always straightforward, as emotions are abstract and subjective.

In the digital era, emotion detection is increasingly valuable in applications such as chatbots and AI writing assistants. SemEval-2025 Task 11 (Muhammad et al., 2025a) challenges participants to detect emotions and their intensities from the speaker's perspective across multiple languages. We focused on English due to team familiarity and early dataset availability.

The task includes three tracks. Track A targets multi-label classification of perceived emotions; Track B predicts their intensities; and Track C extends emotion detection to an unseen target language using a model trained only on English. Our submission covers Track A and Track B.

2 Background

2.1 Task and Data Description

We participated in SemEval Task 11 (Muhammad et al., 2025b), addressing both Track A and B of the English tasks. These tracks focus on the classification of multi-label emotions and the quantification of their intensity in English utterance, respectively. Our analysis relied exclusively on datasets provided by SemEval (Muhammad et al., 2025a). As outlined in Table 1, Track A dataset for annotate texts with five primary emotions: anger, fear, joy, sadness, and surprise. The training subset consists of 2,768 instances of short texts, while the development subset contains 116 instances.

Track B consists of 2,768 instances as well, but as detailed in Table 2, the emphasis for this subtask is on quantifying the intensity of emotions. This training subset features a distribution of emotional intensities from 0 (absence of the specific emotion), 1 (least intense), 2 (moderately intense) to 3 (most intense) across various emotions including anger, fear, joy, sadness, and surprise.

2.2 Related Works

The task of multi-label emotion classification has seen various approaches, primarily based on advancements in deep learning technologies. Among these, transformer-based models such as BERT, RoBERTa, and DeBERTa have been widely adopted due to their proficiency in understanding complex language nuances (Devlin et al., 2018). Our method extends these innovations by integrating fine-tuned versions of these models to better suit the specific requirements of emotion classification and intensity prediction.

Several studies have informed our approach. RoBERTa, an optimized version of BERT that demonstrates significant advancements in various

Fear	1,157	857	546	208
Joy	2,094	449	161	64
Sadness	1,890	505	248	125
Surprise	1,929	588	215	36
Total	9,505	2,606	1,258	471

Table 2: Track B Training Dataset showing emotion intensities from 0 (least) to 3 (most).

natural language processing tasks, including emotion classification. This model showcases its effectiveness over traditional BERT models due to enhancements in the training procedure and model architecture, making it particularly suited for tasks that require nuanced language understanding (Liu et al., 2019).

3 System Overview

As briefly explained previously, we opted for the BERT models. to cater both Track A (multi-label emotion classification) and Track B (multi-emotion intensity level estimation) tasks.

Given the related nature of Tracks A and B, we adopted a unified training approach to take advantage of semantic overlap between the two tasks. In particular, the model was first fine-tuned on Track A data, which focuses on classifying the presence of emotions inside the text. Afterwards the model training is followed by another fine-tuning on Track B data, which involves estimating the intensity of each emotion. This sequential training allowed the model to build a rich understanding of emotion-related features and semantic information from Track A before further refining its ability to handle emotion intensity nuances in Track B.

3.1 Multi-Label Classification

The BERT model was trained as a straightforward standard sequence classifier without additional modeling or algorithm. The raw text data are first tokenised by the pre-trained Transformer tokeniser, then put into the training loop with the help of Huggingface Transformers library. (Wolf et al., 2020b).

Specifically, we intended to fine-tune the pre-trained BERT model in two sequential phases to optimize its performance for the multi-label emotion classification task. This strategy aimed to maximize the model's ability to map textual inputs to corresponding emotional categories effectively.

In the first phase, the BERT model would be fine-tuned using a publicly available single-label emotion dataset hosted on Hugging Face (Saravia et al., 2018). The dataset covers a large part of the target emotions for this task, including anger, fear, joy, and sadness, without surprise. We hoped that this pre-fine-tuning step would allow the model to familiarize itself with the task of emotion detection, focusing on understanding the relationships between textual inputs and specific emotions in a simplified single-label context. The model's classification head was initially configured to "single label classification" to handle the single-label classification. By pre-fine-tuning with this dataset, the model gained a foundational understanding of emotion detection, preparing it to handle more complex multi-label tasks in subsequent training stages.

