Introduction

The Tenth Conference on Machine Translation (WMT 2025) took place on November 8–9, 2025, immediately following the 2025 Conference on Empirical Methods in Natural Language Processing (EMNLP 2025) in Suzhou, China.

This is the tenth time WMT has been held as a conference. The first time WMT was held as a conference was at ACL 2016 in Berlin, Germany, the second time at EMNLP 2017 in Copenhagen, Denmark, the third time at EMNLP 2028 in Brussels, Belgium, the fourth time at ACL 2019 in Florence, Italy, the fifth time at EMNLP-2020, which was held as an online event due to the COVID-19 pandemic, the sixth time at EMNLP 2021 at Punta Cana, Dominican Republic, the seventh time at EMNLP 2022 in Abu Dhabi, United Arab Emirates, the eight time at EMNLP 2023 in Singapore, and the ninth time at EMNLP 2024 in Miami, USA. Prior to being a conference, WMT was held 10 times as a workshop. WMT was held for the first time at HLT-NAACL 2006 in New York City, USA. In the following years the Workshop on Statistical Machine Translation was held at ACL 2007 in Prague, Czech Republic, ACL 2008, Columbus, Ohio, USA, EACL 2009 in Athens, Greece, ACL 2010 in Uppsala, Sweden, EMNLP 2011 in Edinburgh, Scotland, NAACL 2012 in Montreal, Canada, ACL 2013 in Sofia, Bulgaria, ACL 2014 in Baltimore, USA, EMNLP 2015 in Lisbon, Portugal.

The focus of our conference is to bring together researchers from the area of machine translation and invite selected research papers to be presented at the conference.

Prior to the conference, in addition to soliciting relevant papers for review and possible presentation, we conducted 10 shared tasks. These consisted of 5 translation tasks: General Translation, Low-Resource Indic Language Translation, Terminology Translation, Creole Language Translation, and Model Compression, two evaluation tasks: MT Test Suites ("Help us break LLMs, Vol. 2") and Automated Translation Quality Evaluation Systems, two multilingual tasks: Multilingual Instruction and LLMs with Limited Resources for Slavic Languages and finally the Open Language Data Initiative.

The results of all shared tasks were announced at the conference, and these proceedings also include overview papers for the shared tasks, summarizing the results, as well as providing information about the data used and any procedures that were followed in conducting or scoring the tasks. In addition, there are short papers from each participating team that describe their underlying system in greater detail.

Like in previous years, we have received a far larger number of submissions than we could accept for presentation. WMT 2025 has received 60 full research paper submissions (not counting withdrawn submissions). In total, WMT 2025 featured 21 full research paper presentations and 79 shared task presentations.

The invited talk was given by Longyue Wang from Alibaba, China.

We would like to thank the members of the Program Committee for their timely reviews. We also would like to thank the participants of the shared task and all the other volunteers who helped with the evaluations.

Barry Haddow, Tom Kocmi, Philipp Koehn, and Christof Monz

Co-Chairs

Organizing Committee

Chairs

Barry Haddow, University of Edinburgh
Tom Kocmi, Cohere
Philipp Koehn, Johns Hopkins University
Christof Monz, University of Amsterdam

Program Committee

Chairs

Idris Abdulmumin, University of Pretoria
Laurie Burchell, Common Crawl Foundation
Isaac Caswell, Google Research
Daryna Dementieva, Technical University of Munich
Marion Di Marco, TUM
Lukas Edman, TU Munich
Mark Fishel, University of Tartu
Barry Haddow, University of Edinburgh and Aveni
Tom Kocmi, Cohere
Philipp Koehn, Johns Hopkins University
Jean Maillard, Meta AI
Christof Monz, University of Amsterdam
Shu Okabe, TUM Heilbronn
Lisa Yankovskaya, University of Tartu

Program Committee

Sadaf Abdul Rauf, Fatima Jinnah Women Unversity
Kolawole Adebayo, Dublin City University
David Ifeoluwa Adelani, McGill University / MILA
Aniefon Akpan, Univeristy of Uyo
Asim Alaskar, King Saud University
Priscilla Amuok, Masakhane
Antonios Anastasopoulos, George Mason University
Anietie Andy, Howard University

Program

Saturday, November 8, 2025

09:00 - 09:10 *Opening Remarks - 20 Years of WMT*

09:10 - 10:30 *Session 1 - Shared Task Overview Papers I*

Findings of the WMT25 General Machine Translation Shared Task: Time to Stop Evaluating on Easy Test Sets
Tom Kocmi, Ekaterina Artemova, Eleftherios Avramidis, Rachel Bawden, Ondřej Bojar, Konstantin Dranch, Anton Dvorkovich, Sergey Dukanov, Mark Fishel, Markus Freitag, Thamme Gowda, Roman Grundkiewicz, Barry Haddow, Marzena Karpinska, Philipp Koehn, Howard Lakougna, Jessica Lundin, Christof Monz, Kenton Murray, Masaaki Nagata, Stefano Perrella, Lorenzo Proietti, Martin Popel, Maja Popović, Parker Riley, Mariya Shmatova, Steinthór Steingrímsson, Lisa Yankovskaya and Vilém Zouhar

Findings of the WMT25 Multilingual Instruction Shared Task: Persistent Hurdles in Reasoning, Generation, and Evaluation
Tom Kocmi, Sweta Agrawal, Ekaterina Artemova, Eleftherios Avramidis, Eleftheria Briakou, Pinzhen Chen, Marzieh Fadaee, Markus Freitag, Roman Grundkiewicz, Yupeng Hou, Philipp Koehn, Julia Kreutzer, Saab Mansour, Stefano Perrella, Lorenzo Proietti, Parker Riley, Eduardo Sánchez, Patricia Schmidtova, Mariya Shmatova and Vilém Zouhar

Findings of the WMT25 Shared Task on Automated Translation Evaluation Systems: Linguistic Diversity is Challenging and References Still Help
Alon Lavie, Greg Hanneman, Sweta Agrawal, Diptesh Kanojia, Chi-Kiu Lo, Vilém Zouhar, Frederic Blain, Chrysoula Zerva, Eleftherios Avramidis, Sourabh Deoghare, Archchana Sindhujan, Jiayi Wang, David Ifeoluwa Adelani, Brian Thompson, Tom Kocmi, Markus Freitag and Daniel Deutsch

10:30 - 11:00 *Coffee Break*

11:00 - 12:00 *Session 2 - Shared Task Posters*

11:00 - 12:00 *General Translation Task*

Midheind at WMT25 General Machine Translation Task
Svanhvít Lilja Ingólfsdóttir, Haukur Jónsson, Kári Steinn Adhalsteinsson, Róbert Fjölnir Birkisson, Sveinbjörn Thórdharson and Thorvaldur Páll Helgason

A Preliminary Study of AI Agent Model in Machine Translation
Ahrii Kim

Marco Large Translation Model at WMT2025: Transforming Translation Capability in LLMs via Quality-Aware Training and Decoding
Hao Wang, Linlong Xu, Heng Liu, Yangyang Liu, Xiaohu Zhao, Bo Zeng, Longyue Wang, Weihua Luo and Kaifu Zhang

Evaluation of QWEN-3 for English to Ukrainian Translation
Cristian Grozea and Oleg Verbitsky

SYSTRAN @ WMT 2025 General Translation Task
Dakun Zhang, Yara Khater, Ramzi Rahli, Anna Rebollo and Josep Crego

Shy-hunyuan-MT at WMT25 General Machine Translation Shared Task
Mao Zheng, Zheng Li, Yang Du, Bingxin Qu and Mingyang Song

From SALAMANDRA to SALAMANDRATA: BSC Submission for WMT25 General Machine Translation Shared Task
Javier Garcia Gilabert, Xixian Liao, Severino Da Dalt, Ella Bohman, Audrey Mash, Francesca De Luca Fornaciari, Irene Baucells, Joan Llop, Miguel Claramunt, Carlos Escolano and Maite Melero

Instruction-Tuned English to Bhojpuri Neural Machine Translation Using Contrastive Preference Optimization
Kshetrimayum Boynao Singh, Deepak Kumar and Asif Ekbal

SH at WMT25 General Machine Translation Task
Hayate Shiroma

Simple Test Time Scaling for Machine Translation: Kaze-MT at the WMT25 General Translation Task
Shaomu Tan

NTTSU at WMT2025 General Translation Task
Zhang Yin, Hiroyuki Deguchi, Haruto Azami, Guanyu Ouyang, Kosei Buma, Yingyi Fu, Katsuki Chousa and Takehito Utsuro

A Decoding for Machine Translation in LLMs - SRPOL Participation in WMT2025*
Adam Dobrowolski, Paweł Przewłocki, Paweł Przybysz, Marcin Szymański and Dawid Siwicki

In2X at WMT25 Translation Task
Lei Pang, Hanyi Mao, Quanjia Xiao, Chen Ruihan, Jingjun Zhang, Haixiao Liu and Xiangyi Li

CUNI at WMT25 General Translation Task
Josef Jon, Miroslav Hrabal, Martin Popel and Ondřej Bojar

UvA-MT's Participation in the WMT25 General Translation Shared Task
Di Wu, Yan Meng, Maya Konstantinovna Nachesa, Seth Aycock and Christof Monz

AMI at WMT25 General Translation Task: How Low Can We Go? Finetuning Lightweight Llama Models for Low Resource Machine Translation
Atli Jasonarson and Steinthor Steingrimsson

KIKIS at WMT 2025 General Translation Task
Koichi Iwakawa, Keito Kudo, Subaru Kimura, Takumi Ito and Jun Suzuki

Google Translate's Research Submission to WMT2025
Mara Finkelstein, Geza Kovacs, Isaac Caswell, Tobias Domhan, Jan-Thorsten Peter, Juraj Juraska, Markus Freitag and David Vilar

DLUT and GTCOM's Large Language Model Based Translation System for WMT25
Hao Zong, Chao Bei, Wentao Chen, Conghu Yuan, Huan Liu and Degen Huang

Yandex Submission to the WMT25 General Machine Translation Task
Nikolay Karpachev, Ekaterina Enikeeva, Dmitry Popov, Arsenii Bulgakov, Daniil Panteleev, Dmitrii Ulianov, Artem Kryukov and Artem Mekhraliev

IRB-MT at WMT25 Translation Task: A Simple Agentic System Using an Off-the-Shelf LLM
Ivan Grubišić and Damir Korencic

Improving Low-Resource Japanese Translation with Fine-Tuning and Backtranslation for the WMT 25 General Translation Task
Felipe Fujita and Hideyuki Takada

Multi-agentMT: Deploying AI Agent in the WMT25 Shared Task
Ahrii Kim

Laniqo at WMT25 General Translation Task: Self-Improved and Retrieval-Augmented Translation
Kamil Guttmann, Zofia Rostek, Adrian Charkiewicz, Antoni Solarski, Mikołaj Pokrywka and Artur Nowakowski

Command-A-Translate: Raising the Bar of Machine Translation with Difficulty Filtering
Tom Kocmi, Arkady Arkhangorodsky, Alexandre Berard, Phil Blunsom, Samuel Cahyawijaya, Théo Dehaze, Marzieh Fadaee, Nicholas Frosst, Matthias Galle, Aidan Gomez, Nithya Govindarajan, Wei-Yin Ko, Julia Kreutzer, Kelly Marchisio, Ahmet Üstün, Sebastian Vincent and Ivan Zhang

11:00 - 12:00 *Test Suites Shared Task*

GENDER1PERSON: Test Suite for Estimating Gender Bias of First-person Singular Forms
Maja Popović and Ekaterina Lapshinova-Koltunski

Evaluation of LLM for English to Hindi Legal Domain Machine Translation Systems
Kshetrimayum Boynao Singh, Deepak Kumar and Asif Ekbal

RoCS-MT v2 at WMT 2025: Robust Challenge Set for Machine Translation
Rachel Bawden and Benoît Sagot

Automated Evaluation for Terminology Translation Related to the EEA Agreement
Selma Dis Hauksdottir and Steinthor Steingrimsson

Up to Par? MT Systems Take a Shot at Sports Terminology
Einar Sigurdsson, Magnús Magnússon, Atli Jasonarson and Steinthor Steingrimsson

Fine-Grained Evaluation of English-Russian MT in 2025: Linguistic Challenges Mirroring Human Translator Training
Shushen Manakhimova, Maria Kunilovskaya, Ekaterina Lapshinova-Koltunski and Eleftherios Avramidis

11:00 - 12:00 *Translation Quality Evaluation Shared Task*

Tagged Span Annotation for Detecting Translation Errors in Reasoning LLMs
Taemin Yeom, Yonghyun Ryu, Yoonjung Choi and Jinyeong Bak

COMET-poly: Machine Translation Metric Grounded in Other Candidates
Maike Züfle, Vilém Zouhar, Tu Anh Dinh, Felipe Maia Polo, Jan Niehues and Mrinmaya Sachan

Long-context Reference-based MT Quality Estimation
Sami Haq, Chinonso Osuji, Sheila Castilho, Brian Davis and Thiago Castro Ferreira

Evaluating WMT 2025 Metrics Shared Task Submissions on the SSA-MTE African Challenge Set
Senyu Li, Felermino Dario Mario Ali, Jiayi Wang, Rui Sousa-Silva, Henrique Lopes Cardoso, Pontus Stenetorp, Colin Cherry and David Ifeoluwa Adelani

Nvidia-Nemo's WMT 2025 Metrics Shared Task Submission
Brian Yan, Shuoyang Ding, Kuang-Da Wang, Siqi Ouyang, Oleksii Hrinchuk, Vitaly Lavrukhin and Boris Ginsburg

GEMBA V2: Ten Judgments Are Better Than One
Marcin Junczys-Dowmunt

CUNI and Phrase at WMT25 MT Evaluation Task
Miroslav Hrabal, Ondrej Glembek, Aleš Tamchyna, Almut Silja Hildebrand, Alan Eckhard, Miroslav Štola, Sergio Penkale, Zuzana Šimečková, Ondřej Bojar, Alon Lavie and Craig Stewart

MSLC25: Metric Performance on Low-Quality Machine Translation, Empty Strings, and Language Variants
Rebecca Knowles, Samuel Larkin and Chi-Kiu Lo

MetricX-25 and GemSpanEval: Google Translate Submissions to the WMT25 Evaluation Shared Task
Juraj Juraska, Tobias Domhan, Mara Finkelstein, Tetsuji Nakagawa, Geza Kovacs, Daniel Deutsch, Pidong Wang and Markus Freitag

HW-TSC's Submissions to the WMT 2025 Segment-level Quality Score Prediction Task
Yuanchang Luo, Jiaxin Guo, Daimeng Wei, Hengchao Shang, Zongyao Li, Zhiqiang Rao, Jinlong Yang, Zhanglin Wu, Xiaoyu Chen and Hao Yang

UvA-MT at WMT25 Evaluation Task: LLM Uncertainty as a Proxy for Translation Quality
Di Wu and Christof Monz

Submission for WMT25 Task 3
Govardhan Padmanabhan

RankedCOMET: Elevating a 2022 Baseline to a Top-5 Finish in the WMT 2025 QE Task
Sujal Maharjan and Astha Shrestha

Quality-Informed Segment-Level Error Correction Using Natural Language Explanations from xTower and Large Language Models
Prashant Sharma

TASER: Translation Assessment via Systematic Evaluation and Reasoning
Monishwaran Maheswaran, Marco Carini, Christian Federmann and Tony Diaz

12:00 - 14:00 *Lunch Break*

Saturday, November 8, 2025 (continued)

14:00 - 15:00 *Session 3 - Invited Talk by Longyue Wang (Alibaba)*

15:00 - 16:00 *Coffee Break*

16:00 - 17:30 *Session 4 - Research Papers Talk Session*

An Empirical Analysis of Machine Translation for Expanding Multilingual Benchmarks
Sara Rajaee, Rochelle Choenni, Ekaterina Shutova and Christof Monz

Cross-lingual Human-Preference Alignment for Neural Machine Translation with Direct Quality Optimization
Kaden Uhlig, Joern Wuebker, Raphael Reinauer and John Denero

Audio-Based Crowd-Sourced Evaluation of Machine Translation Quality
Sami Haq, Sheila Castilho and Yvette Graham

Meaningful Pose-Based Sign Language Evaluation
Zifan Jiang, Colin Leong, Amit Moryossef, Oliver Cory, Maksym Ivashechkin, Neha Tarigopula, Biao Zhang, Anne Göhring, Annette Rios, Rico Sennrich and Sarah Ebling

Context Is Ubiquitous, but Rarely Changes Judgments: Revisiting Document-Level MT Evaluation
Ahrii Kim

GIIFT: Graph-guided Inductive Image-free Multimodal Machine Translation
Jiafeng Xiong and Yuting Zhao

Sunday, November 9, 2025

09:10 - 10:30 *Session 5 - Shared Task Overview Papers II*

Findings of the WMT 2025 Shared Task on Model Compression: Early Insights on Compressing LLMs for Machine Translation
Marco Gaido, Roman Grundkiewicz, Thamme Gowda and Matteo Negri

Findings of the WMT 2025 Shared Task of the Open Language Data Initiative
David Dale, Laurie Burchell, Jean Maillard, Idris Abdulmumin, Antonios Anastasopoulos, Isaac Caswell and Philipp Koehn

Findings of the WMT 2025 Shared Task LLMs with Limited Resources for Slavic Languages: MT and QA
Shu Okabe, Daryna Dementieva, Marion Di Marco, Lukas Edman, Katharina Haemmerl, Marko Měškank, Anita Hendrichowa and Alexander Fraser

Findings of the First Shared Task for Creole Language Machine Translation at WMT25
Nathaniel Robinson, Claire Bizon Monroc, Rasul Dent, Stefan Watson, Kenton Murray, Raj Dabre, Andre Coy and Heather Lent

Findings of WMT 2025 Shared Task on Low-resource Indic Languages Translation
Partha Pakray, Reddi Krishna, Santanu Pal, Advaitha Vetagiri, Sandeep Dash, Arnab Kumar Maji, Saralin A. Lyngdoh, Lenin Laitonjam, Anupam Jamatia, Koj Sambyo, Ajit Das and Riyanka Manna

Findings of the WMT25 Terminology Translation Task: Terminology is Useful Especially for Good MTs
Kirill Semenov, Xu Huang, Vilém Zouhar, Nathaniel Berger, Dawei Zhu, Arturo Oncevay and Pinzhen Chen

10:30 - 11:00 *Coffee Break*

09:10 - 10:30 *Session 5 - Shared Task Posters II*

11:00 - 12:00 *Model Compression Shared Task*

Vicomtech@WMT 2025: Evolutionary Model Compression for Machine Translation
David Ponce, Harritxu Gete and Thierry Etchegoyhen

Iterative Layer Pruning for Efficient Translation Inference
Yasmin Moslem, Muhammad Hazim Al Farouq and John Kelleher

Sunday, November 9, 2025 (continued)

11:00 - 12:00 *Open Language Data Initiative*

Expanding the WMT24++ Benchmark with Rumantsch Grischun, Sursilvan, Sutsilvan, Surmiran, Puter, and Vallader
Jannis Vamvas, Ignacio Pérez Prat, Not Soliva, Sandra Baltermia-Guetg, Andrina Beeli, Simona Beeli, Madlaina Capeder, Laura Decurtins, Gian Peder Gregori, Flavia Hobi, Gabriela Holderegger, Arina Lazzarini, Viviana Lazzarini, Walter Rosselli, Bettina Vital, Anna Rutkiewicz and Rico Sennrich

A French Version of the OLDI Seed Corpus
Malik Marmonier, Benoît Sagot and Rachel Bawden

Bringing Ladin to FLORES+
Samuel Frontull, Thomas Ströhle, Carlo Zoli, Werner Pescosta, Ulrike Frenademez, Matteo Ruggeri, Daria Valentin, Karin Comploj, Gabriel Perathoner, Silvia Liotto and Paolo Anvidalfarei

Correcting the Tamazight Portions of FLORES+ and OLDI Seed Datasets
Alp Oktem, Mohamed Aymane Farhi, Brahim Essaidi, Naceur Jabouja and Farida Boudichat

Filling the Gap for Uzbek: Creating Translation Resources for Southern Uzbek
Mukhammadsaid Mamasaidov, Azizullah Aral, Abror Shopulatov and Mironshoh Inomjonov

The Kyrgyz Seed Dataset Submission to the WMT25 Open Language Data Initiative Shared Task
Murat Jumashev, Alina Tillabaeva, Aida Kasieva, Turgunbek Omurkanov, Akylai Musaeva, Meerim Emil Kyzy, Gulaiym Chagataeva and Jonathan Washington

SMOL: Professionally Translated Parallel Data for 115 Under-represented Languages
Isaac Caswell, Elizabeth Nielsen, Jiaming Luo, Colin Cherry, Geza Kovacs, Hadar Shemtov, Partha Talukdar, Dinesh Tewari, Moussa Doumbouya, Djibrila Diane, Baba Mamadi Diane, Solo Farabado, Edoardo Ferrante, Alessandro Guasoni, Mamadou Keita, Sudhamoy Debbarma, Ali Kuzhuget, David Anugraha, Muhammad Ravi Shulthan Habibi, Sina Ahmadi, Mingfei Liu and Jonathan Eng

Improved Norwegian Bokmål Translations for FLORES
Petter Mæhlum, Anders Næss Evensen and Yves Scherrer

11:00 - 12:00 *Slavic Languages Shared Task*

NRC Systems for the WMT2025-LRSL Shared Task
Samuel Larkin, Chi-Kiu Lo and Rebecca Knowles

TartuNLP at WMT25 LLMs with Limited Resources for Slavic Languages Shared Task
Taido Purason and Mark Fishel

JGU Mainz's Submission to the WMT25 Shared Task on LLMs with Limited Resources for Slavic Languages: MT and QA

Abstract

The rapid advancement of large language models (LLMs) has introduced new challenges in their evaluation, particularly for multilingual settings. The limited evaluation data are more pronounced in low-resource languages due to the scarcity of professional annotators, hindering fair progress across languages. In this work, we systematically investigate the viability of using machine translation (MT) as a proxy for evaluation in scenarios where human-annotated test sets are unavailable. Leveraging a state-of-the-art translation model, we translate datasets from four tasks into 198 languages and employ these translations to assess the quality and robustness of MT-based multilingual evaluation under different setups. We analyze task-specific error patterns, identifying when MT-based evaluation is reliable and when it produces misleading results. Our translated benchmark reveals that current language selections in multilingual datasets tend to overestimate LLM performance on low-resource languages. We conclude that although machine translation is not yet a fully reliable method for evaluating multilingual models, overlooking its potential means missing a valuable opportunity to track progress in non-English languages.

1 Introduction

Large-scale evaluation of multilingual language models (MLMs) across hundreds of languages has remained a persistent challenge as the existing benchmarks cover a subset, and mostly high-resource, of languages (Singh et al., 2024, 2025). Although human-translated (HT) evaluation sets offer accurate and reliable evaluation of MLMs, creating them for hundreds of languages is costly, time-consuming, and sometimes impossible. Consequently, tracking the progress of MLMs in most languages has lagged behind. Moreover, multilingual benchmarks often cover different subsets of languages, and such inconsistent evaluation setups create a fragmented picture of MLM capabilities (Liang et al., 2020; Hu et al., 2020; Ruder et al., 2021).

Recent advances in machine translation (MT) have emerged as a promising solution to these challenges of multilingual evaluation. Prior studies have shown that state-of-the-art MT systems achieve human-level translation quality in certain high-resource languages (Kocmi et al., 2023, 2024). While MT has been used to construct evaluation sets (Chen et al., 2024), to our knowledge, there has been no systematic study of the viability of MT-based evaluations across different evaluation setups and diverse downstream tasks in nearly 200 languages. Moreover, although previous work has shown the limitations of MT models, such as translation artifacts and stylistic shifts (Park et al., 2024; Wang et al., 2023), there has been no comprehensive analysis of the potential risks of using MT-based datasets for MLM evaluation.

In this work, and by considering recent MT advances, we investigate the viability of using MT for large-scale multilingual evaluation where human-annotated data is unavailable. Using four popular multilingual tasks, we translate their test sets into 198 languages using NLLB ("No Language Left Behind"), which officially supports 200 languages (NLLB Team et al., 2022). We then compare three MLMs' performance, i.e., XLM-R (both base and large versions) (Conneau et al., 2020), BLOOMz (Muennighoff et al., 2022), and AYA-101 (Üstün et al., 2024b), on these MT-based test sets against their HT equivalents, using multiple evaluation setups (zero-shot fine-tuning and zero-shot prompting) and both accuracy and rank correlation as metrics. Beyond overall performance comparisons, we analyze how translation quality relates to evaluation results, detecting MT-specific error types using an LLM-as-a-judge framework in the selected tasks. Finally, we assess whether

[*]Equal contribution.

Proceedings of the Tenth Conference on Machine Translation, pages 1–30
November 8-9, 2025

current multilingual benchmarks misrepresent the performance of MLMs when limited to small language subsets. More specifically, we try to answer the following research questions:

- To what extent does the use of machine translation affect MLM performance estimates?
- To what extent is MLM performance on MT-based evaluations influenced by translation quality?
- What major translation error types occur in cases where MLMs succeed on human translations but fail on machine translations?
- To what extent do existing multilingual benchmarks misrepresent MLM performance?

Across tasks and models, MT-based evaluations yield results that are highly correlated with HT-based evaluations (average Spearman's 0.95), with only small average accuracy differences (<1.5 points), Table 3 and 4. Furthermore, translation quality shows a moderate positive correlation with performance differences, suggesting that MT reliability depends partly on the underlying MT system's accuracy and the sensitivity of the downstream task to the translation quality, Table 5. Our error analysis reveals that lower performance on MT data is often linked to lexical mistranslations and subtle semantic shifts, though major meaning-altering errors are relatively rare. We show that LLM-as-a-judge might serve as a proxy for filtering low-quality translation examples, thereby improving the reliability of MT-based evaluations. Finally, we find that restricting evaluation to the language subsets in the widely-used benchmarks underestimates the performance of MLMs on high-resource languages and overestimates their performance on low-resource languages by up to 4 accuracy points compared to evaluation across 198 languages.

2 Related work

Multilingual large language models (LLMs) are rapidly expanding their language coverage, reaching to hundreds of languages (Üstün et al., 2024a; Yang et al., 2025). Yet, benchmarks have struggled to keep pace, often covering only a fraction of these languages (e.g., Global MMLU covers 42 languages (Singh et al., 2025), whereas models like Gemma 3 support over 140 (Gemma Team et al., 2025)). This imbalance makes it difficult to measure progress fairly and consistently across languages. On the other hand, creating human-annotated benchmarks for every language is impractical due to high costs and limited expertise. In this regard, machine translation is an attractive potential alternative to expand existing multilingual datasets at scale. Although previous studies have shown MT systems may introduce challenges such as hallucinations and translationese artifacts (Artetxe et al., 2020; Wang and Sennrich, 2020; Zhang and Toral, 2019), recent improvements, especially for mid and low-resource languages, have considerably enhanced translation quality (Ranathunga et al., 2023). Thus, leveraging advanced MT systems is an efficient way to expand the language coverage of benchmarks more quickly. This approach opens the door to more comprehensive and equitable evaluations, better reflecting the multilingual capabilities of LLMs. While Thellmann et al. (2024) also investigate whether machine translated benchmarks can reliably assess model performance across languages, they limit the scope of their study to 20 European languages. Since European languages are already overrepresented in existing NLP resources and benchmarks (Asai et al., 2022), while many other languages remain severely underrepresented (Joshi et al., 2020), we instead scale our evaluation to 198 languages to provide a more balanced assessment.

3 Methods

In this paper, we evaluate multilingual LLMs on four tasks across 198 languages. To this end, we create MT test data using the NLLB model and assess performance under two evaluation paradigms: zero-shot testing and zero-shot prompting. In this section we provide a comprehensive overview of our methods used for large-scale multilingual evaluation. In Section 4, we will explain which methods were used to generate the MT test data itself.

3.1 Tasks and datasets

We massively scale the evaluation of LLMs on four datasets.

XNLI The Cross-Lingual Natural Language Inference (XNLI) dataset (Conneau et al., 2018) contains premise-hypothesis pairs labeled with: 'entailment', 'neutral', or 'contradiction' in 15 languages.

The original pairs come from English and the

test sets were human translated into the other languages.

PAWS-X The Cross-Lingual Paraphrase Adversaries from Word Scrambling (PAWS-X) dataset (Yang et al., 2019) requires the model to determine whether two sentences are paraphrases of one another. The parallel test data has been provided in 7 languages. To create this dataset, a subset of the PAWS development and test sets (Zhang et al., 2019) was professionally translated from English to 6 other languages.

XCOPA The Cross-lingual Choice of Plausible Alternatives (Ponti et al., 2020) evaluates common-sense reasoning in 11 languages. The samples contain a premise and question paired with two answer choices from which the model can select. The dataset is manually translated from English into 11 other languages.

XStorycloze The Cross-lingual Storycloze (Lin et al., 2021) proposes a common-sense reasoning task in 11 languages, in which the model predicts which one of two story endings is the most likely to follow after a given short story. The Storycloze dataset was professionally translated from English into 10 other languages.

3.2 Multilingual language models

For the large-scale evaluation, we focus on the base and large version of XLM-R (Conneau et al., 2020) pre-trained on 100 languages as it is one of the most popular MLMs. In addition, we report scores from BLOOMz 7.1b (Scao et al., 2022) and AYA-101 13b (AYA)(Üstün et al., 2024b). BLOOMz is trained on 46 languages and AYA on 101 languages. Moreover, both models are further instruction-tuned on a mixture of prompts in different languages. Given that the PAWS-X dataset was included during instruction-tuning, we evaluate BLOOMz and AYA on the held out datasets only, i.e., XNLI, XCOPA and XStorycloze. Note that BLOOMz and AYA were selected over other MLMs, such as Llama (Touvron et al., 2023), as they are the largest publicly available and explicitly MLMs (i.e., statistics on the pretraining data distribution across languages is publicly available).

3.3 Selection of test languages

For our selection of test languages, there are two constraining factors: (1) the language has to be covered by the NLLB-200 translation model and FLORES-200 dataset, and (2) the script of the language needs to have been seen during the pretraining of the model. We then separately filter out the test languages by unseen scripts for each model. This leaves us with 196, 168, and 198 test languages for XLM-R, BLOOMz, and AYA, respectively, see Appendix J for the complete lists. Note that the number of compatible languages is lower for BLOOMz as it has seen fewer writing scripts during pretraining.

	Unseen	Low	Mid	High	Total
% of data	0	>0 and <0.1	$\geq$ 0.1 and <1	$\geq$1	
XLM-R	106	30	34	26	196
BLOOMz	131	21	7	9	168
AYA	103	57	25	13	198

Table 1: Number of languages categorized as high, mid, low, and unseen languages when looking at the percentage of seen pretraining data of the respective LMs.

Resource categorization by pretraining distribution Moreover, we categorize the test languages for each model separately based on the percentage of total data that they contributed during pretraining. In Table 1, we report the percentage thresholds used for our categorization and the resulting number of test languages for each category and model. As the pretraining data coverage is reported in numbers of GB for XLM-R, we convert these scores to percentages of the full pretraining data. For BLOOMz, we use the reported language distribution numbers [1], and for AYA, we consider mT5 pretraining data distribution as it is utilized as the base model for AYA.

3.4 Evaluation settings

Zero-shot testing We fine-tune XLM-R on the entire training set for each task in English. We then use our fine-tuned model for zero-shot testing in the test languages. We fine-tune our model using the HuggingFace Library, see Appendix A for details.

Zero-shot prompting BLOOMz and AYA are instruction-tuned on multiple classification tasks, thus we test these models out-of-the-box in a zero-shot prompting set up. This has the benefit that dataset artifacts, which are commonly known to be leveraged during fine-tuning, cannot be learned (McCoy et al., 2020). As BLOOMz and AYA fail to predict a third option for XNLI (neutral), we report results on a binarized version of the

metric	High	Mid	Low	Unseen	Ave.	Med.
NLLB-Distil						
chrF++	49.34	46.92	43.22	37.12	44.15	45.07
NLLB-3.3B						
chrF++	52.5	50.8	46.1	40.3	44.5	45.5

Table 2: The quality of the MT system across high, mid, and low-resource languages using chrF++ based on the XLM-R model's categorization.

task by aggregating sentences with the 'neutral' and 'contradiction' labels into one class and making the model predict entailment or not. Moreover, the instructions are given in English. see Appendix A for the prompts per task.
Finally, note that our goal is not to compare performance of BLOOMz and AYA to XLM-R but rather to test the reliability of machine-translated test sets in two popular evaluation paradigms.

Evaluation metric As the automatic evaluation metric for testing our MT quality, we use the chrF++ (Popović, 2017). This metric calculates the character and word n-gram overlap between the machine and human reference translations. It is a tokenization-independent metric aligning better with human judgments for morphologically-rich languages compared to BLEU (Tan et al., 2015; Kocmi et al., 2021; Briakou et al., 2023). We also employ the LLMs-as-a-judge technique to evaluate translation quality and analyze the types of errors that occur in translation. For the evaluation, we use the FLORES-200 dataset (NLLB Team et al., 2022), which includes human-translated data for 200 languages, and select 100 sentences from each language.

4 Machine translating test data

For machine translation, we employ the NLLB model covering 202 languages (NLLB Team et al., 2022). Through extensive analysis, Zhu et al. (2024) have shown that NLLB performance surpasses other powerful LLMs such as ChatGPT (OpenAI., 2022) and GPT-4 (Achiam et al., 2023) when translating out of English ($En \Rightarrow$ `tgt` setting). NLLB also demonstrates a minimal difference to the closed source system, Google translate[2] on the Flores-101 dataset. To gain a better understanding of the role of the MT system on the translated data quality and, consequently, its performance on downstream tasks, we experiment with two NLLB versions. We choose the distill NLLB with 600M parameters and the 3.3B NLLB model using greedy sampling. For each example, we translate each sentence (e.g., SENTENCE1 and SENTENCE2 in PAWS-X) separately. In Appendix B, we provide some of the lessons learned from our MT experiments.

In Table 2, we report the average chrF++ scores for translations obtained with the NLLB-Distil and NLLB-3.3B models on the dev set of FLORES-200 dataset including human translation data in 200 languages (NLLB Team et al., 2022). We categorize languages by XLM-R resource ranking (high, mid, low, and unseen) and observe that NLLB-3.3B consistently performs better than the 600M version across all categories. Thus, while the smaller model has been added for analysis purposes, we use the NLLB-3.3B for translation throughout the paper unless stated otherwise. Moreover, we confirm that our scores for all languages are among the best performance of SOTA multilingual MT systems (Bapna et al., 2022; NLLB Team et al., 2022).

5 Evaluating the reliability of MT data

In this section, we study the opportunities and challenges of using MT to extend multilingual benchmarks and assess model performance across a broader range of languages from two perspectives, i.e. the performance gap when measuring on human versus machine translated data and the quality of the MT data itself. Thus, in Section 5.1, we first study the degree to which machine translation alters the reliability and validity of performance assessments for LLMs. Then, in Section 5.2, we evaluate the quality of the machine translated data itself through automatic metrics and LLM-based judgments, both to analyze error patterns and to serve as a proxy for filtering low-quality translated data for evaluation.

5.1 Evaluation gaps between MT and HT

5.1.1 Average performance changes

The key motivation for using machine translation in expanding multilingual benchmarks is to reduce costly and time-consuming human annotation. However, this raises an important question: *Does relying on machine-translated data compromise the validity of LLMs evaluations?* If model performance on MT data is substantially different from that on human translated data, evaluation outcomes

may become unreliable or biased.

To answer this question, we compare model performance on machine and human translated data. We evaluate all models using the same setups and report accuracy scores on machine and human translated data in Table 3.[3] Our results show that the difference in performance on machine and human-translated data is small (on average, about 2.6%). Moreover, this trend is consistent across all models. In some instances, the models achieve slightly higher performance on machine-translated data. We hypothesize that this may be due to the translationese effect. Conversely, in other cases, we observe a drop in performance, which might be caused by low-quality translations. We investigate this issue in Section 5.2, where we explore methods such as LLM-based filtering to detect and reduce the impact of poor quality MT outputs.

5.1.2 Ranking consistency

Building on the finding that accuracy scores between machine-translated and human-translated data are closely aligned, we further assess the reliability of MT-based evaluation by examining the consistency of model rankings, i.e. whether the relative performance of a model across different languages remains stable. Specifically, we want to see if the accuracy differences observed earlier affect which languages a model performs better or worse on. To measure this, we compute the average Pearson and Spearman rank correlations between model performances on human and machine-translated datasets (see Table 4).

The high correlation across all tasks shows that the rank order of the models' performance across different languages using human and machine-translated data is almost the same. This demonstrates that machine translated data could reliably be used to assess the relative differences in model performance across languages.

5.2 The impact of MT quality

Moreover, we analyze whether the quality of machine translation, as measured by chrF++, correlates with LLM performance. In other words, what matters in this experiment is the consistency of the correlations between human- vs. machine-translated data. Table 5 summarizes the numerical results. The results show no significant correlation in either case. That is, higher MT quality (as indicated by better chrF++ scores) does not systematically correspond to higher model performance. The pattern suggests that small variations in MT quality, as captured by the automatic metric, do not strongly influence LLM accuracy. This further supports the robustness of using MT for multilingual evaluation, although it also highlights that chrF++ may not fully capture the aspects of translation quality that affect downstream performance.

[3] Results of XLM-R base are reported in the appendix.

Table 6: Examples of the MQM framework output for detected errors in translated XNLI test examples.

5.2.1 LLM-as-a-Judge Evaluation

In the earlier experiments, we observed that for certain tasks and languages, model performance on MT data was lower than on HT data. We hypothesize that these drops are often linked to lower translation quality. Automatic metrics such as chrF++, while useful, may be overly sensitive to minor deviations that are not critical for the downstream task, resulting in misleadingly low scores.

To better assess translation quality, we employ an LLM-as-a-judge approach. Specifically, we use it to (1) identify and categorize translation errors in examples where the model makes correct predictions on human translations but fails on machine-translated versions, and (2) evaluate its potential as a filtering mechanism to remove low-quality translations from translated evaluation sets.

To this end, we adopt the Multidimensional Quality Metrics (MQM) framework from Freitag et al. (2021). We prompt the LLM evaluator to follow the evaluation guidelines for the translation task to detect and classify translation errors into major and minor categories. The LLM-based evaluation provides the error span, error type, and error classification. Major errors (true errors) are generally easier to detect, whereas minor errors often stem from minor imperfections in translations, see Table 6 for an example.[4] As our LLM-as-a-judge, we use the Gemma 3 27B model (Gemma Team et al., 2025), covering over 140 languages, in an in-context learning setup to evaluate translation quality.[5]

In Table 7, we report the average number of major errors for all predictions (Ave. #Err.) and for the subset where predictions switch from correct on HT to wrong on MT (C→W). While the average error rates for these two categories are close, C→W shows slightly higher values across most languages, suggesting that these degraded translations can be systematically flagged. Moreover, consistently across all tasks and languages, the most frequent translation error type is *accuracy*, including a mistranslation error or omission from the source sentence. Using this observation, we filter out examples with more than 2 major errors, and evaluate the performance of the AYA model on the higher-quality examples. In Table 8, we present the percentage of gap reduction between the models' performance on HT and MT. Based on the results, in most cases, after removing low-quality MT data, the performance gap between MT and HT data is reduced up to 100%. Our results indicate that integrating LLM-based quality checks into MT-based evaluation pipelines can help reduce evaluation noise and improve the reliability of us-

[4] See Table 2 in Freitag et al. (2021) for an overview of the error categorizations.

6 Large-scale evaluation results

Having confirmed in Section 5 that our translated test sets are of a reliable quality, we now move on to analyze how the MLMs perform on them. In Figure 1, we summarize the performance of XLM-R, BLOOMz, and AYA in 196, 168, and 198 languages, categorized by their data scarcity during the pre-training of each model as explained in Section 3.3. We find that the average performance for all models is similar for high- and mid-resource languages. Yet, while still above the random baseline, there is a notable drop in performance for low-resource and unseen languages. Moreover, we find that standard deviations across low-resource languages are larger than high- and mid-resource ones. This shows that performance across low-resource languages varies a lot, making the average score less reliable. Still, performance in unseen languages is relatively high; for XNLI and PAWS-X, on average, we obtain +18% and +29% above random performance, suggesting cross-lingual knowledge transfer to the unseen languages.

6.1 Representativeness of benchmark language sets

As each dataset contains a distinct selection of languages for testing, we study to what extent each of them provides a reliable estimate for how MLMs performance will generalize to more languages.

	High	Mid	Low	Ave.
XLM-R				
PAWS-X	89.5 / 89.6	- / 87.3	- / 85.6	89.5 / 85.3

XStoryCloze	85.8/89.7	91.0/89.6	85.5/86.4	87.0/87.7

Table 9: The average performance of high, mid, and low-resource languages covered by the original dataset/the languages covered by our machine-translated datasets. All results are computed on the machine-translated data.

While we do not cover all the world's languages, we compare the averages between the languages covered by the original datasets and those covered by our much larger translated datasets that contain 198 languages.

To this end, we split the languages from the original datasets based on our resource categorization reported in Table 1, and report the average performance for each category in Table 9. Importantly, all performance scores are computed on the translated data. From the results, we observe that for high and, to some extent, mid-resource languages, average performance on both language selections

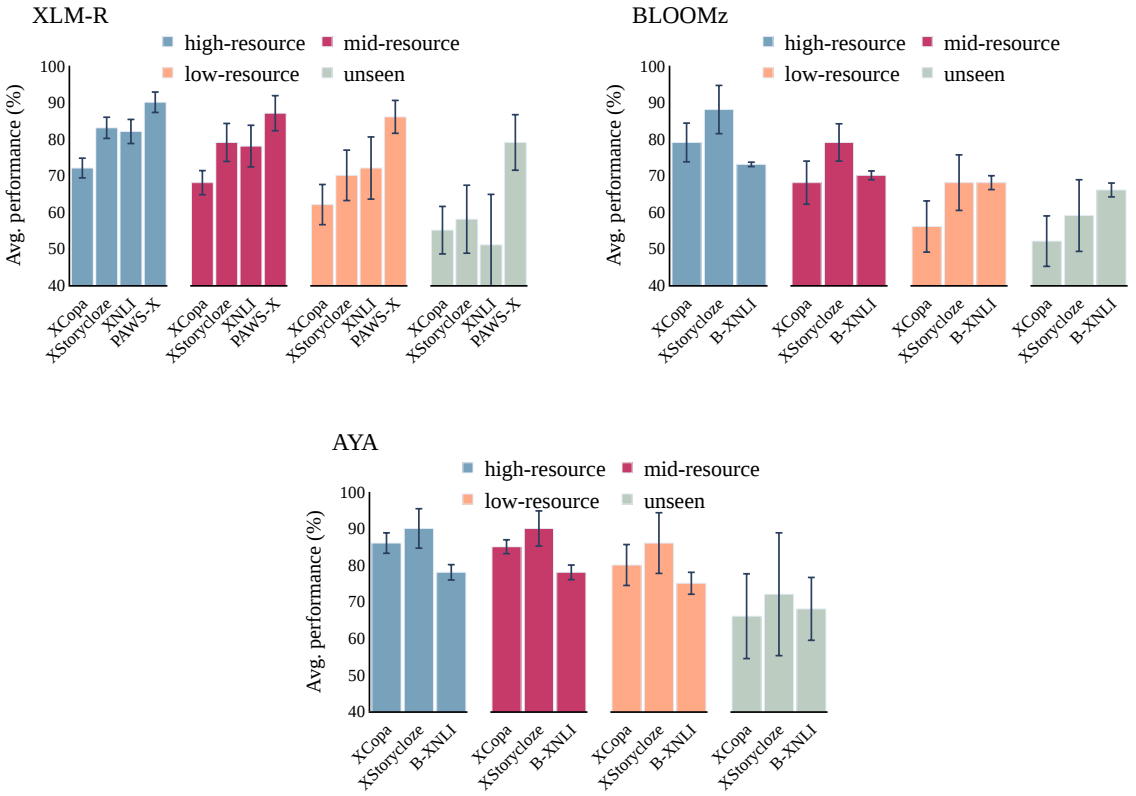

Figure 1: Average performance across test languages in a zero-shot fine-tuning setup for XLM-R and in a zero-shot prompting using BLOOMz. Results are categorized per task and data coverage during pretraining as reported in Table 1. Results across models are not directly comparable as their language categorizations differ.

is similar, making the language coverage from the original datasets sufficiently representative. Yet, for low-resource languages, we find a notable difference, which suggests that the datasets' language coverage is not representative of a wider range of low-resource languages. Specifically, across all tasks, we tend to overestimate performance, which can go up to 4.7% and 8.7% accuracy points (for XCOPA).

7 Conclusions

In this paper, we investigate the use of machine translation to create large-scale multilingual evaluation sets in scenarios where human-translated data is unavailable. Our experiments show that using SOTA MT models for evaluation yields results closely aligned with HT ones, with small average accuracy differences and high rank correlations, indicating stable relative performance across languages. Translation quality, measured by chrF++, does not strongly predict downstream performance differences, suggesting that minor variations in automatic scores are not critical for many tasks. However, LLM-as-a-judge analysis reveals that examples where models succeed on HT but fail on MT often contain more major errors, as such this method could be used to filter low-quality translations to reduce evaluation noise. Scaling evaluations to nearly 200 languages further reveals representativeness gaps in existing benchmarks. For high- and mid-resource languages, original language selections approximate broader trends well, but for low-resource languages, they overestimate performance—by up to 8.7 accuracy points in some cases. This demonstrates that MT-based evaluation can both expand coverage and uncover biases in benchmark design. Overall, our findings indicate that MT, when coupled with targeted quality control, enables broader, more representative, and more equitable multilingual evaluation, while highlighting the need to reassess how language selections in current benchmarks reflect true model capabilities.

A Experimental setups

For the implementation of all models, we rely on the HuggingFace Library (Wolf et al., 2019). XLM-R large, BLOOMz, and AYA-101 (AYA) have 330M, 7.1B, and 13B parameters, respectively. Moreover, we have run all the BLOOMz and AYA experiments on an NVIDIA A100-SXM4 GPU with 40GB memory, and a single NVIDIA A6000 has been used for the MT and XLM-R experiments with 48GB memory.

XLM-R fine-tuning details For the NLI task, we have fine-tuned XLM-R with a learning rate of $2e$-5, AdamW optimizer, and a batch size of 32 for 3 epochs. For the PAWS-X task, we have considered a learning rate of $2e$-6, batch size 16 with a warm-up ratio of 0.01 for 3 epochs. For XCOPA and XStoryCloze tasks, first, we train the model on the training set of Social IQa (Sap et al., 2019) and then fine-tune it on the training set of XCOPA dataset (Gordon et al., 2012). We have selected a learning rate of $3e$-6, batch size of 16 for SIQa and 8 for XCOPA, a warm-up ratio of 0.1, and fine-tune the model for 3 epochs on each dataset.

BLOOMz and AYA zero-shot prompts For zero-shot prompting, we constructed the following prompts for XNLI, XCOPA and XStorycloze respectively:

Premise: `<premise>`
Hypothesis: `<hypothesis>`
Does the premise entail the hypothesis?
Pick between yes or no.

Premise: `<premise>`
Option A: `<choice1>`
Option B: `<choice2>`
Based on the premise, which `<cause/effect>` is more likely?
Pick between options A and B.
Answer:

Consider the following story:
`<story>`
Which ending to the story is most likely?
Pick between options A and B:
A: `<story_ending1>`
B: `<story_ending2>`
Answer:

B Lessons learned for Machine Translation

We now also share a few practical lessons learned from our MT experiments using NLLB to facilitate the translation of new datasets in future work:

- NLLB tends to skip sentences when translating paragraphs. Thus, it is important to translate the sentences one by one.
- NLLB has difficulty translating short phrases/names such as names, dates, locations, etc., because it tends to hallucinate additional content. This makes it challenging to translate the answers from QA datasets such as XQuAD.
- NLLB inconsistently chooses to code-switch to the target language. For instance, when translating the sentence 'Sara is asleep', it can choose to translate it either to 'Sara ? farsi' or 'fully farsi'. This can be particularly challenging for retrieval datasets where the answer does not tend to fully match the context.
- While translation quality tends to be similar for different NLLB model sizes, at least the 3.3B version should be used when translating to languages that were low-resource, considering NLLB's pretraining data.

C Correlation between Chrf++ scores and translations

See Table 10 and Table 11 for Spearman and Pearson correlation results between Chrf++ scores and performance on human and machine translated data.

D LLM-as-a-judge

Following previous work, we use 3-shot prompting for this experiment provided in Table 12.

	XLM-R				BLOOMz			AYA		
	XCOPA	XNLI	PAWS-X	XStoryCloze	XCOPA	XNLI	XStoryCloze	XCOPA	XNLI	XStoryCloze
chrF++ vs. Human translated	29.6	24.4	65.7	16.4	5.7	5.7	68.1	22.7	8.1	-34.6
chrF++ vs. Machine translated	22.6	48.1	82.7	22.4	18.3	14.7	75.8	55.5	26.1	22.4

Table 10: Average Spearman rank correlation between chrf++ scores and human- (original data) and machine-translated data (ours).

	XLM-R				BLOOMz			AYA		
	XCOPA	XNLI	PAWS-X	XStoryCloze	XCOPA	XNLI	XStoryCloze	XCOPA	XNLI	XStoryCloze
chrF++ vs. Human translated	27.4	10.5	89.3	3.3	-10.4	-10.4	64.5	41.0	8.2	-18.5
chrF++ vs. Machine translated	30.3	66.2	96.5	8.8	14.5	2.9	66.7	52.1	16.3	11.3

Table 11: Average Pearson correlation between chrf++ scores and human- (original data) and machine-translated data (ours).

In-context-learning prompt:

Based on the given source, identify the major and minor errors in this translation. Note that Major errors refer to actual translation or grammatical errors, and Minor errors refer to smaller imperfections, and purely subjective opinions about the translation.

Source: I do apologise about this, we must gain permission from the account holder to discuss an order with another person, I apologise if this was done previously, however, I would not be able to discuss this with yourself without the account holder's permission.

Translation: Ich entschuldige mich dafür, wir müssen die Erlaubnis einholen, um eine Bestellung mit einer anderen Person zu besprechen. Ich entschuldige mich, falls dies zuvor geschehen wäre, aber ohne die Erlaubnis des Kontoinhabers wäre ich nicht in der Lage, dies mit dir `involvement`.

Errors:

Major: accuracy/mistranslation – `involvement`; accuracy/omission – `the account holder`

Minor: fluency/grammar – `wäre`; fluency/register – `dir`

Source: Talks have resumed in Vienna to try to revive the nuclear pact, with both sides trying to gauge the prospects of success after the latest exchanges in the stop-start negotiations.

Translation: Ve Vídni se ve Vídni obnovily rozhovory o oživení jaderného paktu, přičemže obě partaje se snaží posoudit vyhlídky na úspěch po posledních výměnách v jednáních.

Errors:

Major: accuracy/addition – `ve Vídni`; accuracy/omission – `the stop-start`

Minor: terminology/inappropriate for context – `partaje`

Source: 大众点评乌鲁木齐家居商场频道为您提供高铁居然之家地址，电话，营业时间等最新商户信息，找装修公司，就上大众点评

Translation: Urumqi Home Furnishing Store Channel provides you with the latest business information such as the address, telephone number, business hours, etc., of high-speed rail, and find a decoration company, and go to the reviews.

Errors:

Major: accuracy/addition – `of high-speed rail`; accuracy/mistranslation – `go to the reviews`

Minor: style/awkward – `etc.,`

Cross-lingual Human-Preference Alignment for Neural Machine Translation with Direct Quality Optimization

Kaden Uhlig[1], **Joern Wübker**[1], **John DeNero**[1], **Raphael Reinauer**[2]*
[1]LILT, [2]Amazon
{kaden.uhlig,joern,john}@lilt.com, raphada@amazon.de

Abstract

Reinforcement Learning from Human Feedback (RLHF) and derivative techniques like Direct Preference Optimization (DPO) are task-alignment algorithms used to repurpose general, foundational models for specific tasks. We show that applying task-alignment to neural machine translation (NMT) addresses an existing task–data mismatch in NMT, leading to improvements across all languages of a multilingual model, even when task-alignment is only applied to a subset of those languages. We do so by introducing Direct Quality Optimization (DQO), a variant of DPO leveraging a pre-trained translation quality estimation model as a proxy for human preferences, and verify the improvements with both automatic metrics and through human evaluation.

1 Introduction

For many natural language generation (NLG) tasks, aligning models to human preferences has led to large performance gains (Ziegler et al., 2020). A strong motivation for this alignment step is that much of the data on which the model was originally trained – internet text – is useful for language generation in general but does not match the desired output for the task. Neural machine translation (NMT) models have not involved alignment to human preferences, in part because of the assumption that supervised training data for NMT does match the desired output of the translation task. However, we show the existence of a mismatch between the NMT task and typical training data.

Machine translation is unusual among NLG tasks in that task-relevant supervised training data – text paired with its translation – is plentiful and publicly available. One might expect that with such a large amount of task-relevant training data, there would be no need for task-alignment. However, we identify an exhaustive list of reasons why training examples in a parallel corpus diverge from the desired output in meaningful ways (see Section 2.2).

Machine translation is also unusual in that human preference data has been collected and published for a large number of systems, and translation quality estimation (QE) is an active research area that has benefited greatly from recent advances in large language models. We introduce a method for using quality estimation models, which themselves are trained from human preference data, in order to perform NMT task alignment. Our method, Direct Quality Optimization (DQO), is a batched online variant of Direct Preference Optimization (DPO) (Rafailov et al., 2023) that uses a QE model as a proxy for human preference.

We show that DQO improves translation quality in terms of BLEU, COMET22, CometKiwi22, and BLEURT, and leads to a reduction in translation errors in a human evaluation using the Multidimensional Quality Metric framework (MQM) (Lommel et al., 2014; Freitag et al., 2021).

We make three notable observations when applying DQO to a multilingual model:

1. Task alignment increases task performance and human preference while also increasing the distance between the model's output distribution and the training data distribution.
2. Improvements carry over to held-out languages and language families, which were not contained in the data used for DQO.
3. Improvements in held-out languages are not limited to general behaviors required by the translation task (e.g. avoiding omissions), but include improving language-specific linguistic features not seen in the DQO alignment data, such as correctly transliterating named entities in Latvian.

While we attribute much of the performance in held-out languages to transfer learning of general behaviors required by the translation task

Proceedings of the Tenth Conference on Machine Translation, pages 31–51
November 8-9, 2025

(e.g. avoiding omissions), the language-specific improvements in held-out languages cannot be explained by transfer learning.

Instead, these results suggest that DQO does not only increase the likelihood of the features present in its task alignment data, but also focuses the model on human preference features that it already learned during supervised training.

2 The Task–Data Mismatch in NMT

2.1 Task: Human-Preferred Translations

Like many NLG tasks, NMT is an open-ended problem, with multiple valid outputs for any given input, each preferred more or less by humans depending on a variety of factors, including adequacy, fluency, context, tone, style, and many other subtle features.

Because of this, the task of NMT cannot be reduced to producing valid translations, nor human-like translations, but instead requires generating human-preferred translations – those judged as at least as good as all other valid translations.

2.2 Training Data Mismatch

The supervised training data used in NMT comes from a variety of sources, each with notable differences from the task distribution of human-preferred translations.

Web Data Mining. A large portion of parallel data is mined from massive collections of web documents, using automated methods to align source and target language segments – e.g. the ParaCrawl (Bañón et al., 2020) and CCMatrix (Schwenk et al., 2021b) datasets. This process may capture human translations, text written independently in both the source and target languages on the same topic, or the output of other MT models. One prominent cause of task–data mismatch in automatically aligned sentence pairs is semantic misalignment. Kreutzer et al. (2022) found semantic misalignment in 15% (ParaCrawl) and 32% (CCMatrix) of sentence pairs in a manual quality audit.

The simplest form is complete semantic misalignment, when the source and target segments are completely unrelated. This certainly contributes to any task–data mismatch, but such pairs are easy to detect with tools such as BiCleaner (Ramírez-Sánchez et al., 2020) or reference-free quality evaluation models such as CometKiwi22 (Peter et al., 2023).

Unfortunately, slight semantic misalignments of source and target are both more prevalent and much more difficult for state-of-the-art filtering systems to detect (Meng et al., 2024). These may include subtle yet significant differences in meaning, factual differences in numbers or names, additions and omissions, and the accompanying losses in translation adequacy. In addition, these segments often still contain useful information that may help the model learn (Meng et al., 2024).

Accidental Inclusion of Machine Translated Content. Web data may also include the outputs of other machine translation models, including neural, statistical and dictionary-based methods of varying quality. The impact of training on low quality machine translations is clear, however even good NMT systems' outputs differ significantly enough from natural text that classifiers can detect machine translated text with high accuracy – and even predict which machine translation system was used to translate a given text (La Morgia et al., 2023).

Recent research suggests that up to 57% of translations mined from the web are multi-way parallel, meaning parallel translations of a segment can be found in more than two languages, and demonstrates a strong correlation between multi-way parallelism and low quality translations likely to be machine translated (Thompson et al., 2024). The authors also found that multi-way parallel translations follow a distinct distribution, focused on low-quality content typically used for search engine optimization.

Translator Skill Level. Another source of task–data mismatch in human translations is the fact that translators differ in skill level (Albir, 2017). This implies that not all human translations will be equally preferred by humans.

Achieving mean human quality in translations is not the task of NMT as defined in Section 2.1. We propose that neither is *maximum* human quality. In theory it is conceivable that humans prefer machine-generated translations over even the best human-generated translations. Therefore, we do not want finite human skill to impose an upper limit on translation quality.

Translationese. Another common issue is a phenomenon known as *translationese*, the observation that human-translated text in a given language differ in distribution from text written independently in that language. Specifically, translated text shows signs of interference from the source language's grammar, word order and word choice, as well as source-language-independent effects of the translation process itself, such as simplification

Table 1: **Evaluation metrics on FLORES+ devtest and NTREX** with the NVIDIA Megatron EN-X model, before and after task-alignment using DQO. Results are shown for relevant groupings of the 30 target languages: all languages, languages used in DQO ($\mathcal{T}$), languages not used in DQO ($\mathcal{T}^c$), languages not used in DQO, but related to those used in DQO ($\mathcal{R} \cap \mathcal{T}^c$), and languages neither used nor related to the languages used in DQO ($\mathcal{R}^c$).

and avoidance of unique language features (Koppel and Ordan, 2011; Laviosa, 1998; Tirkkonen-Condit, 2004). These effects are significant enough that classification models can distinguish translated and original text with high accuracy (Baroni and Bernardini, 2005; Sominsky and Wintner, 2019), as well as identifying the source language of the text (Koppel and Ordan, 2011). As humans show a consistent preference for translations closer to the distribution of original text rather than translationese (Riley et al., 2020; Freitag et al., 2022b), this creates an inherent task–data mismatch for training data translated in the source–target direction.

Source–Target Domain Mismatch. Translation pairs in the other direction, target–source, are better aligned with human preference, as the target labels are drawn from the original text distribution rather than from translationese. Unfortunately, they suffer from another subtle source of task–data mismatch found in human translations: Source–target domain mismatch (Shen et al., 2021) is the observation that speakers of different languages tend to discuss different topics. For instance, a Cherokee newspaper is likely to report on different topics than an Icelandic newspaper would, and translations of these topics would remain representative of the Cherokee domain. This effect is especially pronounced for low-resource language pairs (Shen et al., 2021).

If one were to avoid the task–data mismatch of translationese by using only target–source translation pairs, the training data may lack key information about topics found only in the source domain. Because the task is translation from the source domain into the target language, this, too, would represent an unavoidable task–data mismatch.

3 Human Preference Learning for LLMs

Supervised data showing chat-based dialog between humans and AI assistants was, prior to the wide availability of such agents in the form of LLMs, understandably rare. Even with the advent of high quality proprietary and open-source models, which one could sample to create synthetic data, there is a fundamental task–data mismatch: the task is not to imitate an existing AI assistant, but (ideally) to train a new state-of-the-art model.

LLM training instead follows a two-step process:

1. Supervised learning on massive amounts of web data.
2. Task alignment using instruction fine-tuning and human preference learning.

In step one, the actual task for which the model is optimized is predicting the next token in documents taken from the web. This, when done at scale and with a variety of data sources, provides the model with extensive world knowledge and understanding of a wide array of styles and document types.

This is then followed by instruction fine-tuning, a comparatively brief round of supervised learning on human- or AI-labeled examples of dialogues, which brings the model's output distribution into the general neighborhood of desired behavior. Finally human preference learning, using actual human rankings aligns the model with the desired task: producing human-preferred responses to questions and dialog, while remaining helpful and harmless (Bai et al., 2022).

Direct Preference Optimization (DPO) is a preference learning algorithm that trains on preference pairs of the form (x, y_w, y_l), with x being a model input, and y_w and y_l being two potential model outputs for the input x, marked as chosen (winning) or rejected (losing) by humans during data collection (Rafailov et al., 2023), using the loss function:

$$\mathcal{L}_{\text{DPO}}(x, y_w, y_l) = \log \sigma \left(\beta \log \frac{\pi_\theta(y_w|x)}{\pi_{\text{ref}}(y_w|x)} - \beta \log \frac{\pi_\theta(y_l|x)}{\pi_{\text{ref}}(y_l|x)} \right), \quad (1)$$

where σ is the logistic function.

4 Direct Quality Optimization for NMT

Because of its stability and ease of use, we select DPO as the basis for our experiments with human preference learning as a form of task alignment for NMT. As a proxy for human preferences, we use the CometKiwi22 quality estimation model to score and compare multiple translations of a given source (Rei et al., 2022b). CometKiwi22 is highly multilingual and has been shown to correlate well with human preference (Kocmi et al., 2024). To verify that our method is not dependent on the specific choice of quality estimation model we conducted a brief experiment using MetricX (Juraska et al., 2023) instead of CometKiwi22 and obtained very similar results.

Our main experiments are run with the NVIDIA Megatron English–Many model[1], a 500M parameter encoder-decoder model, which supports translating from English into 30 languages[2] from 14 language families, listed in Table 2. We denote the complete list of supported target languages as $\mathcal{M}$.

Language Family	Languages (ISO 639-1)
Baltic	lt, lv
Germanic	da, **de**, nl, no, sv
Romance	**es**, fr, it, pt, ro
Slavic	bg, cs, hr, pl, **ru**, sl, uk
Uralic	et, fi, hu
Other	el, **hi**, id, ja, ko, tr, vi, **zh**

Table 2: **Target languages supported by the NVIDIA Megatron En-X model**. The category "Other" contains all languages that are the only supported representative of their language family. The languages on which we apply task alignment are denoted in boldface.

[1] https://catalog.ngc.nvidia.com/orgs/nvidia/teams/nemo/models/megatronnmt_en_any_500m

[2] The model was originally trained to support 32 languages, but we found that translating into Arabic and Slovak resulted in degenerate output.

The model's multilingual nature allows us to apply task alignment to a subset of language pairs and observe the effects on unrelated languages, with minimal risk of exposing the model to any new information in those languages.

Any improvements in those languages must either apply to all languages (such as avoiding omissions or additions), or are language specific, and can only have come from previously unused latent knowledge acquired during supervised training.

In our experiments, we selected Chinese, German, Hindi, Russian and Spanish as the target languages used during task alignment, termed $\mathcal{T} = \{de, es, hi, ru, es\}$. Let $\mathcal{T}^C = \mathcal{M} \setminus \mathcal{T}$ be the set containing the 25 target languages not represented during task alignment, R be the set of languages related to at least one language in $\mathcal{T}$ (defined as belonging to the same language family), and $\mathcal{R}^C = \mathcal{M} \setminus \mathcal{R}$ be the languages unrelated to any of the languages used in task alignment. An overview of how many languages belong to each set is shown in Table 3.

Subset	Definition	Size
$\mathcal{T}$	Languages seen in DQO	5
$\mathcal{T}^C$	Languages not seen in DQO	25
$\mathcal{R}$	Languages related to $\mathcal{T}$	19
$\mathcal{R}^C$	Languages unrelated to $\mathcal{T}$	11

Table 3: **Target languages supported by the NVIDIA Megatron EN-X model**, categorized by their relationship with the languages selected for task alignment.

As the seed dataset from which to draw source sentences for human preference learning, we use the source side of a mixture of publicly available English–German MT datasets (see Appendix A.4).

From this dataset, we sample 8000 source segments. For each source segment, we sample a target language from $\mathcal{T}$, the languages used for task alignment, and use the current policy model to sample 64 translations into that language using combined Top-K and Top-P sampling, with $K = 40$, $P = 0.8$ (Fan et al., 2018; Holtzman et al., 2020). We also add the greedy translation for each source segment, obtaining a total of 520 000 translations.

Letting the output of the CometKiwi22 Quality Estimation (QE) model for a source x and translation y be $r_{QE}(x, y)$, we build a relation $\succ_x$ as a proxy for true human preferences:

$$y_1 \succ_x y_2 \equiv r_{QE}(x, y_1) > r_{QE}(x, y_2) + \varepsilon$$

where $\varepsilon \geq 0$ is a tolerance parameter to help miti-

gate proxy model noise. We set $\varepsilon = 0.005$.

To construct preference pairs, we then select the highest scoring translation per source segment as y_w and uniformly sample a single y_l from all remaining translation candidates that satisfy $y_w \succ y_l$ under our proxy model.

This results in slightly under 8000 preference pairs (occasionally the maximum difference in COMET22 score between a segment's highest and lowest scoring sampled translations is less than ε, in which case we do not produce a preference pair), we run DPO training with a batch size of 8192 tokens (counting source, chosen and rejected tokens), a learning rate of $1e{-}6$ and $\beta = 0.5$. See Appendix 8 for a full list of hyperparameters.

At this point, we train on the preference pairs using standard DPO for 8 epochs, after which we sample a fresh set of source segments from the seed dataset, sample translations from the policy model, create a new set of preference pairs, and begin the training again. This resampling process helps ensure that the preference pairs remain relevant to the policy model during training, and leads to substantial performance improvements. In total, we perform 5 rounds of DPO training. We call this end-to-end process Direct Quality Optimization (DQO), detailed formally in Algorithm 1.

DQO can be viewed as a batched online version of DPO, as the updates are performed on batches of data sampled from the policy model.

Algorithm 1: Direct Quality Optimization

Parameters: preference relation $\succ$, number of rounds n, epochs per round m, epoch size d, learning rate α, DPO regularization β, sampled translations per source k

Input: Source language seed dataset S, reference-free QE model r_{QE}, reference model π_{ref}

$\pi_\theta \leftarrow \pi_{\text{ref}}$;
for *round* $i = 1, 2, \ldots, n$ **do**
  $X \leftarrow$ **sample** d sentences from S;
  $P \leftarrow \varnothing$;
  foreach *source* $x \in X$ **do**
    $g \leftarrow \texttt{Greedy}_{\pi_\theta}(x)$;
    $Y \leftarrow$ **sample** k translations of x from π_θ;
    $Y_+ \leftarrow Y \cup \{g\}$;
    $y_w \leftarrow \text{argmax}_{y \in Y_+} r_{QE}(x, y)$;
    $Y_l = \{y' \in Y_+ | y_w \succ_x y'\}$;
    if $Y_l \neq \varnothing$ **then**
      $y_l \leftarrow$ **sample** $y \in Y_l$;
      $P \leftarrow P \cup \{(x, y_w, y_l)\}$;
  end
  for *epoch* $j = 1, 2, \ldots, m$ **do**
    $\pi_\theta \leftarrow \texttt{DPO}(\pi_\theta, \pi_{ref}, P, \alpha, \beta)$;
  end
end

Figure 1: **Direct Quality Optimization (DQO).** $\texttt{Greedy}_\pi(x)$ is the translation of x produced with greedy search and the model π. `DPO` refers to Direct Preference Optimization – for full implementation details see Rafailov et al. (2023).

5 Experimental Results

5.1 Automatic Quality Metrics

We evaluated the model pre- and post-task alignment on the FLORES+ (Team et al., 2024) and NTREX (Federmann et al., 2022; Barrault et al., 2019) datasets, both of which cover all of the languages supported by the Megatron model.

We use corpus-level sacreBLEU[3] (Post, 2018) as well as three neural evaluation models: Reference-free CometKiwi22 (Rei et al., 2022b), reference-based COMET22 (Rei et al., 2022a), and BLEURT (Sellam et al., 2020).

Here it is important to note that the CometKiwi22 model was used as a proxy for human preferences in this experiment, and was thus directly optimized for. The scores from the other two neural evaluation models are thus more reliable measures of general model quality, and allow us to check for reward hacking, i.e. over-optimization for the CometKiwi22 model at the cost of performance.

Results are reported in Table 1 and Figure 2. We find that DPO task alignment increases all three neural quality metrics on both datasets for each of the 30 target languages. BLEU scores increased for all languages on both datasets, with the exception of Hindi, which decreased by 0.40 BLEU on NTREX and 0.4 BLEU on FLORES+ devtest, despite showing improvements on the three neural metrics, like all other languages.

Significantly, translation quality, as measured by all four translation quality metrics, improved even

[3]Signature: `nrefs:1|case:mixed|eff:no|tok:13a|smooth:exp|version:2.4.0`. For JA and ZH, we additionally use the `mecab-ja` and `mecab-zh` tokenizers.

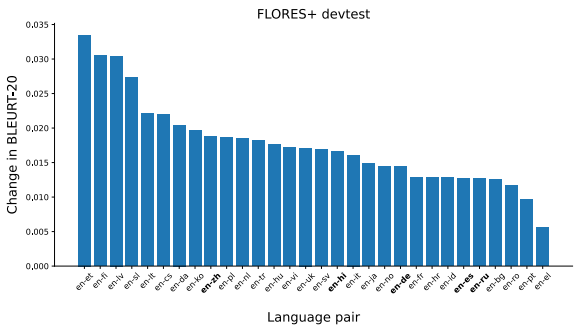

Figure 2: **Changes in BLEURT on FLORES+ devtest** with the NVIDIA Megatron EN-X model, before and after task alignment with DQO. Languages used in DQO are bolded.

for target languages unrelated to the languages used in DPO task alignment. See Appendix A.5 for the metrics for each individual language.

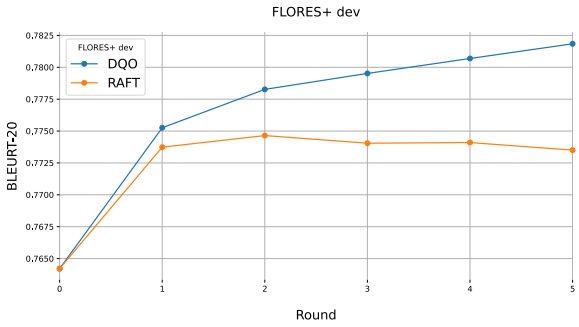

Figure 3: **Mean BLEURT-20 on FLORES+ dev at each round of DQO** with the NVIDIA Megatron EN-X model, using either Direct Quality Optimization (DQO) or Supervised Fine-Tuning (RAFT) to update the model.

To ablate the use of DPO as the update step within DQO, we perform a comparative experiment identical to DQO as described in Section 4 and Algorithm 1, but using standard supervised fine-tuning (SFT) on the preferred translation instead of DPO. Note that this is equivalent to Reward rAnked Fine-Tuning (RAFT) (Dong et al., 2023). Figure 3 shows mean performance for all language pairs through the 5 rounds of DQO. RAFT's lower performance is primarily due to catastrophic behavior for FR, JA, KO, and ZH. The poor performance of RAFT on FR, JA and KO, which were not used in RAFT training, could potentially be explained by a failure to generalize from the training data languages. Regarding ZH, which was one of the five languages used in training, we suspected unintentionally reversed labels. However, careful inspection of the training preference pairs showed no issues. See Appendix A.6, Figure 4 for charts of individual language performance and Figure 5 for mean performance after excluding the above mentioned outliers. We leave a deeper analysis to future work.

5.2 Training Data Perplexity

In order to confirm the existence of a task–data mismatch, we examine DQO's effect on model perplexity over the training data. As we do not have access to the training data used for the NVIDIA Megatron English-Many model, we repeat the above experiment with a proprietary encoder-decoder model trained on publicly available English-to-German data using the NVIDIA NeMo framework (Kuchaiev et al., 2019) (See Appendix A.4). The model architecture is similar to the Megatron model, and follows the deep encoder, shallow decoder recipe from (Kasai et al., 2021), but is larger, with a model width of 2048, a feed-forward width of 8192, 21 encoder layers, 2 decoder layers, and a 32k token vocabulary, totaling 1.3B parameters.

We apply DQO to this model as with the Megatron model, however using only English–German preference pairs. After applying DQO, we see large improvements in CometKiwi22 and COMET22 for a variety of evaluation datasets, confirming that DQO worked as expected. The arithmetic mean of perplexity over a random sample of 1 million segments from the training data increased from 7.219 (baseline model) to 9.435 (DQO), confirming that the improvements in test data preference correspond to a reduction in the model's fit to the training corpus.

5.3 Discussion

The nearly-universal improvements for both FLORES+ and NTREX in all four automatic translation quality metrics (Table 1) provide strong evidence that DQO is a suitable task-alignment algorithm for the task of producing human-preferred translations.

As shown in Section 5.2, while improving task performance, DQO increases perplexity over the training data used during supervised training. This, combined with the finding that DQO is a suitable task alignment algorithm, is evidence for the existence of the task–data mismatch.

Much of this improvement can likely be credited to general, language-agnostic changes in model behavior, even with the restriction to using only 5 of the 30 supported target languages in DQO. If task alignment of a model with a given target lan-

Table 4: **Examples of translations into Latvian from the FLORES+ data set before and after DQO.** Names are bolded to highlight the DQO model's increased ability to consistently transliterate names into Latvian orthography. Names that are incorrectly transliterated are in italics. Sentences are truncated to avoid dataset leakage.

guage reduces the likelihood of untranslated source text, for instance, it would not be surprising to see similar improvements in other target languages.

Similarly, if task alignment for a given target language led to language-specific improvements (e.g., in grammar, sentence structure, punctuation, general fluency, etc.), it seems plausible that transfer learning could lead to improvements in closely related languages that have similar features.

However, manual inspection of translations before and after DQO revealed language-specific improvements in unrelated languages. In Latvian, for instance, foreign names are transliterated to match Latvian orthography and declined for grammatical case and gender, e.g. Klavinska (2021) report that *George Clooney* should be translated as *Džordžs Klūnijs*. While the baseline model applies correct transliteration occasionally and inconsistently, the DQO model almost always produces the correct transliteration. Several examples are included in Table 4.

As DQO was only performed on Chinese, German, Hindi, Russian or Spanish, none of which are closely related to Latvian, this behavior cannot have been learned from scratch during DQO. Although Chinese, Hindi, and Russian also transcribe foreign names, they use non-Latin scripts.

One possible explanation is that the baseline model learned to model both transliteration and non-transliteration, due to the range of translation quality in its supervised training data, causing inconsistent behavior at inference time. When DQO then shifts the output distribution towards certain human-preferred features, the probability of any correlated features (e.g., transliteration in Latvian), also increases.

5.4 Human Evaluation

To verify the presence of further language-specific changes for unrelated languages, we performed a human evaluation using the Multidimensional Quality Metrics framework (MQM) with professional translators (Lommel et al., 2014; Freitag et al., 2021). The translators were trained on MQM and Anthea[4], the open-source tool we used for performing MQM. We follow Freitag et al. (2021) in weighting major non-translations at 25 MQM points, other major errors at 5, and all minor errors at 1, except minor punctuation errors, which are 0.1 points.

For analysis, we selected two target languages not closely related to the languages used for task alignment: Lithuanian and Japanese.

These were selected to provide one low-to-medium resource language written in the Latin script and one in a non-Latin script, because neither is an outlier in quality metric improvement compared to the other supported language pairs, and to avoid the bias of examining Latvian, which we had already manually inspected.

For each language, we sampled complete documents (each generally two to five sentences forming a single paragraph) from FLORES+ until we had 100 source segments. The translators then annotated the baseline and task-aligned translations.

We then sorted the MQM error subcategories into two buckets, language agnostic and language specific, as seen in Table 7 in Appendix A.1.

We observe reduced error rates in both Japanese and Lithuanian in both the language-agnostic and language-specific categories (Table 5). The over-

[4] https://github.com/google-research/google-research/tree/a676d87/anthea

Language	Model	Severity				Language Specific			Weighted MQM ↓
		NT	Major	Minor	Trivial	Yes	No	N/A	
Japanese	Baseline	0	1.15	**0.61**	0.06	1.28	0.50	0.01	6.256
	DQO	0	**0.93**	0.63	**0.03**	**1.16**	**0.40**	0.01	**5.223**
Lithuanian	Baseline	0.03	0.95	0.89	0.12	1.48	0.51	0	6.402
	DQO	**0.01**	**0.80**	**0.77**	**0.10**	**1.24**	**0.44**	0	**5.030**

Table 5: **Mean number of Multidimensional Quality Metrics (MQM) errors per segment**, as annotated by professional human evaluators, with two different groupings: by severity and by whether the MQM subcategory is language specific or agnostic. NT stands for non-translation, i.e., a segment that cannot be construed as a translation of the source. Trivial refers to minor punctuation errors. This covers 100 randomly sampled English segments from the FLORES+ dataset, translated by the NVIDIA Megatron model before task alignment (baseline) and after task alignment (DQO). The weighted MQM score follows Freitag et al. (2021).

all weighted MQM score also decreased for both languages, with significant improvements in both Lithuanian ($p_u = .001$) and Japanese ($p_u = .012$), where p_u-values are conservative estimates of the true p-values computed using paired one-sided approximate randomization (Phipson and Smyth, 2010) with the Marot toolkit.[5]

5.5 DQO for Large Language Models

To compare DQO's performance against the strong baseline of other state-of-the-art DPO variants on a large language model trained specifically for translation, we apply it to the Alma-13B-LoRA model, a LLaMA-2-13B model with continued pretraining on Chinese, Czech, English, German, Icelandic, and Russian monolingual data and LoRA fine-tuning on high quality translation data (Xu et al., 2024a; Hu et al., 2022).

The highest performing human preference alignment method previously reported for this model is Contrastive Preference Optimization (CPO), a variant of DPO applied to the Alma-13B-LoRA model to create Alma-13B-R (Xu et al., 2024b). To ensure a direct comparison of optimization methods, we adopt the same data conditions and parameter masks as that prior work: restricting our seed dataset to the training data used for Alma-13B-R (the combined FLORES+ dev and devtest splits), fine-tuning only the LoRA adapters of the model, and evaluating translation out of English on the WMT'21 (for Icelandic) and WMT'22 (for the other languages) datasets.

Due to the restricted seed dataset used in this experiment, source segments are reused between rounds. As in previous experiments, we sample 8000 source segments, sample 64 translations per segment (as well as the greedy translation), and use CometKiwi22 as a proxy for human preferences. Other hyperparameters were adjusted based on a manual hyperparameter search to accommodate the differing training and sampling dynamics of LoRA training with an LLM (see Appendix A.3 for all hyperparameters).

Table 6 shows the results. The translations for ALMA-13-LoRA and ALMA-13B-R are generated with greedy inference on the publicly available model parameters[6]. This experiment indicates that DQO maintains a substantially higher BLEU score than CPO while providing similar improvements in BLEURT, COMET22, and CometKiwi22. Unlike our encoder-decoder experiments, source segments were reused between rounds to achieve a fair comparison with CPO. We would expect a higher performance with a larger pool of source data, but leave confirmation of this assumption to future work.

6 Related Work

The idea of task–data mismatch in NMT is not new. There has been extensive previous work focused on reducing this mismatch through data filtering, using surface-level heuristics (Koehn et al., 2007), statistical and neural models for alignment and quality evaluation (Sánchez-Cartagena et al., 2018; Heffernan et al., 2022; Peter et al., 2023), language identification (Lui and Baldwin, 2011; Joulin et al., 2016), or ensembles (Koehn et al., 2020).

While data filtering techniques do help reduce the task–data mismatch, they force a trade-off between increasing task alignment and retaining flawed, but potentially useful, training data. To

counter this, curriculum learning can be used, by training first on a conservatively filtered dataset, then shifting to a cleaner subset of the data (Bogoychev et al., 2023).

However, no amount of data filtering can remove the effects of translationese, as it is present in all translations. Riley et al. (2020) and Freitag et al. (2022b) both address this by treating original and translated text as separate languages in a "multilingual" NMT model, by training either a classifier or a contrastive language model to tag each source and target segment as either original or translated. At inference time, they use their model in a zero-shot setting to translate from original source text into the distribution of original target text.

Similarly, Tomani et al. (2024) label each source sentence with a binned QE score. By adding the label of the highest quality bin to a source sentence at inference time, they successfully bias the model towards high quality translations.

Ramos et al. (2024) apply RLHF (Ziegler et al., 2020) to NMT using various QE metrics as reward, and compare it to data filtering, re-ranking using a QE model, and Minimum Bayes Risk decoding (MBR) (Kumar and Byrne, 2004; Freitag et al., 2022a), finding that a combination of data filtering, RLHF, and re-ranking performs best.

In DPO MBR fine-tuning, MBR is used to generate preference pairs for use with DPO (Yang et al., 2024). Compared to DQO, this method is computationally more expensive, and requires a reference-based QE model. In addition, DQO's online nature ensures that preference pairs remain relevant to the policy model.

Xu et al. (2024c) apply RLHF with a reward model trained to distinguish high quality references (from literary translations) and translations sampled from their model. Similar to us, they find evidence of cross-lingual transfer learning during preference learning. Specifically, when optimized only on EN–ZH, their model improved for EN to FR, ES, RU, and AR. When training only on EN–AR, however, they saw improvements in only half of the target languages.

Reward rAnked Fine-Tuning (RAFT) is the method most similar to DQO, but uses SFT to update the model towards a single preferred output rather than using DPO with a preferred/rejected output pair (Dong et al., 2023). As it was not evaluated for the translation task, used an independently trained reward model, and had slight differences in sampling parameters, we ran an ablation on whether to use DPO or SFT in DQO (see Section 4).

7 Conclusion

We demonstrate the existence of a fundamental task–data mismatch in NMT and introduce Direct Quality Optimization (DQO), a method of aligning pretrained models with human preference.

Using DQO on a multilingual NMT model, we find improvements in automatic quality metrics for all supported target languages, even those neither

used for DQO, nor related to the languages used for DQO. A human evaluation confirms that these improvements reflect increased human preference.

The improvements in translation quality for unrelated languages include language specific features that were not seen during DQO, suggesting that the baseline model had, but did not use, knowledge of those features during inference. We suggest that this is the expected behavior of a model trained with supervised learning, and present DQO as an efficient method of aligning a translation model with human preference.

In an experiment on ALMA-13B-LoRA we confirm that DQO is applicable to decoder-only LLMs.

8 Limitations

This work only tests one quality evaluation model as a proxy for human preferences, CometKiwi22, and does not examine the impact of that proxy's quality. We focused primarily on a single translation model, the NVIDIA Megatron English-Many model, using a 1.3B paramter English-German model only for the perplexity experiments (as we had access to the training data), and ALMA-13B-LoRA to verify applicability on decoder-only models. Human evaluation of translation quality was only performed on two language pairs. For all others, we relied on automatic quality evaluation metrics such as BLEURT, COMET22 and BLEU, which may not fully capture true human preference.

A Appendix

A.1 MQM Error Subcategories by Generality

Language-agnostic	**Language-specific**	**Other**
Accuracy/Creative Reinterpretation	Fluency/Grammar	Other
Accuracy/Mistranslation	Fluency/Register	Source issue
Accuracy/Source language fragment	Fluency/Spelling	
Accuracy/Addition	Fluency/Punctuation	
Accuracy/Omission	Fluency/Character encoding	
Fluency/Inconsistency	Style/Unnatural or awkward	
Terminology/Inconsistent	Style/Bad sentence structure	
Non-translation	Terminology/Inappropriate for context	
	Locale convention/Address format	
	Locale convention/Date format	
	Locale convention/Currency format	
	Locale convention/Telephone format	
	Locale convention/Time format	
	Locale convention/Name format	

Table 7: **Multidimensional Quality Metrics error subcategories by generality**. *Language-agnostic errors* are those governed by a principle that can be generalized to all language pairs, e.g., that translations should not omit information. *Language-specific errors* are those that require additional, language-specific information to generalize from one language pair to another, e.g., correcting improper sentence structure requires knowledge of correct vs. incorrect sentence structures for a given language. *Other errors* cannot be assigned to either category.

A.2 Hyperparameters Used in Experiments on NVIDIA Megatron

Hyperparameter	Definition	Value
r_{QE}	Human preference proxy model	`CometKiwi22`
n	Number of rounds	5
m	Epochs per round	8
d	Epoch size (source sentences)	8000
α	Learning rate	1×10^{-6}
β	DPO regularization factor	0.5
k	Sampled translations per source	64
K	Top-K sampling parameter	40
P	Top-P sampling parameter	0.8
ε	Preference margin	0.005
–	Batch size	8096
–	Learning rate schedule	Linear with warmup
–	Learning rate warmup steps	150
–	Gradient clipping threshold (norm)	10

Table 8: **A list of all hyperparameters** used for Direct Quality Optimization in this paper's experiments.

A.3 Hyperparameters for experiments on ALMA-13B-LoRA

Hyperparameter	Definition	Value
r_{QE}	Human preference proxy model	`CometKiwi22`
n	Number of rounds	9
m	Epochs per round	4
d	Epoch size (source sentences)	8000
α	Learning rate	5×10^{-5}
β	DPO regularization factor	0.5
k	Sampled translations per source	64
K	Top-K sampling parameter	∞
P	Top-P sampling parameter	1.0
ε	Preference margin	0.005
–	Batch size	8096
–	Learning rate schedule	Linear with warmup
–	Learning rate warmup steps	150
–	Gradient clipping threshold (norm)	10

Table 9: **A list of all hyperparameters** used for Direct Quality Optimization in the experiments on ALMA-13B-LoRA. See https://github.com/lilt/dqo/blob/main/configs/alma-13b-lora-comparison-with-cpo-4.yaml

A.4 Composition of the DQO Seed Dataset

As described in Figure 1, Direct Quality Optimization requires a seed dataset containing input samples in the source language. This dataset does not need to include references, as the policy model π_θ is used to produce a diverse set of hypotheses, which are then scored under a QE model and transformed into preference pairs.

For our experiments, we used a general and varied seed dataset consisting of the English side of the following publicly available English–German datasets provided by the OPUS project (Tiedemann, 2012):

- bible-uedin (Christodouloupoulos and Steedman, 2015)
- CCAligned (El-Kishky et al., 2020)
- CCMatrix (Schwenk et al., 2021b; Fan et al., 2021)

Abstract

Machine Translation (MT) has achieved remarkable performance in recent times, with growing interest in speech translation and multimodal approaches. However, despite these advancements, MT quality assessment remains largely text-centric, typically relying on human experts who read and compare texts. Since many real-world MT applications (e.g., Google Translate Voice Mode, iFLYTEK Translator) involve translation being spoken rather than printed or read, a more natural way to assess translation quality would be through speech as opposed text-only evaluations. This study compares text-only and audio-based evaluations of 10 MT systems from the WMT General MT Shared Task, using crowd-sourced judgments collected via Amazon Mechanical Turk. We additionally, performed statistical significance testing and self-replication experiments to test reliability and consistency of the proposed audio-based approach. Crowd-sourced assessments based on audio yield rankings largely consistent with text-only evaluations but, in some cases, identify significant differences between translation systems. We attribute this to the richer, more natural modality of speech and propose incorporating speech-based assessments into future MT evaluation frameworks.

1 Introduction

Reliable evaluation process is critical in the development and refinement of MT systems. MT evaluation (MTE) often relies on both automated and manual measurement techniques. Manual evaluation is always a preferred choice and provides a deeper understanding of system quality, while automatic evaluation metrics (AEMs) often serve as a proxy for human judgment (Castilho et al., 2018). AEMs support reusable assessments, system comparison and rapid MT deployment. However, AEMs face several issues including their inability to handle contextual and cultural nuance, the dependency on reference translation, and domain-specific challenges. Therefore, despite being time-consuming and expensive, human assessment is still a fundamental requirement for reliable evaluation.

The annual Conference on Machine Translation (WMT) is the primary forum for collecting human judgments to evaluate metrics and participating systems in its shared translation task each year. In early evaluation campaigns, 5-point adequacy and fluency ratings were gathered from participants as the primary evaluation metric (Koehn and Monz, 2006). Subsequent WMT campaigns adopted a ranking-based evaluation approach as the official metric (Vilar et al., 2007), with rankings still collected from participants of the evaluation campaign. Regarding fluency as a measure of MT output quality, Graham et al. (2013a) argued that using a 1-100 continuous scale yields better inter-annotator consistency compared to a five-point interval scale. Supporting this, Bojar et al. (2016) found strong correlations between adequacy and fluency-based evaluations. These findings led WMT to replace relative ranking with adequacy-based Direct Assessment (DA) on a continuous scale as the official metric (Bojar et al., 2017). For into-English translation tasks, WMT frequently relied on crowd-workers for its human evaluation campaigns. Crowd-based evaluations allow for a fast and cheap MT quality evaluations (Callison-Burch, 2009). When coupled with quality-controlled annotations, non-expert crowd assessments show better inter-annotator consistency (Graham et al., 2013a, 2017). However, Castilho et al. (2017b) found that crowd-workers, compared to professional translators, were less capable of detecting subtle MT errors. Studies by Läubli et al. (2018) and Toral et al. (2018) also favored the use of professional translators over researchers or crowd-workers due to their ability to differentiate between human and machine translations. Consequently, WMT revised its evaluation procedures to prioritize professional transla-

Proceedings of the Tenth Conference on Machine Translation, pages 52–63

tors over crowd-workers (Kocmi et al., 2022, 2023). Despite its limitations, crowd-based assessment remains the most convenient choice for certain tasks, particularly monolingual DA, which does not require human raters to have bilingual knowledge (Graham et al., 2017), making it easier to conduct. More recently, WMT performed evaluations using Error Span Annotation (ESA) protocol (Kocmi et al., 2024), which requires annotators to assign an overall score to each segment, similar to DA and classify errors based on severity (e.g. major or minor).

The human evaluation process has evolved over time; however, there is still no consensus on the best approach to evaluating translation quality (Castilho et al., 2018). Current MT evaluation metrics primarily considers text, despite the fact that many real-world MT applications involve spoken rather than written translation. Most importantly, the recent emergence of pre-trained multimodal models (Barrault et al., 2023) has enabled support for direct speech-to-speech, text-to-speech and speech-to-text translation, however appropriate methods for evaluation for these systems are yet limited or borrowed from text-domain (Salesky et al., 2021; Sperber et al., 2024).

We argue that speech, as a natural and expressive modality, can provide more reliable measures of MT quality. To support this claim, we propose incorporating text-to-speech (TTS) technology into direct MT assessment, allowing for a direct comparison between text-only and speech-enabled evaluation approaches. Our study collects human judgments for German-English translations from WMT shared task using crowd-workers hired via Amazon Mechanical Turk. The evaluation consists of two conditions: (i) a text-only setup, replicating the conventional method where evaluators compare written MT output with a reference translation, and (ii) a text-audio setup, where evaluators listen to the MT output while reading the reference translation. We perform self-replication experiments and statistical significance tests to assess the consistency and reliability of the proposed method.

A comparative analysis of these evaluation conditions yields two key findings. First, rankings derived from text-audio evaluations are broadly similar to the original evaluations but also show notable differences compared to conventional setups, with the audio-based method demonstrating a substantially greater ability to detect significant differences between translation systems. We hypothesize that this difference arises because speech is a natural and rich modality, capable of conveying prosodic and expressive features that text alone cannot capture. Second, consistent with prior research, our results confirm that crowd-workers tend to assign lower rankings to human translations that diverge from the reference, while favoring literal machine translations (Castilho et al., 2017a; Fomicheva, 2017). Furthermore, self-replication experiments reveal a higher positive correlation between repeated runs of audio-based evaluations, indicating improved reliability and consistency of this new approach.

Table 1: Number of segments and average document length (#segments per document) of German-English data used in the general translation test sets.

2 Methodology

2.1 Data set

We used MT outputs from WMT 2022 German-English translation task, comprising around 20,000 translations submitted by 10 participating systems, with each system contributing approximately 2,000 translations. This original evaluation set is a bilingual corpus drawn from different domains, as shown in Table 1, with document lengths varying considerably by domain. To ensure balanced domain representation while preserving document order, a subset of documents was randomly sampled from each domain. We use on average 450 segments per system for multimodal[1] and text-only experiments.

The WMT evaluation campaign has already published results from crowd-based human evaluations of the submitted systems. As WMT now conducts bilingual ('source-based') evaluations using professional translators, we focus on WMT 2022—the most recent workshop to perform monolingual DAs.

[1]In this study, multimodal is used to refer to text-audio based setup

2.2 Assessment Design

AMT crowd-sourcing service was used to design and collect human judgments, with each task consisting of 100 segments. A single segment along with a reference translation is presented at one time. Where possible, segments are collected and shown in document context. In adequacy based assessments, crowd-workers are asked to rate how adequately an MT output expresses the meaning of the reference translation. The scores are collected on 0–100 visual analog scale (VAS) for each segment. Additionally, rater quality control mechanism is implemented to filter out ratings from non-reliable raters, as outlined by Graham et al. (2017). At the end of the task, evaluators have the option to provide feedback on their experience.

The segment-level ratings were used to calculate system-level rankings. At the end of the evaluation, we provide two types of segment-level scores, averaged across one or more raters: raw scores and z-scores, with the latter standardized for each annotator. The final score of an MT system is the mean standardized score of its ratings after filtration. Multiple judgments are collected per segment, increasing the number of annotators per translation enhances the consistency and reliability of the mean score. Since reference-based assessment required only knowledge of the English language; the selection criteria required participants to be native English speakers.

We compare judgments collected using following two different setups:

- *Text-only*: MT output and reference translations, both are presented as text (Figure 1).
- *Multimodal*: MT output is presented in audio (TTS) and reference translation as text (Figure 2).

Overall, we gathered approximately 12,000 crowd-sourced judgments for German-English language pair using DA. Compared to ordinal ranking or relative preference judgments (Callison-Burch, 2009), direct estimation facilitates more robust statistical analysis, thus making it suitable for crowd-sourced annotations (Graham et al., 2013a). When combined with quality control mechanisms, direct assessments have shown effective and relatively consistent human judgments of MT quality in WMT evaluation campaigns (Specia et al., 2020; Akhbardeh et al., 2021; Kocmi et al., 2022).

2.2.1 Text-only setup

We randomly sampled 500 segments per system (with the addition of quality control segments, the total could be increased). The selected translations are then converted into bit-mapped images, in order to deter workers from using speech feature of Web Browsers to read-aloud the translations.

In this scenario, the workers are shown the reference and the MT output as text and asked to rate MT output by moving the slider (as shown in Figure 1). For task simplicity, we kept the structure of assessment similar to existing evaluation setups (Graham et al., 2017; Kocmi et al., 2022). The ratings are collected per segment in a sequential manner, adhering to the document order where feasible. However, longer documents may need to be divided into smaller units to comply with the limit of 100 segments per task. The setup restricts assessors from revisiting and modifying ratings of previous segments to ensure integrity of quality control measures.

2.2.2 Multimodal setup

For comparison, the same segments sampled for the text-only scenario were considered in this experiment. However, this setup utilises TTS technology to present the MT output in an audio-equivalent form. To make the task less cognitively taxing, we present only the MT system's output in audio form. For this, we used the Google Cloud Text-to-Speech (TTS) Service (GCS)[2] to generate audio representations of MT outputs. The service was employed with its default human-like voice settings, which are noted for their high quality and clarity. GCS is well-suited for long-form content[3] due to its close approximation of human speech and its ability to provide an enhanced listening experience (Cambre et al., 2020).

2.2.3 HITs

Both multimodal and text only assessments are carried out separately. Each task, referred to as "HITs" (Human Intelligence Task) contains 100 translations in total for each setup. In addition to system output, a set of quality control segments was added, keeping the total size of HIT to 100. The quality control segments consists of exact repeats (*ask_again*) and degraded translations

[2] https://cloud.google.com/text-to-speech

[3] For multimodal experiments, in total a human assessor may have to listen up-to 20 minutes of machine translation outputs, therefore along with accuracy of TTS, a pleasant listening experience is important.