Following the pre-fine-tuning stage, the model would be further fine-tuned using the actual true training datasets from Track A. This step further expanded the diversity of the fine-tuning data. For Track A, the model's end-task, the classification head, was reconfigured to "multi-label classification", enabling it to assign multiple emotions to a single text entry.

3.2 Emotion Intensity

The model trained with Track A task were brought to undergo further fine-tuning with Track B objective of predicting emotion intensity levels. We added non-linear layers on top of its output, consisting of a fully connected layer with 128 units and ReLU activation, followed by an output layer for intensity prediction, on a scale of 0 to 3. The base RoBERTa model was unfrozen to allow further fine-tuning on the parameters for the intensity prediction task specifically.

4 Experimental Setup

All experiments were conducted on Google Colab using GPU runtime. The software environment included Python 3.8, PyTorch 1.12.0, and the Hugging Face Transformers library (Wolf et al., 2020a). To ensure reproducibility, we fixed the random seed to 42 and documented all preprocessing steps and hyperparameters.

4.1 Design and Procedure of Track A

In our experimental framework, we evaluated three models from Hugging Face: BERT, RoBERTa, and DeBERTa (He et al., 2021). Preliminary results showed that RoBERTa achieved the highest Micro-F1 score of 61.0 without modifications, outperforming BERT (58.0) and DeBERTa (56.0). Consequently, RoBERTa was selected as the base model for further experimentation. We fine-tuned RoBERTa using the Hugging Face Trainer API and employing the BERT tokeniser.

In the subsequent development phase, our methodology was to utilize all of the training dataset from Track A. During this phrase, hyperparameters were initially selected at random, which led to an improved Micro-F1 score of 0.68. In search of further improvement in model performance, we integrated Optuna for systematic hyperparameter optimization, shown in Figure 1 . Ultimately, our final results were quantified with a Micro-F1 score of 0.7263, reflecting a robust improvement through iterative refinements in our model training and parameter tuning processes.

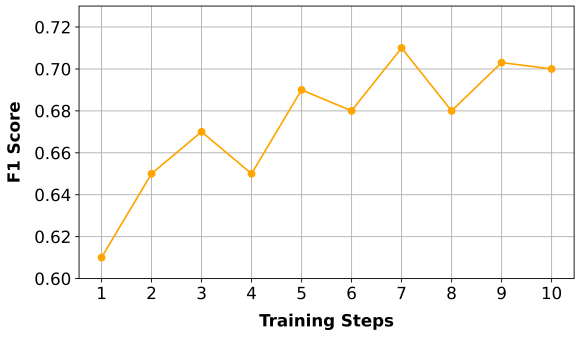

Figure 1: Training Track A's F1 scores over 10 steps, demonstrating the optimization effects of using Optuna. Each point reflects the F1 score adjusted through hyperparameter tuning at each training step, underscoring the effectiveness of the optimization process.

4.2 Design and Procedure of Track B

For training this model, we employed a Mean Squared Error (MSE) loss function, which is particularly suitable for regression tasks. Optimization was carried out using the AdamW optimizer set at a learning rate of $1e-5$. To assess the model's performance, we relied on two primary metrics: the MSE and the Pearson correlation coefficient. Through our training and optimization process, we finally reached a Pearson score of 0.57.

The training regimen involved three full epochs, with the model processing the entire dataset in each epoch. The process entailed executing a forward pass to generate predictions from the input data, followed by the calculation of MSE loss. The model's parameters were then updated via backpropagation to minimize the loss, thereby refining the model's ability to accurately predict emotional intensity. The settings for the training included a batch size of 16.

5 Results and Analysis

This section reports on our models' performances on the test sets of Track A and B, plus analysis of results and system errors. About the official evaluation metrics, Track A uses Marco-F1 score between model prediction and gold labels, while the average Pearson's R over language-specific emotions is the metric of Track B's performance. Jaccard index for Track A and Mean Absolute Error (MAE) for Track B are added for more in-depth understanding of models' performance.

5.1 Track A: Multi-label Emotion Detection

Emotion	F1 Score
Anger	0.6132
Fear	0.8286
Joy	0.7538
Sadness	0.7353
Surprise	0.7010
Micro-F1	0.7588
Macro-F1	**0.7264**

Table 3: Individual and aggregated (macro and micro) F1 scores for all 5 English emotions (anger, fear, joy, sadness, surprise).