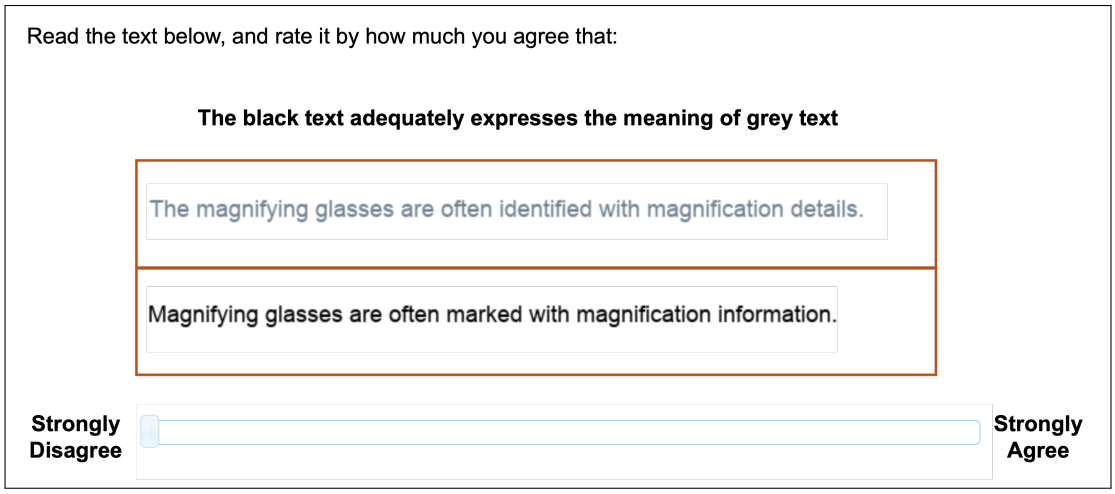

Figure 1: Screenshot of the text-only assessment interface, as presented to an AMT worker. Reference text is presented in grey while MT output is shown in black text. The slider is initially placed at left most corner; workers move it to the right in reaction to the question.

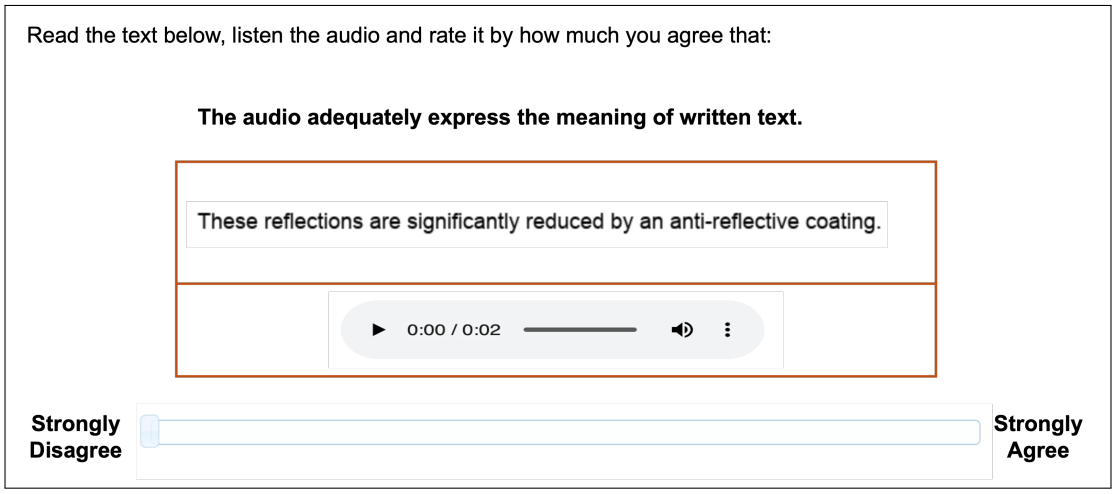

Figure 2: Screenshot of the multimodal assessment interface, as presented to an AMT worker. Worker can use audio control to listen translations, the text in presented in the image form. The slider is initially placed at left most corner; workers move it to the right in reaction to the question.

(*bad_reference*), duplicated from system outputs. Thus, each HIT consists of approximately 20% quality control segments (used to estimate workers' reliability) and 80% genuine system outputs. To create *bad_reference* pairs, we followed the strategy of randomly substituting words in a sentence, as outlined in Graham et al. (2013b). For the multimodal setup, the quality control segments were first prepared using the same strategy in text form and then converted into audio using the TTS API.

Judgments from crowd workers with limited or no knowledge of the assigned task pose a significant risk of inconsistency and discrepancies in the results. Expert-based MT quality assessment is the preferred approach; however, it incurs high economic and time costs, making crowdsourcing a viable alternative. Consequently, assessing worker reliability becomes critically important in crowd-sourced evaluations. Quality control segments within HIT allow for reliability estimates based on workers distribution of scores assigned to *bad_reference* and *ask_again* items. These estimates are based on following two assumptions:

1. The consistent assessor will assign significantly higher score to the system producing high quality translations compared to a system producing inferior outputs.

2. The consistent assessor will assign highly similar scores in repeated evaluations of the same translations.

Analysis of assumptions 1 and 2 can provide a measure of workers' ability to differentiate between a good and inferior translation. Assumptions 1 and 2, based on the sets of *bad_reference* and *ask_again* translations, posit that a consistent worker would assign significantly lower scores to degraded (*bad_reference*) translations and similar scores to repeated (*ask_again*) translations. For this, we apply the Wilcoxon rank-sum test to compare the score differences between *ask_again* and *bad_reference* translation pairs, with a resulting p value as an estimate of reliability. The expectation is that the difference in scores for degraded translation pairs will be smaller than for repeated judgments. A lower p-value ($p < 0.05$) indicates higher reliability, demonstrating that the worker can effectively distinguish between high-quality and degraded translations. As shown in Figure 3, conscientious workers assigned lower scores to degraded translations compared to the original references. Furthermore, for repeated segments, they exhibited a consistent scoring pattern by assigning similar scores to identical pairs.

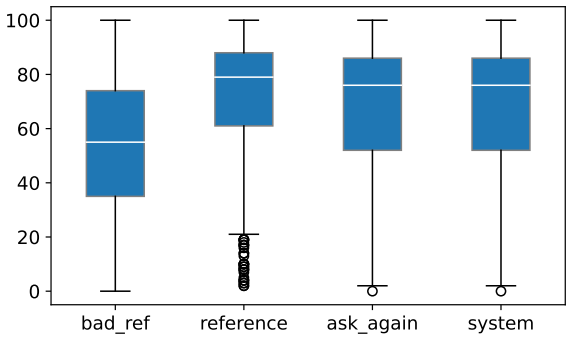

Figure 3: Score distributions of reliable workers across different quality control segments: $bad\_reference$, ask_again, and original system outputs.

Table 2 provides statistics on the number of workers involved in each assessment type and the percentage of workers who passed the quality control threshold. A similar trend was observed across both assessment types, with nearly 20% of workers meeting the reliability criteria. To determine whether to accept or reject HITs, the mean score differences for *bad_reference* and *ask_again* pairs were carefully analyzed, rather than relying solely on automatic quality control checks.[4] This is further reflected in the difference between the number of approved workers and those who met the quality control criteria. Rejected HITs were rescheduled to obtain fresh judgments.

[4]In addition to statistical tests, other measures were in place to detect robotic or low-quality submissions, such as extremely short completion times, lack of slider movement, and assigning the same rating to every judgment.

3 Results

System rankings are calculated for each setup using filtered judgments—only those that passed the quality control criteria. Quality control segments (*bad_reference* and *ask_again*) are excluded from the final system rankings. System rankings are based on the mean raw and standardized (z) scores. To compute the standardized score for each system, individual scores are first normalized using each worker's mean and standard deviation (as per equation 1). The standardized scores for all segments corresponding to a system are then averaged to obtain the system-level score (Graham et al., 2014). Since HITs are structured so that a single worker may assess multiple systems, standardising the scores helps mitigate individual biases and harmonise outputs across workers.

Table 3 presents the raw and standardized scores of the participating systems across different experiments, with the last three columns showing the official results from WMT. Systems are ordered from best to worst based on their average standardized scores, with the raw score used as a secondary criterion when standardized scores are identical to two decimal places.

$$z = \frac{x - \mu}{\sigma} \tag{1}$$

The text-only results show increased correlation between the raw and standardised score, with few exceptions such as system `LT22` and `JDExploreAcademy`, which would have ranked better according to raw score. This close correlation suggests an even distribution of segments from different systems across workers and may also be attributed to the homogeneous nature of the task (text-only data). It is important to note that these rankings may not fully reflect actual system performance or align with the official WMT rankings, as we used a smaller set of judgments per system compared to WMT22, with the primary objective of investigating and comparing audio-based and text-based evaluations.

In the multimodal scenario, the differences in system rankings between z scores and raw scores are more pronounced. Based on the raw scores, a

	Workers			Translations		
modality	Total	Approved	Pass QC	Total	Approved	Pass QC
text only	225	47	42 (18.50%)	23.3k	5.1k	4.6k (19.7%)
multimodal	242	52	48 (19.83%)	26.1k	6.0k	5.3k (20.3%)

Table 2: Numbers of workers and translations, before and after quality control for multimodal and text only experiments.

different ranking emerges, with `Lan-Bridge` performing best. This divergence may be caused by the differing nature of the evaluation setup, particularly the use of both audio and text for evaluation. The out-of-sequence numbers in order column (Table 3) highlight differences in system rankings across different experiments.

A direct comparison of the mean standardized scores across both tables reveals substantial differences in system rankings. For example, in the text-only evaluation, `Online-W` outperforms `PROMT` based on standardized scores, whereas the multimodal evaluation ranks `PROMT` as the top-performing system. Similarly, `Online-G` is ranked sixth, below `Online-A`, `Online-W`, and `Online-Y` in the text-only setup, but is rated higher than these systems in the multimodal evaluation. For most other systems, rankings diverge by one or two places between setups, with the exception of `Human-B`, which consistently ranks as the lowest-performing system in both evaluations. Ideally, `Human-B` (the human reference translation) should be the top-performing system. However, the results suggest that crowd-workers struggled to distinguish between human translations and MT outputs. This aligns with prior research suggesting that crowd-workers tend to favor literal, straightforward translations, resulting in lower rankings for human translations that deviate from the reference (Fomicheva, 2017; Freitag et al., 2021).

3.1 Significance Test Results

Since both approaches yield different system rankings without a clear indication of which better reflects actual performance, more robust testing is required to determine whether the observed ranking differences are genuine. To address this, we employ two techniques: statistical significance testing and self-replication. Significance testing estimates the likelihood that ranking differences between system pairs occurred by chance, while self-replication examines the reproducibility of results to verify their reliability and consistency.

The results of significance tests are visualised as heat maps in Figure 4 for the multimodal and text-only setups. Specifically, we apply one-sided Wilcoxon rank-sum test to compare the standardized human assessment score distributions for each pair of systems.

Tables with head-to-head comparisons between all systems are included in Appendix A.

The significance matrices are constructed under the hypothesis that the scores of system X are significantly better than those of system Y at a given confidence level, p. A comparison of the text-only and multimodal heat maps reveals that the multimodal approach results in a slightly higher proportion of significant differences between systems with fewer uncertainties. For example, at a confidence level of $p < 0.05$, the text-only method identifies relatively few significant differences, whereas the multimodal method demonstrates more distinct separations among systems. For example, the multimodal heat map shows that `Online-G` performs significantly better than `JDExploreAcademy`, `LT22`, `Lan-Bridge`, and `Online-B`, as confirmed by its higher multimodal average z-score. Similarly, for `Online-A`, both the text-only and multimodal evaluations lead to similar conclusions.

3.2 Self-replication Results

Figure 5 presents scatter plots comparing initial and self-replicated judgments from multimodal and text-only experiments. To assess the consistency of judgments collected using the multimodal (text and audio) approach, we conduct two independent runs and compute the Pearson correlation (r) between the initial and self-replicated results. In Figure 5 (a), self-replicated and original multimodal assessments are plotted on the x-axis and y-axis, respectively. Figure 5 (b) illustrates the correlation for text-only and multimodal scores, with the former on the x-axis and the latter on the y-axis. A high correlation would be indicated by points

System	text			official-text			multimodal

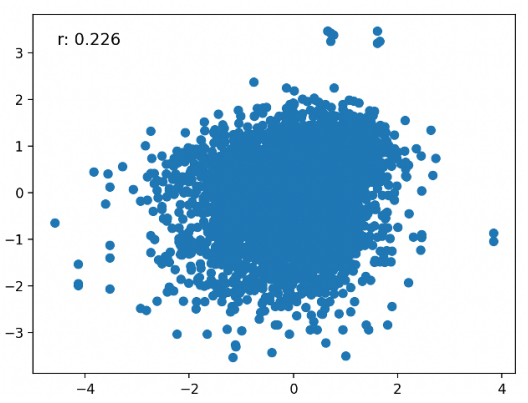
Table 3: Comparison and system rankings based on scores from the text-only and multimodal (text + audio) setup for the German–English translation direction. Systems are ordered by their average standardized (z) scores. In cases of a tie in z scores, the average raw (raw ave.) score is used as a secondary ranking criterion.

Figure 4: Significance test outcomes for text-only and multimodal method of human evaluation. Colored cells indicate that the scores of the row i system are significantly greater than those of the column j system.

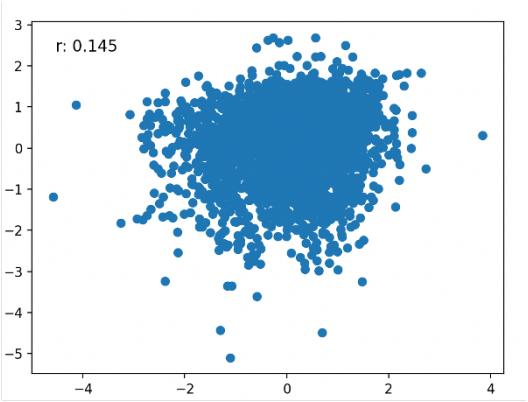
closely aligning with a straight line. While both approaches show a weak positive correlation, the multimodal setup exhibits a slightly higher correlation than the text-only setup, suggesting the potential of audio-based evaluation for providing reliable MT quality estimates.

3.3 Discussion

The results of significance and correlation tests suggest that speech can offer consistent and valuable insights into MT quality. We hypothesize that these differences arise because speech is a richer modality, capable of conveying prosodic and expressive features (Kraut et al., 1992). As a result, evaluators listening to translations were better able to detect major variations and unnatural-sounding MT outputs. Furthermore, feedback from evaluators at the end of the assessment indicated no challenges with audio-based evaluation. For instance, one worker stated that "all the audio samples were good," while another noted that "the audio is very clear". A general comment read, "the HIT is very unique, and there were no issues during the experiment". These preliminary results, obtained using non-expert crowd workers, suggest the effectiveness of speech in MT evaluation. However, further investigation may be required, and a more fine-grained approach—such as error annotation—could help better quantify the impact of audio in MT assessment.



(a) Self-replication (multimodal vs multimodal)



(b) text-only vs multimodal

Figure 5: Scatter plots illustrating the correlation (r) between different evaluation approaches. (a) shows the correlation between two runs of the multimodal approach, while (b) compares the results of the text-only and multimodal approaches.

4 Conclusion

We have presented our findings on integrating speech into human evaluation of MT quality. Our experiments with crowd workers compared MT system rankings from text-only and speech-enabled evaluation setups.

Despite using basic TTS tools and crowd workers, our study extends MT evaluation beyond traditional text-based assessments, highlighting the potential of audio-based evaluation to provide distinct insights into MT evaluation. As MT research increasingly embraces multimodal translation, our findings provide empirical evidence that text-only evaluation may be insufficient. Beyond MT, this approach could benefit fields such as automatic dubbing, AI-assisted interpreting, and multilingual speech interfaces. Overall, our study emphasizes the need for more holistic evaluation benchmarks that better reflect the complexity of real-world language use.

Our code[5] and collected human annotation data are freely available.

5 Limitations

We performed a general adequacy-based MT evaluation using crowd-workers on a limited dataset. Since the primary goal was to test whether audio-based judgments make a difference, we employed a simplified assessment approach and focused only on the German-English language pair. We acknowledge that even expert-based human judgments can be noisy, potentially leading to low inter-annotator agreement (IAA) if not carefully conducted. Nevertheless, we collected a large sample of annotations from crowd-workers to compare the two approaches. With intrinsic quality control measures, crowd-sourced annotations have been shown to achieve higher IAA (Graham et al., 2017). However, due to limited time and platform constraints, manual filtering of noisy annotations was not feasible, making it difficult to eliminate all low-quality responses. Furthermore, we did not calculate inter-annotator or intra-annotator agreement, as these aspects have already been extensively studied in the context of crowd-sourced direct assessment (Graham et al., 2013a, 2017).

Regarding the TTS model, we relied on a single vendor and did not conduct comparisons across different voices, speech rates, or providers. This restricts the generalizability of our findings, as results may vary with alternative TTS configurations. Nonetheless, we selected the model judged to have the most human-like voice based on a review of the vendor's technical documentation.

As MT quality evaluation has increasingly moved toward ESA-style (Kocmi et al., 2024) annotations (at least in WMT), audio-based evaluation could be integrated into such platforms to identify error spans by listening to translations and assigning final scores. However, accurately segmenting the audio for this purpose would pose a significant challenge.

6 Ethical Considerations

The human annotations collected via Amazon Mechanical Turk were fully anonymous. Anonymous users with MTurk accounts (meeting the defined criteria) submitted the tasks using numeric worker IDs. Although no personal identity information

[5] https://github.com/sami-haq99/Multimodal_Direct_Assessment

was revealed, we removed the worker IDs after payments were processed. Since the crowd-workers only needed to be native speakers and were not required to be expert translators, they were compensated according to the platform's minimum task rate.

In cases where crowd-workers did not meet the quality control criteria—such as submitting robotic responses or completing tasks in an unrealistically short time—we rejected their submissions and did not provide payment.

A Head to Head Significance test Results

The following tables (4–6) show differences in average standardized human scores for a system in that column and the system in that row for the German–English language pair. We applied the Wilcoxon rank-sum test to measure the likelihood that such differences could occur simply by chance for text-only, text-audio and WTM22 official[6] experiments. In the following tables, * indicates statistical significance at $p < 0.05$, ** indicates statistical significance at $p < 0.01$, and *** indicates statistical significance at $p < 0.001$, according to the Wilcoxon rank-sum test.

Each table contains a final column showing the total number of judgments used to calculate the results. The number for the official results is much greater than in our experiments; therefore, a direct comparison should only be made between the text-only and multimodal scores.

Abstract

We present a comprehensive study on meaningfully evaluating sign language utterances in the form of human skeletal poses. The study covers keypoint distance-based, embedding-based, and back-translation-based metrics. We show tradeoffs between different metrics in different scenarios through (1) automatic meta-evaluation of sign-level retrieval, and (2) a human correlation study of text-to-pose translation across different sign languages. Our findings, along with the open-source `pose-evaluation` toolkit, provide a practical and reproducible approach for developing and evaluating sign language translation or generation systems.

1 Introduction

Automatic evaluation metrics are essential for assessing the quality of automatically generated language content and tracking progress over time. For instance, machine translation (MT) studies rely heavily on BLEU (Papineni et al., 2002), even though newer metrics have shown stronger correlation with human judgment (Freitag et al., 2022). This trend continues in sign language processing (SLP; Bragg et al. (2019); Yin et al. (2021)), an interdisciplinary subfield of natural language processing and computer vision. Sign language translation (SLT; Müller et al. (2022, 2023a); De Coster et al. (2023)), denoting the part of SLP concerned with translating sign language videos into spoken language text, reuses text-based metrics.

Müller et al. (2023b) puts forward concrete suggestions on evaluating generated text (especially glosses) in a sign language context. They suggest always computing metrics with standardized tools (e.g., SacreBLEU (Post, 2018) for BLEU) and reporting the metric signatures for reproducibility and fair comparison with other work. The opposite direction—generating or translating into sign language utterances (usually from source text)—presents additional challenges for evaluation. Namely, standardized metrics, tooling, and correlation with human evaluation are lacking.

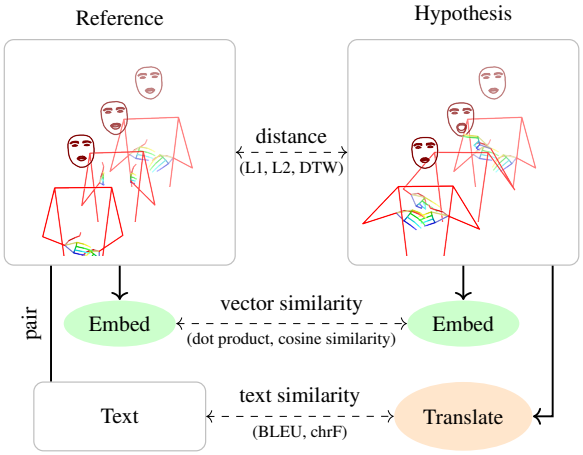

Figure 1: Pose-based evaluation taxonomy overview. We compare a reference and a hypothesis pose sequence by one of the following three ways: (a) computing distance-based metrics directly on the keypoint sequences, optionally aligned by dynamic time wrapping (DTW); (b) encoding each sequence into a shared embedding space and measuring similarity; and (c) back-translating the hypothesis poses into text to apply conventional machine translation metrics on text.

In this work, we systematically examine the metrics employed for evaluating sign language output, especially formatted as human skeletal poses (Zheng et al., 2023) that contain motion of signing (e.g., MediaPipe Holistic; Lugaresi et al. (2019); Grishchenko and Bazarevsky (2020)). We start by a literature review of current research practices in §2, and summarize two major families of metrics: (a) distance-based metrics (§3.1) informed by human motion generation (§2.3) and sign language assessment (SLA; §2.4), assuming the access to reference poses and then computing the distance from the predicted poses to the reference poses, either in the

Proceedings of the Tenth Conference on Machine Translation, pages 64–80
November 8-9, 2025

raw 2D/3D keypoint space or an embedding space; (b) back-translation-based metrics (§3.3) borrowed from MT (Zhuo et al., 2023) and speech translation (Zhang et al., 2023), assuming the pre-existence of a pose-to-text translation model.

After the initial conceptual review, we select, implement, and meta-evaluate typical metrics along with additional innovative ones proposed by us (as summarised in Figure 1), through two empirical approaches: automatic meta-evaluation with a sign-level retrieval task (§4); and a sentence-level correlation study between metrics of interest versus deaf evaluator ratings on three text-to-pose MT systems in three spoken-sign language pairs (§5).

We find that keypoint distance-based metrics, when carefully tuned, can rival more advanced approaches for sign retrieval and human-judgment correlation. On the other hand, embedding-based metrics, including those borrowed from SLA, excel in their own domain but struggle at the sentence level across different systems. Back-translation likelihood emerges as the most consistent metric, highlighting the need for open, standardized pose-to-text models alongside human evaluation.

The source code of the suggested evaluation metrics and the proposed meta-evaluation protocols in §4 are openly maintained in `pose-evaluation`, a public GitHub repository. The human correlation data and evaluation scripts in §5 are also released in a separate `text2pose-human-eval` repository to encourage future research.

2 Related Work

We discuss four related fields in this section with a special emphasis on the evaluation methodology, and outline recent work in sign language generation (SLG; §2.2) in Table 1. The remaining three fields provide additional background relevant to evaluating these SLG systems.

2.1 Sign Language Understanding

Sign language recognition (Adaloglou et al., 2021) and translation (De Coster et al., 2023) are the two most prevalent tasks of understanding sign language from video recordings. The former aims to classify signing into a fixed vocabulary of signs in a particular sign language, either from isolated video clips of single signs (isolated sign language recognition, ISLR) or continuous video footage spanning multiple signs (continuous sign language recognition, CSLR). Given its classification nature, the evaluation efficiently utilizes classic statistical metrics, such as accuracy, F_1 score, and word error rate.

Early SLT attempts rely on glosses (Moryossef et al., 2021b; Müller et al., 2023b), produced manually by humans or a CSLR model. Camgoz et al. (2018, 2020) starts end-to-end neural SLT and leads a wave of gloss-free SLT work (Zhou et al., 2023; Zhang et al., 2024a), where evaluation is typically done with BLEU and BLEURT (Sellam et al., 2020) but not possible with source-based metrics like COMET and quality estimation models like COMET-QE (Chimoto and Bassett, 2022) due to the input modality constraint on sign language. WMT-SLT campaigns for two consecutive years (Müller et al., 2022, 2023a) carry out a rigorous human evaluation process as seen in traditional MT research. Yet the correlation between automatic evaluation metrics and human judgments in SLT has not been reported; quantifying this correlation would yield valuable insights.

2.2 Sign Language Generation

The landscape of SLG is more complicated than SLT, with various inputs, namely, (a) spoken language *text*; (b) sign language *glosses*; (c) iconic *phonetic writing systems* of sign language; (d) textual *phonetic descriptions* of signing, and various outputs, usually, 2D/3D pose; or RGB video frames[1]. We note that in the case of (a) *text*, the generation process involves translation from a spoken language to a sign language with possibly reordering and rephrasing of words, while starting with (b), (c), or (d) merely convert sign language approximated in textual forms into visuals (also known as sign language production[2]), possibly with a preceding step in the pipeline that translates from (a) *text* to (b) *SignWriting* (Jiang et al., 2023), (c) *glosses* (Zhu et al., 2023), or (d) *descriptions*[3]. Our work evaluates poses as the primary representation of sign language motion and semantics, deliberately excluding RGB videos to avoid confounding factors such as visual appeal or signer identity. Evaluating videos using the same methods is possible after first estimating them into poses.

[1]For further details about these representations, please refer to the explanatory figures on https://research.sign.mt/.

[2]The terms are sometimes used interchangeably and thus confuse. This work adheres to the broad term of sign language generation, which involves generating signing from any source.

[3]For example, signing HELLO in ASL: dominant B-hand at forehead → short outward stroke; friendly/smiling face.

Table 1: Literature review of recent works on pose-based sign language generation (May 2025). P=RWTH-PHOENIX-Weather2014T, H2=How2Sign; T=Text, G=Gloss, H=HamNoSys; M=MediaPipe, O=OpenPose, S=SMPL-X; D=DTW-MJE (and other distance-based metrics), B4=BLEU-4 (and other back translation-based metrics); </> and θ represent the availability of source code and model weights for the generation model and the evaluation metrics (including the back translation model if involved), respectively. The check mark symbols (✔) are clickable links in these columns, and *n/a* denotes not-applicable cases, such as model weights for gloss-based systems and back-translation for HamNoSys input. Other image-based metrics are left as less relevant.

We present prominent pose-based SLG studies from recent years, along with their evaluation methods, in Table 1, grouped by input modalities. Following a similar roadmap as SLT, SLG takes off with a gloss-based cascading approach (text-to-gloss-to-sign; Stoll et al. (2018, 2020)) and then gradually switches to an end-to-end fashion in a series of follow-up work (Saunders et al., 2020b,a, 2021a,b). Attempts have also been made with alternative phonetic inputs such as HamNoSys (Prillwitz and Zienert, 1990; Arkushin et al., 2023).

Unlike SLT, however, gloss-based baseline approaches for SLG remain competitive and practical choices (Moryossef et al., 2023b; Zuo et al., 2024b) due to accessible sign language dictionary resources that enable straightforward mapping of glosses to sign language pose sequences. Modern end-to-end approaches utilise vector quantization, diffusion models, and LLMs, and the output pose format spans from classic 2D standards such as MediaPipe Holistic and Openpose (Cao et al., 2019) to 3D SMPL-X (Pavlakos et al., 2019).

Popular datasets used in this line of work include RWTH-PHOENIX-Weather 2014T, in German Sign Language (DGS), introduced by Forster et al. (2014); Camgoz et al. (2018); CSL-Daily, in Chinese Sign Language (CSL), introduced by Zhou et al. (2021); and How2Sign, in American Sign Language (ASL), introduced by (Duarte et al., 2021). We choose Signsuisse (Müller et al., 2023a) in this work (§5) for its multilingual nature and richer vocabulary than others[4].

As for evaluation, the SLRTP Sign Language Production Challenge 2025 summarises the most common evaluation metrics: (a) keypoint distance-based, such as DTW-MJE (Dynamic Time Warping - Mean Joint Error); and (b) back-translation-based, such as BLEU and BLEURT. Human evaluation is conducted briefly in Saunders et al. (2021a,b), Baltatzis et al. (2024), and Zuo et al. (2024a) and more extensively in another concluded campaign–Quality Evaluation of Sign Language Avatars Translation (Yuan et al., 2024). Unfortunately, like in SLT, the correlation between automatic metrics and human judgments has never been formally validated. Upon reviewing Table 1, we spot two significant issues in the current development of SLG: (a) Most systems and their evaluations are non-reproducible due to the lack of source code and model weights (including the back-translation models if involved). (b) Cross-work comparisons are unrealistic given the fragmented implementation of the evaluation metrics (in contrast to MT, where standardized tools like SacreBLEU are available).

2.3 Human Motion Generation

Motion generation from natural language is a related field where human pose sequences are synthesized to reflect described actions (Tevet et al., 2022; Zhang et al., 2024b). Evaluation typically involves distance-based metrics (e.g., joint or velocity error), perceptual similarity (e.g., Fréchet Inception Distance adapted to motion), and alignment metrics, such as R-Precision, to measure text-motion coherence. However, Voas et al. (2023) shows that many of these automated metrics correlate poorly

[4]PHOENIX and CSL-Daily feature 1066 and 2000 signs.

with human judgment on a per-sample basis. They propose MoBERT, a BERT-based learned evaluator, which achieves higher agreement with human ratings, highlighting the ongoing challenge of designing semantically meaningful motion evaluation.

2.4 Sign Language Assessment

SLA research compares student-produced signing against canonical references. Cory et al. (2024) evaluates sign language proficiency by modeling the natural distribution of signing motion across multiple references and demonstrating a strong correlation with human ratings. Tarigopula et al. (2024, 2025) proposes a posterior-based analysis of skeletal or spatio-temporal features to assess both manual and non-manual signing components, improving alignment with human evaluation as well.

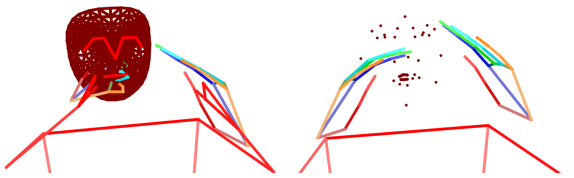
3 Evaluation Metrics

In this section, we formally define common evaluation metrics mentioned in related work (§2) and implement them, reusing open-source code where available, to prepare for the upcoming empirical study on pose evaluation in §4 and §5.

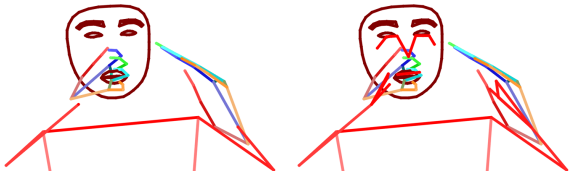
3.1 Keypoint Distance-Based Metrics

We borrow keypoint distance-based metrics from prior work on sign language generation, notably Ham2Pose (Arkushin et al., 2023). These metrics, e.g., APE (Average Position Error)—initially developed for general pose estimation and motion analysis—quantify geometric similarity using frame-wise errors and alignment strategies. However, they are not designed for sign language and ignore critical linguistic properties such as signer speed variation, hand dominance, and missing keypoints. Moreover, they have not been systematically validated against human judgments in sign language contexts, motivating our extended investigation.

During (re-)implementation, we identify significant sources of variation that affect the outcomes of distance-based metrics: (a) whether and how the coordinate values of the keypoints are normalized (e.g., based on the shoulder position as the origin $(0, 0)$ and the shoulder width being 1); (b) whether videos are trimmed to exclude signing-inactive frames; (c) which subset of the keypoints from the pose estimation library is selected for comparison (Figure 2; e.g., hands-only vs. full body); (d) how framerate mismatches are handled (e.g., interpolating to a consistent FPS); (e) how masked

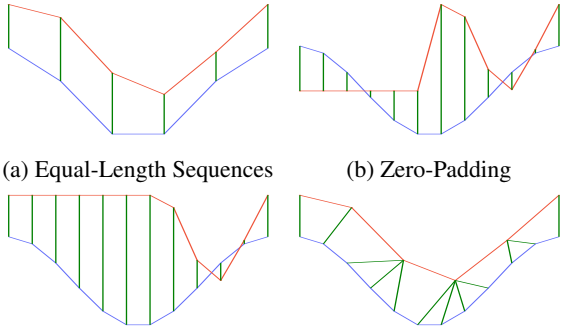


(a) Full (586 Points) (Grishchenko and Bazarevsky, 2020)
(b) YouTube-ASL (85 Points) (Uthus et al., 2023)



(c) Face-contour (178 Points) (Moryossef et al., 2021a)
(d) SignCLIP (203 Points) (Jiang et al., 2024)

Figure 2: MediaPipe keypoint selection strategies.



(a) Equal-Length Sequences
(b) Zero-Padding
(c) Pad with First Frame
(d) Dynamic Time Warping

Figure 3: Sequence alignment (in green) between a shorter sequence (in red) and longer sequence (in blue). In reality, pose keypoint trajectories are aligned temporally in 3D and then averaged for the whole body. Paddings take values from the first frame or simply 0s.

or missing keypoints are treated (e.g., filled with a value, or a default distance returned, or simply ignored); and (f) how sequences of unequal length are aligned before applying APE (Figure 3; e.g., using zero-padding, frame repetition, or DTW).

We examine these variations and provide a reproducible toolkit that enables tuning these design choices explicitly—including keypoint selection, normalization, and masking, sequence trimming and alignment with different distance measures—rather than inheriting arbitrary defaults. The toolkit supports the generation of possibly thousands of metric variants to be tested in §4.

3.2 Embedding-Based Metrics

Rather than operating on the keypoints' raw spatial positions, we categorize embedding-based metrics that calculate distance or similarity in a latent em-

bedding space provided by a trained model.

3.2.1 Sign Language Assessment Metrics

We adopt two metrics for comparing two poses from the SLA task (§2.4): the Skeleton Variational Autoencoder (SkeletonVAE) model from Cory et al. (2024) and the posterior-based scores from assessment models developed in Tarigopula et al. (2024).

SkeletonVAE Score The SkeletonVAE is trained to produce a per-frame latent embedding. 2D MediaPipe poses are first uplifted to constrained 3D skeletons using the method of Ivashechkin et al. (2023) and then embedded into a 10-dimensional β-VAE latent space (Higgins et al., 2017). We define *SkeletonVAE Score* as the L2 distance between the reference and hypothesis sequences' DTW-aligned latent trajectories, optionally normalized by the DTW path length.

Skeleton Posterior-based SKL Score Following Tarigopula et al. (2024), we first extract two sets of linguistically informed features from the pose sequences with the same missing keypoint preprocessing as Eq. 6 in Arkushin et al. (2023). For hand movement, we compute 36-dimensional feature vectors representing hand position and velocity relative to the head, shoulders, and hips with a temporal context of 9 frames. For handshape, we calculate joint positions relative to the wrist and input them into a separate MLP to obtain handshape posteriors. The resulting stack of shape and movement posteriors from both the reference and hypothesis examples is then aligned using DTW with a cost function based on the Symmetric Kullback–Leibler (SKL) divergence. The cost is aggregated over the DTW time steps as the final score with two variants–*SKL_mvt Score* (movement only) and *SKL_mvt_hshp Score* (movement + handshape), respectively.

3.2.2 SignCLIP Score

One step further than §3.2.1, we follow *CLIPScore* (Hessel et al., 2021) and use SignCLIP (Jiang et al., 2024), a model repurposed for representing sign language poses by multilingual contrastive learning, to derive *SignCLIPScore P-P* (pose-to-pose), based on the dot product of the embeddings of the reference and hypothesis on the example level instead of frame-level latents plus DTW alignment.

Reference-Free Quality Estimation Variant We introduce *SignCLIPScore P-T* (pose-to-text). It computes the dot product between the text and pose embedding, eliminating reliance on scarce or even unreliable ground-truth signing references (Freitag et al., 2023).

3.3 Back-Translation-Based Metrics

Assuming the existence of the corresponding spoken language text and a reliable pose-to-text SLT model, we can evaluate a sign language pose by: (a) *Sampling*: translate the pose sequence into text, then compare with the source text using BLEU[5], chrF[6], or BLEURT. (b) *Scoring*: compute the log-likelihood of the text given the pose sequence as input to the SLT model. This avoids errors introduced by decoding and supports more consistent comparisons across systems. In this study, we adopt an SLT model from Zhang et al. (2024a), which is pretrained on a large-scale YouTube SLT corpus and massive MT data. We use *system 8* from their study (*YT-Full + Aug-YT-ASL&MT-Large + ByT5 XL*), i.e., the current state of the art, and preprocess the generated pose sequences by selecting the same 85 keypoints specified in their paper[7].

4 Automatic Meta-Evaluation

In this section, we explore methods to automatically (meta-)evaluate proposed metrics, especially when there are many variants as seen in §3.1.

We adopt the retrieval-based evaluation protocol from Arkushin et al. (2023) to assess how well different metrics capture meaningful distinctions between signs. Each pose sequence is treated as a query, and the goal is to retrieve other samples of the same sign (*targets*) from a pool that includes unrelated signs (*distractors*). We focus primarily on the distance-based metric variants introduced in §3.1, and compare them against embedding-based alternatives such as *SignCLIP Score* (§3.2.2).

Evaluation is conducted on a combined ASL dataset of ASL Citizen (Desai et al., 2023), SemLex (Kezar et al., 2023), and PopSign ASL (Starner et al., 2023). For each sign/gloss, we use all available samples as targets and sample four times as many distractors, yielding a 1:4 target-to-distractor ratio. For instance, for the sign *HOUSE* with 40 samples (11 from ASL Citizen, 29 from Sem-Lex), we add 160 distractors and compute pairwise dis-

SignCLIPScore P-P (multilingual)						50%	48%
SignCLIPScore P-P (ASL finetuned)						**91%**	**92%**

Table 2: Automatic meta-evaluation of reference-based evaluation metrics on sign retrieval across various settings: (a)-(f) enumerated in section 3.1. The table presents a representative subset of top-performing metrics. *Fill* indicates the value used to fill in missing keypoint; *zero* indicates zero-padding; *first-frame* indicates padding with the first frame. *YT-ASL* includes a subset of keypoints used and described in Uthus et al. (2023). *Reduced* includes a subset of keypoints used and described in Jiang et al. (2024). * Ham2Pose nAPE implements missing-filling slightly differently–filling in zeros for both trajectories if one of them has a missing value (see details in Appendix A).

tance from each target to all 199 other examples. The pairwise distance is defined by each of these proposed metric scores. Retrieval quality is measured using Mean Average Precision (mAP↑) and Precision@10 (P@10↑). The full evaluation covers 5362 unique signs and 82,099 pose sequences. After several pilot runs to rule out clear bad choices, we finalize a subset of 169 signs with at most 20 samples each, and evaluate 48 representative keypoint distance-based metric candidates and *SignCLIP Score* with different SignCLIP checkpoints provided by the authors[8] on this subset. For reference, we also reproduce the metrics proposed by Arkushin et al. (2023). The key results, including the best metrics, are presented in Table 2.

[8] https://github.com/J22Melody/fairseq/tree/main/examples/MMPT#demo-and-model-weights

The results show that, as expected, DTW-based metrics outperform padding-based APE baselines. While selecting hands-only keypoints appears to yield the best results, a more sophisticated selection that includes non-manuals might still be desirable. Embedding-based methods, particularly SignCLIP models fine-tuned on in-domain ASL data, achieve the strongest retrieval scores. We mark the two best DTW-based metrics by ‡ and †, and rename them *DTWp* and *nDTWp* for use in the rest of the paper.

5 Text-to-Pose Translation Study with Human Evaluation

This section shifts our evaluation focus from automatic sign-level tasks to a sentence-level text-to-pose sign language machine translation scenario. Due to their subjective and diverse nature, open-

ended text or utterance generation tasks inherently lack a single "correct"/"ground-truth" answer. Consequently, **automatic evaluation metrics are only *meaningful* if they correlate closely with human judgments** (Reiter, 2018; Sellam et al., 2020).

5.1 Dataset: WMT-SLT Signsuisse

We use the Signsuisse dataset released in the WMT-SLT 23 campaign. The dataset comprises 18,221 lexical items in three spoken-sign language pairs, represented as videos and glosses. One signed example sentence for each lexical item is presented in a video along with the corresponding spoken language translation, which forms parallel data between the sign and spoken languages. The test set is used to test different text-to-pose translation systems. It contains 500 German/Swiss German Sign Language (DSGS) segments, 250 French/French Sign Language (LSF) segments, and 250 Italian/Italian Sign Language (LIS) segments.

5.2 Systems

We utilize three text-to-pose translation systems that convert spoken language text inputs into corresponding sign language represented by the MediaPipe Holistic pose formats.

Reference* MediaPipe poses are estimated from the reference translation videos, i.e., ground truth.

sign.mt Based on Moryossef et al. (2023b), this open system converts text into sign language glosses through rule-based reordering and selective word dropping. Glosses are mapped to skeletal poses retrieved from a lexicon and are then concatenated to form coherent sequences. When a gloss is missing from the lexicon, the system defaults to fingerspelling the corresponding word.

sign.mt v2 During evaluation, we found that frequent fingerspelling of missing glosses was cumbersome and frustrating for evaluators. Therefore, in this version, we opted to omit glosses without lexical mappings, acknowledging that while this may result in information loss, it significantly improves user experience and evaluation efficiency.

Sockeye We adapt Sockeye (Hieber et al., 2022) to continuous pose sequences by modifying both the encoder and decoder to handle continuous sequences. The text-to-pose Sockeye model is trained on the Signsuisse training set with 60k updates on a 32GB NVIDIA Tesla V100 GPU.

To avoid exposure bias—where the decoder overfits to gold frames and fails at inference, we first predict only the initial pose y_1 from the encoder output, then feed y_1 as input for all subsequent steps $y_{2:n}$, training the decoder to output frame-to-frame deltas $\Delta y_t = y_t - y_1$ instead of absolute poses. Since the target sequence is continuous, we replace the cross-entropy loss function with mean squared error on the poses. Additionally, there is no `<EOS>` token with continuous output; instead, we learn to output the length of the pose sequence based on the length ratios from the training data. We provide the link to the adapted Sockeye repository and a demo of translation output.

5.3 Human Evaluation

We collect system translations and use Appraise (Federmann (2018); Figure 4) to allow evaluators to rate the translations on a continuous scale between 0 and 100 as in traditional direct assessment (Graham et al., 2013; Cettolo et al., 2017) but with 0-6 markings on the analogue slider and custom annotator guidelines designed explicitly for our task (similar to WMT-SLT, but reverse translation direction). Evaluation instructions are sent out in DSGS, LSF, and LIS, which are translations of the respective spoken language instructions in WMT-SLT. The instructions are attached in Appendix B.

We hire seven DSGS, two LSF, and four LIS evaluators, all of whom are native deaf sign language users[9]. All work is done with informed consent in written and signed form. Of the seven native DSGS deaf signers, four have never participated in such an evaluation campaign before, two have participated once, and one has attended more than once. Concerning their professional backgrounds, four are deaf translators; one also interprets live. Complete demographics are presented in Table 4.

An initial round of evaluation informs us about the cost, roughly 100 example segments per hour, with a compensation of ∼40 USD per hour. Evaluators also provide constructive feedback on the Appraise platform and the translation systems, which results in the switching into the v2 version of sign.mt. Therefore, the number of evaluated examples varies slightly between systems and languages.

Statistics The evaluation comprises 2650 unique examples and 11,471 ratings across all four systems (3275 reference, 4032 Sockeye, 861 sign.mt,

[9]One additional DSGS evaluator, a hearing interpreter, did a pilot study with us to test the Appraise system.

Table 3: Segment-level Spearman correlations with average human judgments calculated for several pose-based evaluation metrics for sign language. nAPE=`normalized APE`, nDTW=`normalized DTW-MJE` (two metrics taken from Arkushin et al. (2023) and re-implemented for MediaPipe, normalized by pose shoulder); DTWp=`DTW+Trim+MaskFill10.0+Hands-Only`, nDTWp=`DTW+MaskFill1.0+Norm.+Hands-Only` (top metrics selected in §4 implemented by `pose-evaluation`, denoted by ‡ and † in Table 2, without/with pose normalization, respectively); SVAE=`SkeletonVAE Score`, SVAE$_n$=`SVAE normalized by DTW path`, SKL=`SKL_mvt Score`, SKL$_h$=`SKL_mvt_hshp Score`; P-P=`Pose-to-pose embedding distance`, P-T=`Pose-to-text embedding distance`; B4=`BLEU-4`, chrF=`chrF`, B-RT=`BLEURT`, Lik. =`Likelihood`. H* denotes mean inter-evaluator Spearman correlation. SD represents the standard deviation across each column and is expected to be small for an ideal metric.

and 3303 sign.mt v2) and three language pairs (7861 DSGS, 1210 LSF, and 2400 LIS).

We follow the practices set by WMT-SLT. The inter-annotator agreement, measured with an approximation of Fleiss κ (Fleiss, 1971) by discretizing the continuous scale 0-100 in seven bins in the scale 0-6, is $\kappa = 0.36 \pm 0.05$. We also randomly mix 500 references and some repeated hypothesis segments for sanity checks and quality control. The mean intra-annotator agreement over all evaluators is $\kappa = 0.49 \pm 0.09$, calculated over 50-100 segments evaluated twice by the same evaluator. We find the inter- and intra-annotator agreement to be lower than in the WMT-SLT study for the sign-to-text translation direction, and posit that the lack of a clear definition and criteria for translation quality in sign language poses a significant challenge.

	Evaluation experience			SL professional			Avg yr.
	Never	Once	> Once	Translator	Interpreter	Teacher	
DSGS (7)	4	2	1	4	1	4	39.0
LSF (2)	0	1	1	1	0	1	35.0
LIS (4)	1	1	2	3	4	0	42.5

Table 4: Raters overview: system evaluation and professional experience with sign language, average number of years signing (in most cases equivalent to age).

5.4 Correlation Analysis

We perform a correlation analysis between the metrics proposed in §3 and the human scores averaged over evaluators at the segment level, as presented in Table 3. The metrics are divided into families, where *reference-based* means that the quality of the translated poses is measured in relation to reference poses derived from signing videos. The absolute scores per metric/system are presented in Table 5.

For the distance-based metrics, we reproduce *nAPE* and *nDTW(-MJE)* for MediaPipe poses based on the open implementation from Arkushin et al. (2023) as a reference, and additionally compare them to the best-performing metrics informed by the automatic meta-evaluation in §4 on ASL, a different sign language. We flip the signs of the metrics that quantify errors to keep a positive correlation for analytical convenience. Row-wise, we first break down the correlation by system and language into relevant rows, and then present the overall correlation, including all systems and languages, to reflect performance at the system level.

6 Discussion and Recommendations

Distance-based metrics are efficient defaults, but the devil is in the implementation details. Although seemingly straightforward to implement, distance-based metrics involve many design choices, including pose format and keypoint selection. We empirically demonstrate the effectiveness of correcting these choices through a random parameter search, following our established meta-evaluation protocols in §4. We recommend using the tuned versions—*DTWp* and

Table 5: Mean absolute scores for each metric across systems. Rows and columns mirror those in Table 3.

nDTWp—in our `pose-evaluation` library, or tuning your distance-based metrics when necessary.

Upon successful tuning, a distance-based metric achieves decent sign retrieval and correlation with humans in text-to-pose translation. Our tuned metrics can even be used as a distance function for a nearest neighbor classifier[10], and reach close performance as the SignCLIP model pretrained on multilingual sign language data; still, it lags behind a SignCLIP model fine-tuned on in-domain data (Table 2). When used to evaluate translation output, keypoint distance-based metrics can range from negatively correlated with human judgments (as seen for *nAPE* and *nDTW*), to being the best metrics tested. *DTWp* wins the overall correlation while *nDTWp* is more sensitive on the segment level within a specific system (Table 3).

SLA metrics correlate with humans on the segment level but are confused on the system level. While verified to align with human ratings for their tasks on evaluating human-produced signing (usually involving fixed individual signs), text-to-pose translation is more lengthy and open-ended, which hinders direct transferability. A proper length normalization (as seen in the case of *SVAE*$_n$ vs. *SVAE*) might help on the system level at the price of losing precision on the segment level.

SignCLIP, used as a multilingual embedding device, excels on the sign level, but falls short for sentence-level translation evaluation. We speculate that using a single embedding to summarize a long-duration ($>$ 10 seconds) signing video is inherently limited, especially for DSGS, a language unseen during SignCLIP's pretraining. Nevertheless, the reference-free variant exhibits a moderate correlation at the system level, and we observe a similar tradeoff (*P-P* vs. *P-T*) between segment and system level correlations, as seen in the SLA metrics.

[10]Upon quick experimentation, *nDTWp* with KNN (n=10) achieves 19% ISLR accuracy on the ASL Citizen test set. We leave a more systematic evaluation on this end to future work.