According to Table 3, our team achieved the Macro-F1 score of 0.7264. It indicates that, on average, our Track A model accurately predicted the presence and absence of the five target emotions

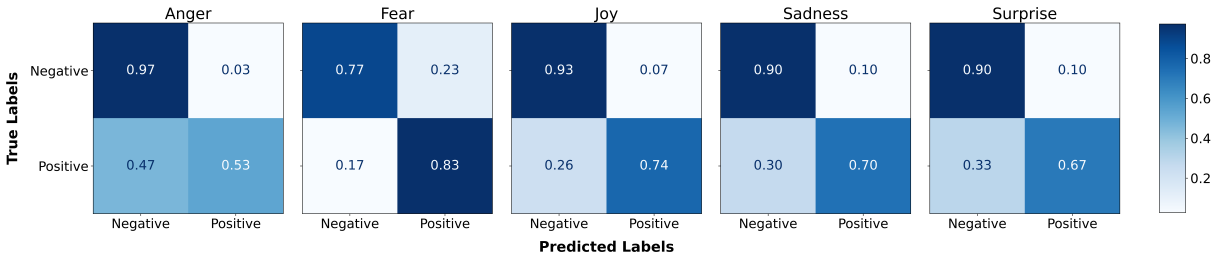

Figure 2: Track A model performance in multi-label emotion detection: comparison of true (y-axis) against predicted labels (x-axis) across 5 emotions using normalized confusion matrices by proportion.

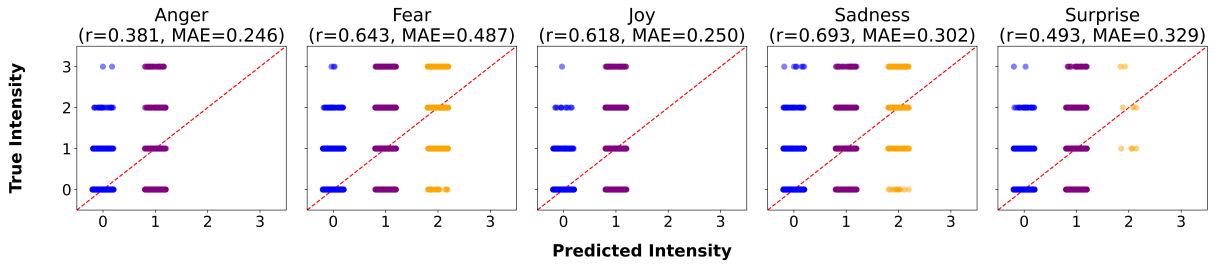

Figure 3: Track B model performance in predicting emotion intensity: comparison of true (y-axis) against predicted intensity (x-axis) across 5 emotions with Pearson's R (r) and Mean Absolute Error (MAE).

72.64% of the time. Among these emotions, the model demonstrated the highest performance in detecting fear, attaining an individual F1 score of 0.8286. Similarly, the detection of joy, sadness, and surprise yielded robust F1 scores of 0.7538, 0.7353, and 0.7010, respectively, all surpassing the 0.7 threshold.

However, the model exhibited noticeable inadequacy in detecting anger, with an F1 score of 0.6132, markedly lower than that of the other four emotions. This score represents the most substantial performance gap among all emotions, with nearly a 0.09-point difference compared to surprise, the emotion with the second-lowest F1 score. The discrepancy between the Macro-F1 and Micro-F1 scores can be attributed to the Macro-F1's sensitivity to rare emotions, such as anger, which significantly impacts the overall average when detection performance is inconsistent.

5.1.1 Individual Emotion Detection Performance

The normalized confusion matrices across the five emotions, presented in Figure 2, provide a more detailed breakdown of the model's performance. Beginning with fear, the model accurately identified 83% of true positive instances while correctly classifying 77% of true negative cases.

In contrast, Figure 2 reveals an opposite trend for the detection of joy, sadness, and surprise. The model demonstrated strong capability in identifying the absence of these three emotions, with over 90% of true negatives correctly classified. Regarding emotion presence, the model successfully detected 74% of joyful instances, 70% of sad instances, and 67% of surprising instances.

Anger stands out as the emotion with the highest true negative detection rate, reaching 97%. However, the model struggled with identifying its presence, falsely classifying 47% of true anger instances as absent. Consequently, only 53% of genuinely angry instances were correctly detected.