Back-translation-based approaches correlate properly with human judgment; a gap remains compared to inter-human correlation. In addition to the standard practices suggested by Müller et al. (2023b) on computing text-based metrics, we call for open, standardized pose-to-text translation models that include both the model weights and the source code. Yet, as noted in Table 1, this is hardly the case in current research, and having a dedicated back-translation model for each translation direction (or even dataset) is a luxury. The above-mentioned metrics, which do not rely on in-domain data but function to a decent degree, are valuable in a more generic setting. Human evaluation shall be used as the final quality assessment resort.

When using back translation, likelihood is consistent and more reliable than text metrics. BLEU, chrF, and BLEURT show weaker or unstable correlations with humans in Table 3. It is recommended that back-translation likelihood be included as a primary metric when a pose-to-text model is available.

7 Conclusion

This work presents a unified framework and an open-source `pose-evaluation` toolkit for systematically assessing (generated) sign language utterances based on human skeletal poses. We implemented and compared a wide range of metrics (§3)—distance-based, embedding-based, and back-translation-based—via automatic meta-evaluation on sign retrieval (§4) and a comprehensive human correlation study across three sign languages (§5). Our results demonstrate that carefully tuned distance metrics, namely *DTWp* and *nDTWp*, and back-translation likelihoods yield the strongest agreement with native signer judgments. We release our code, evaluation protocols, and human ratings to foster reproducible and fair comparisons in computational sign language research.

8 Limitations

8.1 3D Pose Representation

While our study focuses on using MediaPipe Holistic as the pose format for representing sign language motion, other specifics, especially the recently developed 3D SMPL-X (Pavlakos et al., 2019) would be a visually more expressive choice. However, the lack of a common way to extract and use 3D poses as easily as MediaPipe Holistic makes the latter the most used choice in SLP.

8.2 Missing Publicly Available Systems

Our study is further limited by the number of public systems (Table 1) we can use to run the correlation analysis, unless we implement everything from scratch (including the pose estimation pipelines, text-to-pose systems, and back-translation models). We hope the release of this work will alleviate the situation.

8.3 Automatic Evaluation beyond Sign Level

The automatic meta-evaluation in §4 is capped by the sign-level retrieval task, and we envision extending it to the phrase level. One possible approach is to leverage the Platonic Representation Hypothesis proposed by Huh et al. (2024). In the pose evaluation scenario, we hypothesize that the similarity given by a good pose metric between two pose segments should correlate with the similarity given by a text embedding model between the two text segments paired with the two pose segments, respectively. We leave exploration on this end for future work, which will likely connect the automatic meta-evaluation more closely to the sentence-level human correlation study in §5.

8.4 Tokenized Evaluation

Inspired by how text metrics like BLEU collect surface-form overlapping statistics, we envision a tokenized evaluation as promising for sign language evaluation. Although a sign language pose sequence cannot be discretely tokenized and matched like text tokens, the combination of a sign language segmentation model (Moryossef et al., 2023a) plus SignCLIP embedding can be utilized in a way similar to BERTScore (Zhang* et al., 2020), where a similarity matrix is constructed between the reference and hypothesis tokens to derive the final similarity score on phrase level.

Acknowledgments

This work is funded by the Swiss Innovation Agency (Innosuisse) flagship IICT (PFFS-21-47) and by the SIGMA project at the UZH Digital Society Initiative (DSI).

We thank the deaf evaluators for their efforts in the human evaluation and valuable feedback on the evaluated systems. We thank SWISS TXT for helping organize the evaluation campaign. We thank Roman Grundkiewicz for troubleshooting the Appraise platform and thank Lisa Arter for a pilot test on it. We thank Andreas Säuberli for the insightful discussion on inter-annotator agreement. We also thank Garrett Tanzer for answering questions about the MediaPipe version used in Google's pose-to-text translation system, and Ronglai Zuo for the advice on the paper draft.

A Ham2Pose Metrics Re-Implementation via `pose-evaluation`

`pose-evaluation` toolkit enables the flexible creation of various metrics and pose processing pipelines. We successfully re-implemented the *nMSE*, *nAPE*, and *nDTW-MJE* metrics, and verified that the new implementation gave exactly identical results on a small collection of test files.

All metrics share certain preprocessing steps before comparison, in this order:

1. Remove `world landmarks`.
2. Calling the `reduce_holistic` function from the `pose-format` library, effectively reducing the keypoints to the face contour and the upper body.
3. Normalization by shoulder joints.
4. Hide low-confidence joint predictions.

In addition, *nMSE* and *nAPE* metrics do trajectory-based preprocessing, for each pair of keypoint trajectories:

1. Zero-pad the shorter trajectory.
2. Fill with zeros anywhere where either one of the trajectories is missing a value. For example, if trajectory A had [7, —, 7] and trajectory B had [—,8,8], the result would be thus: Trajectory A: [0,0,7], B: [0,0,8].

In contrast, the metrics implemented for the automatic meta-evaluation in §4, e.g., `DTW+Trim+MaskFill10.0+Hands-Only`, behave differently, filling each pose in without regard to the other. The result of trajectory A = [7,—,7] vs Trajectory B [—,8,8] would thus become A = [7,10,7] vs Trajectory B [10,8,8].

B Extended Human Evaluation Details

Figure 4 presents a screenshot of the Appraise platform we customized for the text-to-pose evaluation, where the instruction text is translated into English. The sign language versions of the instructions are linked: DSGS, LSF, LIS. The original text instructions in German, French, and Italian are below:

German Unten sehen Sie 10 Sätzen auf Deutsch (linke Spalten) und die entsprechenden möglichen Übersetzungen in Deutschschweizer Gebärdensprache (DSGS) (rechte Spalten). Bewerten Sie jede mögliche Übersetzung des Satzes. Sie können bereits bewertete Sätze jederzeit durch Anklicken eines Quelltextes erneut aufrufen und die Bewertung aktualisieren.

Bewerten Sie die Übersetzungsqualität auf einer kontinuierlichen Skala mit Hilfe der nachfolgend beschriebenen Qualitätsstufen:

0: Unsinn/Bedeutung nicht erhalten: Fast alle Informationen zwischen Übersetzung und Ausgangstext sind verloren gegangen. Es ist irrelevant, ob die Bewegungen natürlich sind.

2: Ein Teil der Bedeutung ist erhalten: Die Übersetzung behält einen Teil der Bedeutung der Quelle bei, lässt aber wichtige Teile aus. Die Erzählung ist aufgrund von grundlegenden Fehlern schwer zu verstehen. Bewegungen können mangelhaft sein.

4: Der grösste Teil der Bedeutung ist erhalten und die Bewegungen sind akzeptabel: Die Übersetzung behält den grössten Teil der Bedeutung der Quelle bei. Sie kann kleine Fehler oder kleinere kontextuelle Unstimmigkeiten aufweisen. Bewegungen sehen teilweise nicht natürlich aus.

6: Perfekte Bedeutung und Natürlichkeit: Die Bedeutung der Übersetzung stimmt vollständig mit der Quelle und dem umgebenden Kontext (falls zutreffend) überein. Bewegungen wirken natürlich.

French Vous voyez ci-dessous un document avec 10 phrases en français (colonnes de gauche) et leurs traductions candidates correspondantes langue des signes française (LSF) (colonnes de droite). Veuillez attribuer un score à chaque traduction possible de la phrase dans le contexte du document. Vous pouvez revisiter les phrases déjà évaluées et mettre à jour leurs scores à tout moment en cliquant sur un texte source.

Évaluez la qualité de la traduction sur une échelle continue en utilisant les niveaux de qualité décrits ci-dessous:

0: Absence de sens/aucune signification préservée: Presque toutes les informations sont perdues entre la traduction et la source. Le caractère naturel du mouvement n'est pas pertinent.

2: Une partie du sens est préservée: La traduction préserve une partie du sens de la source mais omet des parties importantes. Le récit est difficile à suivre en raison d'erreurs fondamentales. Le mouvement n'est pas toujours naturel.

4: La majeure partie du sens est préservée et le caractère naturel du mouvement est acceptable: La traduction conserve la majeure partie du sens de la source. Elle peut comporter quelques erreurs

mineures ou des incohérences contextuelles. Le mouvement peut sembler peu naturel.

6: Sens parfait et mouvements naturels: Le sens de la traduction est totalement cohérent avec la source et le contexte environnant (le cas échéant). Les mouvements sont naturels.

Italian Qui sotto trovate un documento con 10 frasi in italiano (colonne di sinistra) e lecorrispondenti possibili traduzioni nella lingua dei segni italiana (LIS) (colonne di destra). Valutate ogni possibile traduzione della frase nel contesto del documento. Potete rivedere le frasi valutate in precedenza e aggiornarne le valutazioni in qualsiasi momento cliccando sul testo sorgente.

Valutate la qualità della traduzione su una scala continua utilizzando i livelli di qualità descritti di seguito:

0: Privo di senso/significato non conservato: Quasi tutte le informazioni tra la traduzione e il testo sorgente sono andate perse. La naturalezza del movimento è inconsistente.

2: Parte del significato è conservato: La traduzione conserva parte del significato del testo sorgente, ma omette parti importanti. La narrazione è difficile da capire a causa di errori fondamentali. La naturalezza del movimento può essere insufficiente.

4: La maggior parte del significato è conservato e il movimento è accettabile: La traduzione conserva la maggior parte del significato del testo sorgente. Può contenere errori o discrepanze contestuali di entità minore. Il movimento può sembrare innaturale.

6: Significato perfetto e naturalezza: Il significato della traduzione è completamente coerente con il testo sorgente e con il contesto dato (se applicabile). Il movimento sembra naturale.

Context is Ubiquitous, but Rarely Changes Judgments: Revisiting Document-Level MT Evaluation

Ahrii Kim
AI-Bio Convergence Research Institute
South Korea
ahriikim@gmail.com
trotacodigos/H-FALCON.git

Abstract

As sentence-level performance in modern Machine Translation (MT) has plateaued, reliable document-level evaluation is increasingly needed. While the recent FALCON framework with pragmatic features offers a promising direction, its reliability and reproducibility are unclear. We address this gap through human evaluation, analyzing sources of low inter-annotator agreement and identifying key factors. Based on these findings, we introduce **H-FALCON**, a **H**uman-centered refinement of FALCON. Our experiments show that, even with limited annotator consensus, H-FALCON achieves correlations comparable to or better than standard sentence-level protocols.

Furthermore, we find that contextual information is inherent in all sentences, challenging the view that only some require it. This suggests that prior estimates such as "n% of sentences require context" may stem from methodological artifacts. At the same time, we show that while context is pervasive, not all of it directly influences human judgment.

1 Introduction

The conventional approach to automatic machine translation (MT) evaluation has focused primarily on sentence-level analysis, emphasizing lexical overlap or n-gram similarity, as seen in BLEU (Papineni et al., 2002), METEOR (Banerjee and Lavie, 2005), and chrF (Popović, 2015). More recent methods account for semantic similarity through embedding-based metrics such as BERTScore (Zhang et al., 2019) and COMET (Rei et al., 2020), while LLM-based (large language model) metrics, including XCOMET (Guerreiro et al., 2024) and Meta-Metrics (Anugraha et al., 2024), demonstrate improved alignment with human judgments. Despite these advances, their scope remains confined to sentence-level evaluation, failing to capture discourse phenomena such as cohesion, coreference, consistency, and pragmatic adequacy. Document-level metrics have been proposed (Jwalapuram et al. 2021; Zhao et al. 2023; Jiang et al. 2022), but they typically target narrow aspects of discourse and lack comprehensive coverage.

Human evaluation at the document level poses additional challenges due to the complexity of quantifying context-dependent phenomena. Approaches that rely only on overt discourse markers risk underestimating the role of context (Voita et al. 2019; Castilho 2022). Furthermore, protocols vary in context length, annotation granularity, and guideline specificity (Hardmeier et al. 2015; Kocmi et al. 2022). The resulting cognitive burden on evaluators can lead to longer annotation times and reduced inter-annotator agreement (IAA) (Läubli et al., 2018; Bawden et al., 2018; Graham et al., 2017). Collectively, these factors render document-level evaluation both methodologically complex and resource-intensive, limiting its adoption in MT research and practice (Sharma and Sridhar, 2025).

To address this gap, the FALCON framework (**F**unctional **A**ssessment of **L**anguage and **Co**ntextuality in **N**arratives; Kim 2025) integrates pragmatic features into a structured document-level protocol, with LLMs as judges. However, its human evaluation component remains underdeveloped and untested for reproducibility and reliability. We therefore conduct a meta-evaluation of FALCON through human assessments with professional translators, and extend the protocol by introducing H-FALCON, a reproducible and streamlined human evaluation framework. Our contributions are as follows:

- Conduct the first systematic reliability study of FALCON, identifying sources of inter-annotator variation,
- Provide a comprehensive meta-evaluation of FALCON across diverse proprietary models, revealing its limitations,

Proceedings of the Tenth Conference on Machine Translation, pages 81–97
November 8-9, 2025

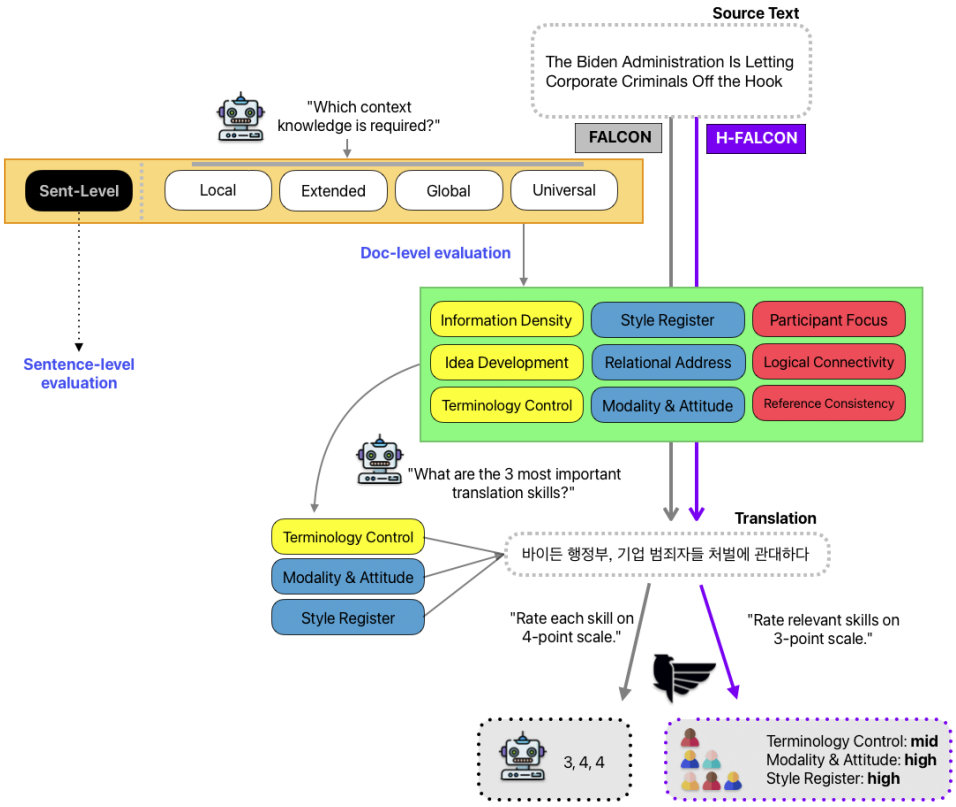

Figure 1: The evaluation process of FALCON consisting of labeling 1) relevant context knowledge and 2) assessment of translation skills, accompanied by 3) rating. This dual-phase process is integrated in H-FALCON by simultaneously conducting labeling and rating for all sentences.

- Introduce H-FALCON, a simplified and reliable protocol for document-level human evaluation,
- Present evidence that contextual information is inherent in all sentences,
- Demonstrate statistically that document-level evaluation contributes 10% to holistic evaluation scores.

2 Related Works

Document-level evaluation is not merely a scaled-up version of sentence-level evaluation; it captures translation phenomena that rely on extended context, such as coreference resolution, lexical cohesion, discourse connectives, and pragmatic intent (Thai et al. 2022; Dahan et al. 2024). These features recur across the document, with evidence distributed over multiple segments, shaping a distinctive atmosphere or nuance (Halliday and Matthiessen, 2004). Evaluating such phenomena enables a more accurate assessment of MT systems that appear statistically indistinguishable at the sentence level (Sharma and Sridhar, 2025). This section reviews prior efforts in both manual (§ 2.1) and automatic (§ 2.2) evaluation of document-level phenomena, including FALCON (§ 2.3).

2.1 For Manual Evaluation

The most visited sentence-level evaluation frameworks are MQM (Multidimensional Quality Metrics; Lommel et al. 2014) and TAUS DQF (Dynamic Quality Framework; Valli 2015). Their comprehensive error categories encompass some discourse elements such as *Language register* and *Inconsistent use of terminology*,[1], but predominantly focus on textual quality.

Document-level evaluation was initially driven by community efforts such as DiscoMT (Workshop on Discourse in Machine Translation; Hardmeier et al. 2015) and WMT (Conference on Machine Translation). Barrault et al. (2019) proposed a document-level scoring protocol (DR+DC), but its effectiveness was limited by low statistical power, often producing tied rankings. As a result, evaluations were shifted to the sentence level, either by considering adjacent segments (SR+DC) (Barrault et al., 2019) or entire documents (SR+FD)

[1] https://themqm.org/the-mqm-full-typology/

(Akhbardeh et al., 2021) to assess cross-sentence dependencies. The SR+DC approach later became standard practice (Kocmi et al. 2022; Kocmi et al. 2023), with Kocmi et al. (2024) extending the context window to ten consecutive sentences. In parallel, new error categories were introduced for discourse-related issues such as *Accuracy/Gender mismatch* and *Style/Archaic or obscure word choice* (Freitag et al., 2024). While these initiatives primarily focus on contextual conveyance, **our work broadens error typology by shifting from textual to discourse-level quality, systematically incorporating pragmatic, referential, and thematic dimensions into a structured protocol.**

2.2 For Automatic Evaluation

On the machine side, several automatic metrics have been developed to better capture discourse and context in MT evaluation. DiscoScore (Zhao et al., 2023) explicitly models discourse relations and coreference chains to assess cohesion and coherence. BlonDE (Jiang et al., 2022) integrates lexical, syntactic, semantic, and discourse-level features, making it suitable for narrative and dialogic text. Doc-COMET (Vernikos et al., 2022) extends COMET (Rei et al., 2020) to accept document-level inputs, leveraging contextual embeddings to evaluate translations within their broader discourse environment. While these approaches mark progress toward automated document-level evaluation, they generally emphasize only one or two discourse aspects—such as coherence or coreference—rather than offering a comprehensive, structured assessment of discourse phenomena.

Another line of research has focused on test suites targeting specific discourse elements. These include domain-specific investigations (Vojtěchová et al. 2019; Biçici 2019; Mukherjee and Yadav 2024; Bhattacharjee et al. 2024; Rozanov et al. 2024; Bawden and Sagot 2023), studies examining linguistic features (Avramidis et al. 2019; Popović 2019; Raganato et al. 2019; Zouhar et al. 2020; Macketanz et al. 2021; Manakhimova et al. 2023; Savoldi et al. 2023; Ármannsson et al. 2024; Friðriksdóttir 2024; Manakhimova and Macketanz 2024; Dawkins et al. 2024), and analyses incorporating discourse phenomena (Rysová et al. 2019; Kocmi et al. 2020; Avramidis et al. 2020; Scherrer et al. 2020; Mukherjee and Shrivastava 2023). DiscoBench (Wang et al., 2023) further addresses discourse-sensitive content, detecting pronoun mistranslation, topic drift, and other cross-sentence errors overlooked by sentence-level metrics.

Overall, these benchmarks highlight that document-level evaluation introduces qualitatively distinct challenges and opportunities, necessitating dedicated protocols and models for holistic MT quality assessment.

2.3 The FALCON Framework

FALCON (Functional Assessment of Language and Contextuality in Narratives; Kim 2025) proposes a structured protocol for document-level MT evaluation by incorporating pragmatic and discourse-level factors into a unified scoring scheme. It rests on two hypotheses:

(a) Document-level evaluation can be approximated at the sentence level if contextual information is effectively propagated across sentences.

(b) Such information can be inferred solely from the source, independent of the target language.

Discourse phenomena are classified into three meta-categories (MODE, TENOR, FIELD) and nine subcategories (specified in §3) collectively termed "translation skills." For each sentence, the judge selects the three most salient skills, with this restriction enhancing scoring stability.

Sentences not requiring context are first excluded through a labeling step, where annotators assign one of five context types (specified in §3). In the subsequent rating stage, each selected skill receives a 4-point score, as illustrated in Figure 1. Scores are then aggregated per segment or skill set to yield interpretable document-level indicators.

This protocol has so far been validated only indirectly: human annotators were asked to judge whether the model' s selections were appropriate, yielding an acceptance rate of 80.4% for context labeling and 71.6% for skill selection. However, no direct evaluation from a classification perspective has been conducted, which is the focus of the present study. Additional concerns may arise from the way context is presented, but this issue falls outside the scope of our work.

3 Experiment Setup

We conduct direct human evaluation of FALCON across two tasks and assess whether the current experimental design yields reproducible human judgments (§4). Using these gold annotations, we

Domain	Dataset	#Doc	#Seg	#Sent/Doc	#Sent/Seg
Canary	Original	1	1	–	–
	Ours	–	–	–	–

	Ours	–	–	–	–
All	Original	171	998	30.73	3.27
	Ours	38	809	22.53	1.06

Table 1: Comparison of dataset statistics between the original WMT24++ corpus and our filtered dataset. Here, **Seg** denotes a segment (paragraph in WMT24++), and sentence counts are reported per document and segment.

further perform a meta-evaluation to validate the framework's reliability (§5). The tasks are:

Task I: Context Knowledge Judges assign one of five levels of contextual knowledge required for translation: Sentence-level, Local, Extended, Global, Universal.

Task II: Translation Skills Judges select the three most relevant skills from nine predefined categories: Information Density, Idea Development, Terminology Control, Style Register, Relational Address, Modality & Attitude, Reference Consistency, Participant Focus, Logical Connectivity.

3.1 Dataset

The original WMT24++ English–Korean dataset (Deutsch et al., 2025) contains 998 segments from four domains (social, news, speech, and literary) with translations from ten systems. Because many segments span multiple sentences, it is unsuitable for our *sentence-level* design.

We construct a filtered subset while preserving domain balance. The speech domain is removed, as each document corresponds to a single segment without context, and the literary domain is partially pruned due to disproportionate length. Sentences with hyperlinks, hashtags, or timestamps are discarded, while emojis and user tags are retained as they are considered relevant to the evaluation.

The remaining data are re-segmented into individual sentences using NLTK (Bird et al., 2009) for English and KSS[2] for Korean. Source, target, and reference segments are automatically aligned with newline markers and then manually verified. For translation, we select the best-performing system (based on COMET scores), assuming that context-aware translation is unlikely from low-quality systems.

The final evaluation set consists of 809 unique sentences across three domains (social, news, and literary), preserving proportional domain distribution (Table 1). All retained segments preserve document boundaries, with sentence order tracked by custom IDs.

3.2 Recruitment & Training

We recruited three professional translators, all native Korean speakers with 5–10 years of English translation experience. For confidentiality, they were anonymized as Judge 1, Judge 2, and Judge 3 and are collectively referred to as judges. Based on the reduced segment length relative to the original dataset, we estimated an average throughput of 60 sentences per hour, corresponding to 13.3 hours per task and 27 hours in total per judge across two tasks. Judges were compensated at $30 per hour.

An online orientation was conducted via Google Meet to introduce the evaluation guidelines and demonstrate the platform. During the session, participants performed a preliminary evaluation using the platform. For the main study, judges were given one week to complete their evaluations. Time was tracked per item, and participants were instructed to maintain focus during annotation. They were provided full access to the document and permitted to review and revise their annotations prior to final submission.

3.3 Platform & Interface

We used Label Studio[3] as the evaluation platform (see Figure 9 in the Appendix). The interface allowed evaluators to consult label definitions, prior annotations, and relevant domain information throughout the task.

3.4 Metrics

We use IAA as the primary metric of reproducibility. For Task I, Cohen's Kappa (κ) is computed for each judge as in Equation 1, where P_o denotes the observed agreement and P_e the expected agreement under chance.

[2] https://github.com/hyunwoongko/kss
[3] https://labelstud.io

	(κ) ↑	(J) ↑
Judge 2–Judge 3	0.4995	0.6098
Judge 1–Judge 2	0.3883	0.4629
Judge 3–Judge 1	0.3646	0.4529
Avg.	**0.4175**	**0.5085**

Table 2: Pairwise IAA scores for Task I (Cohen's Kappa) and Task II (Jaccard similarity).

$$\kappa = \frac{P_o - P_e}{1 - P_e} \quad (1)$$

For Task II, which involves multi-label annotation, we use the Jaccard similarity J (Equation 2), where A and B are the label sets from two annotators. For qualitative assessment, we collect participant feedback via Google Sheets and conduct subsequent linguistic analysis.

$$J(A, B) = \frac{|A \cap B|}{|A \cup B|} \quad (2)$$

4 Result

4.1 Reproducibility

Table 2 reports IAA for the two tasks. Across tasks, judges reach a **fair to moderate level of agreement** according to empirical standards (Landis and Koch 1977; Zhang and Zhou 2014; Rajpurkar et al. 2016), with average scores of $\kappa = 0.42$ and $J = 0.51$, and maximum scores of $\kappa = 0.50$ and $J = 0.61$. Agreement is highest between Judge 2 and Judge 3, suggesting that Judge 1 applied different criteria.

4.2 Analysis

We analyze disagreement by computing the proportion of pairwise label mismatches per task. For each judge pair, we identify the labels on which they disagreed and calculate their distribution. As shown in Figure 2, the largest divergence arises in the SENTENCE-LEVEL and LOCAL categories, accounting for 39.7% and 36.4% of disagreements, respectively, between Judge 1 and Judge 2.

To further examine this confusion, we merge related labels and recompute IAA. As shown in Table 3, the primary source of disagreement across judges lies in distinguishing SENTENCE-LEVEL from LOCAL. Merging these categories increases agreement from $\kappa = 0.4995$ to $\kappa = 0.58$.

To better understand this ambiguity, we analyze qualitative feedback on the difficulty of distinguishing context-independent (SENTENCE-LEVEL) from context-dependent labels. A recurring theme is the treatment of pronouns. For example, when the English pronoun "it" is translated into an equivalent pronoun in Korean and judged correct, the label is typically SENTENCE-LEVEL. By contrast, if the same translation is considered inadequate—requiring explicit mention of the referent noun—the label shifts to LOCAL. An illustrative case is shown in Table 4. As Judge 2 noted, "the interpretation of a pronoun's referent also influences verb choice, and thus I categorize the sentence as LOCAL."

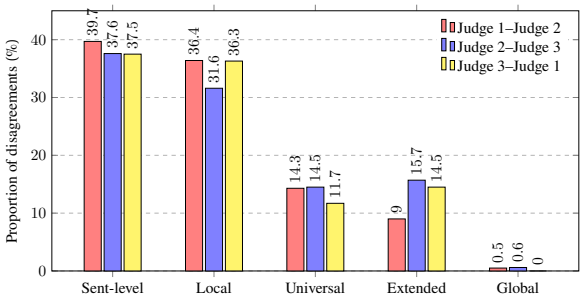

Figure 2: Distribution of Task I label disagreements across judge pairs (%).

Group	J_1–J_2 (Δ)	J_2–J_3 (Δ ↑)	J_3–J_1 (Δ)
L + S	**0.482 (+0.093)**	**0.580 (+0.080)**	**0.454 (+0.090)**
E + U	0.411 (+0.022)	0.568 (+0.069)	0.411 (+0.046)
E + L	0.414 (+0.026)	0.500 (+0.001)	0.397 (+0.033)
E + S	0.372 (–0.016)	0.480 (–0.020)	0.340 (–0.025)
L + U	0.372 (–0.017)	0.463 (–0.036)	0.343 (–0.022)
S + U	0.298 (–0.091)	0.418 (–0.081)	0.264 (–0.100)

Table 3: Cohen's κ after merging two labels. Parentheses indicate the change from the original κ. The highest agreement per column is shown in bold. Labels are abbreviated as L = Local, S = Sentence-level, E = Extended, and U = Universal. Judges are abbreviated as J_i.

SRC	I bought it like that and couldn't modify it, so I had to design around it.
TGT	구매했을 때부터 그런 형태였고, 수정할 수 없어서 그 형태에 맞춰 디자인해야 했어요.
BT	*It was in that form from the moment I purchased it, and since I couldn' t change it, I had to design everything to fit that shape.*

Table 4: A notable instance of pronoun provoking frequent misunderstanding between SENTENCE-LEVEL and LOCAL labels. The source (SRC) and target (TGT) segments are exemplified with the help of back-translation (BT).

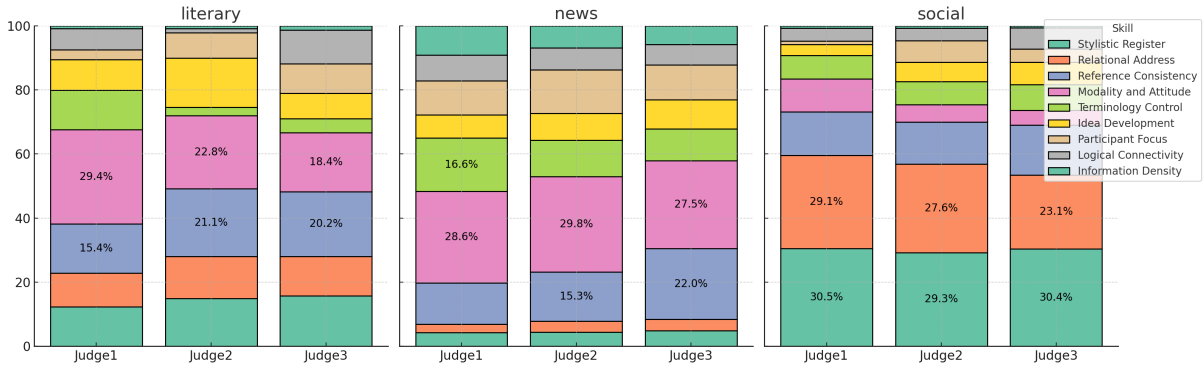

Figure 3: Distribution of Task II label choices across domains and judges. Values are shown for the largest slices.

4.3 Analysis

While sentence-level agreement on selected translation skills is limited, we analyze the distribution of skill choices per domain and per judge. Figure 3 shows that the three judges assign broadly similar proportions of skill labels across domains, suggesting that individual-level disagreements in exact label sets do not obscure shared evaluative priorities.

Closer inspection reveals domain-specific emphases. In the social domain, judges consistently highlight Style Register (avg. 30.1%) and Relational Address (26.6%), reflecting the importance of interpersonal stance in user-generated content. In the news domain, Modality & Attitude (28.6%) and Reference Consistency (16.7%) dominate, consistent with the demands for precision and coherence in reporting—a tendency also observed in literary text, where Modality & Attitude (23.5%) and Reference Consistency (18.9%) are most frequent. This indicates that low pairwise agreement does not necessarily reflect fundamental divergence, but rather differences in specific label selection. At the same time, the results point to a limitation of the current protocol: constraining annotators to exactly three skills per segment may not capture the full range of relevant judgments.

5 Meta-Evaluation of FALCON

The highest human IAA in our configuration is $\kappa = 0.50$ for Task I and $J = 0.61$ for Task II. Using these gold scores as reference, we evaluate the reliability of FALCON as an LLM-as-judge framework. As baselines, we test multiple proprietary models—OpenAI's `gpt-o3`, `o4-mini`, and the baseline from Kim (2025), `4.1-mini`. Model performance is assessed using the same reproducibility metrics defined in §3.4, complemented by accuracy for Task I, where the output is a single categorical label, and Micro-F1 for Task II, where multiple labels must be selected simultaneously.

Group	Pair	acc (%)↑	κ
vs.	**J_2, J_3**	**70.09**	**0.4995**
	J_1, J_2	66.25	0.3883

vs.	**`o3`, `o4-mini`**	**71.69**	**0.5239**
	`4.1-mini`, `o4-mini`	47.22	0.2046
	`o3`, `4.1-mini`	40.30	0.1068

Table 5: Pairwise accuracy and Cohen's Kappa κ by human () and model () groups for Task I.

5.1 Reliability of context knowledge

Table 5 reports pairwise accuracy and IAA across human–human, human–model, and model–model comparisons. The best-performing model, `o4-mini`, achieves 53.89% accuracy, which falls short of even the weakest human pair (Judge 1–-Judge 3, 62.92%). No model approaches the agreement level of the strongest human pair (Judge 2–-Judge 3). The concordance with human annotations remains at most **fair** ($\kappa = 0.25$ for `o4-mini`), underscoring the limited ability of current LLMs to reliably distinguish context categories at a human-comparable level.

To better understand this gap, we analyze which labels drive model–human discrepancies. Figure 4

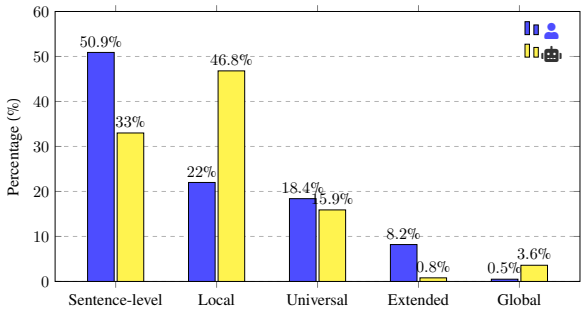

Figure 4: Task I label distribution of disagreements between Judge 2 ( ) and `o4-mini` ( ), identified as the most aligned human–model pair.

illustrates the disagreement distribution between Judge 2 and `o4-mini`, the pair with the highest human–model consensus. The largest share of divergence arises from SENTENCE-LEVEL (50.9%) from the human part and from LOCAL (46.8%) from the machine part. These categories mirror the main sources of confusion among human annotators, suggesting that while models replicate human-like weaknesses, they lack the robustness to resolve such ambiguities consistently.

5.2 Reliability of translation skill

Table 6 shows that the strongest human–model agreement is attained with `o4-mini` ($J = 0.406$), substantially lower than both human–human and model–model levels. Model precision reaches 53.6%, comparable to the earlier task, but still insufficient to approximate human reliability. Interestingly, model–model agreement is relatively high, reaching up to $J = 0.597$, on par with the stronger human–human pairs.

These findings suggest that models produce consistent predictions across systems, yet this consistency reflects shared internal heuristics rather than alignment with human reasoning. While human annotators converge through pragmatic interpretation, models seem to exploit surface-level patterns that do not fully capture evaluative criteria. Closing this gap demands not just higher accuracy, but agreement with humans based on human-like reasoning.

5.3 Summary

The central hypothesis of FALCON—that document-level evaluation can be approximated at the sentence level—requires caution. Our results show that judges often confuse adjacent levels of context, underscoring the need for clearer definitions

Group	Pair	avg. $J\uparrow$	f1
vs.	J_2–J_3	**0.6098**	**0.7183**
	J_1–J_2	0.4629	0.5915

	`4.1-mini`, `o3`	0.4250	0.5554

Table 6: Average pairwise Jaccard Similarity J and Micro F1 between human ( ) and model ( ) groups for Task II.

of "context." Furthermore, the low agreement in Task II suggests that identifying universal translation skills solely from the source text risks poor reproducibility of gold judgments.

6 Refined Protocol: H-FALCON

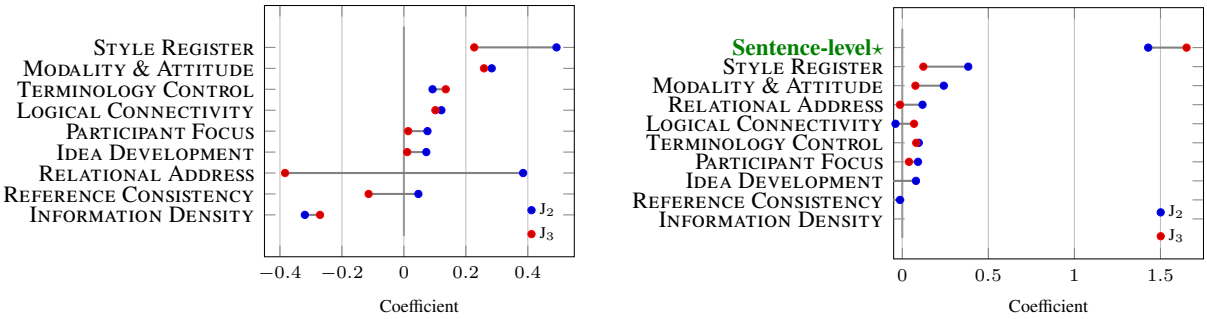
The current protocol of FALCON suffers from ambiguous definitions of context and limited reproducibility in skill selection, calling into question its central hypotheses. Building on these findings, we identify three structural limitations of FALCON: unclear translation objectives for human evaluators, the rigid requirement to assign exactly three skills per sentence, and the lack of adaptability to the domain and language pair.

To address them, we propose H-FALCON (**H**uman-centered FALCON), grounded in two revised hypotheses: (i) every sentence is influenced by context, and (ii) judges should flexibly decide the number of translation skills.

6.1 Design

Given these assumptions, H-FALCON removes Task I, since all sentences are subject to evaluation. For Task II, rather than selecting a fixed set of relevant skills, judges directly evaluate the pertinence of each skill, thereby unifying annotation and rating into a single step (Figure 1).

To support this protocol, every skill is initialized as NOT RELEVANT. Judges then assign one of three



(a) Doc Features

(b) Doc + Sent Features

Figure 5: Linear regression coefficients for Judge 2 (J_2) and Judge 3 (J_3) with (b) and without (a) **sentence-level** score. Features with scores near 0 have minimal influence on the holistic score.

ratings—High, Medium, or Low—following House's theoretical framework (House, 2015). This triadic scale replaces the 4-point scheme of Kim (2025), to represent preliminary feedback from our evaluators that three levels suffice, as discourse phenomena often lend themselves to relatively clear judgments.

6.2 Experiment

To verify the reproducibility of the refined H-FALCON protocol, we sample 300 new instances from WMT24++ (Deutsch et al., 2025) that are not included in the earlier experiments. Human evaluation is conducted by Judge 2 and Judge 3, the pair with the highest agreement in prior tasks.

The evaluation environment remains unchanged, using the same platform as in Figure 10. In this setting, judges simultaneously select and rate relevant skills, eliminating the separation of annotation and scoring. To provide additional baselines, we also collect MQM-style sentence-level error annotations on a 4-point scale and holistic quality scores (sentence + document level) on a 10-point scale. These parallel evaluations allow us to establish a benchmark IAA threshold for H-FALCON and to examine relationships among the three metrics. All ratings are obtained at the sentence level, and scale variation is deliberately employed to minimize task confusion.

The reliability of skill selection is measured by excluding Not Relevant labels and computing Jaccard similarity between the two judges. Correlations between evaluation metrics are quantified using Pearson, Spearman, and Kendall's tau coefficients.

6.3 Reproducibility of H-FALCON

The Jaccard similarity for overlapping translation skills between the two judges is 0.532, remaining consistently low and consistent with the earlier experiment. This highlights the inherent difficulty of achieving consensus, regardless of the method of label collection.

To further examine how the judges weigh each skill when assigning holistic scores, we fit a linear regression model for each judge, using the holistic score as the dependent variable and the individual label scores as predictors (with an intercept). This analysis quantifies the relative contribution of each skill while controlling for the others. As shown in Figure 5 (a), the judges diverge most clearly on Relational Address: Judge 2 associates higher holistic scores with stronger performance in this skill, whereas Judge 3 tends to assign lower scores. A similar but weaker divergence is observed for Reference Consistency. Importantly, these opposite directions remain significant within 95% confidence intervals, underscoring that the divergence reflects genuine differences in evaluative criteria rather than statistical noise. These divergent patterns suggest that the guidelines for the labels may require refinement and additional evaluator training to ensure consistent application.

6.4 Further Analysis

H-FALCON score as a proxy measure

We examine whether the obtained labels can serve as proxies for document-level scoring. Each annotation is assigned a numerical value (High=3, Medium=2, Low=1, Not Relevant=0), and scores are computed either by aggregating values ("sum") or by counting non-zero labels. Correlation between the two judges across sentence-, document-, and holistic-level scores (Table 7) indicates that the document-level scheme achieves agreement comparable to sentence-level evaluation ($\rho = 0.55$ vs.

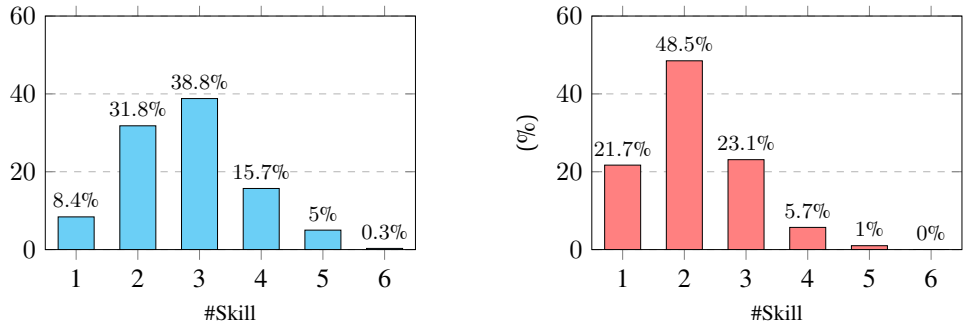


Figure 6: Distribution of the number of selected skills per sentence for each judge (left: Judge 2, right: Judge 3).

0.44). Notably, the counting method yields slightly higher consensus (0.55 vs. 0.48), highlighting its potential as an effective approach for annotating document-level quality.

Type	Pearson	Spearman	Kendall
Sentence-level	0.494	0.441	0.413
H-FALCON (sum)	0.499	0.483	0.378
H-FALCON (count)	0.562	0.545	0.486
Holistic	0.650	0.587	0.502

Table 7: Correlations between two raters across sentence-level, document-level (using two aggregation styles), and holistic scores.

Limited explanatory power of document-level score

To further assess the relative impact of sentence- and document-level features on holistic judgments, we extend the regression model by adding the sentence-level score as an independent variable. As shown in Figure 5 (b), the sentence-level score is the strongest predictor of holistic quality, with coefficients of 1.43 (95% CI: 1.22–1.63) for Judge 2 and 1.65 (95% CI: 1.49–1.82) for Judge 3.

Table 8 reports the explanatory power (R^2) of models with and without the sentence-level score. Document-level scores alone account for little variance in holistic judgments ($R^2 = 0.11$), explaining only 11% of the variance in holistic judgments. However, incorporating the sentence-level score increases explanatory power to 0.54 and reduces the intercept from 7.11 to 2.29. These results confirm that sentence-level quality is the primary driver of holistic assessments.

At least one discourse feature per sentence

We calculate the number of translation skills annotated per judge. Figure 6 shows that every sentence is annotated with at least one skill, most frequently with three to four skills (38.8% and 48.5% for Judge 2 and Judge 3, respectively). This finding challenges the claim that only a subset of sentences requires contextual information (Castilho, 2022). On the contrary, we emphasize that contextual information can influence translation in all cases—even for simple utterances such as "hi." However, as shown in the previous section, its impact on the holistic score is relatively limited. Still, this does not diminish the importance of document-level evaluation, which remains a key factor for distinguishing higher-performing models.

	Doc			Doc + Sent		
	J_2	J_3	Avg	J_2	J_3	Avg
R^2	0.12	0.09	0.11	0.47↑	0.61↑	0.54↑
Intercept	6.46	7.76	7.11	2.10↓	2.48↓	2.29↓

Table 8: The explanatory power (R^2) of models with document-level score (**Doc**) and with document- and sentence-level scores (**Doc+Sent**). Doc+Sent results are highlighted.

7 Conclusion

Our findings challenge prevailing assumptions in MT evaluation by demonstrating that contextual information, though modest in magnitude, is both universal and consequential for human judgment. Operationalizing this insight, H-FALCON provides a reproducible, context-aware evaluation protocol that aligns as closely with human preferences as traditional sentence-level approaches. These results underscore the need to move beyond narrow, sentence-bounded metrics toward richer document-level assessments that capture the pragmatic realities of translation quality. As MT performance converges at the sentence level, such holistic, context-sensitive evaluation will be essential for driving the next phase of progress in the field.

8 Limitation

Our study is limited to a single mid-resourced language pair. While this is acceptable given our focus on the human evaluation setting—which is largely consistent across languages—the reproducibility and reliability of FALCON may be underestimated. For the same reason, we did not experiment with other open-weight models such as LLaMA or Mistral.

On the human side, only three annotators were engaged, one of whom showed notably divergent behavior. In addition, even under the refined protocol, the consensus on translation skills remained low (§ 6.3). These issues highlight the need for more proactive calibration sessions among annotators.

Finally, we did not investigate how context should be presented or which types of context were most informative on the target side for FALCON. We leave this as an avenue for future work.

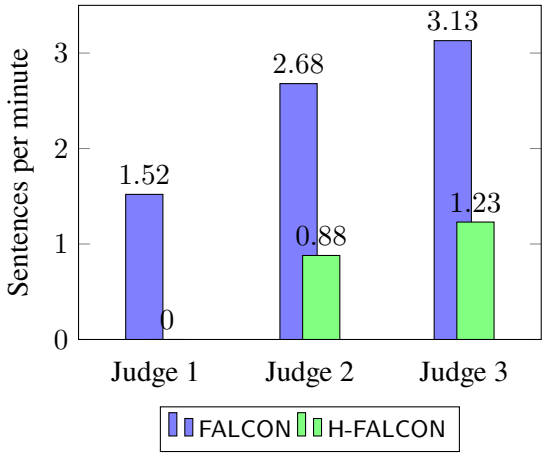

Figure 7: Average throughput per judge in FALCON vs. H-FALCON. Judge 1 was not hired for H-FALCON.

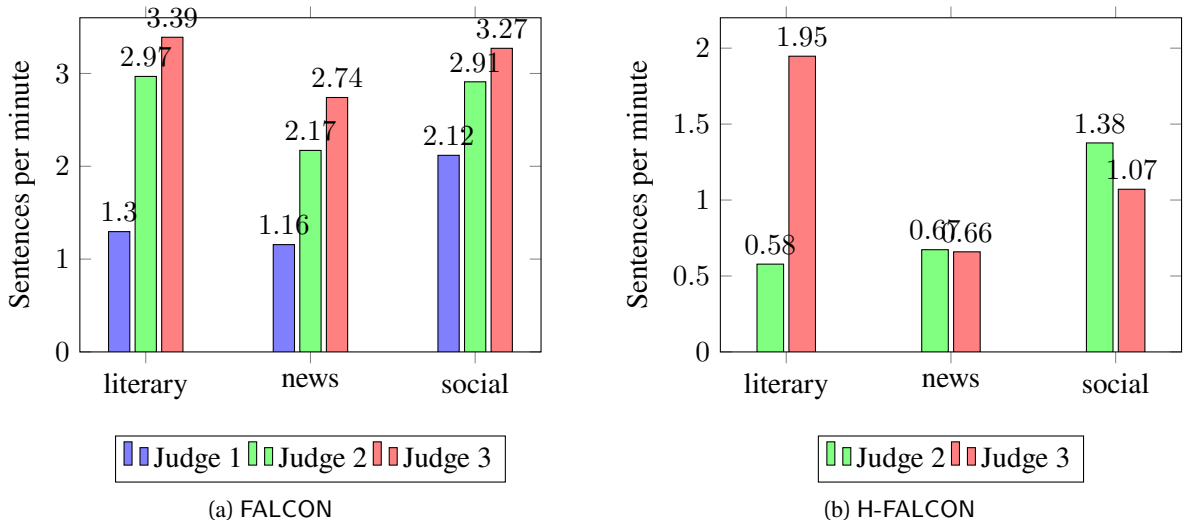
Appendix

A Evaluation Throughput

We calculate throughput per judge under two different frameworks: FALCON and H-FALCON. The key distinction is that the H-FALCON setting requires both label annotation and rating, which introduces additional cognitive load and time, whereas the FALCON condition measures throughput without the rating phase.

Figure 7 shows that throughput values are consistently lower in H-FALCON than in FALCON, reflecting the extra annotation steps. For example, the average throughput per judge decreases from 1.52–3.13 sent/min in FALCON to 0.88–1.23 sent/min in H-FALCON. This suggests that rating is the most time-consuming component of the evaluation: despite H-FALCON consolidating the task into a single step, throughput falls to less than half of FALCON, indicating that the rating phase dominates the overall processing time.

When examining domain-level performance in Figure 8, consistent patterns emerge across both setups. Social texts yield the highest throughput, reflecting their relatively simple and conversational style, while literary texts slow down judges the most, likely due to complex syntax and stylistic density. News texts fall in between, with moderate difficulty and processing speed. This ordering is preserved in both FALCON and H-FALCON, though absolute throughput values are lower in the latter due to the added annotation and rating tasks. These results confirm that genre characteristics strongly shape translation throughput, and that such effects remain robust even under heavier annotation requirements.