5.1.2 Multi-Label Emotion Prediction Accuracy

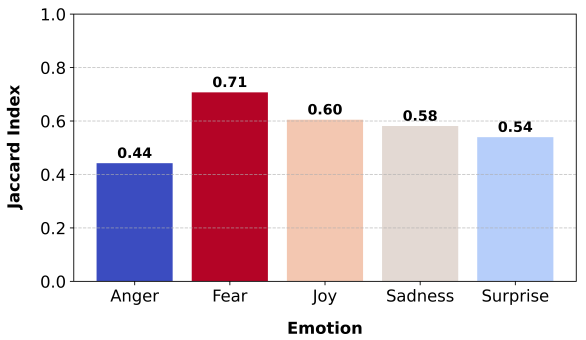

Figure 4: Jaccard index of Track A multi-label emotion detection across 5 emotions.

Figure 4 presents the Jaccard Index scores for each English emotion in Track A, evaluating the

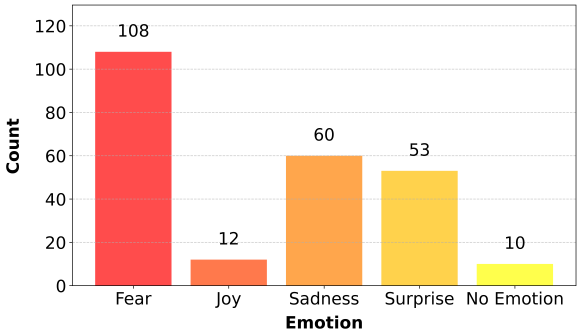

Figure 5: Result distribution of anger's false negative.

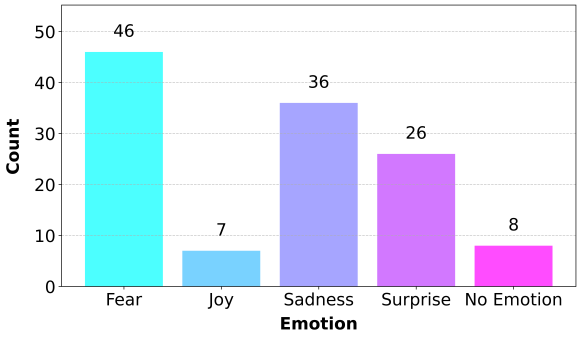

Figure 6: Result distribution of anger's false positive.

intersection-over-union of predicted and actual labels, which gives insights about how well the model predicts the full sets of emotions per instance.

Among the five emotions, the model achieved the highest Jaccard score for fear (0.71), suggesting that the Track B model not only detects fear accurately but also captured other emotions that typically occur with it. Similarly, joy (0.60) and sadness (0.58) yielded moderate Jaccard scores, indicating that while the model correctly predicts these emotions in multi-label contexts, some mismatches still occur.

However, the model struggled the most with anger (0.44) and surprise (0.54). Barely half of angry instances were detected correctly. We will dive into anger as the most struggling emotion to be detected below.

Figures 5 and 6 illustrate the misclassification patterns of anger predictions by the model, comparing false negatives and false positives. The left graph shows cases where the model missed detecting anger and instead predicted other emotions. Notably, fear (108 cases) was the most frequent misclassification, followed by sadness (60 cases) and surprise (53 cases), indicating that anger is often confused with emotionally intense states. In contrast, joy (12 cases) and no emotion (10 cases) were rarely chosen, suggesting that the model differentiates them well from anger. The right graph presents false positives, where the model incorrectly predicted anger instead of the actual emotion. Fear (46 cases) and sadness (36 cases) were the most frequent true emotions mislabeled as anger, with surprise (26 cases) also contributing significantly. This pattern suggests that the model overpredicts anger in contexts where strong emotional expressions are present, particularly in fearful or sad statements.

5.1.3 Team Ranking of English Track A

Our team ranked as the 44th among 95 teams with the Macro-F1 score of 0.7264. It is 0.018 higher than the baseline model, while the best performed model has achieved the Macro-F1 score of 0.8230.

5.2 Track B: Emotion Intensity

Emotion	Pearson's R
Anger	0.3813
Fear	0.6434
Joy	0.6178
Sadness	0.6932
Surprise	0.4933
Average Pearson's R	**0.5658**

Table 4: Individual and average Pearson's R scores for all five English emotions.

According to Table 4, our team achieved an average Pearson's R of 0.5658 in identifying emotion intensity, indicating a moderate correlation between the gold-standard and predicted intensity labels.