(a) FALCON (b) H-FALCON

Figure 8: Throughput by domain and judge across FALCON and H-FALCON setups. Higher values indicate faster processing.

B Descriptions of Context Levels

Sentence-level The sentence can be fully understood and translated without any outside information. All necessary meaning is present within the sentence itself — vocabulary, grammar, and semantics are straightforward.

Local Understanding requires minimal surrounding context — maybe the previous or next sentence — but nothing broader. Without it, pronouns, references, or logical connectors might be confusing.

Extended Grasping the meaning requires understanding the broader scene, paragraph, or emotional flow. Cultural nuance, emotional undertones, or evolving character perspectives start to matter.

Global The sentence depends on knowledge of the entire work (novel, article, movie) or even multiple entries (book series, TV seasons). Important world-building, character arcs, fictional history, or long-term motifs influence meaning.

Universal Understanding draws on extensive external knowledge — history, philosophy, science, mythology, social structures, or famous world events. Without that shared knowledge, translation risks misfiring badly.

C Descriptions of Translation Skills

Information Density Does the sentence compress information into abstract or complex structures required by the genre or audience? Important linguistic devices are nominalization, complex noun phrases, embedded clauses, compounding, metaphors, analogies, symbolic imagery, etc.

Idea Development Do some elements in the sentence influence the development of the central theme and the rhetorical structure expected by the genre? Important linguistic devices are discourse markers, schematic structures (e.g., introduction-body-conclusion), paragraph transitions, etc.

Terminology Control Does the sentence have technical or domain-specific vocabulary that requires accurate and consistent use across an entire text? Important linguistic devices are technical nouns, specialized terminology, standard collocations, fixed expressions, etc.

Style Register Do some elements in the sentence require a degree of linguistic politeness and stylistic appropriateness suited to the context and purpose of the text? Important linguistic devices are lexical choice, pronoun usage, verb conjugation, discourse markers, euphemisms, idiomatic expressions, etc.

Reference Consistency Does the sentence contain elements that refer to the same entity within

(a) Task I

Label	J_1	J_2	J_3	Avg↑
Sent-level	63.16	60.57	54.14	59.29
Local	23.11	21.76	26.33	23.73
Universal	10.88	13.23	10.01	11.37
Extended	2.84	4.08	9.52	5.48
Global	0.00	0.37	0.00	0.12

(b) Task II

Label	J_1	J_2	J_3	Avg↑
Style Register	21.26	20.77	21.67	21.23
Relational Address	19.70	19.28	16.44	18.47
Reference Consistency	13.51	14.50	17.84	15.28
Modality and Attitude	17.39	14.05	12.48	14.64
Terminology Control	10.47	7.95	8.24	8.89
Idea Development	5.07	7.62	7.70	6.80
Participant Focus	4.04	8.82	6.55	6.47
Logical Connectivity	5.40	4.49	6.84	5.58
Information Density	3.17	2.51	2.22	2.63

Table 9: Proportion of Task I, II labels annotated by three judges (%).

the text? The consistent use of such elements creates connections and coherence and ensures clear identification of participants, objects, and ideas throughout the text. Important linguistic devices are reference, substitution of clause, gender/tense/number agreement, deixis, ellipsis, repetition, synonyms, etc.

Logical Connectivity Does the sentence have connectors or structures that require clear expression of relationships — such as cause, contrast, or sequence — between ideas? Important linguistic devices are logical connectors (e.g., however, therefore), adversatives, causal linkers, etc.

Modality and Attitude Do some elements in the sentence express possibility, obligation, certainty, or speaker/writer's stance that convey the text's mood and tone? Important linguistic devices are modal verbs and auxiliaries (e.g., must, might), evaluative adjectives (e.g., important, unfortunate), stance adverbs (e.g., perhaps, clearly, surprisingly), emotionally charged expressions, subjunctive or conditional constructions, etc.

Relational Address Does the sentence rely on an understanding of the author's cultural, historical, or social background that affects his/her voice, intent, and the nuanced relationships with listener/reader? Important linguistic devices are gendered forms, titles and vocatives, pronoun, honorifics, relational expressions, sociolect, etc.

Participant Focus Should the emphasis of the sentence on key participants or elements (such as people, places, or objects) be preserved to convey the original meaning across a text? Important linguistic devices are subject-specific terminology, transitivity structures (verb types, selection of active/passive, selection of grammatical subject, use of nominalization instead of verb), etc.

D Analysis of Collected Data

Table 9-(a) reports the number of annotations per context type, indicating broadly consistent distributions across judges. Roughly 60% of sentences were judged as translatable without additional context, though the exact subset of sentences varied considerably by annotator. Among context-dependent categories, Local was the most frequent, averaging 24%. By contrast, Global was almost never selected, suggesting that this type of context is difficult to capture reliably at the sentence level.

Turning to translation skills in Table 9-(b), Style Register (21.23%) and Relational Address (18.47%) emerged as the most frequently required skills, aligning with qualitative feedback that highlights their importance in context-sensitive translation. Conversely, Information Density was rarely chosen (2.6%), which may reflect either limited judge awareness or the relatively low salience of this feature in the dataset. These observations underscore the need for further clarification of certain skill definitions to improve annotation reliability.

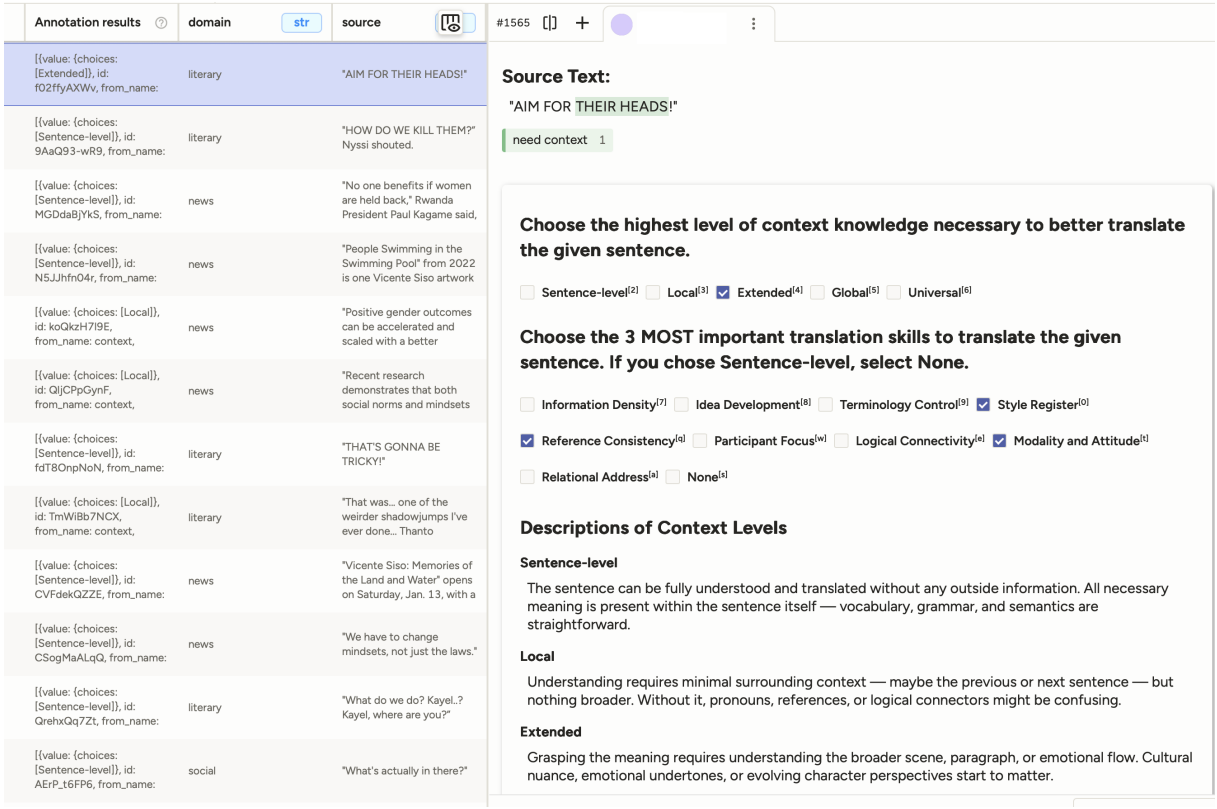


Figure 9: Label Studio interface for human evaluation in FALCON, showing labels of Task I and II. Expanded views provide consistent explanations for each category.

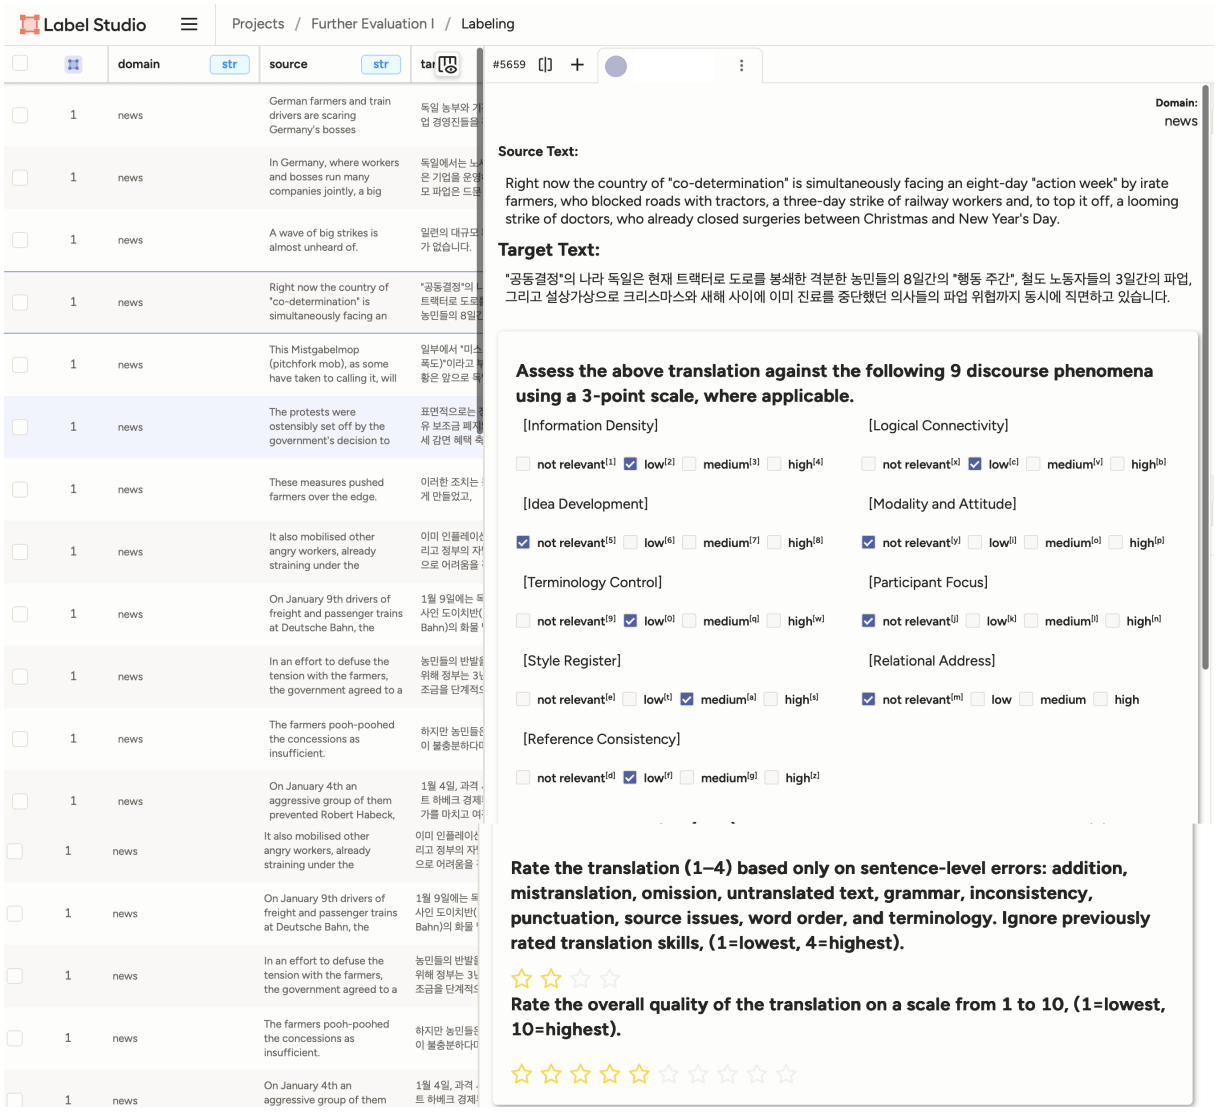

Figure 10: Interface of Label Studio for the human evaluation in H-FALCON. All translation skills are set to “not relevant” by default, and both sentence-level and holistic scores are collected concurrently.

GIIFT: Graph-guided Inductive Image-free Multimodal Machine Translation

Abstract

Multimodal Machine Translation (MMT) has demonstrated the significant help of visual information in machine translation. However, existing MMT methods face challenges in leveraging the modality gap by enforcing rigid visual-linguistic alignment whilst being confined to inference within their trained multimodal domains. In this work, we construct novel multimodal scene graphs to preserve and integrate modality-specific information and introduce **GIIFT**, a two-stage **G**raph-guided **I**nductive **I**mage-**F**ree MM**T** framework that uses a cross-modal Graph Attention Network adapter to learn multimodal knowledge in a unified fused space and inductively generalize it to broader image-free translation domains. Experimental results on the Multi30K dataset of English-to-French, English-to-German, and English-to-Ukraine tasks demonstrate that our GIIFT surpasses existing MMT baselines even without images during inference. Results on the WMT benchmark show significant improvements over the image-free MMT translation baselines, demonstrating the strength of GIIFT towards inductive image-free inference [1].

1 Introduction

Multimodal machine translation (MMT) aims to improve traditional text-only neural machine translation (NMT) by incorporating multimodal data, particularly visual inputs (Specia et al., 2016; Elliott et al., 2017; Barrault et al., 2018). Existing methods mostly focus on forcing the alignment between image and text to improve MMT, that they have demonstrated the effectiveness benefited from the aligned visual information in disambiguating text (Ive et al., 2019; Zhao et al., 2022b; Futeral et al., 2023). However, an aligned form of multimodal dataset in both the training and inference phases has disabled the MMT model to generalize further in the normal pure-text machine translation setup. Although the rich information of images can bring benefits to translation beyond the level of text, when aligned image information is indispensable for inference in the translation process, the application of MMT models will be severely limited. Therefore, the inability to get rid of aligned images in the inference phase is the critical bottleneck for the flexible application of MMT models.

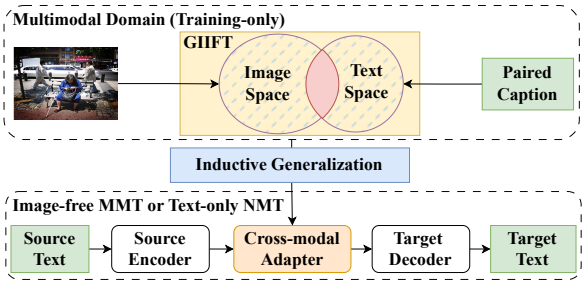

Figure 1: The inductive image-free generalization of GIIFT. GIIFT inductively learns from an entire multimodal domain, then enables image-free inference for MMT or text-only NMT via cross-modal generalization. In contrast, previous models can only learn from the limited overlap between image and text in red.

To address the bottleneck mentioned above, there have been a few methods that attempt to explore resolutions for achieving image-free inference in MMT models. For example, synthesizing visual hallucination from text or textual scene graph during training is used for the image-free inference (Li et al., 2022; Fei et al., 2023); transfer learning from the image-to-text captioning task to the text-to-text translation task (Gupta et al., 2023). However, none of these efforts has managed to consistently reach the performance of fully bridging the gap between multimodal and image-free inference. There are still critical challenges in advancing image-free inference in MMT.

First, previous models learn inadequately because they forcibly align the modality gap, typically the intrinsic information imbalance between im-

Proceedings of the Tenth Conference on Machine Translation, pages 98–112
November 8-9, 2025

ages and texts (Schrodi et al., 2025). Consider the case in Figure 1, this constraint limits image-free inference generalized from only the red overlap in the multimodal domain. Recent work (Ramasinghe et al., 2024; Schrodi et al., 2025), however, shows that accepting this gap and exploiting the full information (the entire collection in Figure 1) substantially enhances multimodal learning. Second, current image-free MMT approaches fail to realize cross-modal generalization, resulting in a marked drop in image-free inference compared with traditional MMT with multimodal inference (Fei et al., 2023). Third, current MMT models are transductive (Sutskever et al., 2014), which struggle with inductively generalizing from multimodal domains to text-only domains for broader applications. Facing these challenges, we investigate the following research questions in this work: *RQ1: How can we fully represent different modalities to embrace the modality gap? RQ2: Can we effectively make image-free inference via cross-modal generalization without downgrading performance? RQ3: Can MMT have the inductive ability to generalize multimodal domains to broader text-only domains?*

We propose **GIIFT**, a two-stage **G**raph-guided **I**nductive **I**mage-**F**ree MM**T** framework. As shown in Figure 1, the GIIFT learns from the entire multimodal domain in the first stage, and aims to achieve inductive generalization for image-free MMT or text-only NMT in the second stage. Graph-structured novel Multimodal Scene Graph (MSG) and Linguistic Scene Graph (LSG) are proposed to represent the multimodal domain, in which each modality informs and enriches the other by graph representation in the unified space. Specifically, we extract visual relationships from images and linguistic relationships from text, then preserve and integrate them via global super nodes to construct MSGs. LSG is a linguistic version, preserving linguistic relationships with global super nodes. These relations' and nodes' features are mutually enriched and uniformly initialized via M-CLIP (Carlsson et al., 2022). To enable cross-modal generalization to image-free or broader text-only domains, GIIFT is designed with a cross-modal GAT adapter to inductively learn multimodal knowledge from the multimodal domain via MSGs in the first stage, and generalize it for image-free inference via LSGs in the second stage, based on a replaceable backbone, mBART (Liu et al., 2020).

Overall, the main contributions are:

(i) We build novel MSGs and LSGs to fully represent different modalities in a unified space for embracing the modality gap.

(ii) We propose the two-stage GIIFT framework with a novel lightweight GAT adapter to achieve inductive cross-modal generalization for image-free inference MMT via MSGs and LSGs.

(iii) Experimental results on En→{Fr, De, Uk} Multi30K show that GIIFT outperforms most of the existing MMT methods even without image during inference. On En→{Fr, De} WMT, GIIFT surpasses the best image-free baseline, CLIPTrans, by average gains of **+1.92 (8.00%) BLEU** and **+2.82 (4.80%) METEOR**, demonstrating effective induction from multimodal Multi30K to other text-only NMT domains.

(iv) Further analysis demonstrates that the proposed GIIFT can effectively embrace modality gaps via MSGs and achieve robust image-free inference via two-stage cross-modal generalization, and shows that the GIIFT can achieve consistent performance of fully bridging the gap between multimodal inference and image-free inference.

2 Related Work

2.1 Multimodal Machine Translation

MMT research integrates visual and textual information for machine translation with an increasing number of models (Grönroos et al., 2018; Huang et al., 2020; Zhao et al., 2022a; Cheng et al., 2024). Early approaches commonly adopted RNN-based architectures enhanced with attention mechanisms to incorporate global or spatial visual features (Calixto et al., 2017). Transformer variants soon supplanted RNNs, introducing tighter cross-modal fusion such as dynamic token re-weighting (Caglayan et al., 2018; Lin et al., 2020), double attention mechanisms (Zhao et al., 2020), gating mechanisms (Wu et al., 2021), multimodal adapters (Zhao and Calapodescu, 2022) or multi-granular fusion via graph structures (Krishna et al., 2017; Wang et al., 2018; Yin et al., 2020). Recent research leverages pre-trained resources such as CLIP (Gupta et al., 2023; Li et al., 2022) or BERT (Li et al., 2020). Within the widely adopted encoder-decoder framework, MMT research has progressed along two fronts in representation and inference:

(1) Visual-linguistic representation. Most MMT models enforce rigid visual-linguistic alignment. Disambiguation work (Ive et al., 2019; Zhao et al., 2022b; Futeral et al., 2023) links each textual token to a matching image region to resolve lexi-

cal ambiguity. UMMT(Fei et al., 2023) aligns every hallucinated visual scene graph node with textual counterpart. CLIPTrans (Gupta et al., 2023) trains sequentially on two stages, image captioning and the corresponding translation, enforcing alignment across both stages. Such alignments discard modality-specific information by merely learning the overlap between modalities.

(2) Image-free inference. Previous MMT relies on access to the paired image at test time. To mitigate this limitation, researchers have pursued three lines of work. First, retrieval-based models replace the missing picture with visual features fetched from an indexed caption-image bank into the decoder (Zhang et al., 2020). Second, hallucination methods (Johnson et al., 2018; Li et al., 2022; Fei et al., 2023) synthesize visual inputs from texts. Third, using transfer learning to train the NMT models with images (Gupta et al., 2023).

2.2 Graph Neural Networks

GNN is powerful in modeling relational structures by leveraging message-passing mechanisms (Wu et al., 2020; Liang et al., 2022), which iteratively aggregates and updates nodes' representation with information from their neighbors, capturing both local and global relational patterns. Some GNNs, such as Graph Convolutional Network (GCN) (Kipf and Welling, 2017) and its variants, are only transductive, while others, including GAT (Veličković et al., 2018), and GraphSAGE (Hamilton et al., 2017), also enable inductive learning (Battaglia et al., 2018; Xiong et al., 2025) to handle previously unseen nodes (Zhou et al., 2020). GNNs also use hierarchical or global pooling techniques (Ying et al., 2018; Lee et al., 2019; Gao and Ji, 2019) to capture subgraph-level or graph-level embeddings (Zhou et al., 2020).

3 Methodology

In this work, we construct unified MSGs and LSGs to generalize multimodal knowledge for image-free inference. We design the GIIFT framework with two-stage continuous learning via a lightweight GAT adapter for inductive cross-modal generalization. Our methodology is structured as follows: 1) We introduce the problem definition of our inductive image-free inference (Subsection 3.1). 2) The details of the MSG and LSG scene graph generation (Subsection 3.2). 3) The description of the GIIFT framework (Subsection 3.3).

3.1 Problem Definition

Let $\mathcal{D}_m$ be a multimodal multilingual dataset of triplets (i, c_s, c_t), where i is an image and (c_s, c_t) are its source and target captions, and let $\mathcal{D}_l$ be a text-only parallel corpus of pairs (t_s, t_t). Traditional MMT methods align i with c_s during training and then perform image-free inference based on that alignment, but the visual knowledge remains tied to c_s and $\mathcal{D}_m$. Our inductive image-free inference instead learns multimodal knowledge from i and (c_s, c_t) in $\mathcal{D}_m$ that cross-modally generalizes to both $\mathcal{D}_m$ or translation pairs $(t_s, t_t) \in \mathcal{D}_l$.

3.2 Scene Graph Generation

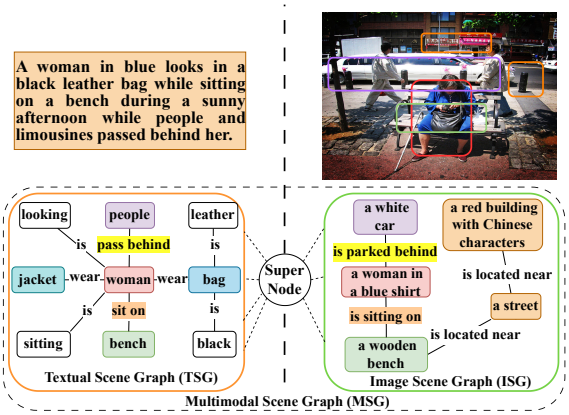

Figure 2: Representation of textual and visual information via MSG. Corresponding objects, attributes, and relations across both Textual Scene Graphs and Image Scene Graphs are depicted using identical colors.

To preserve modality-specific information and extract complex relations (e.g., spatial relations, environmental scene, and event states of people and objects) during data preprocessing, we use a multimodal Large Language Model (LLM) as the image parser and an off-the-shelf text parser to build the MSG and LSG, respectively. Figure 2 shows that the MSG comprises an Image Scene Graph (ISG) and a Textual Scene Graph (TSG), and a visual super node to bridge ISG and TSG included in a unified space, whereas the LSG replaces the visual super node with a textual one and omits the ISG.

(1) Image Scene Graph. ISGs are obtained from images i using LLaVA-34B (Liu et al., 2023). To obtain coherent and well-structured outputs, we set the sampling temperature to 0 for deterministic generations and raise it to 0.4 for more challenging cases requiring exploratory outputs. Our prompts (details in Appendix A) comprise: **(i) Task Description**, specifying how to formulate relations and produce structured scene graph content; **(ii)**

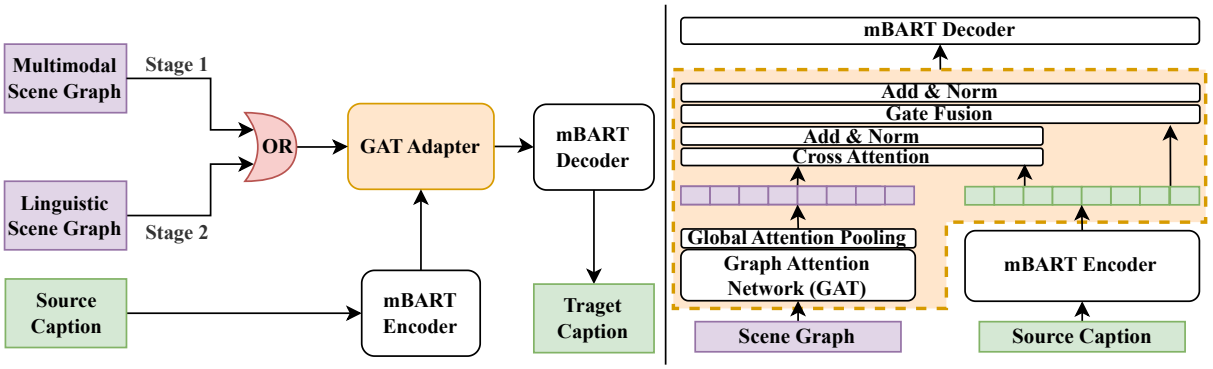

Figure 3: Left: Overview of the two-stage GIIFT framework. Stage 1: multimodal learning via MSGs. Stage 2: cross-modal generalization via LSGs. Right: Overview of the architecture of the cross-modal GAT adapter, which inductively learns and fuses the multimodal knowledge for the backbone, mBART.

Negative Examples, illustrating common errors in output formatting and how to rectify them; **(iii) Format Examples**, providing abstract but well-formed scene graph templates without using specific objects, thus preventing prompt contamination. Therefore, we generate ISGs with unique and relational visual information, such as event states.

(2) Textual Scene Graph. TSGs are parsed by FACTUAL (Li et al., 2023) from texts c_s or t_s. FACTUAL is lighter and more efficient than LLMs for large-scale corpora. TSGs encode entities and their relations as the textual analogue to ISGs. Thus, we obtain TSGs with structured linguistic relationships and unique semantic information.

(3) Multimodal Scene Graph. For each pair (i, c_s), we merge the ISG and TSG into an MSG by introducing a super node that encodes holistic image embeddings from the M-CLIP image encoder. This super node connects to all ordinary ISG and TSG nodes to unite modality-specific information and deliver diverse granular information, serving as a critical bridge to accept the modality gap and build multimodal relationships. We embed all ordinary node and relation features by the M-CLIP text encoder, enabling a unified representation of multimodal relationships and inductive foundations.

(4) Linguistic Scene Graph. For cross-modal generalization, we construct the LSG for text pairs (t_s, t_t) by retaining only the TSG with a super node representing the entire text embedding via the M-CLIP text encoder, which shares the unified hidden space with MSG's. Similarly, we embed all ordinary nodes and edges using the M-CLIP text encoder. The super node connects to all ordinary TSG nodes, enabling multi-granular textual information for image-free inference.

3.3 GIIFT Framework

Harnessing scene graphs as modality-bridges, GIIFT uses MSGs and LSGs, which are inductively learned for multimodal knowledge and generalized for image-free translation, respectively, via an essential cross-modal GAT adapter to guide the backbone mBART in two-stage training pipelines. The proposed lightweight GAT adapter is completely decoupled from the pre-trained mBART backbone (as shown in Figure 3), which can be flexibly incorporated with other language models for deployment.

3.3.1 Two-stage Training Framework

Stage 1: Multimodal Learning via MSG. As shown in Figure 3 (Left), Stage 1 trains a shared GAT adapter on MSGs from paired images and captions, inducing multimodal knowledge that guides image-free translation. Within the MSG, $\mathcal{N}_i^{\mathrm{SG}}$ is the neighbors of the ordinary node i from ISG or TSG, reflecting the structured relationships from image or text. The embedding $\mathbf{Z}_i^{(l)}$ of node i at layer $l, (0 \le l \le L)$ in GAT is calculated recursively as:

$$\begin{aligned}\mathbf{Z}_i^{(l)} = \sigma\Big(\sum_{j\in\mathcal{N}_i^{\mathrm{SG}}} \alpha_{ij}^{(l)}\, \phi(\mathbf{W}[\mathbf{Z}_i^{(l-1)} \| \mathbf{Z}_j^{(l-1)} \| \mathbf{E}_{ij}]) \\ + \alpha_{i,\mathrm{SN}}^{(l)}\, \phi(\mathbf{W}[\mathbf{Z}_i^{(l-1)} \| \mathbf{Z}_{\mathrm{SN}}^{(l-1)} \| \mathbf{E}_{i,\mathrm{SN}}])\Big).\end{aligned} \tag{1}$$

Here, $\mathbf{Z}_i^{(l-1)}$ is the embedding of node i at the previous layer (with initial node embedding $\mathbf{Z}_i^{(0)}$ via M-CLIP text encoder), $\mathbf{Z}_{\mathrm{SN}}^{(l-1)}$ is the global multimodal embedding from the super node at layer $l-1$ which is passed to all the ordinary nodes, and $\mathbf{E}_{ij}$ or $\mathbf{E}_{i,\mathrm{SN}}$ denotes edge embedding of the relationships in the scene graph via M-CLIP text encoder, the $\alpha_{ij}^{(l)}$ and $\alpha_{i,\mathrm{SN}}^{(l)}$ are attention weights, $\sigma(\cdot)$ is

an activate function and $\phi(\cdot)$ is the LeakyReLU. $\mathbf{E}_{ij}$ is the embedding of the relation content in the scene graph, obtained with the M-CLIP text encoder, whereas $\mathbf{E}_{i,\mathrm{SN}}$ is the embedding of the edge between the super-node and each ordinary node i. Because these super-node edges have no textual content, we initialize $\mathbf{E}_{i,\mathrm{SN}}$ as a ones vector whose dimensionality matches that of the embeddings produced by the M-CLIP text encoder.

From Eq. (1), we can observe that the shared weight $\mathbf{W}$ enables learning of multi-granular multimodal relationships by jointly processing local textual embeddings from ISG or TSG nodes ($\mathcal{N}_i^{\mathrm{SG}}$) and global multimodal context from the super node. This shared weight $\mathbf{W}$ is crucial in capturing these multimodal relationships and will be leveraged for the cross-modal generalization process in Stage 2.

The initial MSG super node provides the global image embedding $\mathbf{Z}_{\mathrm{SN}}^{\mathrm{MSG}(0)}$ and aggregates information from all ordinary nodes as follows:

$$\mathbf{Z}_{\mathrm{SN}}^{\mathrm{MSG}(l)}=\sigma(\sum_{i\in\mathcal{N}_{\mathrm{SN}}^{\mathrm{MSG}}}\alpha_{\mathrm{SN},i}^{(l)}\phi(\mathbf{W}[\mathbf{Z}_{\mathrm{SN}}^{(l-1)}\|\mathbf{Z}_i^{(l-1)}\|\mathbf{E}_{\mathrm{SN},i}])) \tag{2}$$

where $\mathcal{N}_{\mathrm{SN}}^{\mathrm{MSG}}$ contains all ordinary nodes in MSG.

Through the Global Attention Pooling (Li et al., 2015) layer in the GAT adapter, we then obtain the multimodal graph representation $\mathbf{Z}_g^{\mathrm{MSG}} \in \mathcal{D}_m$:

$$\mathbf{Z}_g^{\mathrm{MSG}} = \mathrm{AttnPool}(\{\mathbf{Z}_i^{\mathrm{MSG}} : i \in \mathcal{V}_{\mathrm{MSG}}\}), \tag{3}$$

where $\mathcal{V}_{\mathrm{MSG}}$ denotes the set of nodes in the MSG, including ordinary nodes and the super node.

$\mathbf{Z}_g^{\mathrm{MSG}}$ is then fed into the decoder for translation. The encoder remains frozen and the decoder learns a balanced representation to generate translations based on the gate mechanism (see Eq. (8)) between multimodal representations $\mathbf{Z}_g^{\mathrm{MSG}}$ and the source embedding $\mathbf{H}$.

Stage 2: Cross-modal Generalization via LSG. As shown in Figure 3 (Left), Stage 2 inputs the same GAT adapter with LSGs built from texts, allowing multimodal knowledge to be cross-modally generalized to broader image-free domains. In the LSG, each ordinary node i represents a textual entity with the initial embedding $\mathbf{Z}_i^{(0)}$ and a super node of the global text embedding, $\mathbf{Z}_{\mathrm{SN}}^{\mathrm{LSG}(0)}$ by the M-CLIP text encoder. The embedding $\mathbf{Z}_i^{(l)}$ of node i at the layer l for an ordinary node is:

$$\begin{aligned}\mathbf{Z}_i^{(l)} = \sigma(&\sum_{j\in\mathcal{N}_i^{\mathrm{LSG}}}\alpha_{ij}^{(l)}\phi(\mathbf{W}[\mathbf{Z}_i^{(l-1)}\|\mathbf{Z}_j^{(l-1)}\|\mathbf{E}_{ij}]) \\ &+\alpha_{i,\mathrm{SN}}^{(l)}\phi(\mathbf{W}[\mathbf{Z}_i^{(l-1)}\|\mathbf{Z}_{\mathrm{SN}}^{\mathrm{LSG}(l-1)}\|\mathbf{E}_{i,\mathrm{SN}}])).\end{aligned} \tag{4}$$

The LSG super node is updated as:

$$\mathbf{Z}_{\mathrm{SN}}^{\mathrm{LSG}(l)}=\sigma(\sum_{i\in\mathcal{N}_{\mathrm{SN}}^{\mathrm{LSG}}}\alpha_{\mathrm{SN},i}^{(l)}\phi(\mathbf{W}[\mathbf{Z}_{\mathrm{SN}}^{(l-1)}\|\mathbf{Z}_i^{(l-1)}\|\mathbf{E}_{\mathrm{SN},i}])), \tag{5}$$

with $\mathcal{N}_{\mathrm{SN}}^{\mathrm{LSG}}$ denoting all LSG ordinary nodes. The LSGs help the generalization of shared multimodal knowledge weight $\mathbf{W}$ from $\mathcal{D}_m$ in Stage 1 to the image-free domain $\mathcal{D}_l$ in Stage 2.

Similar to Eq. (3), we obtain the graph representation of LSG $\mathbf{Z}_g^{\mathrm{LSG}}$. The mBART decoder is enhanced by generalized knowledge $\mathbf{Z}_g^{\mathrm{LSG}}$ from $\mathcal{D}_m$ and adapted to the image-free domain $\mathcal{D}_l$ with unfrozen mBART encoder hidden state.

3.3.2 Cross-modal GAT Adapter

We employ a multi-layer GAT with residual connections (He et al., 2015; Veličković et al., 2018; Li et al., 2019) to learn multimodal knowledge and cross-modally generalize it to a broader image-free domain. Figure 3 (Right) shows the architecture of the GAT adapter fusing the output from the mBART encoder and enhancing the mBART decoder. We denote $\mathbf{Z}_g$ as the graph representation of MSG or LSG by the Global Attention Pooling. The fusion output $\mathbf{O}$ between the graph representation $\mathbf{Z}_g$ and mBART encoder hidden states $\mathbf{H}$ is performed via the cross attention as:

$$\mathbf{A} = \mathrm{MultiHeadAttn}(\mathbf{H}, \mathbf{Z}_g, \mathbf{Z}_g) + \mathbf{H} \tag{6}$$

$$\mathbf{O} = \mathrm{LayerNorm}(\mathrm{Dropout}(\mathbf{A})) \tag{7}$$

A gate mechanism $\mathbf{g}$ balances the embedding flow:

$$\mathbf{g} = \sigma(\mathbf{W}_2\mathrm{ReLU}(\mathbf{W}_1[\mathbf{O}\|\mathbf{H}])) \tag{8}$$

$$\mathbf{H}' = \mathrm{LayerNorm}(\mathbf{g}\odot\mathbf{O} + (1-\mathbf{g})\odot\mathbf{H}) \tag{9}$$

where $\odot$ denotes element-wise multiplication and $[\cdot\|\cdot]$ represents concatenation, $\mathbf{H}'$ is the input of mBART decoder. This two-stage process demonstrates the central inductive role of the cross-modal GAT adapter in representing and generalizing structured multimodal relationships.

4 Experiments

Datasets. We conduct experiments on two benchmarks: Multi30K (Elliott et al., 2016) and WMT2014 (Bojar et al., 2014). Multi30K is a widely used MMT benchmark as a multilingual extension of the Flickr30k. WMT is a text-only multilingual NMT dataset. For evaluation, we conduct EN→{DE, FR} translation tasks on Multi30K's

Table 4: Comparison of domain generalization on text-only WMT. "(*w/o.* Stage 1)" denotes model trained without image involvement from Multi30K.

three standard test splits: Test2016, Test2017, and MSCOCO. We also train and test EN→{DE, FR} on WMT with multimodal knowledge from Multi30K to evaluate the inductive image-free inference. We downsample WMT train set matching Multi30K's size, while keeping the validation and test sets unchanged.

Implementation Details. We train GIIFT on an A100 GPU, with AdamW optimizer (polynomial decay). The batch size is 64, learning rate is $2e^{-5}$ (Stage 1) and $1e^{-5}$ (Stage 2). The GAT Adapter is 9 layers with the same 1024 dimensions as M-CLIP. Text decoding is beam search with size 5. Implementations are in PyTorch and Huggingface

Transformers library. We report BLEU (Papineni et al., 2001) and METEOR via SacreBLEU (Post, 2018) and the evaluate library (Banerjee and Lavie, 2005), respectively. Results are three-run averages with early-stop patience 5 on BLEU. We chose mBART as our backbone to ensure a fair comparison with baselines such as CLIPTrans (Gupta et al., 2023) and to highlight our improvements. All tables bold the best and underline the second-best. Baseline figures are derived from papers or repositories. All the numbers of each model reported are from their fine-tuned version on the corresponding dataset.

4.1 Results on Multi30K

Table 1 and 2 contain translation performance comparison of BLEU and METEOR on EN→{DE, FR} tasks of Multi30K. Table 3 shows the BLEU and METEOR on EN → UK (Ukraine) task of Multi30K compared with baselines. "GIIFT (with image)" is a single-stage variant where both training and testing use paired images and texts, and the mBART backbone remains fully unfrozen throughout. "GIIFT (image-free)" is the full image-free model trained in two-stage framework as Subsection 3.3.

From Table 1 and 2, we observe that GIIFT (image-free) surpass the strongest baseline, Soul-Mix (even tested with images), with an average gain of +0.61 (1.37%) BLEU and +1.01 (1.55%) METEOR, and over the best scene-graph-based image-free baseline, UMMT, by +13.525 (42.27%) BLEU and +18.865 (36.07%) METEOR. It shows the effectiveness of GIIFT by preserving the entire information from images and texts.

Moreover, the GIIFT (image-free) model with cross-modal generalizing multimodal knowledge for image-free inference and GIIFT (with image) with multimodal inference secure top-two ranks on 5 out of 6 benchmarks with overall parity. GIIFT (image-free) even surpasses GIIFT (with image) by +0.21 (0.63%) BLEU and +0.1 (0.17%) METEOR on average. In contrast, UMMT degrades dramatically without images, scoring on average -5.4 (-12.76%) BLEU and -5.45 (-8.53%) METEOR below UMMT$^{\#}$ with multimodal inference. This demonstrates that the GIIFT has the robustness of cross-modal generalization for image-free inference, which can mitigate the gap between multimodal inference and image-free inference.

From Table 3, we can find that GIIFT (image-free) consistently outperforms both mBART and CLIPTrans baselines on the EN→{UK} task of Multi30K. We can observe that GIIFT achieves an average of +1.45 higher than mBART and +1.15 higher than CLIPTrans in BLEU; and an average of +0.65 higher than mBART and +0.46 higher than CLIPTrans in METEOR. It shows the effectiveness of GIIFT by preserving and learning multimodal information from images and texts for cross-modal generalization.

4.2 Results on WMT

In Table 1, CLIPTrans outperforms other image-free inference baselines, so we adopt it as our primary baseline and use its official repository for experiments. Like GIIFT (image-free), this two-stage mBART-based model is trained with Stage 1 on Multi30K and Stage 2 on WMT. The results of CLIPTrans and GIIFT in Table 4 are obtained under the same model parameter setup.

Table 4 shows that GIIFT achieves the highest BLEU and METEOR scores overall, while also significantly outperforming GIIFT (*w/o.* Stage 1) trained without images from Multi30K on both metrics. This validates GIIFT's inductive ability to achieve robust image-free inference via cross-modal generalization.

The difference between CLIPTrans and GIIFT stems from how each model handles the modality gap and the resulting impact on cross-modal generalization. CLIPTrans attempts to align images to textual captions for transferring the Stage 1 visual features into Stage 2 caption translations via a mapping network, which limits the multimodal correlation for cross-modal generalization. By contrast, GIIFT can effectively embrace the modality gap via graph-guided fusion and achieve inductive generalization via a cross-modal GAT adapter. In Stage 1, all the modalities are learned and represented in a *unified multimodal knowledge space* via multimodal scene graphs (MSGs). In Stage 2, the proposed cross-modal GAT adapter generalizes that knowledge into the text-only domain via the assistance of linguistic scene graphs (LSGs). Benefit from a two-stage inductive learning via MSGs or LSGs, GIIFT shows better performance in achieving robust image-free inference performance.

4.3 Human Evaluation

Table 5 presents human evaluation on the Multi30K EN→FR test set using a 10-point Likert scale for completeness, ambiguity, and fluency, alongside

Model	BLEU	Completeness ↑	Ambiguity ↓	Fluency ↑
mBART	63.37	7.0	7.3	8.1
CLIPTrans	64.55	8.0	5.5	8.8
GIIFT (image-free)	**65.61**	**9.3**	**4.6**	**9.5**
(*w/o.* Stage 1)	64.91	8.8	5.1	9.0

Table 5: Human evaluation metrics (10-point Likert scale) and BLEU scores on Multi30K EN→FR task.

BLEU scores for reference.

Results in Table 5 show that our GIIFT substantially enhances key translation dimensions that correlate with human satisfaction. Compared with the baselines, GIIFT significantly outperforms in completeness, indicating that the model can utilize more multimodal context information. GIIFT achieves the highest completeness, fluency ratings, and the lowest ambiguity among all baselines, demonstrating practically meaningful gains even when BLEU is already high. These gains highlight that our method delivers practical improvements across dimensions that BLEU alone cannot capture.

4.4 Comparison with Multimodal LLMs

Table 6 shows the experimental comparison of BLEU and METEOR on EN→{DE, FR} tasks of Multi30K with multimodal LLMs.

We use an RTX A6000 GPU to employ LlaVA-7B, LlaVA-34B (Liu et al., 2023) and Llama3-70B (Grattafiori et al., 2024) based on Ollama. We adopt LLaVA's few-shot inference paradigm (Brown et al., 2020) by prompting the model with a small set of (image, source caption, target translation) examples drawn from Multi30K and then asking it to translate a new image's caption into the target language.

From Table 6, we observe that our GIIFT achieves the highest BLEU and METEOR scores on EN→{DE, FR} benchmarks, with significant improvements over mBART and LLMs. These results confirm the effectiveness of our GIIFT model and show that compact, domain-specialized multimodal MMT models can outperform larger general-purpose LLMs on the translation task.

Considering the parameter complexity compared with multimodal LLMs, the GIIFT only introduced the GAT adapter in the framework, which is lightweight and efficient for training. For instance, the mBART backbone has approximately 600M parameters, while our GIIFT framework adds only about 33.2M parameters in total, approximately 27M in the GAT adapter layers and 6.2M in the gated fusion layer. Although LLaVA has far more parameters for supporting broad capabilities, our GIIFT's parameters are wholly devoted to yielding greater efficiency and accuracy for the translation.

4.5 Ablation Study

To further verify the effectiveness of the different components in the GIIFT framework, we showed the experimental results of the ablated versions in Table 7 on EN→{DE, FR} Multi30K.

As shown in Table 7, the GIIFT (image-free) with two-stage continuous learning by the proposed GAT adapter achieves the best performance across all benchmarks. Removing the gating mechanism, GIIFT (*w/o.* gate), results in a more significant reduction in BLEU and METEOR scores, underscoring the critical balancing role of the gating mechanism to fuse multimodal knowledge and mBART information. Additionally, omitting the multimodal learning stage 1, GIIFT (*w/o.* Stage 1), leads to a decrease in performance, highlighting the importance of learning generalizable multimodal knowledge from MSGs. The performance of GIIFT (unfrozen) is significantly lower than GIIFT (image-free), and closer to the backbone model mBART. This underscores freezing the mBART encoder in Stage 1 to maintain its stable embedding. Compared with the backbone mBART, there is a substantial drop in BLEU and METEOR, which demonstrates the effectiveness of the GIIFT framework in learning multimodal knowledge and cross-modal generalization for image-free inference.

5 Case Study

To investigate the advantages of GIIFT, we examine cases in comparing: the GIIFT (image-free), which learns multimodal knowledge from MSGs for cross-modal image-free generalization via LSGs; GIIFT (*w/o.* Stage 1), which only learns linguistic relationships from LSGs; and the text-only mBART.

(i) Environmental scene. In Figure 4 (left), GIIFT (image-free) and GIIFT (*w/o.* Stage 1) both correctly capture the spatial preposition "on" through MSG or LSG, respectively, despite the source English caption omitting the spatial information. But lacking the scene graph, mBART produces imprecise translations without "on", which highlights the functions of LSGs to guide the learning and generalize the spatial relation knowledge. This case shows that LSGs guide GIIFT to better generalize spatial relation information from MSGs' multimodal knowledge in Stage 2 for image-free translation inference. Additionally, as shown in

Table 7: Ablation study on Multi30K. "GIIFT (*w/o.* freezing)" has an unfrozen mBART encoder in Stage 1. "GIIFT (*w/o.* Stage 1)" is trained without images. "GIIFT (*w/o.* gate)" is trained in two stages without gate fusion.

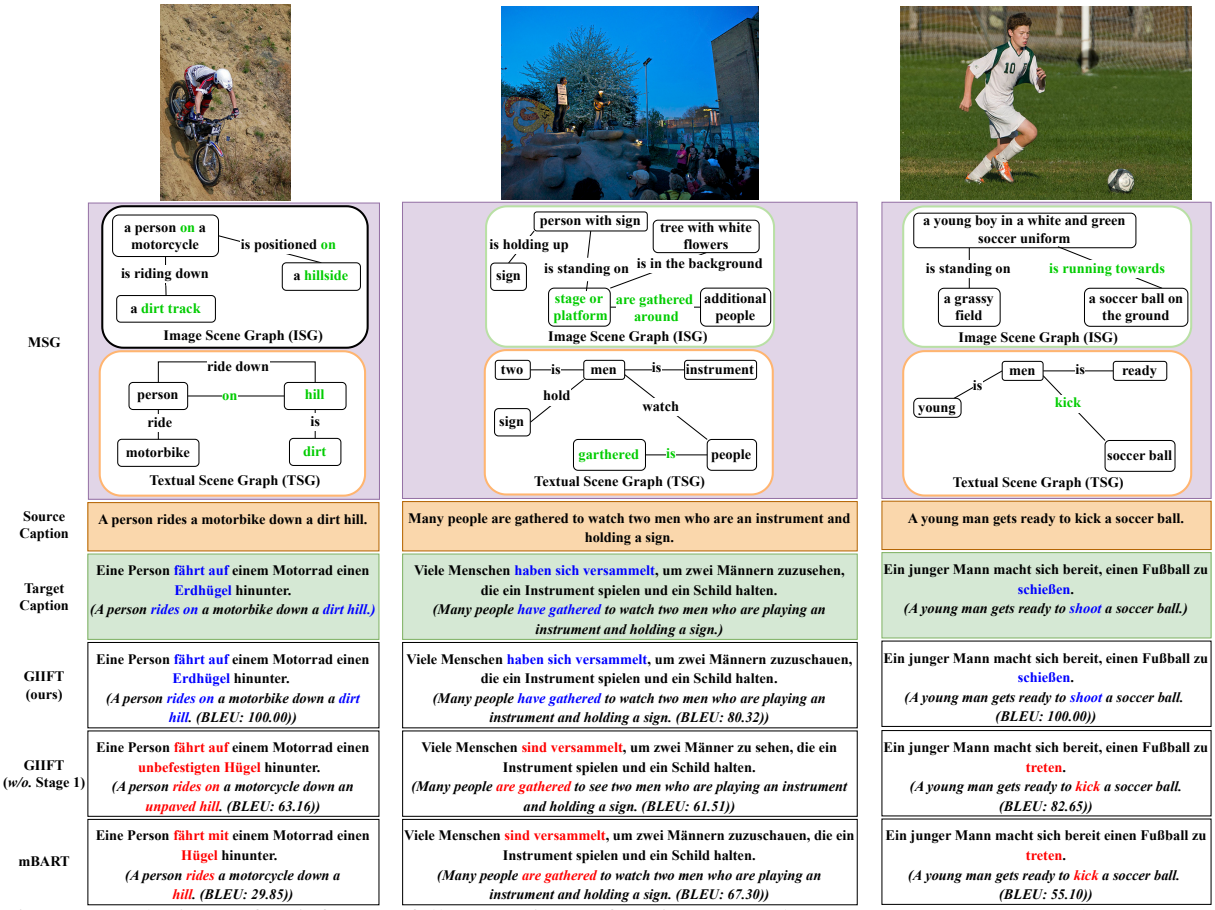

Figure 4: Under image-free inference, full GIIFT (image-free) is compared to GIIFT (*w/o.* Stage 1) and mBART on Multi30K validation set. The italicized bracketed translations of the German caption mark the differences in red.

Figure 4 (left), the environmental scene "dirt hill", is only accurately translated by full GIIFT (image-free) with multimodal knowledge from MSGs. GIIFT (*w/o.* Stage 1) and mBART, although "dirt" in the source caption, produce imprecise translations, reflecting overlooking of the modality-specific information. This case shows the effectiveness of MSGs that can well embrace modality gaps by multimodal graph fusion and fully preserve multimodal information for improving translation. Other cases from Test2016 are shown in Appendix B.

(ii) Temporal states. In Figure 4 (middle), the MSG captures a scene with "are gathered around the stage or platform", enabling full GIIFT to recognize it as a completed state and generate the appropriate perfect tense in German. In contrast,

both GIIFT (*w/o.* Stage 1) and mBART, limited by modality gap, cannot capture the temporal state from an aligned visual-linguistic space, which eliminates the unique temporal state from the image. So they translate English "are gathered" directly into the German present tense.

(iii) Action states. Figure 4 (right) shows the MSG's action state "is running towards" guides GIIFT (image-free) to correctly translate the action as "shoot" rather than "kick". The visual information, available only through MSG, enables the correct translation from multimodal knowledge. GIIFT (*w/o.* Stage 1) and mBART, however, can only literally translate to "kick" in German, which also shows the importance of accepting different modality-specific information rather than alignment.

6 Conclusion

This work introduces GIIFT, a two-stage graph-guided inductive MMT framework, along with novel Multimodal and Linguistic Scene Graphs. GIIFT outperforms existing MMT models on Multi30K even with image-free inference, demonstrating the effectiveness of learning multimodal knowledge in a unified space via MSGs and achieving cross-modal generalization via LSGs. Its image-free performance remains robust, matching its multimodal-inference counterpart. GIIFT also outperforms both the text-only NMT backbone and leading image-free MMT baselines on WMT, showing effective induction of multimodal knowledge to broader text-only domains. Further analysis highlights the advantages of multimodal graph-guided generalization for image-free inference and confirms the effectiveness of the two-stage framework with a lightweight but efficient GAT adapter for cross-modal inductive learning.

A Scene Graph Prompts for LLaVA

Please analyze the image provided and construct a structured scene graph, adhering to the following guidelines, and represent it in a JSONL (JSON Lines) format:
1. Entities: List all significant objects or subjects visible in the image, which may include things, animals, or people. Describe each entity in detail, noting their quantities, colors, and any distinctive features. Each description should be distinct and consistent across the document to ensure clarity.
2. Relations: Define all pivotal relationships between the entities using tuples. Each tuple must maintain the exact terminology used in the entities' descriptions. These relationships should be expressed as triplets: [subject entity, predicate, object entity]. Importantly, ensure that the scene graph forms a connected structure. Every entity appearing as a subject or object in one relation must connect to another entity in a different relation, preventing any isolated nodes or subgraphs within the graph. In cases involving an entity related to multiple others, such as being 'between' or 'consist of' them, express this by dividing the relationship into distinct tuples using descriptors like 'is positioned between' and 'and also between' to maintain clarity. Generate triplets with a subject, an active verb or relational word, and a distinct object. Each triplet should clearly describe an action or relationship, avoiding states or implied conditions.
Avoid focusing on too detailed or minor elements that do not significantly contribute to the scene's overall understanding. Use active verbs that show a clear action or relationship. Avoid state or possession verbs like "have" that imply a condition without a distinct action. Incorrect Relations Examples to Avoid:

1.["one person in red shirt", "one dog", "one cat"] (lacks clear action)
2.. . . . . .
Correct Relations Examples of the above, the number of the example is the same as the number of the incorrect example:

1.["one person in red shirt", "is holding", "a book"]
2.. . . . . .
Key Point: Ensure every triplet uses an active verb or distinct relational word to connect the subject and object, clearly describing a specific action or relationship and forming a triplet.

This structure ensures that the scene graph is comprehensive and interconnected, accurately reflecting the dynamics and layout of the scene. The response must strictly follow the JSONL format specified here and not include any extraneous text.

This is a scene graph JSONL example response of the Example Image, the entity_descriptions1, entity_descriptions2, entity_descriptions3, entity_descriptions4 and entity_descriptions5 need to be replaced by specific entities in the image. The relation word1, relation word2, and relation word3 are also need to be replaced by the specific action or relation you observe in the given image. Also, the number of entities and relations is not fixed. It should depend on the given image. The following scene graph JSONL is just an example. You need to describe the real relations based on your given image.

```
{"entities": ["entity_descriptions1", "entity_descriptions2", "entity_descriptions3",
"entity_descriptions4", entity_descriptions5], "relations": [["entity_descriptions1",
"relation word1", "entity_descriptions3"], ["entity_descriptions2", "relation word2",
"entity_descriptions4"], ["entity_descriptions1", "relation word3", "entity_descriptions5"]]}
```

You must not include the word 'image' in the scene graph JSONL. You must not copy the example above! You must describe the entities and their relationships in the given image. Now, you must respond to the scene graph based on the image provided! Straitly follow my instructions. Now what is the scene graph of the image?

We use an RTX A6000 GPU to employ Llava-34B. For each query, the system info explains the task description and provides guidelines for scene graph generation in JSONL format. We also have a quality assessment script to discard any ISG data that fails to meet our generation task description presented in the prompts. We take a temperature of 0 as the default for multimodal large language models (MLLMs) to have a relatively robust performance. If the MLLM can't generate scene graphs that meet the requirements with a temperature of 0, we'll switch to a temperature of 0.4. We exclusively use MLLM for image preprocessing to generate scene graphs according to our task description, with quality ensured by the script.

Source Caption	**Several women are performing a dance in front of a building**	**A crowd gathered around a park water fountain in the rain.**
Target Caption	**Mehrere Frauen führen vor einem Gebäude einen Tanz auf.** ***(Several women perform a dance in front of a building.)***	**Eine Menschenmenge hat sich im Regen um einen Springbrunnen im Park versammelt.** ***(A crowd has gathered in the rain around a fountain in the park.)***
GIIFT (ours)	**Mehrere Frauen führen vor einem Gebäude einen Tanz auf.** ***(Several women perform a dance in front of a building. (BLEU: 100.00))***	**Eine Menschenmenge hat sich im Regen um einen Springbrunnen im Park versammelt.** ***(A crowd has gathered in the rain around a fountain in the park. (BLEU: 100.00))***
GIIFT (*w/o.* Stage 1)	**Mehrere Frauen führen vor einem Gebäude einen Tanz vor.** ***(Several women present a dance in front of a building. (BLEU: 78.25))***	**Eine Menschenmenge versammelt sich im Regen um einen Springbrunnen im Park.** ***(A crowd is gathering in the rain around a fountain in the park. (BLEU: 64.56))***
mBART	**Mehrere Frauen führen einen Tanz vor einem Gebäude auf.** ***(Several women perform a dance in-front-of a building up. (BLEU: 33.03))***	**Eine Menschenmenge hat sich um einen Springbrunnen im Regen versammelt.** ***(A crowd has gathered around a fountain in the rain ~~in the park~~. (BLEU: 45.52))***

Figure 5: Case study of GIIFT on image-free inference when compared to GIIFT (*w/o.* Stage 1) and the mBART. Data points are drawn from the Test2016 set of Multi30K. The gold sentence represents the ground truth. The italicised sentence in the bracket presents the English translation of the German text, while red words highlight the crucial translation differences.

B Case Study on Multi30K Test2016 Set

As shown in Figure 5 (Left), our full model, GIIFT (image-free), correctly associates the text with visual scene context to translate the separable verb accurately, using "auf" to express the "perform" action, whilst GIIFT (*w/o.* Stage 1) incorrectly translates it as "vor" to express "present". mBART fails to properly understand the scene, resulting in disordered word arrangement.

As shown in Figure 5 (Right), our full model, GIIFT (image-free), correctly generalizes the tense from textual to visual information, accurately translating the crowd's gathered state as "has gathered" rather than directly translating "gathered". GIIFT (*w/o.* Stage 1) incorrectly translates it as the progressive tense "is gathered". Although mBART uses the correct tense, it still fails to properly understand the scene context, omitting the location "in the park" and misattributing the modifier "in the rain", leading to overall semantic confusion.

Specification-Aware Machine Translation and Evaluation for Purpose Alignment

Yoko Kayano[1,2] **Saku Sugawara**[1,2]

Abstract

In professional settings, translation is guided by communicative goals and client needs, often formalized as specifications. While existing evaluation frameworks acknowledge the importance of such specifications, these specifications are often treated only implicitly in machine translation (MT) research. Drawing on translation studies, we provide a theoretical rationale for why specifications matter in professional translation, as well as a practical guide to implementing specification-aware MT and evaluation. Building on this foundation, we apply our framework to the translation of investor relations texts from 33 publicly listed companies. In our experiment, we compare five translation types, including official human translations and prompt-based outputs from large language models (LLMs), using expert error analysis, user preference rankings, and an automatic metric. The results show that LLM translations guided by specifications consistently outperformed official human translations in human evaluations, highlighting a gap between perceived and expected quality. These findings demonstrate that integrating specifications into MT workflows, with human oversight, can improve translation quality in ways aligned with professional practice.

1 Introduction

High-quality translation in professional settings requires more than a literal rendering of the source text. It must also fulfill a communicative purpose, which depends on factors such as the intended function, target audience, and the broader context of the original text (Reiss and Vermeer, 1984; Nord, 2006). A single source text may yield different translations depending on these factors.

These contextual factors are typically documented as *translation specifications*. A specification is a predefined set of conditions that guide the translation process, including purpose, audience, tone, style, and content priorities (ISO17100:2015; JTF, 2018). They help translators make informed decisions and ensure that the translation meets user needs (Reiss and Vermeer, 1984; Nord, 2006). Without such guidance, translators may struggle to begin the process at all.

Specifications are also essential in translation evaluation. Frameworks such as ISO 5060 and the Multidimensional Quality Metrics (MQM) emphasize specification-based assessment (ISO5060:2024; Lommel et al., 2013). Lommel et al. (2013) state that "translation quality can only be assessed in terms of whether or not a translation meets specified requirements and meets its communicative purpose." When specifications are absent or vague, evaluations tend to focus on surface-level features such as lexical accuracy or fluency, rather than on whether the translation achieves its communicative purpose. This perspective is also central to functionalist theories in translation studies, which hold that quality should be judged by how well a translation fulfills its intended purpose in the target context, rather than by equivalence with the source text (Reiss and Vermeer, 1984).

MQM is widely adopted in machine translation (MT) research, including the Conference on Machine Translation (WMT), where it underpins human evaluation (Freitag et al., 2021, 2024; Zerva et al., 2024). Its detailed error typology has contributed to translation evaluation. However, specifications are often treated implicitly, and the idea of translation as a goal-oriented process is not fully integrated into MT research. As a result, MT outputs often fall short in real-world applications where purpose and audience matter. This gap is increasingly problematic as industry clients now expect translations to serve specific business objectives (Lommel et al., 2024a).[1]

In response, we propose a framework for specification-aware MT and evaluation. Figure 1 outlines this framework, contrasting traditional

[1]See Appendix A for further discussion.

Proceedings of the Tenth Conference on Machine Translation, pages 113–141
November 8-9, 2025

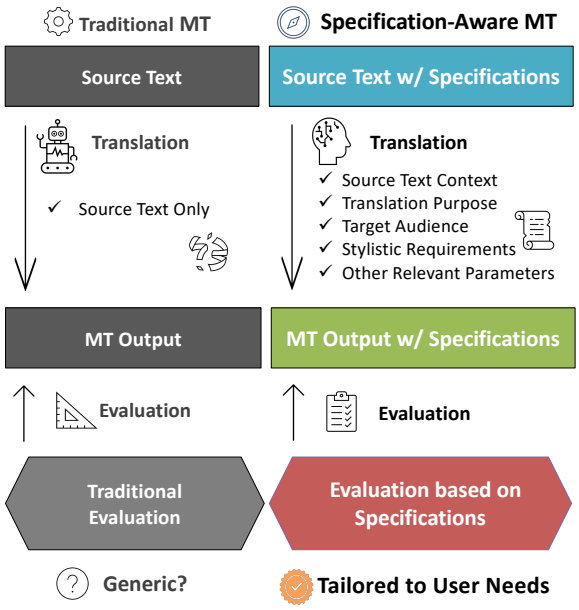

Figure 1: Comparison of traditional MT pipelines, based solely on the source text, and specification-aware pipelines that incorporate contextual and purpose-specific information.

MT pipelines with our approach, which incorporates contextual information and specification-based evaluation. This approach reflects the functionalist view that translation should be guided by purpose, audience, and context. Incorporating specifications into MT workflows and evaluation is essential for improving translation quality in professional domains. To support this claim, we present the theoretical foundation for understanding the role of specifications in Section 3. We introduce a practical guide based on international standards such as ISO 5060, ISO 17100, MQM, and the JTF guidelines in Section 4 (ISO5060:2024; ISO17100:2015; MQM, 2025; JTF, 2018). We apply this framework to a case study in Section 5.

Our case study focuses on investor relations (IR) texts from 33 publicly listed Japanese companies, where alignment with specifications is crucial. We compare five English translations: the company's official version, a proprietary MT output, a basic prompt-based LLM output, a prompt-based LLM output using specifications, and a prompt-based LLM post-edit of the MT output.[2]

We evaluate the translations through expert error analysis, user rankings, and a reference-free automatic metric. Results show that prompt-based LLM outputs with specifications receive the highest ratings from both experts and users. Official translations score lower due to stylistic shortcomings, and conventional MT outputs also underperform. In contrast, the automatic metric favors MT output, highlighting a misalignment with human judgment. This suggests that specification-aware LLM outputs better fulfill communicative goals, even if not fully reflected in current automatic metrics.[3]

Our contributions are as follows:

- We provide a theoretical foundation for incorporating translation specifications into MT and its evaluation.
- We propose a practical guide for applying specifications in MT workflows and test it on IR texts.
- We demonstrate that specification-aware prompt-based LLMs outperform official human translations in human evaluations, supported by detailed analysis.

2 Related Work

2.1 Customizable Machine Translation

Recent studies have explored how MT can be adapted to specific contexts using external knowledge, prompts, and post-editing beyond the source text.[4] Though not framed as translation specifications, these efforts share similar goals with ours.

Fujita (2021) highlights the limits of text-to-text neural machine translations (NMT), emphasizing the need for style guides, terminology, and domain knowledge. He (2024) and Jiao et al. (2024) show that prompting GPT-4 with contextual cues and post-editing improves translation quality. Liu et al. (2025) further finds that detailed, domain-specific prompts enhance performance in specialized tasks.

For stylistic and functional control, Moslem et al. (2023), Wang et al. (2023), and Yamada (2023) show that incorporating tone, terminology, and information about the translation's purpose and audience leads to more targeted outputs. Raunak et al. (2023) also demonstrate that post-editing

[2]Throughout this paper, *LLM* refers to large language models guided by prompt-based customization. We use *post-edit* in a broad sense, including automated revision, and not limited to human editing as defined in ISO 18587 (ISO 18587:2017, 2017).

[3]All translation data and evaluation results are available at https://github.com/nii-cl/Specification_aware_MT.

[4]For a discussion of prior work on controllable MT in the Statistical Machine Translation (SMT) and NMT eras, see Appendix B.

GPT-4 output improves English–Chinese and English–German translation quality.

These studies share motivations with our work on specification-aware translation. Our study extends these efforts by using real corporate materials and evaluating translation outputs in a practical setting. We explore the potential of prompt-based LLMs to meet specific professional translation requirements, based on human evaluation.

2.2 Advances in Translation Evaluation

Recent work in translation evaluation moves beyond gold references and explores reference-free approaches (Blain et al., 2023; Freitag et al., 2023, 2024; Zerva et al., 2024). Evaluation criteria also expand to include contextual coherence and fine-grained error types. For document-level automatic evaluation, Vernikos et al. (2022) improve sentence-level metrics by incorporating context. Jiang et al. (2022) propose BlonDe, a metric that evaluates discourse coherence using span-level F1 scores. Meta-evaluation, such as that of Moghe et al. (2025), examine whether metrics can detect diverse error types and highlight their limitations.

MQM-based automatic evaluation has gained traction: GEMBA-MQM (Kocmi and Federmann, 2023a), AutoMQM (Fernandes et al., 2023), and xCOMET (Guerreiro et al., 2024) identify error spans and types without language-specific tuning. CATER (Iida and Mimura, 2024) offers reference-free, multi-dimensional evaluation with LLMs, while MQM-APE (Lu et al., 2025) adds automatic post-editing to LLM-based error annotation to focus on quality-improving edits.

Human evaluation also remains essential. Lommel et al. (2024b) present an MQM scoring framework with calibrated models. MQM-Chat (Li et al., 2025) adapts MQM for chatbot, and ESA (Kocmi et al., 2024) streamlines span-level annotations for non-expert assessments.

Building on these developments, our study incorporates ISO 5060 and MQM principles into a specification-aware evaluation framework. To better capture translation quality, we assess translations using expert annotators, end-user judgments, and automatic metrics, highlighting both linguistic quality and functional adequacy.[5]

[5]Appendix C provides more context on discussions of evaluation method reliability and improvement in NLP.

2.3 Translation Theory and Machine Translation

Several studies explore interactions between translation studies and MT research. Tan et al. (2023) apply Skopos-based criteria to compare human and NMT outputs, showing that human translations perform better due to NMT's contextual and lexical limitations. Liu et al. (2024) recommend integrating Skopos theory into human evaluation, while Na et al. (2024) show that theory-informed prompts affect LLM outputs. Hiebl and Gromann (2023) call for a unified concept of translation quality to support collaboration between the fields.

The point raised by Hiebl and Gromann (2023) is important: clarifying how the two fields define and evaluate translation quality may help advance both. To this end, we combine theoretical insights from translation studies with empirical experiments based on real-world workflows, aiming to explore how MT can better address the practical needs of professional translation. This integration of theory and practice enables a more realistic understanding of MT's role in professional contexts.

3 Theoretical Background

While translation is often seen as producing an equivalent text in another language, the notion of *equivalence* has faced criticism in translation studies since the late 1970s. In response, functionalist approaches have gained prominence, viewing translation as a purpose-driven communicative act. Skopos theory, a widely cited framework, holds that translations should be guided by their purpose. Based on this view, we argue that translation specifications are essential for developing and evaluating MT systems that meet real-world goals.

We begin with equivalence theory, which frames translation as reproducing the meaning or value of the source text, a view reflected in early MT systems and many current automatic evaluation methods (Section 3.1). We then turn to Skopos theory, a functionalist perspective aligned with our emphasis on translation specifications (Section 3.2). Finally, we discuss how specifications matter not only for translation but also for evaluation (Section 3.3).

3.1 Equivalence Theory in Translation Studies and Machine Translation

Equivalence theory (Nida, 1964), which views translation as reproducing the source text's meaning and value, has long been central to translation

studies.[6] Dyvik (1992) explores this concept in MT, proposing a *situation schema*, an abstract representation that links source and target texts through shared meaning. He emphasizes the importance and difficulty of achieving equivalence, even with linguistic theories and technology.

In contrast, Hardmeier (2015) analyzes how statistical machine translation (SMT) operationalizes equivalence through techniques such as word alignment and domain modeling. While SMT reflects equivalence-based assumptions, he argues it oversimplifies translation complexity.

These studies illustrate how earlier MT systems, primarily rule-based and statistical, were shaped by equivalence-oriented thinking. Although neural networks and deep learning emerged in the mid-2010s (Bahdanau et al., 2015), earlier systems dominated the field and adhered to formal equivalence.

Even with advances in MT technology, equivalence continues to shape quality evaluation. Metrics such as BLEU (Papineni et al., 2002) and METEOR (Banerjee and Lavie, 2005) assess similarity to references, often through n-gram overlap, reflecting a formal equivalence perspective. Recent model-based metrics like COMET (Rei et al., 2020) and BLEURT (Sellam et al., 2020) seek semantic equivalence, yet rely on source-text alignment.

Since the late 1970s, however, equivalence theory has faced criticism. Snell-Hornby (1995) argues that it lacks precision and falsely implies symmetry between languages. She identifies the 1980s cultural turn as a shift from language-based approaches to views considering sociocultural context and the translator's role (Snell-Hornby, 2006).[7]

Although equivalence has become less central in translation studies, it is still prominent in MT practice and evaluation. While semantic equivalence remains foundational, it does not fully address the diverse purposes and communicative contexts of real-world translation. Functionalist approaches, such as Skopos theory, offer a useful complement. Emphasizing the intended function, Skopos theory provides a more practical framework for guiding both human and MT in applied settings.

[6]Equivalence theory includes various perspectives, including formal equivalence, which preserves structure, and dynamic equivalence, which aims for a similar reader response (Nida, 1964; Munday et al., 2022; Pym, 2023).

[7]This shift is reflected in major anthologies such as *The Translation Studies Reader* (Venuti, 2021), whose fourth edition retains only Nida (1964) for equivalence theory, omitting figures like Vinay and Darbelnet (1958) and Catford (1965).

3.2 Skopos Theory and the Functional Approach to Translation

Skopos theory defines translation not as a linguistic transfer but as an intentional activity to fulfill communicative goals (Reiss and Vermeer, 1984). Nord (2006) develops this perspective by introducing translation brief (or specification), a set of instructions outlining the purpose, audience, and conditions for the translation. She emphasizes that translation decisions are not solely determined by the source text, but by how well it serves its function.

Gouadec (2007) applies the functionalist approach to translation workflows by identifying three criteria: the client's objectives (e.g., increasing sales or enhancing brand image), the user's needs (e.g., clarity in technical documentation), and the relevant usage norms and standards. As Pym (2023) notes, this positions translators as "language technicians" who operate within a broader communication strategy, ensuring that the translation fulfills its specific role.

This functionalist perspective, once limited to human translation, may now extend to MT with the emergence of prompt-based LLMs. Earlier domain-specific MT systems required significant resources, including specialized datasets, expert tuning, and time-consuming model training (Saunders, 2022; Wang et al., 2023). In contrast, prompt-based LLMs allow users to specify translation requirements through prompting or fine-tuning, making it easier to adapt translations to their intended purpose (Section 2.1). Although empirical evidence is still emerging, customization is now easier, and the rise of LLMs marks a technological shift that aligns with the functionalist view of translation.

Our study investigates whether and how recent advances in MT, especially prompt-based LLMs, can support a functionalist approach by producing translations aligned with specifications. This perspective shifts the focus from linguistic equivalence to functional effectiveness and offers insights for improving MT design and evaluation.

3.3 Why Specifications Matter

Specifications may include parameters such as purpose, target audience, style, register, domain, timeline, cost, volume, reference materials (e.g., glossaries and style guides), file format, and quality evaluation methods (ISO17100:2015; JTF, 2018). In professional settings, such specifications guide translation decisions and ensure the translation

	Parameter	Description
1	Purpose of translation	Communicative goal (e.g., inform, persuade, comply, etc.)
2	Target audience	Intended readers and their language background or expectations
3	Style, register, and tone	Formality, style, and tone appropriate for the target context
4	Terminology and reference resources	Use of glossaries, style guides, and prior translations
5	Domain and legal requirements	Industry norms and compliance with relevant laws
6	Cultural adaptation	Adjustments for cultural norms or sensitivities
7	Length and formatting	Constraints on text length, layout, or structure
8	Localization needs	Regional or language variant customization

Table 1: Translation specification parameters. Items 1–3 are essential; others may vary by project.

meets client expectations. Even if undocumented, essential requirements are typically agreed upon in advance and vary by project. For example, legal translations emphasize consistency with terminology and style guides, while marketing texts prioritize creativity and persuasive language.

The importance is also reflected in how translation quality is evaluated. The MQM framework defines translation quality as follows:

> A quality translation demonstrates required accuracy and fluency for the audience and purpose and complies with all other negotiated specifications, taking into account end-user needs (Melby, 2012a; Lommel et al., 2013).

As explained in the Multi-Range Theory (Lommel et al., 2024b), quality evaluation begins with an analysis of project specifications and user needs. Evaluators should *select* appropriate error categories and scoring models based on this analysis. These ideas are emphasized in the 2024 MQM anniversary paper (Lommel et al., 2024b).[8]

Specifications not only guide translators but also constrain the range of acceptable choices, helping to reduce subjectivity. As Gouadec (2007) argues, translators are language technicians whose "plurality is his enemy," highlighting the importance of clear instructions (Pym, 2023). This applies equally to evaluation: assessments grounded in specifications are less influenced by personal interpretation.

Research shows that providing clear criteria and context improves inter-annotator agreement (IAA) (Castilho, 2021; Popović, 2021). The official MQM website also notes that the framework supports standardized, objective evaluation by minimizing subjective judgment (MQM, 2025). For details on how translation specifications can be incorporated into MQM-based evaluation, see Appendix E.

[8]The MQM framework draws on Garvin (1984)'s approach to quality. See Appendix D for further explanation.

4 A Practical Guide for Specification-Aware MT and Evaluation

We provide a brief overview of our practical framework for integrating translation specifications into both MT workflows and evaluation, where MT is performed using prompt-based LLMs.[9] A full version is available in Appendix F.

4.1 Specification-Aware Machine Translation with Prompt-Based LLMs

Step 1: Define Specifications Clarify translation requirements. These form the basis for both machine output and human review. Our specification parameters, listed in Table 1, are independently developed based on professional translation practice and informed by existing standards and research (ISO17100:2015; 11669:2024; Melby, 2012b).

The top three items are essential for all translation projects, regardless of domain or medium. The remaining items are project-dependent and may be included as needed. Additional parameters may be added depending on the context or client requirements. A brief explanation and examples for each item are provided in Appendix F.1.

Step 2: Design Instructions Specifications should be reflected in prompts or fine-tuning. It is important that the instructions also include source text information, target language, and relevant specification parameters, while preventing hallucination and over-generation.

Step 3: Generate and Review Use LLMs to generate the translation, followed by human review to ensure the output meets specifications. Reviewers make corrections and finalize the translation.

[9]We base our translation and evaluation guidelines on a typical professional workflow and ISO 17100 for translation, and on ISO 5060, JTF guidelines, and MQM for evaluation (ISO17100:2015; ISO5060:2024; JTF, 2018; MQM, 2025).

4.2 Specification-Aware Evaluation

Translation evaluation is not always conducted alongside the translation itself. It may be required in various contexts, such as accepting or rejecting a translation, comparing outputs, selecting the best version, ensuring quality in professional workflows, evaluating MT results, or training and certifying translators. We outline a framework that incorporates both objective and subjective evaluations.

Step 1: Make Specifications Accessible Ensure all evaluators have access to the translation specifications. If not provided in advance, define them before evaluation begins.

Step 2: Define Error Categories Set error categories (e.g., Accuracy, Style, Terminology, etc.) aligned with the specifications. Use established frameworks such as MQM and ISO 5060 (MQM, 2025; ISO5060:2024).

Step 3: Weight and Score Errors Assign weights to error categories based on project priorities. Evaluate severity (e.g., minor, major) and calculate a total score using a weighted formula.

Step 4: Add Subjective Evaluation (Optional) In addition to error-based scoring, subjective evaluation helps assess whether a translation is appropriate, persuasive, and effective for its intended audience. Feedback from experts or users can offer insights into clarity, tone, and impact that error metrics alone may overlook.

The following case study demonstrates the application of this practical guide.

5 A Case Study in Japanese-to-English Translation of Investor Relations Materials

We present a case study to show how specification-aware translation can be applied using a prompt-based LLM. We compare it with human translation and non-prompt-based MT outputs, examining how each is evaluated through both human and automatic methods. This case study puts into practice the notions discussed earlier in Section 3 and assesses the effectiveness of our approach in a real-world Japanese-to-English translation task.

Figure 2 provides an overview of the case study. For LLM, we use ChatGPT via its public interface to simulate a scenario in which non-expert users, such as translators or corporate communications personnel, can control translation output through prompting, without needing specialized tools or programming skills.

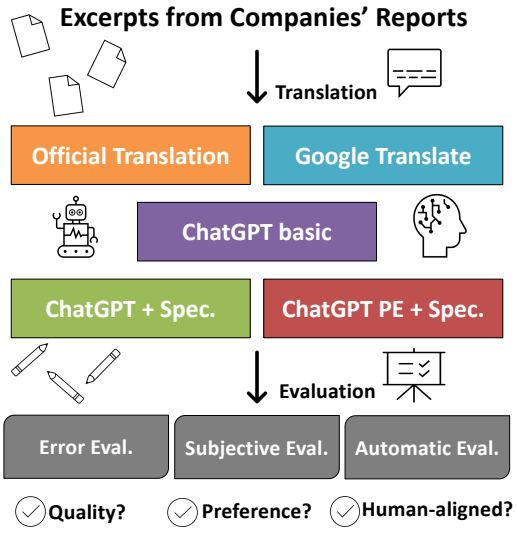

Figure 2: Overview of the case study: Five translation types and their evaluation via expert, user, and automatic methods.

5.1 Experimental Setup

5.1.1 Integrated Reports

We use IR materials excerpted from integrated reports by publicly listed Japanese companies as the source text. The focus is on Japanese-to-English translation; the rationale for using this language pair is explained in Appendix G.

Integrated reports combine financial and non-financial information to communicate a company's value creation to investors and other stakeholders. Although not legally required in Japan, their publication has increased with growing interest in ESG investment. As of the end of 2023, 1,019 companies issue integrated reports, 70 percent of which also provide English versions (ESG/Integrated Reporting Research Laboratory, 2024). Among Prime Market companies, over half publish integrated reports. We choose integrated reports because they are more structured than websites and more interpretive than financial statements, posing challenges for both human translators and MT systems.

We focus on the corporate philosophy section, typically found at the beginning of these reports. According to the *Guidance for Collaborative Value Creation 2.0* (Ministry of Economy, Trade and Industry, 2022), such statements are central to investor communication and must clearly express a company's unique values. Translating them re-

Type	Translation Output
Source	“ワクワク”は, 人を動かすエネルギー. それは人から人へと伝わり、世界をあかるく元気にする。
Official	“Waku waku” is what moves people to push what’s possible. It’s Japanese for the joy and excitement of discovering the unknown. And when passed from person to person, becomes a force that creates a brighter world, united in wonder.
Google	“Excitement” is the energy that moves people. It spreads from person to person, making the world brighter and more energetic.
GPT-b	“Excitement” is the energy that moves people. It spreads from person to person, bringing brightness and vitality to the world.
GPT+Sp	Excitement is the energy that moves people. It spreads from person to person, brightening and invigorating the world.
PE+Sp	“Excitement” is the spark that moves people, spreading from one person to another, brightening and energizing the world.

Table 2: Differences in translations (All Nippon Airways Co., Ltd.)

quires not only literal accuracy but also clarity, an appropriate corporate tone, and expressions that enhance appeal to stakeholders.

We select one company from each of the 33 industries defined by the Tokyo Stock Exchange (Japan Exchange Group, Inc., 2021), prioritizing those with higher market capitalization (27 first-ranked, five second-ranked, and one fourth-ranked).[10] The extracted sections range from 240 to 927 Japanese characters, with an average of 610.

We manually confirmed alignment with the Japanese source texts and asked companies how their English versions were produced. Of the 33 companies, 20 responded. Among these, 15 used only human translation, two combined human and MT, two declined to disclose their method, and one outsourced the work without providing details. None reported using MT alone, suggesting that human translation remains standard.

5.1.2 Five Translation Methods

To compare translation quality and effectiveness, we prepare five versions using different methods. The official translation consists of excerpts from English versions of integrated reports published by the companies.

We then create four MT-based versions:

- **Google Translate**: raw output from Google Translate
- **ChatGPT basic**: ChatGPT with a minimal prompt
- **ChatGPT + Spec**: ChatGPT with specifications
- **ChatGPT PE + Spec**: Google Translate post-edited by ChatGPT with specifications

To ensure consistency, we use the first output for all versions. All ChatGPT translations are generated using ChatGPT-4o.

[10]The full list appears in Appendix H.

For the specification-aware methods, we provide prompts that reflect key information such as source text context, intended purpose (e.g., appealing to global investors), target audience, and stylistic tone. The full prompt is shown in Appendix I.

Using these methods, we generate five translations for each of the 33 companies. Manual review indicates that all versions maintain overall meaning without serious accuracy errors. However, we observe a recurring issue in ChatGPT translations: kanji misinterpretation. For example, 文殊院旨意書 (Monjuin Shiigaki) is rendered incorrectly as *Monjuin Shiisho*, lacking accurate transliteration. This suggests that ChatGPT struggles with domain-specific terminology and proper nouns.

Table 2 shows translations of a corporate philosophy excerpt from All Nippon Airways Co., Ltd.’s integrated report. The official translation contains a grammatical error (“And when passed... becomes...”) and phrases that may be unclear or unnatural (“to push what’s possible”). It also gives an extended explanation of *waku waku*. The Google translation is grammatically correct but closely mirrors the source, resulting in a literal tone and basic vocabulary. The ChatGPT basic version improves fluency and uses slightly richer expressions (“vitality”), but its tone and structure remain similar to the Google version. The ChatGPT version with specifications uses more active verbs and parallel phrasing (“brightening and invigorating”), resulting in smoother rhythm and tone. The post-edited version with specifications introduces vocabulary like “spark” and “energizing,” while preserving the original meaning and structure.

These examples show that each method yields distinct results and that adding specifications to ChatGPT prompts may encourage more purposeful and expressive language. Appendix J provides a comparative analysis of a longer excerpt from the same source, focusing on linguistic and stylistic differences.

5.2 Human Evaluation

After preparing translations for all 33 companies, we conduct two human evaluations of the five translation methods: expert error evaluation and subjective evaluation.

5.2.1 Error Evaluation

We conduct an error-based evaluation using the specification-aware framework introduced in Section 4.2 and detailed further in Appendix F.2. This evaluation focuses on three core categories: Accuracy, Linguistic Conventions, and Style. Other categories defined in the MQM framework, such as Design and Markup, are excluded as they are not applicable to the scope of this study.

All category definitions are based on the MQM standard and were provided to the evaluators to ensure consistency and shared understanding (MQM, 2025). See Appendix K for the detailed error categories used in the annotation.

Given the importance of stylistic quality in IR materials, we include four subtypes under Style: (1) Language register mismatch, (2) Awkward style, (3) Unidiomatic expressions, and (4) Inconsistent style. These errors do not hinder comprehension but result in unnatural English that may reduce clarity and impact. Subtypes help clarify scope, but annotators classify errors only at the main category level to reduce cognitive burden. Error categories are weighted based on JTF guidelines: Accuracy (0.7), Linguistic Conventions (0.8), and Style (1.5), averaging to 1.0 overall (JTF, 2018). We do not apply severity levels, as the texts do not involve high-stakes content such as financial figures.

Two professional evaluators, each either a professional translator or an expert in linguistics and culture, bilingual in Japanese and English, and with English as their first language, are recruited via Prolific.[11] They receive the Japanese source text, translation specifications, five anonymized English translations, an error typology table with definitions, and sample annotations. They identify errors, assign them to one of the three categories, mark their locations, and record error counts. Each evaluator is compensated £40 for approximately 270 minutes of work. Only two out of 24 recruited participants completed the task, highlighting the practical difficulty of securing qualified evaluators and the cognitive demands of error annotation, as noted in prior research (Kocmi et al., 2024; Zouhar et al., 2025).

[11] https://www.prolific.com

Type	Official	Google	GPT-b	GPT+Sp	GPT PE+Sp
Eval. 1	*2.60*	1.82	1.04	0.70	**0.38**
Eval. 2	*3.01*	2.29	1.28	1.29	**1.03**

Table 3: Weighted error scores averaged across 33 companies. Lower scores indicate fewer errors and higher translation quality.

Table 3 presents the evaluation results. ChatGPT PE + Spec receives the lowest error score (highest quality), followed by ChatGPT + Spec, ChatGPT basic, and Google Translate. The official translation ranks lowest, with particularly frequent Style errors, which will be discussed in Section 5.2.3. These findings suggest that LLM-based translations guided by specifications can outperform human translations in this context, challenging the assumption that human translations should serve as the default gold standard in MT evaluation.

We also assessed inter-annotator reliability by calculating the correlation between the error scores assigned by the two evaluators. Pearson's correlation is very high (r = 0.985 and p = 0.0021), while Spearman's rank correlation is also strong (ρ = 0.90 and p = 0.037), indicating statistically significant agreement. Nonetheless, we observe inconsistencies: the same expression was sometimes marked as an error in one translation but not in another by the same evaluator. This indicates the inherent difficulty of ensuring consistency in error-based evaluation, even among professionals. The low completion rate suggests that translation evaluation is time-consuming, cognitively demanding, and difficult to delegate, as it requires a high level of expertise. Our evaluation process incidentally reflected these challenges in practice.

5.2.2 Subjective Evaluation

To understand how translations are perceived by intended end users, we conduct a subjective evaluation alongside expert-based error analysis. As discussed in Section 4.2 and detailed in Appendix F.3, combining error-based and subjective evaluation is useful not only when qualified annotators are limited, but also when end-user perspectives take precedence. For texts like integrated reports, which aim to build trust and attract investment, reader impression may matter more than linguistic accuracy, making subjective feedback particularly valuable.

Subjective evaluation is generally divided into expert and end-user perspectives (JTF, 2018).

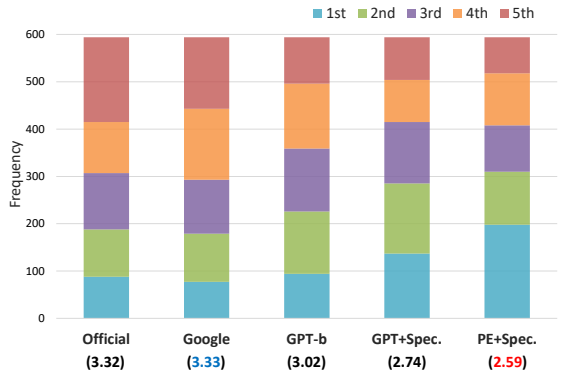

Figure 3: Ranking counts from the subjective evaluation. The x-axis shows translation methods, and the y-axis shows frequency. Each bar is stacked by rank (1st to 5th). Numbers in parentheses indicate mean rankings; lower values reflect higher preference.

Since integrated reports target investors, we adopt an end-user perspective. We recruited eighteen native English speakers via Prolific. Participants are compensated £13.50 for approximately 90 minutes of work. Seventeen hold degrees in fields such as accounting or finance. One participant is a translator and linguistic expert who also took part in the error evaluation. Each evaluator receives the translation specifications and five English translations, without knowing the translation methods or having access to the Japanese source. They are asked to rank the translations based on overall appeal, defined as clarity, readability, word choice, and company presentation.

Figure 3 shows the distribution of rankings across translation types. ChatGPT PE + Spec is most often ranked 1st, whereas the official translation is most often ranked 5th. Google Translate is the least often ranked 1st, while the three ChatGPT-based translations are less often ranked last. Numbers in parentheses indicate mean rankings: ChatGPT PE + Spec has the best (lowest) average ranking, followed by ChatGPT + Spec, ChatGPT basic, and the official translation. Google Translate ranks lowest overall.

To assess significance, we conduct Wilcoxon signed-rank tests on all ten translation pairs, reporting the test statistic (W), p-values, and effect sizes (r) in Table 4. A p-value below 0.05 is considered significant; effect sizes are interpreted as small ($r = 0.1$), medium ($r = 0.3$), or large ($r = 0.5$). All comparisons are significant except Official vs. Google Translate and ChatGPT + Spec vs. ChatGPT PE + Spec. Pairs with ChatGPT PE + Spec (vs. Official and Google Translate) show the strongest effects, with $p \approx 0$ and medium effect sizes.

Pair	W	Z	p	r
Off. vs Ggl	88018	0.081	0.9341	0.003
Off. vs GPT-b	74913	3.213	0.00113	0.132
Off. vs GPT+Sp	**63954**	**5.832**	$p < 0.00001$	**0.239**
Off. vs PE+Sp	**59011**	**7.013**	$p < 0.00001$	**0.288**
Ggl vs GPT-b	73843	3.469	0.00043	0.142
Ggl vs GPT+Sp	**62409**	**6.201**	$p < 0.00001$	**0.254**
Ggl vs PE+Sp	**57082.5**	**7.474**	$p < 0.00001$	**0.307**
GPT-b vs GPT+Sp	75367	3.104	0.00162	0.127
GPT-b vs PE+Sp	68326.5	4.787	$p < 0.00001$	0.196
GPT+Sp vs PE+Sp	81396.5	1.664	0.0903	0.068

Table 4: Wilcoxon signed-rank test for translation pairs. A significant difference is defined as $p < 0.05$. Effect size (r) is interpreted as small (0.1), medium (0.3), and large (0.5).

These results show that ChatGPT PE + Spec is consistently preferred, in line with error-based evaluation findings. The low ranking of the official translation is notable, despite its presumed status as the gold standard. However, human translations often vary more than MT, depending on translator performance (Freitag et al., 2023; Ramos and Guzmán, 2024; Volz and von Thiessen, 2024). As a result, while the official translation was most frequently ranked in the lowest position, the number of times it was placed second, third, or fourth did not differ significantly. Moreover, it was ranked first more often than Google Translate and not far behind ChatGPT basic.

5.2.3 Qualitative Analysis

To gain insight into the stylistic and structural differences across translation types, we examine their sentence structure, focusing on relative clauses and clausal coordination. Our analysis shows that Google Translate and the official translations tend to use these forms more frequently, potentially reflecting source-language influence. Japanese allows for long, additive sentence constructions, which can lead to overuse of relative clauses or clausal coordination when translated too literally into English. Such structures may reduce readability, especially in English writing that values clarity and conciseness. Further details are provided in Appendix L.

We also analyze excerpts from the official translations and find recurring issues in grammar, style, and semantic clarity. For example, the expression "offering both a multitude of choices" contains a semantic mismatch between "both" and "multitude."

Type	Official	Google	GPT	GPT+Sp	GPT PE+Sp
Mean	*0.783*	**0.830**	0.822	0.821	0.810
SD	0.043	0.031	0.039	0.033	0.037

Table 5: Mean COMETKiwi scores and standard deviations for each translation type.

Other examples involved unidiomatic phrasing, sentence fragments, and inconsistent style. For detailed examples and qualitative error analysis, see Appendix M. These problems suggest that the low rating of the official translation may not stem from a lack of specifications but from variation in translator skill or mismatches with task requirements.

As mentioned in Section 5.2.2, human translations often vary in quality due to individual differences (Freitag et al., 2023; Ramos and Guzmán, 2024; Volz and von Thiessen, 2024). Combined with Japan's shortage of high-proficiency English translators (Appendix G), this may explain the observed results. By contrast, ChatGPT-based translations guided by specifications performed consistently well, suggesting their potential as a viable complement to traditional workflows.

5.3 Automatic Evaluation

We examine whether a reference-free automatic metric can capture differences in translation quality across specification and method types, compared to human judgment. To this end, we use COMETKiwi, a reference-free metric with the highest correlation to human evaluations in the WMT23 Metrics Shared Task (Rei et al., 2022; Freitag et al., 2023).[12] We adopt a reference-free approach because the official translations, typically used as references, are themselves part of the evaluation as one of the five translation types.

Table 5 shows scores from 0 to 1, with higher values indicating better quality. Low standard deviations suggest internal consistency, though overlapping ranges point to limited differences between types. Unlike the human rankings, COMETKiwi assigns the highest score to Google Translate and the lowest to the official translation. This divergence likely reflects differences in what COMET values, specifically literal fidelity and lexical similarity, as opposed to the more context-sensitive and stylistic qualities emphasized in our evaluation (Rei et al., 2022).

[12]We use the model `wmt22-cometkiwi-da`, also adopted as the WMT24 baseline for reference-free evaluation (Freitag et al., 2024).

Although the official translation appears to preserve source-like structures such as relative clauses and clausal coordination (Section 5.2.3, Appendix L), its low score may be partly explained by a few explanatory additions not present in the source, intended to assist international readers. Such additions may reduce source alignment and result in lower automatic scores.

ChatGPT PE + Spec scores slightly below Google Translate, though the difference is small. This may reflect Google Translate's more literal style, while ChatGPT PE + Spec balances fidelity and fluency, resulting in higher subjective appeal despite a lower COMET score. ChatGPT translations, particularly those guided by specifications, prioritize clarity and appeal over strict lexical matching, which COMET may not fully capture.

Although COMET metrics are known to struggle with numbers and named entities (Amrhein and Sennrich, 2022), our manual check found no significant errors in these areas, suggesting they did not affect the results.

As MT evaluation increasingly considers contextual and communicative goals, it is vital to develop automatic metrics that better capture functional aspects of translation quality, such as how well a translation fulfills its purpose in context.

6 Conclusion

We demonstrate that translation specifications can improve MT quality and enable more targeted evaluation. We provide a theoretical rationale for the importance of specifications, drawing on Skopos theory to support a functionalist perspective. Based on this foundation, we outline a practical guide for specification-aware MT using LLMs, including prompt design, generation, and both error-based and subjective evaluation.

In our case study, LLM outputs guided by specifications received higher ratings than official translations, Google Translate, or unguided LLM outputs. Although COMET scores favored Google Translate, they diverged from human evaluations. These findings suggest that specifications help LLMs produce more contextually appropriate translations that better align with communicative goals. The gap between human and automatic evaluations highlights the limitations of current metrics in capturing functional adequacy. Through this work, we demonstrate the potential of specification-aware MT for professional, real-world use cases.

Limitations

First, we use only a single LLM, ChatGPT. While its outputs are generally well-received, it occasionally introduces information not present in the source text. This highlights the importance of careful prompt design and human oversight, as is standard in professional translation workflows. Evaluating other LLMs remains an important area for future research to assess whether the findings generalize across models.

Second, our dataset consists of corporate philosophy statements from 33 Japanese companies, focusing solely on the Japanese-to-English language pair. While this allowed for a focused case study, broader validation will require larger datasets covering more diverse domains (e.g., legal and medical) and content types (e.g., marketing and technical manuals), as well as other language pairs.

Finally, our human evaluation process highlighted the difficulty of securing qualified annotators. Both the error analysis and the subjective evaluation were conducted through crowd-sourcing, and the compensation was set above the standard rates of that framework. For error analysis, which requires more specialized expertise, an alternative approach could have been to recruit evaluators through a more specialized platform and set the compensation accordingly. Such difficulties in recruiting and compensating qualified annotators emphasize the need to develop an automated and specification-based evaluation model. Future work could explore the *LLM as a Judge* (Zheng et al., 2023; Kocmi and Federmann, 2023b; Feng et al., 2025; Gunathilaka and de Silva, 2025), where an LLM evaluates outputs based on the same detailed specifications provided to human experts, potentially offering a scalable alternative to manual annotation.

Acknowledgments

We sincerely thank the anonymous reviewers for their insightful and constructive comments, which helped us improve this paper. This work was supported by JST FOREST Grant Number JPMJFR232R.

A Industry Trends from CSA Research

According to Lommel et al. (2024a) from CSA Research, an independent research firm specializing in the language services industry, language service providers (LSPs) that rely heavily on traditional human translation are experiencing declining performance. At the same time, while the growing demand for translation has outpaced the capacity of human translators, the increased use of MT alone has not led to sustainable growth (Lommel et al., 2024a).

The report encourages LSPs to shift their focus from merely producing high-quality translations to delivering greater value, such as providing cultural adaptation, adapting content for specific audiences, and training and customizing LLMs for domain-specific communication. It clearly states: "LSPs must focus on messaging that resonates with enterprise goals, and demonstrate that they use technology to achieve them (Lommel et al., 2024a)."

In response to these challenges, our study proposes a framework for specification-aware MT and evaluation.

B Historical Context of Controllable MT

As noted in Section 2.1, the goal of tailoring translation output is not new. In the eras of SMT and NMT, significant research focused on incorporating external knowledge to control specific aspects of translation.

For example, a major line of work involved leveraging existing human translations to improve consistency. This began with the convergence of Translation Memories and SMT (Koehn and Senellart, 2010) and was later adapted to NMT, such as through neural fuzzy repair mechanisms (Bulte and Tezcan, 2019). Other approaches focused on controlling discrete linguistic features, including methods to enforce terminology constraints during NMT decoding (Dinu et al., 2019) and to manage stylistic aspects such as formality (Niu and Carpuat, 2020).

While these approaches provided powerful control over discrete phenomena, they often required specialized data preparation or model retraining.

Our work builds upon this tradition but explores how prompt-based LLMs can manage a broader set of communicative specifications in a more flexible manner.

C Reliability of Evaluation Methods

Recent research has highlighted the need for more robust and transparent evaluation methods across NLP tasks, including but not limited to MT. This includes a growing interest in developing evaluation frameworks that are comprehensive, detailed, and interpretable. For instance, Nimah et al. (2023) propose the *Metric Preference Checklist*, an analytical framework that evaluates automatic natural language generation (NLG) metrics from five distinct perspectives, providing a more multifaceted evaluation of their alignment with human judgments.

In contrast, Xiao et al. (2023) point out that most research focuses only on how well metrics correlate with human ratings, often overlooking the reliability and measurement error of the metrics themselves. They argue that concepts from Measurement Theory, used in educational and psychological testing, should be applied to NLG evaluation to better assess the reliability and validity of evaluation metrics.

Gehrmann et al. (2023) outline a long-term agenda for improving NLG evaluation, including robust human evaluation protocols and the development of metrics that go beyond surface-level overlap. Meanwhile, Ruan et al. (2024) emphasize the low reliability of human evaluation guidelines in NLG, showing that only 29.84 percent of 3,233 papers in major NLP conferences shared their guidelines, and 77.09 percent of those contained some kind of vulnerability. They propose principles for more reliable guideline design and introduce a method using LLMs to detect guideline flaws.

These concerns are relevant to evaluation in MT. If the evaluation procedures are unclear, the reliability of the results cannot be ensured. In our study, we develop guidelines for both translation and evaluation and describe the experimental procedure based on these guidelines. In addition, instead of simply reporting the results, we offer analysis and possible interpretations for each finding to improve clarity and transparency.

D Garvin's Approach to Understanding Quality

Since the MQM framework is grounded in Garvin (1984)'s approach to quality, we provide a brief overview of his perspectives.

Garvin (1984), a prominent scholar in quality management, introduces five approaches to understanding quality: transcendent, product-based, user-based, manufacturing-based, and value-based. Among these, the manufacturing-based approach defines quality as meeting pre-set specifications, and the user-based approach emphasizes satisfying user needs.

Fields et al. (2014) discuss the importance of incorporating Garvin (1984)'s approach into translation quality assessment. Although the definition of translation quality is debated and Fields et al. (2014) disagree on some points, they generally agree that the production-based approach (originally "manufacturing-based" in Garvin's words), evaluating translation according to specifications, is important.

E Incorporating Specifications in MT and its Evaluation: The Case of MQM

Current research using MQM in MT evaluation often focuses on detailed error assessment. For example, the MQM framework has been used in shared tasks at the Conference on Machine Translation (WMT), such as the General Translation Task, the Metrics Task, and the Quality Estimation Shared Task.

However, specifications are not explicitly addressed in these tasks. This is because the purpose of the General Translation Task is to evaluate general MT capabilities, which may not require specific requirements, such as the purpose of the translation or the target audience, to translate the source text. This kind of general MT capability can be useful when users simply want to gain a general understanding of foreign content. However, if the goal is to communicate clearly in the target language, the translation must convey the message in a way that reflects its purpose and suits the intended reader. This cannot be done without specifications.

Freitag et al. (2021) report that in MQM evaluations of English-to-German and Chinese-to-English translations, approximately 80 percent of errors fall into the accuracy and fluency categories, with accuracy-related mistranslations being the most common. While accuracy and fluency are

relatively straightforward to assess, other error categories may be more difficult to judge without specifications. For example, the definition of the *Style* error is simply "Translation has stylistic problems" (Freitag et al., 2021). While this is distinct from *Fluency-grammar* errors, it may be difficult for evaluators to identify a stylistic issue if the purpose of the translation is not known.

In specification-based evaluation, if the purpose of the translation is to convey the cultural otherness of the source text and the specified style is a literal translation that closely follows the original, the translation should adhere to that style. In this case, the translation is expected to preserve the expressions and cultural markers of the source to maintain the visibility of the translation. In other words, even a natural and fluent translation may be considered an error if it minimizes the sense of translation under such specifications.

As mentioned earlier, specifications can also serve as a guide for evaluators, helping to reduce subjectivity in the evaluation process. In this sense, the detailed error types in MQM could be applied more effectively when used in conjunction with detailed specifications.

Several recent MQM-based approaches, such as GEMBA-MQM (Kocmi and Federmann, 2023a), Auto-MQM (Fernandes et al., 2023), xCOMET (Guerreiro et al., 2024), and MQM-APE (Lu et al., 2025), have laid important groundwork for the automation of fine-grained evaluation. However, translation specifications are not the central focus of these approaches.

While human evaluation approaches like MQM-Chat adapt MQM error categories to specific settings (e.g., chatbot applications), they do so by simply modifying the original MQM typology (Li et al., 2025). Their approach could be further extended to integrate detailed specifications. For example, it could require translations to preserve source-text ambiguity as a stylistic feature or to handle internet slang accurately as part of terminology, in line with MQM's original design.

These considerations highlight that MQM, while widely used, can be made more effective when applied in combination with translation specifications.

F A Practical Guide for Specification-Aware Machine Translation and Evaluation

We present guidelines for specification-aware translation and evaluation, drawing on the translation process in a typical professional workflow and the "Production Process" outlined in ISO 17100 —Requirements for Translation Services. This standard states that translation should be "in accordance with the purpose of the translation project, including the linguistic conventions of the target language and relevant project specifications" (ISO17100:2015).

Our evaluation method draws on ISO 5060, the JTF guidelines, and the MQM framework (ISO5060:2024; JTF, 2018; MQM, 2025).[13] Our approach combines these frameworks to make use of their different strengths in evaluation. MQM provides detailed error types for fine-grained analysis, while ISO 5060 and the JTF guidelines allow for weighted error categories based on specifications.[14] The JTF guidelines also emphasize the role of subjective evaluation (JTF, 2018). These evaluation guidelines are designed for use with both human and MT and assume that human evaluators will assess the output.

We first explain the method of specification-aware translation with prompt-based LLMs (Appendix F.1), followed by a description of the human error analysis procedure (Appendix F.2). It also addresses subjective evaluation, which provides a different perspective from error analysis for assessing whether the translation fulfills its intended purpose (Section F.3).

F.1 Specification-aware Machine Translations with Prompt-Based LLMs

Step 1: Define Translation Specifications Define detailed translation specifications. When working with clients or translation teams, all stakeholders should reach an agreement on the specifications. The following are examples corresponding to the parameters listed in Table 1, using a single translation project as context: the English translation of

[13]The European Commission's Directorate-General for Translation also provides quality evaluation guidelines based on a "fit for purpose" approach (Strandvik, 2017). Translations are assessed using error categories (e.g., Accuracy, Terminology, Linguistic Conventions, Style, and Formatting) with severity levels to calculate a quality score (Directorate-General for Translation (DGT), European Commission, 2015).

[14]The error classification used in ISO 5060 is based on the MQM framework (ISO5060:2024).

an integrated report published by a publicly listed Japanese company.

1. **Purpose of translation:** The translation's communicative goal (e.g., to inform, persuade, promote, or comply).

   Example: The goal is to attract foreign institutional investors. Therefore, the translation must emphasize growth potential and sustainability strategies in persuasive, investor-friendly language.

2. **Target audience:** The intended readers and their background knowledge, expectations, or needs.

   Example: The audience consists of non-Japanese institutional investors who may not be familiar with Japanese corporate structures. Key terms may require explanatory phrasing.

3. **Style, register and tone:** The desired level of formality, stylistic conventions, and voice appropriate to the target context.

   Example: A moderately formal and confident tone is preferred, neither overly technical nor overly casual, consistent with ESG reports by global competitors.

4. **Terminology and reference resources:** Required use of specific terms, glossaries, or past translations to ensure consistency.

   Example: The company previously translated 企業理念 as *Corporate Philosophy*, and this terminology should be maintained consistently across sections and future documents.

5. **Domain and legal requirements:** Industry-specific norms or legal constraints that affect wording or structure.

   Example: The report includes financial statements that must conform to IFRS terminology, and disclosures must reflect the Japan Financial Services Agency's guidelines on non-financial reporting.

6. **Cultural adaptation:** Modifications made to accommodate cultural expectations or sensitivities.

   Example: A phrase like *wa no seishin (*和の精神*)* may be unfamiliar to global readers and can be replaced with a culturally adapted equivalent such as *a spirit of harmony and mutual respect*.

7. **Length and formatting:** Constraints or allowances regarding text length, layout, or formatting elements.

   Example: Since the English translation must fit within the same layout as the Japanese version, sentence length and paragraph structure must be carefully managed to avoid overflow.

8. **Localization needs:** Adjustments for language variants, regional conventions, or localized preferences.

   Example: Dates, currencies, and units should follow international conventions (e.g., *FY2023* instead of *2023*年度, *million yen* instead of 百万円), and U.S. spelling is preferred for the target audience.

As these specifications demonstrate, creating appropriate translations requires numerous decisions. Defining these requirements in advance helps ensure that translations meet their intended purpose and are suitable for the target context.

Step 2: Define Roles Separate tasks performed by the machine, such as generating translations based on the given specifications, from those handled by humans, including supervision, quality assurance, verification of specification adherence, and the management of responsibilities such as meeting deadlines. Human reviewers oversee the overall process and focus on elements requiring expert judgment or domain-specific knowledge.

Step 3: Design Instructions Aligned with Specifications Create instructions for the LLM that reflect the defined specifications. Use the listed specifications to identify aspects that can be included in the model instructions. These instructions may include parameters such as:

- Source text information
- Target language
- Purpose of translation
- Target audience
- Style, register, and tone
- Length and formatting

These parameters may vary depending on the specific translation project. The instructions should also state that LLM must not add any information

that is not present in the original text. This is especially important in creative translation tasks, where the model may over-generate and introduce information not found in the source text.

Fine-tuning may be applied as needed, such as specifying terminology, aligning with existing translations, using consistent phrasing, maintaining preferred styles, or handling domain-specific vocabulary accurately.

Step 4: Generate Translation Use the instructions to generate the initial translation.

Step 5: Review and Finalization A human reviewer, or a team of reviewers, must carefully check whether the initial translation is accurate and ensure that it follows the defined specifications. Any errors should be corrected, and the translation should be finalized for delivery. This review process should be given sufficient time in the project schedule. It is standard practice to have reviewers check the translation to ensure quality and accuracy, even when the initial translation is done by professional human translators. The review helps identify issues that a single translator may miss. The same applies to LLMs.

F.2 Human Error Analysis Approach

Translation evaluation is not always conducted alongside the translation itself. There are various situations in which translation evaluation is required, such as deciding whether to accept or reject a translation, comparing multiple translation outputs, or selecting the most suitable version among candidates. Evaluation may also be needed for quality control in professional workflows, for assessing MT outputs, or for translator training and certification purposes.

Our error analysis methodology combines ISO 5060, the JTF guidelines, and the MQM framework to create a specification-aware evaluation system. This system is designed to score each translation based on how well it meets the predefined specifications. The more errors are found, the higher the score. Therefore, translations of higher quality should receive lower scores. By using these established frameworks, we develop a practical process that can be applied in various translation contexts.[15]

[15] Although full-text evaluation is ideal, practical constraints sometimes necessitate the use of samples. When translation samples are selected for evaluation, ISO 5060, MQM, and the JTF guidelines each offer instructions on how to carry out the sampling process (ISO5060:2024; MQM, 2025; JTF, 2018).

Step 1: Ensure Specifications Are Accessible Before evaluation begins, ensure that the translation specifications are available and accessible. If, for any reason, clear specifications are not defined at the time of translation, they should be established at this stage. The specifications should remain accessible throughout the evaluation process so that evaluators can refer to them consistently. Clear documentation helps ensure that all evaluators apply the same criteria and share a common understanding of the communicative goals of the translation.

Step 2: Define Error Categories Based on Specifications Establish error categories aligned with the specifications to ensure consistency. ISO 5060 defines a translation error as a "failure to adhere to translation project specifications" (ISO5060:2024).

However, it is important to distinguish between specifications and error categories. Specifications describe the requirements agreed upon for a project. In contrast, error categories cover a broader range of issues, including problems that are commonly assumed but not always stated directly in the specifications. For example, accuracy-related errors or violations of general linguistic conventions, such as grammar or punctuation, are typically included in error taxonomies even when they are not listed in the specifications. As long as the selected error categories do not contradict the specifications, they can be applied to support consistent evaluation.

Reference standards like the JTF guidelines and MQM for error categorization (JTF, 2018; MQM, 2025). MQM provides fine-grained error categories that are especially valuable for detailed error analysis (MQM, 2025).

Error levels can be customized based on project priorities. For example, when translating a company's corporate philosophy for investor relations materials, where conveying nuance and tone is more important than achieving word-for-word accuracy, the following adjustments can be made:

- Accuracy: Prioritize mistranslation errors, while placing less emphasis on over-translation and under-translation.
- Style: Use more specific subcategories, such as:
  - Language register: Inappropriate level of formality
  - Awkward phrasing: Grammatically correct but stylistically poor

  - Unidiomatic expressions: Unnatural to native speakers
  - Inconsistent style: Stylistic variations across the document

This targeted approach allows evaluators to focus on errors that are most relevant to the specifications. Error categories should be adjusted to reflect the specific requirements of each project.

Step 3: Apply Weights to Error Categories ISO 5060 and the JTF guidelines apply weights to error categories based on project specifications. These weights can be set in advance by the client or project owner. Since different document types prioritize different aspects of translation quality, stakeholders should agree on appropriate weights (ISO5060:2024; JTF, 2018):

- 2.0 – Highly Important
- 1.5 – Somewhat Important
- 1.0 – Standard Importance (default)
- 0.5 – Less Important

To maintain balance, the average weight across all categories should be approximately 1.0. The weighting example below places greater emphasis on accuracy and consistent currency formatting, while giving less weight to stylistic elements:

Example: Financial Report—Revenue Forecast Section

- Accuracy: 1.0 (Standard): Basic factual correctness is required, with some flexibility in expressing forecasts.
- Style: 0.5 (Less Important): A professional tone is preferred, but it has little impact on understanding.
- Locale Convention: 1.5 (More Important): All monetary values must be shown in US dollars to ensure a consistent interpretation.

Step 4: Select Qualified Evaluators Evaluators should be professional translators or subject matter experts who are not only bilingual but also native speakers of the target language. Being bilingual alone is not sufficient for proper evaluation; evaluators must have a deep understanding of the linguistic nuances and cultural context of the target language.

Regarding the qualifications and competencies of evaluators, the ISO 5060 and MQM frameworks provide more rigorous requirements (ISO5060:2024; MQM, 2025). Practitioners should refer directly to these standards to ensure that evaluators meet the necessary professional criteria.

However, these strict requirements can be challenging in practice, as it is often hard to find and recruit qualified evaluators. When qualified evaluators are difficult to recruit, it may be useful to combine error-based evaluation conducted by available bilingual reviewers with subjective assessment by domain experts in the target language or end users. Domain experts may detect inconsistencies or errors by closely reading the content, while end users can provide direct feedback on whether the translation feels natural or conveys the intended message.

Step 5: Identify and Assess Errors Qualified evaluators identify errors, record them, and assess their severity. Severity indicates how serious an error is. It should always be judged based on whether the translation achieves its intended purpose and how much real-world impact the error may have (JTF, 2018). If an error has little or no practical impact, assigning a severity level may not be necessary.

Severity levels and their corresponding scores follow JTF (2018):

- Neutral (0): No penalty. These include stylistic preferences or repeated minor issues that do not affect comprehension.
- Minor (1): Errors that slightly affect readability but do not interfere with understanding.
- Major (10): Errors that significantly affect readability and comprehension.
- Critical (100): Errors that make the translation unusable and may cause harm, such as health risks, financial losses, or reputational damage. These must be corrected before publication.

Whether to count repeated errors multiple times should be decided through agreement among stakeholders (JTF, 2018).

Step 6: Calculate the Score Each identified error receives a score calculated as:

$$\text{Error Score} = \text{Category Weight} \times \text{Severity Score} \quad (1)$$

After assessing all errors, sum the scores to calculate the total error score. If severity scoring is not used, simply multiply the number of errors in each category by its assigned weight, and then sum the results.

A lower total score indicates fewer errors, and therefore a higher-quality translation. These scores make it possible to directly compare different translations.

For projects that require pass/fail decisions, evaluators can set a passing threshold based on acceptable error levels. Refer to the JTF guidelines or the MQM framework for recommended threshold values that fit different translation contexts (JTF, 2018; MQM, 2025).

As the evaluation is based on detailed specifications, it allows for a more objective assessment, reducing subjectivity and ensuring consistent criteria among evaluators.

F.3 Human Subjective Evaluation Approach

The JTF guidelines emphasize that while error-based evaluation methods provide a systematic approach, they represent only one aspect of translation quality (JTF, 2018). Error-based methods focus primarily on objectively identifiable errors and do not account for subjective quality factors that are essential in certain types of documents, such as advertisements, literary works, corporate vision statements, marketing slogans, and brand messages. For a more comprehensive assessment of quality, it is advisable to combine error-based evaluation with other approaches, particularly subjective evaluation by experts or end users, depending on the translation context (JTF, 2018).

Moreover, when qualified evaluators for error-based assessment are unavailable, subjective evaluation can complement error analysis performed by available bilingual reviewers. Subjective evaluation captures aspects such as clarity, persuasiveness, and appropriateness, which are essential for determining whether a translation effectively serves its intended purpose.

Subjective evaluation can be integrated with error-based assessment in the following ways:

A. Subjective Evaluation by Experts : Experts assess translations based on their specialized knowledge and professional judgment. Examples of such expert evaluations include:

- Legal professionals assess the accuracy and appropriateness of legal translations.
- Marketing specialists review the effectiveness and cultural relevance of promotional content.
- Technical staff on the client side evaluate clarity, precision, and technical correctness in the documentation.

B. Subjective Evaluation by End Users : End users evaluate translations based on their own perceptions and practical experience. For example, in the case of investor relations materials, investors may be asked:

- *Did you find the explanation clear, convincing, and appropriate?*
- *Were there any unnatural expressions or confusing elements in the translation?*

Their feedback is usually collected through surveys or questionnaires and provides valuable insight into how clear and usable the translation is.

Incorporating specifications into translation and evaluation enables both to go beyond basic accuracy and focus on communicative effectiveness. This ensures translations are not only correct but also appropriate for their intended audiences and contexts.

G Why Focus on Japanese-to-English Translation

Our experiment focuses on Japanese-to-English translation of integrated reports, which are typically published annually by companies. Here, we explain why this particular language pair and translation direction were chosen.

MT research often prioritizes universal approaches, aiming to develop models and evaluation methods that generalize across many language pairs. For example, Liu et al. (2024) note that this focus on generalization is evident in the field's pursuit of standardized methods. While such approaches help improve general performance across languages, they may overlook challenges specific to individual language pairs.

Indeed, prior research has reported substantial differences in MT performance between high-resource and low-resource languages (Team et al., 2022; Pang et al., 2025). These disparities have been attributed not only to the quantity of training data but also to inherent linguistic factors. For instance, Sarti et al. (2022) found that post-editing greatly improved English–Italian translations, but

had limited impact on English–Turkish and English–Japanese, likely due to word order and morphology differences. Similarly, Lee et al. (2022) report that mBART (Tang et al., 2021) performs well across domains but struggles with typologically distant languages, scoring below 3.0 BLEU (Papineni et al., 2002).

In response, our study takes a more targeted perspective, recognizing that translation difficulty varies widely depending on linguistic distance, grammatical structure, and cultural context. Japanese–English translation presents unique challenges due to fundamental differences in linguistic structure and writing systems. Unlike English–European language pairs, which often require minimal restructuring, Japanese–English translation typically involves major changes in sentence structure and word choice (Carl et al., 2016). Ogawa (2021) states that translating between Japanese and English takes significantly more processing time than English–German or English–French translation, leading to a higher cognitive load.

Due to these complexities, general approaches to translation models and evaluation, particularly those designed for multilingual settings, may not fully reflect the specific challenges of Japanese–English translation. Therefore, a specialized approach is necessary to understand not only how MT systems handle these linguistic difficulties, but also how their outputs can be appropriately evaluated.

We focus on the Japanese-to-English translation direction for two main reasons. First, ChatGPT and other LLM-based translation systems tend to perform better in English than in many other languages, due to the abundance of high-quality English training data (Chowdhery et al., 2022; Wendler et al., 2024). For example, OpenAI reports that GPT-3's training data is "primarily English (93 [percent] by word count)," and similar English-centric characteristics are reflected in the design and evaluation of GPT-4, as noted in its System Card (Brown et al., 2020; OpenAI et al., 2024). Working in this direction allows for both practical translation and evaluation while minimizing the influence of data-related limitations.

Second, the demand for Japanese-to-English translation greatly exceeds the supply of qualified human translators. Japan continues to face a shortage of professionals who can produce high-quality English translations, especially in specialized fields such as investor relations and corporate communications (Nagata, 2025; Ueno, 2025). Given this shortage, MT guided by translation specifications represents a practical alternative that may help meet the demand for high-quality and cost-effective translations. In this study, we examine whether this approach can improve translation quality while also addressing the translator shortage and meeting international communication needs.

H Company List

Table 6 lists the integrated reports used in this study. One company is selected from each of the 33 industry categories defined by the Tokyo Stock Exchange, prioritizing those ranked among the top four in market capitalization within each category during the data collection period (August 28–September 9, 2024).

The table includes the industry, company name, and publication year of the report used. Major companies with larger market capitalizations are chosen under the assumption that they are more likely to publish well-developed English versions of their integrated reports. As a result, many of the companies listed are well-known Japanese corporations.

I Prompt Design for Specification-Aware ChatGPT Translations

Table 7 summarizes the prompts used for each ChatGPT translation method. For ChatGPT basic, ChatGPT receives only a minimal instruction: "Please translate the following Japanese text into English." For ChatGPT + Spec, we incorporate the content of the assumed specifications for the translation of integrated reports:

- **Source text context**: The official company name and a description of the integrated report as an IR document
- **Target language**: English
- **Intended purpose**: To enhance the company's appeal to a broad audience of investors
- **Target audience**: International investors
- **Style**: Clear and persuasive, suitable for a global investor audience

In the ChatGPT PE + Spec method, the model is instructed to improve the Google Translate out-

Industry	Company	Year
Transportation Equipment	Toyota Motor Corp.	’23
Banks	Mitsubishi UFJ Financial Group, Inc.	’23
Electric Appliances	Sony Group Corp.	’23
Retail Trade	Fast Retailing Co., Ltd.	’23
Services	Recruit Holdings Co., Ltd.	’23
Information & Communication	Nippon Telegraph and Telephone Corp.	’23
Chemicals	Shin-Etsu Chemical Co., Ltd.	’24
Wholesale Trade	Mitsubishi Corp.	’23
Pharmaceuticals	Chugai Pharmaceutical Co., Ltd.	’23
Other Products	ASICS Corp.	’23
Insurance	Tokio Marine Holdings, Inc.	’23
Foods	Japan Tobacco Inc.	’23
Precision Instruments	Terumo Corp.	’23
Fishery, Agriculture & Forestry	Nippon Suisan Kaisha, Ltd.	’23
Mining	Japan Petroleum Exploration Co., Ltd.	’23
Construction	Daiwa House Industry Co., Ltd.	’23
Textiles & Apparels	Goldwin Inc.	’23

Warehousing & Harbor Transportation Services	Mitsui-Soko Holdings Co., Ltd.	’23
Securities & Commodity Futures	Nomura Holdings, Inc.	’24
Other Financing Business	Japan Exchange Group, Inc.	’23
Real Estate	Mitsui Fudosan Co., Ltd.	’23

Table 6: Integrated reports of 33 listed companies used in the experiment.

put based on the same specifications, without access to the original Japanese text. This is a deliberate design choice; providing the source text risks the model disregarding the MT output and producing a new translation from scratch, a phenomenon observed in our initial pilot experiments. We therefore ensured that the task remained genuine post-editing, focused solely on enhancing the fluency and appeal of the existing translation. In both specification-aware methods, we instruct ChatGPT to avoid adding information not present in the source.

Since this is not a commissioned project, we define realistic specification parameters based on industry practices. Items like deadlines and formatting are excluded due to experimental constraints.

J Example Comparison of Five Translation Methods: All Nippon Airways Co., Ltd.

The five translations in Table 8 illustrate different approaches to conveying the original Japanese text in English. The source text is an excerpt from the corporate philosophy section of the integrated report published by All Nippon Airways Co., Ltd.

The official translation retains the Japanese term “waku waku,” along with an explanatory note. It is unclear whether the original specifications required preserving the Japanese phrase. However, even if the intention was to reflect a sense of Japanese cultural identity, the primary objective should be to ensure that the translation appeals to international investors. One notable issue is that in the phrase “[a]nd when passed from person to person, becomes a force,” the subject is missing, which could be considered an error. Additionally, the phrase “explore more incredible discoveries” may sound awkward, as “explore” typically refers to something unknown rather than something already discovered (Harper, 2025).

Google Translate output is simple and easy to understand, but expressions such as “make travel more fun” and “more exciting sky experiences” might be too casual and do not fit the context of

Translation Type	Prompt
ChatGPT basic	Please translate the following Japanese text into English.
ChatGPT + Spec	The following Japanese text is an excerpt from the integrated report of [company name], a key part of the company's investor relations materials. Please translate this text into English in a way that will be appealing to international investors. The purpose of this translation is to enhance the company's appeal to a wider audience of investors. Please do not add any additional information.
ChatGPT PE + Spec	The following text is a translation of an excerpt from the integrated report of [company name], a key part of the company's investor relations materials. The purpose of this translation is to enhance the company's appeal to a wider audience of investors. The initial translation was done using Google Translate. Please refine this translation to make it more engaging and appealing in English. Please do not add any additional information.

Table 7: Examples of ChatGPT prompts used in our study.

Type	Translation Output
Source	"ワクワク"は, 人を動かすエネルギー. それは人から人へと伝わり、世界をあかるく元気にする。私たちは, 空の可能性を信じ, ヒト・モノ・コトをつなぐことで, これまでたくさんの笑顔と歓びに出会ってきた. そして今, 新しい未来に向けて, 次のワクワクを生み出す. 移動をもっと楽しいものにできないか, モノの運び方を新しくできないか, 心躍る日常を届けられないか, どこまでも地球にやさしくなれないか. これまで以上の空の体験とともに, 驚きと感動を創りたい.
Official	"Waku waku" is what moves people to push what's possible. It's Japanese for the joy and excitement of discovering the unknown. And when passed from person to person, becomes a force that creates a brighter world, united in wonder. The sky is full of possibilities, which has allowed us to bring together people, products and experiences for decades. Now, we're expanding our horizons and spreading "waku waku" across the world. So, we wonder, can we make travel more enjoyable? Can we renew the way we transport products? Can we bring excitement to life, while being kind to the earth? Together with an elevated experience in the sky, we can explore more incredible discoveries that will lead to a better tomorrow.
Google	"Excitement" is the energy that moves people. It spreads from person to person, making the world brighter and more energetic. We believe in the possibilities of the sky, and by connecting people, things, and events, we have encountered many smiles and joy. And now, we are creating the next excitement for a new future. Can we make travel more fun, can we innovate the way we transport things, can we deliver an exciting daily life, and can we be kind to the earth as much as possible? We want to create surprises and excitement along with more exciting sky experiences than ever before.
GPT	"Excitement" is the energy that moves people. It spreads from person to person, bringing brightness and vitality to the world. Believing in the possibilities of the sky, we have connected people, goods, and experiences, encountering countless smiles and joy along the way. Now, we are setting out to create the next source of excitement for a new future. Can we make travel more enjoyable? Can we reinvent the way goods are transported? Can we deliver everyday moments that make your heart dance? Can we be more environmentally friendly than ever before? Along with new and enhanced experiences in the sky, we aim to create wonder and inspiration.
GPT+Sp	Excitement is the energy that moves people. It spreads from person to person, brightening and invigorating the world. We believe in the limitless potential of the skies and, through connecting people, goods, and experiences, we have encountered countless smiles and moments of joy. Now, as we look toward a new future, we are ready to create the next wave of excitement. Can we make travel more enjoyable? Can we innovate the way things are transported? Can we bring a sense of wonder to everyday life? Can we go further in protecting our planet? We aim to create surprises and inspiration with an even greater sky experience.
GPT PE+Sp	"Excitement" is the spark that moves people, spreading from one person to another, brightening and energizing the world. Believing in the boundless potential of the skies, we bring people, goods, and experiences together, creating countless moments of joy and countless smiles. Now, we are embarking on a new journey to inspire even greater excitement for the future. Can we make travel more delightful, revolutionize the way we transport goods, infuse everyday life with excitement, and care for our planet in the best possible ways? We are committed to creating moments of surprise and delight, offering more thrilling experiences in the skies than ever before.

Table 8: Differences in translations: All Nippon Airways Co., Ltd.

investor relations materials. The phrase "encountered many smiles and joy" also sounds unnatural, as "encounter" is typically used with concrete entities or situations, such as difficulties or opposition, rather than with abstract concepts like joy or smiles (Merriam-Webster Dictionary, 2025).

ChatGPT basic captures the emotional aspects of the original text, particularly with phrases like "moments that make your heart dance." However, the use of "encountering countless smiles and joy," similar to Goolge Translate, does not sound natural in English.

ChatGPT + Spec employs expressions such as "limitless potential of the skies," which are effective in creating a positive and aspirational tone. However, the use of "things" in "the way things are transported" sounds casual, and "even greater sky experience" would sound more natural if "experiences" were used in the plural form.

ChatGPT PE + Spec employs strong and active expressions. The word "spark" in "[e]xcitement is the spark that moves people" creates a vivid and powerful impression, while the phrase "embarking on a new journey to inspire even greater excitement" conveys a positive and future-oriented feeling.

These observations suggest that each translation method tends to produce distinct results, and that including specifications in ChatGPT prompts may encourage the use of more purposeful and engaging language.

K Error Typology for Human Error Evaluations

We use the following categories and subtypes for error annotation: Accuracy (subtypes: mistranslation, addition, omission), Linguistic Conventions (grammar, spelling, unintelligible, textual conventions), and Style (language register, awkward style, unidiomatic style, inconsistent style). Definitions and examples of each error type are available on the official MQM website (`https://themqm.org/downloads/`). Evaluators are instructed to refer to this table during error analysis. However, only the main categories are used for error counting; subtypes are provided to help annotators better understand and identify specific issues.

L Syntactic Pattern Analysis of Translation Outputs

To investigate stylistic tendencies, we analyzed syntactic patterns across the five translation types, focusing on relative clauses and clausal coordination. Specifically, we counted the number of relative pronouns (*which*, *who*, *that*) and clausal instances of *and* (i.e., those connecting two clauses with subject-verb structures). We excluded uses of *that* as complementizers, demonstratives, or in cleft constructions, and excluded *and* used at the phrase or word level.

These structures are common in Japanese texts and may reflect a literal transfer of source syntax. Their frequent use can lead to complex, additive structures that may reduce readability in English.

Table 9 reports total word counts, raw counts, and normalized frequencies per 1,000 words. The results show that Google Translate and the official translations use relatively more relative clauses and clause-level coordination, suggesting less restructuring. In contrast, ChatGPT outputs display simpler sentence structures regardless of prompt specificity. These patterns indicate that prompt-based LLMs tend to favor fluency and conciseness.

M Examples and Error Analysis from Official Translations

To explore why the official translations received low ratings, we examined problematic excerpts from companies' corporate philosophies. Table 10 presents these examples.

To begin with, Excerpt (1) contains the phrase "offering both a multitude of choices," in which the use of *both* appears semantically inappropriate. The word *both* typically introduces two parallel elements, but "a multitude of choices" is a singular, collective concept, resulting in a semantic mismatch. In this context, *both* is presumably intended to refer to the two entities mentioned earlier, *individuals* and *businesses*. However, its placement creates a structurally awkward and confusing expression.

Excerpt (2) opens with the sentence "[w]hat we do isn't a job," which appears to aim for an inspirational tone but lacks a clear referent or elaboration. As a result, its meaning may be ambiguous to readers who are not familiar with the intended message behind the expression. A clearer alternative might be "[w]hat we do is more than a job," which conveys the intended message more directly.

Excerpt (3) contains the phrase "in this era of search," which is not a commonly used expression in English discourse and may not be immediately clear. Additionally, the combination of the degree

Type	Official	Google	ChatGPT	ChatGPT+Sp	ChatGPT PE+Sp
Word Count	8,776	**8,894**	8,655	8,351	8,216
Clausal *and*s	58	**66**	54	53	57
Rel. Pronouns	72	**83**	61	59	61

No.	Excerpt
(1)	Opportunities for Life. Faster, simpler and closer to you. Since our foundation, we have connected individuals and businesses, offering both a multitude of choices. (Recruit Holdings Co., Ltd.)
(2)	What we do isn't a job. We enjoy exploring what is possible for our future. We question the status quo, fail well and overcome with resilience. We are a force for change. (Recruit Holdings Co., Ltd.)
(3)	In this era of search, where information has become available anytime anywhere, we need to focus more on proposing the optimal choice. We seek to provide 'Opportunities for Life,' much faster, surprisingly simpler and closer than ever before. (Recruit Holdings Co., Ltd.)
(4)	Today, what we mean by Our Hopes for the Future, a world where we are our truest selves, respecting, and inspiring each other. Living together in harmony with our planet—in harmony with People and Nature. (Daiwa House Industry Co., Ltd.)
(5)	Create a virtuous cycle between Society and Earth by fully utilizing less of her limited resources. Make the world a richer, better place by bringing out the best out in people and the potential of buildings. (Daiwa House Industry Co., Ltd.)
(6)	For the sake of the Earth, which future generations of children have entrusted in our care. Together with you. (Bridgestone Corp.)
(7)	The single continuous curve represents the dynamism and our commitment for continuous innovation and delivering value to people and society. (Nippon Telegraph and Telephone Corporation)

Table 10: Excerpts from the official translation cited in the qualitative analysis.

adverb *surprisingly* with the comparative adjective *simpler* creates a stylistic inconsistency.

Excerpt (4) is grammatically incomplete. The subject and predicate do not form a complete clause, making the intended meaning difficult to determine.

Excerpt (5) uses the phrase "fully utilizing less," which appears to aim for a concise message about efficiency, likely meaning "to make the most of fewer resources." However, the expression is semantically ambiguous. The adverb *fully* suggests maximization, while *less* implies minimization, creating a tension that may confuse readers rather than clarify the company's commitment to sustainability. In addition, the phrase "bringing out the best out in people" is grammatically incorrect. The structure redundantly includes both "out" before and after "the best," where only one instance is appropriate. A corrected version would be "bringing out the best in people," which is idiomatic and clear.

Excerpt (6) contains grammatical issues. The phrase "entrusted in our care" is unidiomatic. In standard English, the verb *entrust* typically appears in the form "entrust someone with something" or entrust something to someone." In addition, the sentence lacks a main clause and does not constitute a complete grammatical unit.

Finally, Excerpt (7) contains two issues. First, "commitment for" is a grammatical error. The standard preposition in this context is "commitment to." Second, the coordination of "continuous innovation," a noun phrase, and "delivering value," a gerund phrase, is unbalanced and stylistically awkward. For clarity and parallel structure, both elements should be in the same grammatical form, such as "continuous innovation and value creation," or "innovating continuously and delivering value."

As these examples show, the official translation includes not only grammatical inaccuracies but also semantic and stylistic inconsistencies, which may have contributed to its lower rating in the evaluation.

The characteristics of the source texts themselves may help explain the relatively low ratings of the official translations. Integrated reports sometimes contain expressions that are abstract, culture-specific, or metaphorical in Japanese, which can result in awkward or even ungrammatical output if translated too literally. In some cases, the official translations appear to reflect such overly direct translations, suggesting that the translator may have prioritized fidelity to the source text's wording or syntax at the expense of naturalness and clarity in English. While this approach may have been inten-

tional, for example to preserve a uniquely Japanese tone, it can hinder readability and reduce the overall appeal of the translation. This is reflected in the lower rankings observed in the subjective evaluation.

However, it is important to note that professional translations are typically produced based on specifications or an internal guideline (ISO17100:2015). In practice, translators are expected to follow such instructions from the outset; without them, it would be difficult to even begin the task. Therefore, the types of problems identified in the official translations, such as grammatical errors or awkward phrasing, are unlikely to stem from missing or unclear specifications. Rather, these issues may be related to language proficiency or a mismatch between the translator's background and the specific requirements of the task.

Specifications can support translation decisions, but achieving linguistic accuracy and fluency may still require a high level of language proficiency. As noted earlier (Section 5.2.2), human translation quality tends to vary, as translators differ in background and ability (Freitag et al., 2023; Ramos and Guzmán, 2024; Volz and von Thiessen, 2024).

Furthermore, as discussed in Appendix G, Japan continues to face a shortage of translators capable of producing high-quality English translations. This shortage may have influenced the present results.

In this context, the potential of MT systems that use specifications, such as ChatGPT with customized prompts or post-edited outputs, deserves more attention. Both ChatGPT + Spec and ChatGPT PE + Spec are favorably evaluated in our study, not only in subjective rankings but also in error-based analysis, suggesting that specification-aware MT may offer a useful complement to traditional workflows.

OpenWHO: A Document-Level Parallel Corpus for Health Translation in Low-Resource Languages

Abstract

In machine translation (MT), health is a high-stakes domain characterised by widespread deployment and domain-specific vocabulary. However, there is a lack of MT evaluation datasets for low-resource languages in this domain. To address this gap, we introduce OpenWHO, a document-level parallel corpus of 2,978 documents and 26,824 sentences from the World Health Organization's e-learning platform. Sourced from expert-authored, professionally translated materials shielded from web-crawling, OpenWHO spans a diverse range of over 20 languages, of which nine are low-resource. Leveraging this new resource, we evaluate modern large language models (LLMs) against traditional MT models. Our findings reveal that LLMs consistently outperform traditional MT models, with Gemini 2.5 Flash achieving a +4.79 ChrF point improvement over NLLB-54B on our low-resource test set. Further, we investigate how LLM context utilisation affects accuracy, finding that the benefits of document-level translation are most pronounced in specialised domains like health. We release the OpenWHO corpus to encourage further research into low-resource MT in the health domain.

1 Introduction

Translation in the health domain combines clinical risks, widespread demand, and domain-specific complexity (Mehandru et al., 2022; Neves et al., 2024). By offering a timely and resource-efficient complement to human translation, machine translation (MT) can lower the barrier to disseminating health content, from education materials for local health workers (Hammond et al., 2024) to public safety information during crises (Federici et al., 2023; Utunen et al., 2023b). However, evaluation of MT in the health domain is hampered by a lack of datasets that cover a wide range of languages, particularly low-resource ones. The TICO-19 corpus (Anastasopoulos et al., 2020) stands as a notable exception, yet its focus on COVID-19 limits its utility on broader health topics, and its age raises the risk of training data contamination.

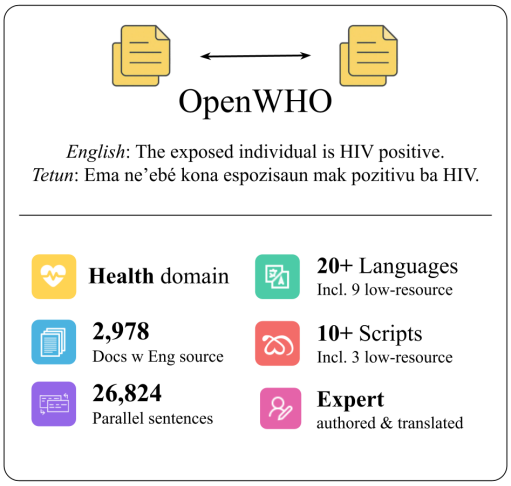

Figure 1: Overview of the OpenWHO parallel dataset, highlighting its depth across low-resource languages and scripts.

To address this gap, we introduce OpenWHO, a document-level parallel corpus designed for evaluating health MT. Sourced from the World Health Organization's multilingual e-learning platform, its content is expert-authored, professionally translated, and shielded from web-crawling, thus minimising contamination risk. The corpus covers over 20 languages, nine of which are low-resource, including some with low-resource scripts like Armenian, Georgian, and Sinhala. By focusing on health education, a domain fundamental to local quality of care (Merx et al., 2024b), OpenWHO provides a realistic benchmark for a high-impact MT use case.

Leveraging this new resource, we conduct a systematic evaluation comparing modern large language models (LLMs) against traditional NMT systems. For LLMs, we study different context strategies (document-level, sentence-level, etc) and to

Proceedings of the Tenth Conference on Machine Translation, pages 142–160

determine whether the benefits of document-level translation are specific to our dataset, we extend our evaluation to the news and literary subsets of the WMT24++ benchmark (Deutsch et al., 2025).

Our main contributions are [1]:

- **We introduce and release OpenWHO**, a parallel corpus for health MT that covers low-resource languages. It comprises 2,978 documents and 26,824 parallel sentences from expert-authored, professionally translated materials (§3).
- **We show that modern LLMs outperform traditional NMT models** for low-resource translation in the health domain. Our findings show Gemini 2.5 Flash with document-level context achieves a +4.79 ChrF point improvement over NLLB-54B on our test set (§4.2).
- **We find that the benefit of document-level context is model and domain-dependent** for low-resource MT. Accuracy gains are most pronounced when using best-performing models to translate specialised domains like health and literature, while the general (news) domain shows more modest improvements, highlighting that domain complexity drives context utility (§4.2).

2 Related Work

Document-level MT Document-level MT has long been recognised as desirable, as it allows models to leverage broader discourse for improved coherence and accuracy (Maruf et al., 2021). Early work with traditional NMT models has shown mixed results, with some studies demonstrating that document-level context can significantly improve translation quality (Miculicich et al., 2018; Wang et al., 2023; Post and Junczys-Dowmunt, 2024), while others questioned whether these improvements stemmed from true contextual understanding, arguing that the context encoder was not modeling discourse but acting as a "noise generator" that improves model robustness, rather than leveraging discourse information (Li et al., 2020; Appicharla et al., 2024).

LLMs for document-level MT LLMs, given their ability to process extended contexts, are well placed to benefit from document-level context. Koneru et al. (2024) explored contextual translation with Llama2-13B on English-German, finding mixed results, where document-level context sometimes providing no performance gains over sentence-level translation. Karpinska and Iyyer (2023) demonstrated that paragraph-level translation outperforms sentence-level approaches in literary fiction using GPT-3.5, though they have noted that their findings might not generalise to low-resource settings. Yang et al. (2024) fine-tuned LLaMA3-8B for context-aware translation, showing that increasing context window size yields gains, particularly when evaluated with neural metrics. Recent mechanistic analysis by Mohammed and Niculae (2025) revealed that LLMs can be surprisingly "context-insensitive," with smaller models showing limited ability to effectively utilise available context, a finding that may explain varying performance observed in earlier works.

Low-resource MT with LLMs While LLMs have shown promising results on low-resource MT

Table 1: Comparison with prior work on context utilisation for MT.

(Guo et al., 2024; Merx et al., 2024a), evaluation has been predominantly limited to sentence-level translation. Enis and Hopkins (2024) demonstrated that Claude significantly outperforms NLLB on Yoruba-English translation, finding substantial improvements from document-level over sentence-level translation, though their evaluation focused solely on the low-resource-to-English direction. Zebaze et al. (2025) explored low-resource translation with LLMs using compositional approaches on datasets including FLORES, NTREX, and TICO-19, but operated at the sentence level with few-shot learning rather than document-level context. This sentence-level focus in low-resource settings represents a significant gap, as the dynamics of context utilisation may be fundamentally different for low-resource languages where models have seen limited training data and where translation errors could compound across sentences within a document.

Gaps remain in our understanding of document-level translation for low-resource languages in specialised domains. First, there is a shortage of evaluation data for document-level low-resource machine translation in specialised domains, such as healthcare. Second, there has been no systematic analysis of how LLMs utilise document-level context when translating low-resource languages, particularly in specialised domains where coherence and terminological consistency are required.

3 The OpenWHO dataset

3.1 Source and Motivation

The OpenWHO platform. Our corpus is drawn from OpenWHO.org, the World Health Organization's (WHO) former e-learning platform for public health education. Active from 2017 to 2024, the platform's primary goal was to disseminate health knowledge to healthcare professionals, frontline responders, and the public, particularly during health emergencies (George et al., 2022; Utunen et al., 2023a). The content was authored and vetted by WHO experts and its global network of partner institutions, ensuring that the information and its translations were authoritative, accurate, and reflected up-to-date scientific guidance (George et al., 2022). The topics covered a wide range of public health issues, including specific disease responses (e.g., COVID-19, Ebola), vaccination protocols, infection prevention, and emergency preparedness (Utunen et al., 2020, 2023a).

Multilingual focus. A key tenet of the OpenWHO initiative was to ensure equitable access to information, which included a deliberate strategy of multilingual dissemination. Course materials were translated from English into a range of languages, with a focus on providing resources for low- and middle-income countries (George et al., 2022; Utunen et al., 2023a). The course-based format ceased operations in December 2024, transitioning to a static resource library. The data for our corpus was collected prior to this change and exclusively comprises materials from the course-based period (2017–2024). This commitment to creating expert-authored, multilingual content made the OpenWHO platform a high-quality source for extracting a document-level parallel corpus in the health domain, covering several low-resource languages.

Because all course material was hosted behind a login screen, it was shielded from the large-scale web crawling that constitutes the training data for most LLMs, mitigating risk of pre-training contamination. To confirm this, we conducted searches across publicly available web-scraped corpora (C4, MADLAD), and performed targeted web searches (via Google Search) using sentences found in OpenWHO course content. These searches revealed only publicly accessible OpenWHO course descriptions

(which are not part of our corpus), with no course content found within these data sources.

3.2 Data Curation Pipeline

3.2.1 Document Extraction

Scraping While we secured authorization from the WHO to collect and release this data, a direct database export was not available. Therefore, in consultation with the WHO, we developed a web scraping pipeline to gather the course materials. Using the Scrapy framework,[2] we developed a web scraper to navigate the OpenWHO site, enrol in each individual course, and extract the raw HTML content of every course page. Each page was uniquely identified by its course ID and language, as well as its position within the course structure (section and subsection numbers).

Content filtering. A significant portion of the OpenWHO curriculum relies on video-based learning. As our focus is on creating a parallel text corpus, we filtered out pages where video was the primary medium. To further ensure the quality of the extracted documents, we applied a series of heuristic filters to remove low-value content: we discarded pages that primarily consisted of a list of references, contained fewer than ten words, or featured boilerplate text used to introduce a course or section.

3.2.2 Document Pairing

The structured nature of the OpenWHO platform facilitated document alignment. For any given course page, the quadruplet (`language code`, `course id`, `section index`, `subsection index`) serves as a unique identifier. By varying the `language code`, we could accurately identify and group parallel course pages that are direct translations of one another.

After applying the quality filters described in the previous section, this pairing process yielded $2,978$ parallel documents. This set includes significant coverage for several low- and mid-resource languages, with Tetun, Albanian, Macedonian, Azerbaijani, Kazakh, Georgian, and Armenian each having more than 50 parallel documents. A breakdown of document counts per language is presented in Table 5.

[2] https://www.scrapy.org/

3.2.3 Sentence Mining

Traditional NMT models rely on sentence-level translation. To release a dataset that can be used for NMT evaluation, and potentially fine-tuning, we mined parallel sentences from parallel documents.

Annotation To evaluate our sentence mining pipeline, we manually annotated 10 parallel documents for 8 target low-resource languages (Macedonian, Georgian, Armenian, Azerbaijani, Tetun, Albanian, Kazakh, Tamil) that are of interest to our experiment. For each document pair, we manually segmented the source and target texts into aligned sentences (relying on back-translation for the languages we are not familiar with), ensuring one-to-one correspondence. This process yielded a reference corpus totalling $2,645$ parallel sentences. This annotated set serves as the ground truth for the subsequent sentence-splitting and alignment evaluation.

Sentence splitting Using the target-language sentences from our manually annotated corpus as a reference, we evaluated the performance of three sentence-splitters: `NLTK` (Bird and Loper, 2004), `Stanza` (Qi et al., 2020), and `pysbd` (Sadvilkar and Neumann, 2020). We measured sentence splitting performance as accuracy of sentence boundaries against our ground truth segmentation. The results (shown in Appendix B) indicated that `pysbd` achieves the highest accuracy overall with accuracy ranging from 82.0% for Kazakh to 94.0% for Tetun, but `stanza` performs better for Kazakh (89.1%), Tetun (94.6%) and Georgian (93.2%). NLTK's performance was generally lower than the other two. Based on these findings, we selected the best-performing tool (either `pysbd` or `stanza`) on a per-language basis to segment the entire corpus.

Sentence alignment After sentence splitting, we aligned sentences to create parallel pairs. Here we rely on sentence semantic similarity, using LaBSE (*Language-agnostic BERT Sentence Embedding* (Feng et al., 2022)), which supports all our languages of interest except Tetun (as a consequence, for Tetun, we first translated target sentences back to English before encoding). Because the OpenWHO documents are relatively short, this approach is highly effective: when evaluated against our manually annotated ground truth, the method yielded F1 scores ranging from 98.6% (for Tetun) to 100% (for Kazakh and Georgian).

Strategy	Description
Sentence level	Our baseline. Each sentence is translated independently without any additional context.
Sentence window (batched sliding window in Koneru et al. (2024))	A constrained-context approach. The model receives only the immediately preceding and succeeding sentences as context, aiming to capture local discourse phenomena without overwhelming the model.
Sentence + doc context	The model is provided with the full source document as context within the prompt but is instructed to translate only the single, target sentence.
Document level	The model is given the entire source document and instructed to translate the whole text. As per Enis and Hopkins (2024), we use one sentence per line, and evaluate at the sentence level after translation.
Doc-level + self-correct, as per (Wu et al., 2025)	A two-step approach: (1) Document-level translation then (2) feed the generated translation back to the model with a new prompt asking it to review and improve its own output, testing its self-correction and refinement capabilities.

Table 2: The five translation strategies evaluated in our experiments. Each strategy represents a different approach to leveraging context for machine translation. Associated prompts are in Appendix F.

Quality Control and Filtering Finally, to ensure the quality of the mined sentence pairs, we implemented an additional filtering stage based on empirical rules. We removed sentence pairs that were likely to be misaligned or uninformative for translation tasks. This included removing (1) pairs where the source English sentence contained fewer than five words, as these are often section headers or fragments; (2) pairs where the target-language side was in English; and (3) sentence pairs that were exact duplicates across different course pages, which often correspond to repeated instructions or boilerplate phrases.

Starting from an initial pool of $43,732$ candidate sentence pairs, we arrived at a final, clean set of **26,824** parallel sentences. This includes nine low-resource languages with over 200 parallel sentences (Macedonian, Georgian, Armenian, Azerbaijani, Tetun, Albanian, Kazakh, Somali, Sinhala). The count of sentence pairs per language is detailed in Table 5.

3.3 Dataset Statistics

The resulting OpenWHO corpus comprises **2,978** parallel documents and **26,824** aligned parallel sentences between English and over 20 other languages. The corpus contains a mix of high-resource and low-resource languages, with significant depth in the latter, including six with over 1,000 parallel sentences (Macedonian, Georgian, Armenian, Albanian, Kazakh, and Tetun). A key feature of this dataset is its origin: all content is expert-authored and professionally translated, providing high-fidelity, domain-specific text that is a level above standard web-crawled corpora in terms of quality and consistency. The data is structured at both the document and sentence level, enabling experiments in document-level machine translation, terminology extraction, and domain adaptation. However, a potential weakness of this dataset is its unbalanced language distribution, as not all courses were translated into all languages.

3.4 Data Availability

With permission from the WHO, we release this dataset under a Creative Commons NonCommercial license (CC BY-NC 4.0), allowing re-use, modification and distribution for non-commercial use, while requiring attribution. Data will be available both at the document level and at the sentence level.

4 Experiments

Having established an evaluation corpus for document-level low-resource MT in the health domain, we now turn to investigating what models perform best on this dataset, and how context utilisation strategies affect LLM performance on this dataset. Our experimental design addresses a fundamental tension in document-level translation: while broader context can improve coherence and terminological consistency, it may also introduce noise or lead to error propagation.

We work with the following research questions:

- **RQ1**: How do state-of-the-art LLMs compare to traditional NMT models for health low-resource translation?
- **RQ2**: What is the most effective context strategy for LLM-based translation into

low-resource languages? (sentence-level, document-level, sliding sentence window, etc)

- **RQ3**: How does model capability interact with these context strategies?

4.1 Experimental Setup

Datasets We evaluate on two datasets, always in the EN-XX direction. The first is our newly introduced OpenWHO corpus. To ensure a controlled comparison across languages, we focus our experiments on a single, extensively translated course: "Infection Prevention and Control through Hand Hygiene (IPC-HH)". We select the nine low- to mid-resource languages available for this course for our evaluation: Albanian (sqi), Armenian (hye), Azerbaijani (aze), Georgian (kat), Kazakh (kaz), Macedonian (mkd), Sinhala (sin), Somali (som), and Tetun (tet). For a comparison with high-resource languages, we separately evaluate on French (fra), Russian (rus) and Spanish (spa).

To test the generalisability of our findings beyond the health domain, we also evaluate on the WMT24++ benchmark (Deutsch et al., 2025), an expansion of the WMT24 dataset to 55 languages. To align with our research focus, we select a sample of five low- to mid-resource languages present in this dataset: Bulgarian (bul), Serbian (srp), Swahili (swh), Tamil (tam), and Zulu (zul). Because this dataset is available at the paragraph level, for our sentence-level analysis, we split paragraphs into aligned sentences using Gemini 2.5 Flash.

Models Our model selection is designed to compare modern LLMs (both open and closed weights) against conventional NMT baselines. For NMT baselines, we select NLLB-200 (3.3B & 54B, Costa-jussà et al., 2024) and MADLAD-400 10B (Kudugunta et al., 2023), both of which cover languages covered in our evaluation (except Tetun for NLLB). For LLMs, we select Gemini 2.5 Flash (Gemini Team, 2025), a powerful closed-weight model, DeepSeek-V3 671B (DeepSeek-AI, 2024), which represents the state-of-the-art in open-weight models at the time of our experiments, and Gemma 3 27B (Team, 2025), a smaller LLM with broad multilingual support. We run all model calls through OpenRouter.[3]

Metrics We primarily evaluate with ChrF++ (Popović, 2017), an n-gram based metric which has been shown to correlate better with human judgement than BLEU (Papineni et al., 2002) particularly for morphologically rich languages like Kazakh or Georgian. To validate results found with ChrF++, we also evaluate with MetricX-24[4] (Juraska et al., 2024) and AutoMQM (Fernandes et al., 2023). MetricX is a neural metric which correlates better with human judgement than ChrF++ for high-resource languages. While it has not been evaluated on low-resource languages, it is based on mT5 (Xue et al., 2021), which has been pretrained on all languages in our study, aside from Tetun. AutoMQM uses a large language model to characterise translation errors using MQM (Lommel et al., 2013). To avoid self-preference bias that may arise from using the same LLM for AutoMQM as that used for translation (Wataoka et al., 2025), we run AutoMQM with Kimi K2 (Kimi-AI, 2025).

	ChrF ↑	MetricX ↓

NLLB 54B	53.58	3.45
Gemini	54.83 ↑ **1.24**	2.69 ↓ **-0.76**
DeepSeek-v3	51.40 ↓ **-2.18**	3.42 ↓ **-0.04**
Gemma 3	50.71 ↓ **-2.87**	3.61 ↑ **0.16**

Table 3: Average performance per model, with score difference from NLLB 54B. Modern LLMs like Gemini outperform NLLB on specialised domain low-resource MT, like health or literary fiction. See Tables 7 and 10 for scores per language, which vary from 37 to 63 ChrF.

Translation Strategies For LLM translation, we rely on a fixed one-shot prompt (Appendix F), and we systematically evaluate five translation strategies that introduce contextual information in different ways. Detailed in Table 2, these include translating sentences one at a time, translating sentences with some surrounding context, and translating entire documents at once. For NMT models (NLLB

[3] https://openrouter.ai/

[4] google/metricx-24-hybrid-large-v2p6-bfloat16

and MADLAD), as they were trained at the sentence level, we evaluate only at the sentence level. To ensure a fair comparison across models and strategies, all outputs, including those generated at the document level, are segmented and evaluated at the sentence level against the reference translations.

4.2 Results

LLMs outperform NMT on health low-resource translation (RQ1). On OpenWHO, Gemini 2.5 Flash, when translating at the document level, outperforms NLLB 54B across all languages,[5] by an average of +4.79 ChrF points (Table 3). MetricX and AutoMQM results confirm this overall trend. However, other LLMs evaluated (DeepSeek-v3 and Gemma 3) are still outperformed by NLLB-54B, albeit by a small margin for DeepSeek. This means that among open weight models, NLLB-54B is still the preferred choice. Further, at equivalent performance before fine-tuning, LLMs require far more computation, with around one order of magnitude more parameters for the same performance (e.g. DeepSeek-v3 671B roughly equivalent to NLLB 54B; Gemma 3 27B equivalent to NLLB 3.3B).

Error analysis: Gemini vs NLLB Error analysis using AutoMQM (Table 12) shows that Gemini translations contain substantially fewer critical errors than NLLB, with less mistranslations (where target text does not accurately represent the source meaning) and less incorrect terminology, at the cost however of more omissions (where target text is missing information present in the source) and overtranslations (target text more specific than the source).

On high-resource languages, NLLB and LLMs are very close to each other. On our sample of high-resource OpenWHO languages (French, Russian, Spanish), the average scores for NLLB 54B, Gemini, DeepSeek, and Gemma 3 are all remarkably close to each other, as measured by both ChrF (averages in the 59-62 range for all 4 models) and MetricX (averages in the 2.3-2.4 range). This result indicates that in the health domain, the advantage of LLMs over NMT is more pronounced on low-resource languages compared to high-resource. Unsurprisingly, performance on high-resource languages is notably higher than on low-resource ones, with a gap of 7-12 ChrF points between high-resource and low-resource across all models.

LLMs tend to work best at the document level, for specialised domains (RQ2). On OpenWHO, both Gemini and DeepSeek translate best at the document level, with +3.62 and +2.00 ChrF points over sentence-level translation respectively (Table 4), but no measurable improvements in MetricX scores. On WMT24++ literary, the advantage of document-level over sentence-level is even clearer, with +6.37 Chrf points for Gemini, +3.34 for DeepSeek, and similar improvements in MetricX scores (Table 11). For Gemma 3 27B however, additional context from document-level only marginally improves translation accuracy, on both OpenWHO and WMT24++ literary. Overall, we observe a trend where **the larger the LLM, the more it benefits from document-level translation (RQ3)** over sentence-level translation.

In the general domain, the advantage of modern LLMs and document-level translation are less clear. On the WMT24++ news set, we do not see meaningful accuracy improvements for document-level over sentence-level translation, using either metric (ChrF and MetricX). We also see less variation in scores between models on this domain, both when comparing NLLB to LLMs, and when comparing LLMs with each other. Overall, the advantage of document-level translation over sentence-level translation for low-resource MT is not uniform across domains and models.

5 Discussion

Our experiments present **three key findings**: First, modern LLMs tend to outperform NMT (e.g. Gemini outperforms NLLB 54B) on low-resource translation in specialised domains (health with OpenWHO, literary text with WMT24++). Second, modern LLMs translate best at the document-level in specialised domains (health and literary), but the advantage of document-level translation is less clear for smaller models and for the general domain. Third, other context-utilisation strategies (e.g. sentence window, document context with one sentence at a time) tend to perform less well than whole-document translation.

Why Gemini outperforms NLLB in low-resource specialised domain MT (RQ1) Our investigation into performance differences between

[5] We exclude Tetun from this comparison, as NLLB does not support it.

Doc vs sent	ChrF Δ	MetricX Δ
OpenWHO (9 low-res langs)		
Gemini	↑ 3.62	→ 0.00
DeepSeek	↑ 2.00	→ 0.02
Gemma3	↓ -0.21	↑ 0.24
WMT literary (5 low-res langs)		
Gemini	↑ 6.37	↓ -1.18
DeepSeek	↑ 3.34	↓ -0.79
Gemma3	↑ 2.06	↓ -0.14
WMT news (5 low-res langs)		
Gemini	↑ 1.24	↓ -0.08
DeepSeek	↓ -0.82	↓ -0.11
Gemma3	↓ -0.14	↑ 0.13

Table 4: Performance difference for document-level vs sentence-level translation, averaged across languages. In specialised domains (health, literary fiction), the larger the LLM, the more it benefits from doc-level translation. See Tables 8 and 11 for scores per language.

LLMs and NMT models reveals that Gemini's advantage over NLLB 54B in specialised domains stems directly from its ability to leverage document-level context. When both models are constrained to sentence-level translation, their performance is very similar across all three datasets evaluated (OpenWHO, WMT24++ literary, and WMT24++ news, all within a narrow 1.5 ChrF point margin). It is only when Gemini is provided with the full document that it establishes a clear performance lead.

The role of context strategy across domains Our findings show that the optimal context strategy depends on both text domain (RQ2) and model capability (RQ3). The benefit of document-level translation is most pronounced in specialised domains like health and literature, potentially because their discourse structure requires a high degree of linguistic coherence for both accuracy (e.g. correct health terminology) and stylistic integrity (e.g. sustained narrative tone). In contrast, the news domain may rely more on self-contained sentences that allow skimming and quoting, reducing the benefit of context. Further, our results indicate that smaller models only gain marginal benefits from document context, potentially lacking the capacity to maintain coherence without introducing noise.

Our findings, particularly the dependence of context utility on model capability and domain specificity, offer a nuanced picture for where document-level context is most useful, which may explain past work that either did not (Li et al., 2020; Appicharla et al., 2024; Koneru et al., 2024) or did (Wang et al., 2023; Post and Junczys-Dowmunt, 2024; Wu et al., 2024) find added benefits from contextual level translation.

Recommendations Based on our results, we offer three recommendations for researchers working on low-resource MT:

1. **Evaluate LLMs at the document level for specialised domains.** Sentence-level evaluation can mask the advantage of modern LLMs, which lies in their ability to use context.

2. **Utilise the most capable LLMs to maximise the benefit of document context.** The performance gains from document-level translation are most significant with the largest models.

3. **Analyse performance on a per-language basis.** Average model rankings do not always reflect performance on individual languages, making granular analysis essential for model selection.

Future directions Several avenues for future work emerge from our findings. First, the development of reliable evaluation metrics tailored to low-resource MT in the health domain. Second, further exploration of strategies to optimise LLM-based translation for low-resource health contexts, such as fine-tuning on domain-specific data or different prompting techniques. Third, the creation of evaluation benchmarks for low-resource health on other tasks, such as question answering, which OpenWHO could be leveraged for.

6 Conclusion

In this work, we introduced OpenWHO, a high-quality parallel corpus for health MT, with a focus on low-resource languages. Sourced from the World Health Organization's expert-authored materials, it addresses a gap in evaluation resources and provides a benchmark for future research at the intersection of health and low-resource languages. The dataset strengths include (1) the grounding of its source English text in evidence-based WHO guidance (2) its professional translation into various languages and (3) its availability at both the document and sentence level. However, OpenWHO is language imbalanced (not all courses were translated into all languages), which can limit its comparative value.

Our experiments demonstrate that modern LLMs, when provided with full document-level context, outperform traditional NMT models on low-resource translation in specialised domains like health and literature. We found that this advantage is most pronounced for the largest models and diminishes in the general (news) domain, highlighting that the utility of context depends on both model capability and domain complexity. Our work underscores the potential of document-aware LLMs to improve translation quality in high-impact settings, while also revealing the critical need for domain-specific evaluation benchmarks and context-aware translation strategies.

7 Limitations

Metrics Our findings rely exclusively on automated metrics (ChrF, MetricX, AutoMQM). While these metrics give a useful signal when they all agree, we have limited ability to resolve differences when they arise. ChrF is a recognised standard for low-resource MT but may not always correlate well with human judgement (Wang et al., 2024); MetricX and AutoMQM have not been evaluated on low-resource languages, let alone in the health domain. Overall, more work is needed to determine what is the right metric for low-resource health MT, including a comprehensive human evaluation to validate our findings and gain a more nuanced understanding of translation quality.

Generalisability across other domains In our experiments on context utilisation, we rely on two specialised domains: health (OpenWHO) and literary fiction (WMT24++). While we find similar trends, our findings may not generalise to other specialised domains, such as legal, financial, or technical texts. The specific characteristics of each domain may influence the utility of document-level context, and a broader, structured evaluation across multiple domains would be needed to draw more general conclusions.

Caveats of a direct comparison between LLMs and NMT While document-level LLM translation beats sentence-level NMT translation for the languages and specialised domains we evaluate on, this comparison might be unfair to NMT models, which could be adapted to benefit from document-level context for a more equivalent comparison, and have far fewer model parameters at equivalent performance levels. In practice, LLM outputs could be leveraged for knowledge distillation, creating smaller, domain-specific models that retain much of the performance advantage while being more efficient (Gibert et al., 2025).

Dataset language imbalance Finally, the OpenWHO dataset itself has limitations. Its language distribution is imbalanced, as not all source materials were translated into every target language. This can constrain its utility for direct cross-language comparisons.

8 Ethics Statement

Consent This work adheres to ethical guidelines for data collection and research in natural language processing. The OpenWHO corpus was compiled from the WHO's e-learning platform with explicit authorization from the WHO for both data collection and public release. Our work aligns with the WHO's mission to disseminate health information globally and respects their ownership of the content.

Dual use and societal impact We have carefully considered the potential for dual use of the OpenWHO dataset and our research findings. Our primary objective is to enhance access to health education material by improving MT for low-resource languages in the high-stakes health domain. The dataset comprises expert-authored, professionally translated public health materials, limiting risks of misuse. The humanitarian and public health benefits of facilitating information access in underserved languages significantly outweigh dual-use concerns.

Acknowledgements

We are deeply grateful to the World Health Organization (WHO) for their collaboration and for granting us permission to collect and publicly release the OpenWHO dataset. In particular, we would like to express our sincere gratitude to Heini Utunen, Corentin Piroux, and Melissa Attias for their support and guidance on this project.

This research was supported by The University of Melbourne's Research Computing Services and the Petascale Campus Initiative.

Table 12: AutoMQM analysis comparing NLLB-54B and Gemini 2.5 Flash (sentence-level) on the OpenWHO test set. **Top**: Overall MQM scores (higher is better). Gemini consistently outperforms NLLB. **Bottom**: Difference in error counts (Gemini errors minus NLLB errors) per category. Negative values indicate Gemini made fewer errors for that category. Gemini outputs less major errors like mistranslations and incorrect terminology, at the cost of a slight increase in over-translation and omissions.

F Prompts

System: Translate from English to [target lang name]. Give only the translation, and no extra commentary, or chattiness. Wrap the translated sentence in <result></result> tags.

User: <text to translate>She lives in Boston.</text to translate>

Assistant: <result>[Google Translate of "She lives in Boston." into target lang]</result>

User: <text to translate>[sentence to translate]</text to translate>

Prompt used for **Sentence level** translation. We ask the model to wrap the translation in <result> tags to avoid model commentary interfering with translation accuracy measurement.

System: Using the provided context, translate the "Sentence to translate" from English to [target lang name]. Give only the sentence translation, and no extra commentary, or chattiness. Wrap the translated sentence in <result></result> tags.

User: <context>
Her name is Mary. She lives in Boston. She is a doctor.
</context>
Sentence to translate:
She lives in Boston.

Assistant: <result>[Google Translate of "She lives in Boston." into target lang]</result>

User: <context>
[preceding sentence][sentence to translate][next sentence]
</context>
Sentence to translate:
[sentence to translate]

Prompt used for **Sentence window** translation.

System: Using the provided context, translate the "Sentence to translate" from English to [lang name]. Give only the sentence translation, and no extra commentary, or chattiness.

User: <context>
Her name is Mary. She lives in Boston. She is a doctor.
</context>
Sentence to translate:
She lives in Boston.

Assistant: <result>[Google Translate of "She lives in Boston." into target lang]</result>

User: <context>
[whole document for the sentence]
</context>
Sentence to translate:
[sentence to translate]

Prompt used for **Sentence + doc context** translation.

System: Translate from English to [lang name]. Give only the translation, and no extra commentary, or chattiness. Use the same formatting as the source text to translate, with one sentence per line. Enclose your translation in <result></result> tags.

User: <text to translate>
Her name is Mary.
She lives in Boston.
She is a doctor.
</text to translate>

Assistant: <result>
[Google Translate of "Her name is Mary." into target lang]
[Google Translate of "She lives in Boston." into target lang]
[Google Translate of "She is a doctor." into target lang]
</result>

User: <text to translate>
[document sentence 1]
[document sentence 2]
...
</text to translate>

Prompt used for **Document level** translation.

System: Translate from English to [lang name]. Give only the translation, and no extra commentary, or chattiness. Use the same formatting as the source text to translate, with one sentence per line. Enclose your translation in <result></result> tags.

User: <text to translate>
Her name is Mary.
She lives in Boston.
She is a doctor.
</text to translate>

Assistant: <result>
[Google Translate of "Her name is Mary." into target lang]
[Google Translate of "She lives in Boston." into target lang]
[Google Translate of "She is a doctor." into target lang]
</result>

User: <text to translate>
[document sentence 1]
[document sentence 2]
...
</text to translate>
Assistant: [assistant response from above]
User: Please translate again for a better version. Be particularly mindful of using the right script and tone, of adapting to context, and of translating each sentence faithfully.
<text to translate>[same as above]</text to translate>]

Prompt used for **Doc-level + self-correct** translation.

Factors Affecting Translation Quality in In-context Learning for Multilingual Medical Domain

Jonathan Mutal, Raphael Rubino, Pierrette Bouillon
TIM/FTI, University of Geneva
1205 Geneva, Switzerland
firstname.surname@unige.ch

Abstract

Multilingual machine translation in the medical domain presents critical challenges due to limited parallel data, domain-specific terminology, and the high stakes associated with translation accuracy. In this paper, we explore the potential of in-context learning (ICL) with general-purpose large language models (LLMs) as an alternative to fine-tuning. Focusing on the medical domain and low-resource languages, we evaluate an instruction-tuned LLM on a translation task across 16 languages. We address four research questions centered on prompt design, examining the impact of the number of examples, the domain and register of examples, and the example selection strategy. Our results show that prompting with one to three examples from the same register and domain as the test input leads to the largest improvements in translation quality, as measured by automatic metrics, while translation quality gains plateau with an increased number of examples. Furthermore, we find that example selection methods – lexical and embedding based – do not yield significant benefits over random selection if the register of selected examples does not match that of the test input.

1 Introduction

Multilingual communication in clinical settings is often hindered by the lack of quality translation tools for low-resource languages (Zappatore and Ruggieri, 2024). Building machine translation (MT) systems in the medical domain is challenging: parallel corpora is scarce and mistakes can lead to disastrous outcome (Chan et al., 2024). This challenge is intensified when translating into or from low-resource languages (Phan et al., 2023). Traditional neural MT models require supervised training on domain-specific data, which is not feasible for many low-resource language pairs. On the other hand, large language models (LLMs) possess broad world knowledge through pre-training and can be instructed to perform various tasks. Yet, general-purpose LLMs, when translating only with instructions (in zero-shot setting), often fail to produce adequate translations for specialized domains (Neves et al., 2024; Hu et al., 2024).

In-Context Learning (ICL) offers a way to guide LLMs at inference time by providing a few input-output pairs examples as part of the prompt (Brown et al., 2020). Unlike fine-tuning, ICL does not update model parameters; instead, the model learns from examples on the fly. This approach has gained popularity for low-resource scenarios (Zebaze et al., 2025), since only a handful of examples (as few as 1–5) can significantly improve performances on a given task. Prior studies have explored various strategies to optimize ICL for MT (Vilar et al., 2023). For instance, selection of examples that are similar to the test input yields better translation output. Similarity can be defined lexically (word overlap) or semantically (vector distance), and there is ongoing debate on which is more effective (Zebaze et al., 2025). Recent work has also examined the impact of the number of examples: some found that using up to 5 examples is beneficial (Zhu et al., 2024a), while others observed improvements up to 8 examples before performance plateau (Zhu et al., 2024b). Additionally, domain match is believed to be important: examples from the same domain as the task can guide the model's lexical and stylistic choices (Agrawal et al., 2023; Aycock and Bawden, 2024). However, to the best of our knowledge, ICL for MT in the medical domain is yet to be explored.

Our work aims to provide an evaluation of in-context learning for low-resource medical text translation. In particular, our goal is to quantify the impact of three key factors that may influence translation quality: the number of in-context examples, the register of those examples, and the strategy used to select them. We evaluate how each factor affects translation quality using two automatic metrics, namely ChrF++ (Popović, 2015)

Proceedings of the Tenth Conference on Machine Translation, pages 161–179
November 8-9, 2025

and COMET (Rei et al., 2020). More precisely, we seek answers to the following research questions (RQ1, RQ2, RQ3 and RQ4):

RQ1: Effect of Number of Examples – Does increasing the number of in-context examples improve translation quality?

RQ2: Effect of Register – Do examples with matching registers yield better translations than mismatched ones?

RQ3: Effect of Selection Strategy – Does semantic similarity (content-based) versus lexical similarity (form-based) selection of examples impact translation quality?

RQ4: Effect of Linguistic Characteristics - Which linguistic characteristics of the in-context examples (corpus- and prompt-level) most strongly influence translation quality?

Our contributions include: (1) an extensive empirical evaluation on 16 diverse languages (covering African, European and Asian languages and dialects) in a medical setting (Section 4), (2) a statistical analysis of the different factors, individually and in combination, that contribute to translation quality (3) a linguistic analysis of how corpus and prompts characteristics affect translation quality measured by automatic metrics (Section 5).

2 Related Work

Low-resource MT A low-resource language is typically defined as a language for which limited annotated data, such as parallel corpora or monolingual text, is available for training data-driven NLP models. The lack of resources may apply to text quantity, domain coverage, or availability of evaluation benchmarks (Joshi et al., 2020). In MT research, a low-resource language pair refers to a translation direction where parallel corpora are insufficient to train reliable MT systems. This limitation may reflect the absolute size (e.g., <1M sentence pairs), the domain (e.g., biomedical), or the bilingual coverage (Koehn and Knowles, 2017). In (bio)medical machine translation, even high-resource languages can become low-resource in-domain, due to the scarcity of domain-specific aligned corpora (e.g., medical records, Cochrane reviews, or medical dialogues) (Neves et al., 2024).

ICL for MT Early work on prompting LLMs for MT showed that models like GPT-3 can perform translation tasks without fine-tuning, particularly for high-resource languages (Brown et al., 2020). However, for low-resource languages and specialized domains, zero-shot performance is often weak, motivating research into few-shot prompting techniques (Hendy et al., 2023). One factor shown to influence translation quality is the number of examples. For instance, Peng et al. (2023) found improvements up to about five examples, while Zhu et al. (2024c) reported gains up to eight examples before saturation (translation quality scores plateau). These differences suggest that task- or model-specific characteristics can affect translation quality. This research direction allows us to answer RQ1.

Few-shot selection The example selection strategy for ICL is another impacting factor for MT, which has produced mixed results. Vilar et al. (2023) did not observe significant differences between random examples and lexically similar examples in some setups. In contrast, Zebaze et al. (2025) found that a semantic or lexical selection of examples based on the similarity with the source text to be translated improves translation quality. Moslem et al. (2023) proposed a more fine-grained approach, identifying which source words contribute most to guide example selection. More recently, Zebaze et al. (2025) showed that a small number of similar examples can yield large gains in translation quality for low-resource languages, even if the impact is limited for high-resource pairs where the LLM is already strong. We contribute to this debate by comparing form-based and meaning-based retrieval (answering RQ3), using BM25 (Robertson and Zaragoza, 2009) and LASER (Artetxe and Schwenk, 2019), respectively. This comparison has not been extensively explored in a multilingual medical setting.

Domain, Register and MT Domain is another influencing factor in MT quality. Farajian et al. (2017) observed that domain-matching data between training and testing leads to MT improvement, which motivates our experiments on few-shot selection from various sample pools, including in- and out-of-domain corpora. Following these ideas, Agrawal et al. (2023); Sia and Duh (2023); Aycock and Bawden (2024) showed that using ICL for MT, using in-domain data (e.g., medical or legal) as examples helps the model to produce appropriate terminology and style. In this work, we examine not only the domain but also the register (Lecorvé et al., 2023) of the texts (RQ2), as both can influence translation quality – an aspect that has received little attention in prior work. While

domain refers to the subject matter of a text, such as medicine, law, or education, register describes how language is used in a specific situation within that domain, shaped by factors like the relationship between speakers, the communication channel, and the purpose of the interaction. For example, both a doctor–patient dialogue and a medical research paper belong to the medical domain while being in different registers and thus exhibit different styles, choices in vocabulary, and overall communicative intent.

3 Methodology

3.1 Test Data

Our evaluation spans 16 languages: Albanian, Modern Standard Arabic, Moroccan Arabic, Tunisian Arabic, Dari, Farsi (Persian), Russian, Romanian, Ukrainian, English, French, Spanish, German, Polish, Czech and Tigrinya. These include low-resource languages/dialects (e.g. Moroccan, Tunisian and Tigrinya) as well as higher-resource ones (French, Spanish). We consider translation between all pairs and translation directions among these languages.

We evaluate various prompt engineering settings on three test sets in the medical domain that differ in register. These test sets are n-way parallel–each sentence translated into multiple languages–thus allowing us to assess: i) cross-linguistic variations, ii) differences in style and iii) communicative purposes within medical texts.

Cochrane is an internationally recognized source of evidence-based clinical research, providing reviews that synthesize medical studies to inform clinical practice[1]. The language used in Cochrane documents is formal, technical, and structured, making it representative of technical biomedical content. The content of this article is aimed at medical professionals, particularly researchers in the medical field.

NHS24 consists in publicly available health articles from Scotland's national telehealth service [2]. These articles are designed for the general public and provide accessible medical information, symptom explanations, and healthcare guidance. The language used in this article aims to be understandable, non-technical, and oriented toward patient comprehension, distinguishing it from more technical registers such as Cochrane. This corpus represents a patient-facing, health communication register, in a scenario where translation clarity and simplicity are critical.

Medical Dialogues is a set of medical question-and-instruction sentences from Bouillon et al. (2021). This corpus has never been released publicly, thus constitute an annotated *no-leakage* evaluation set never seen by LLMs. Sentences in this corpus are characterised by short, directive, and information-seeking utterances typical of clinician–patient interactions (e.g., asking about symptoms, giving instructions for treatment, etc.). The sentences were translated from French.[3]

An important characteristic of our medical dialogue data is that the translators were instructed to generate target-oriented translation that read as if originally written in the target language. They were also asked to take the communicative context and audience into account (e.g., patient vs. clinician) and allowed freedom of reformulation rather than adhering to the source structure. As a result, the dataset avoids many of the typical artifacts of translationese – such as literal lexical choices, unnatural word order, or oversimplification – while still maintaining terminological accuracy (Gerlach et al., 2018). An example of the translations is shown in Table 2. For the other datasets, we acknowledge the potential influence of translationese, but because both training and evaluation rely on the same language pairs (including artificial test pairs), the artifacts introduced by translationese is expected to be consistent across sets and therefore less likely to distort automatic scores (Ni et al., 2022).

3.2 Register and Domain Selection

To assess the effect of test and n-shot source mismatch, various datasets are used as sources for few-shot sampling: datasets described in Section 3.1, as well as a general-domain corpus: FLORES+ (Team et al., 2022). In our experiments, we control for all other factors (model, language pair, test sentence, prompt length, and evaluation metric) and vary only the source of the in-context examples, allow-

[1] An example can be found at https://pmc.ncbi.nlm.nih.gov/articles/PMC7045447/

[2] For instance, https://www.nhsinform.scot/healthy-living/preventing-falls/falls-and-dementia/

[3] The dataset is available in https://huggingface.co/datasets/jonathanmutal/Medical-Questionnaire-Multilingual-Translation

ing us to compare matched vs. mismatched domain and register. We follow the standard dataset splits for Cochrane and NHS24 (Haddow, 2015) and for FLORES+ (Team et al., 2022). For the Medical Dialogues set, we randomly extracted 1,000 segments. The number of n-way parallel segments for each dataset is shown in Table1.

Dataset	Split	#Sentences
Cochrane	Train	759
	Test	672
NHS24	Train	1200
	Test	1257
Medical Dialogues	Train	8511
	Test	1000
FLORES+	Train	997

Table 1: Number of sentences for each dataset and split.

3.3 In-Context Example Selection

To address RQ3, we consider three example selection strategies:

Random: We randomly sample n examples from the available pool of parallel data. This acts as a baseline and helps quantify variance. To ensure fairness, the same set of random examples (for a given n) is used across different languages when evaluating the number of examples. This way, any observed differences are not due to content variations across languages.

Lexical Similarity (BM25): We retrieve examples that are lexically similar to the input, using the BM25 (Robertson and Zaragoza, 2009) ranking function. BM25 scores examples based on overlapping words (with term-frequency and length normalization). This method prioritizes examples containing similar medical terms or phrases, reinforcing consistent terminology.

Semantic Similarity (LASER): We use multilingual LASER embeddings (Artetxe and Schwenk, 2019) to find examples with high cosine similarity to the input sentence. This can retrieve examples that are paraphrases or semantically related, even if they do not share keywords. The goal is to help the model generalize to similar meanings expressed using various surface forms.

For both BM25 and LASER, we retrieve the top n examples from each dataset individually. We also follow a specific ordering when placing examples in the prompt: we sort the retrieved examples by descending similarity to the input (most similar last, closest to the input). This ordering, suggested by prior work (Chitale et al., 2024), may maximize the utility of the demonstration closest to the test query.

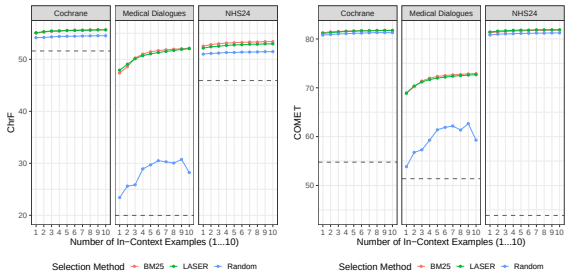

Figure 1: Effect of the number of in-context examples on ChrF scores across datasets and selection methods. ChrF performance is plotted for three datasets – Cochrane, Medical Dialogues, and NHS24– using three selection strategies: BM25 (red), LASER (green), and Random (blue). Scores are averaged across all languages. The dashed horizontal lines represent zero-shot performance.

3.4 Experimental Settings

We use Mistral-7B-Instruct[4] with a fixed JSON-based prompt format to ensure systematic outputs and isolate the effect of example content on translation quality (cf. Appendix B for more details). We vary the number of in-context examples n from 0 (zero-shot, only instruction) up to 10 to address RQ1. Each configuration (defined by the number of examples n, the selection method, and the domain of the selected examples) is applied to all test sentences. For stochastic settings (random selection), we repeat each test 30 times with different random seeds and average the results. This yields robust estimates of performance by smoothing the results obtained with random sampling and allows for significance testing.

We evaluate translation quality with two automatic metrics:

- ChrF++: Character n-gram F-score, which correlates well with adequacy especially for morphologically rich languages (Popović, 2015).
- COMET: A learned metric that predicts human judgment scores using multilingual em-

beddings; effective for capturing semantic adequacy (Rei et al., 2020).

All metrics are computed against reference translations. We conduct significance testing Factorial Analysis of Variance (Factorial ANOVA, Ross and Willson, 2017) to understand the effect of each factor (number of examples, register and selection strategy) on the translation quality, and also understand the effect of multiple factors on translation quality. This analysis allows us to understand, for example, the effect of the number of examples and selection strategy on the translation quality. We used eta squared (η^2) test (Adams and Conway, 2014) to quantify the effect size in analysis of variance and determine which factor has the largest effect on translation quality according to automatic metrics.

4 Effect of Factors in Translation Quality

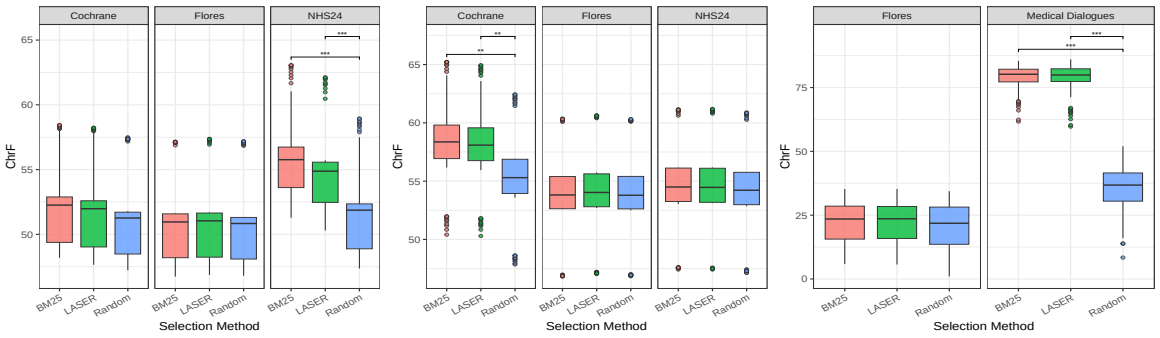
In this section, we describe the results collected during our experiments. We divide the results following the RQ1, RQ2 and RQ3 from Section 1 before comparing the effects of all factors on translation quality.

4.1 Results

Number of Examples: Figure 1 illustrates the effect of the number of examples on translation quality. We observe that increasing the number of in-context examples improves translation quality for all test sets, but differences are observed in terms of n-shot configuration.

With no translation examples in the prompt (0-shot, the dashed line in Figure 1), the LLM reaches the lowest scores on the medical dialogues test set. With just a single example, automatic scores more than doubled (from 20.01 to 48.20 ChrF using BM25). For the best selection method on this test set (medical dialogues), there are diminishing returns above 4 to 5-shot configuration.

For Cochrane and NHS24, the difference between 0-shot and n-shot is smaller based on ChrF (51.25 vs. 55.21 for Cochrane, 45.23 vs. 53.25 for NHS24). For these particular test sets, most gains are obtained with 2 to 3 examples, followed by a plateau with no significant improvement when increasing the number of shots. This may be due to the fact that the Cochrane and NHS24 datasets are publicly available and may have been seen by the LLM during pre-training, whereas this is not



(a) Target test data: NHS. (b) Target test data: Cochrane. (c) Target test data: Medical Dialogues.

Figure 3: Effect of selection method on translation quality across different test datasets. ChrF and COMET scores are shown for in-context examples drawn from different selection methods (BM25, LASER, RANDOM) on the different domain examples. Statistical significance among results is indicated by *** when $p < 0.001$, ** when $p < 0.01$ and * when $p < 0.05$.

the case for Medical Dialogues.

To answer RQ1, these results show that increasing the number of examples has an effect on translation scores measured by automatic metrics. However, a plateau is quickly reached on all test sets (max. with a 5-shot prompt), and adding more examples does not lead to significant improvements. This is observed when examples are retrieved based on their similarity with the source using BM25 and LASER.

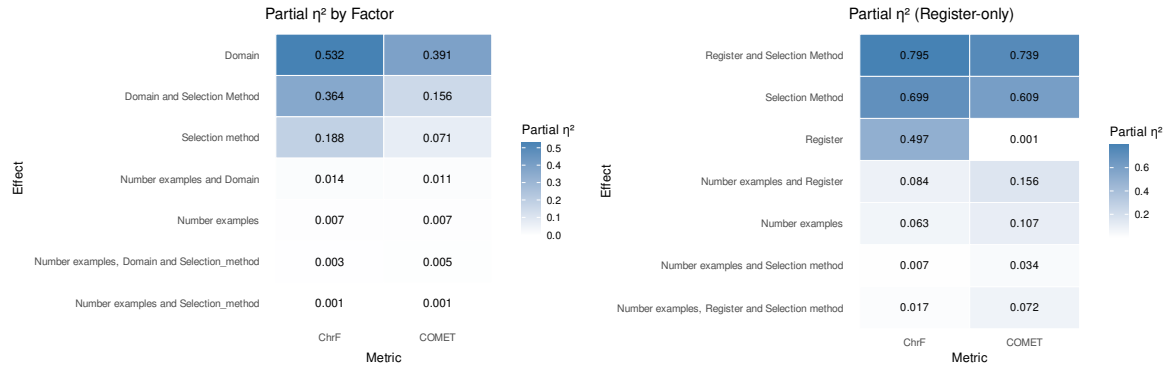
Source of Examples: Figure 2 shows translation results on our test sets when various sample pools are used to build the prompt.

Matching-domain exemplars (n-shot and test sentences sampled from the same corpus) result in significant score gains for all selection methods. The figures show that sampling from FLORES+ consistently underperforms compared to sampling from in-domain datasets. We also observe that random sampling from in-domain data outperforms a selection strategy using an out-of-domain dataset, showing that the domain of the data have a strong effect on translation quality.

Additionally, results show that matching registers yields the highest scores. However, unlike domain mismatch, we found that using a non-random selection method with Cochrane on the NHS24 test set yields higher ChrF scores compared to randomly sampling from the same register (sampling from NHS24), although the difference is not statistically significant according to COMET. This may be due to the content of the NHS24 corpus, written for patients and thus using less technical vocabulary compared to Cochrane.

To answer RQ2, the results show that register and domain have a significant effect on translation quality.

Example Selection Method: We compare lexical vs. semantic retrieval (BM25 vs. LASER, respectively) against random examples selection to address RQ3. Figure 3 illustrates the box plot for the different test data with the n-shot retrieval methods. Overall, BM25 and LASER yield nearly identically scores on automatic metrics. BM25 had a slight higher automatic scores (but not statistically significant). We found that when using BM25 for lower-resource languages seems to be more beneficial (we refer to Figure 10 for these



(a) Partial η^2 for different domains and registers.

(b) Partial η^2 for the same domain and different registers.

Figure 4: Heatmap of partial η^2 values indicating the percentage of variance explained by each factor and interaction in the model. Darker shades represent greater effect on translation quality. Register and Selection method show the highest effects, while all interactions involving Number examples contribute minimally. Note that partial eta-squared values are not additive and do not sum to 100%.

results).

BM25 and LASER achieve higher translation quality, as measured by the automatic metrics, compared to random sampling when the domain and register match those of the test data. However, when using data from a different domain or register, the selection methods do not yield significant improvements compared to random sampling. This provides further evidence of n-shot domain and register impact on translation quality, adding support to the findings for RQ2. We can therefore answer RQ3: there is an effect of selection strategy when the examples match the register. Otherwise, there is no statistical difference between BM24, LASER and random selection.

Comparing Effects: We conducted a factorial ANOVA to quantify the contribution of each factor to the variance in translation quality, as measured by ChrF and COMET, illustrated by Figure 4a.

Using common benchmarks for partial η^2 ($\sim$ .01 small, $\sim$ .06 medium, $\sim$ .14 large)[5], this analysis reveals that register and domain shows the largest effect ($\eta^2 = 0.53$), suggesting the highest variance in translation quality is associated with whether the train and test are sampled from the same dataset. The selection method ($\eta^2 = 0.18$) has also a large impact on translation quality. However, the interaction between the selection method and matching dataset effects on translation quality is higher (η^2 = .36), indicating that the selection method has a larger impact only when accompanied by matching n-shot register and domain.

[5] https://resources.nu.edu/statsresources/eta

On the other hand, increasing the number of examples in the prompt does not seem to have a strong impact ($\eta^2 = .0028$) compared to the other factors, i.e. domain and register. This supports the importance of the data source for n-shot selection. Increasing the number of examples provided as prompt to the LLM shows small additional variance on translation quality (above 1-shot).

When measuring translation quality variance within the medical domain, the main drivers are the selection method ($\eta^2 = 0.699$) and its interaction with the register ($\eta^2 = 0.795$). Number of examples is modest ($\eta^2 = 0.063$), and other interactions are small. Within the same domain, the choice of example selection strategy have a strong influence on both ChrF and COMET scores ($\eta^2 = 0.795$ and $\eta^2 = 0.739$ respectively), with its impact varying across registers. Figure 4b illustrates this values in a heatmap figure.

These results confirm our findings of the most important factor of translation quality: register and domain of the examples. To understand the causes, we carry out a lingistic evaluation in the following section.

5 Linguistic Analysis

Based on the previous results, which showed that the domain and register of the examples have the strongest impact on translation quality, we conduct a linguistic evaluation to determine which linguistic characteristics from the examples have the most influence on translation quality (RQ4). Because our goal is to assess how domain and register alignment shape translation quality, we select three corpus-

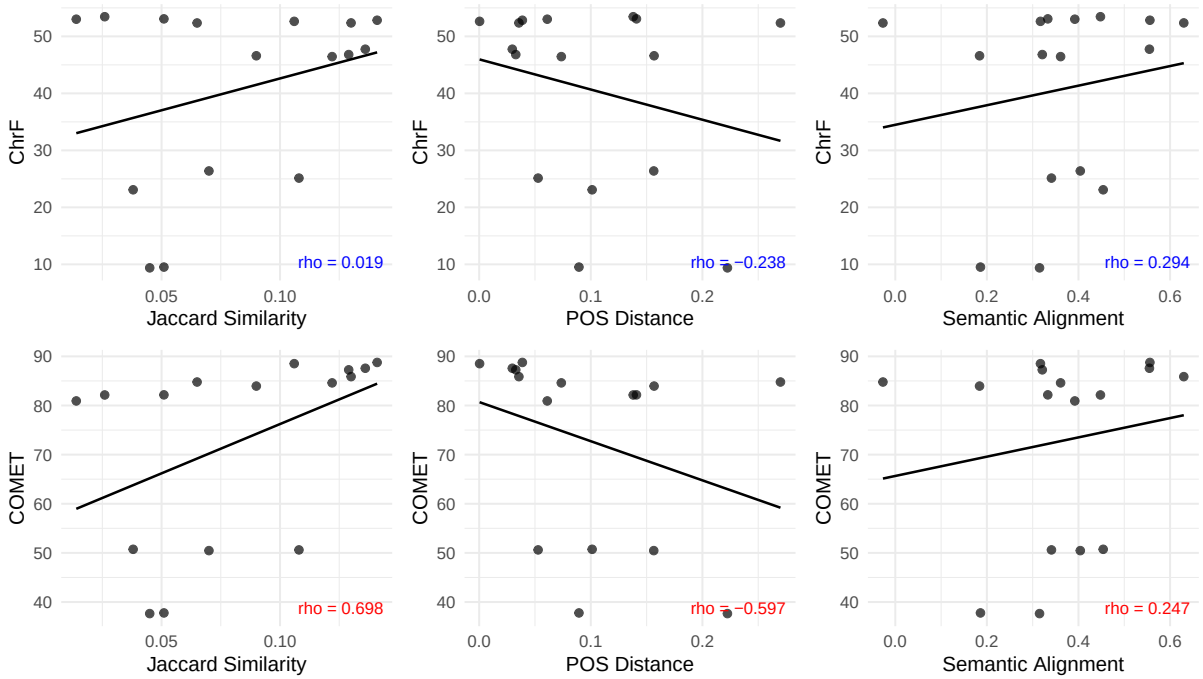


Figure 5: Scatterplots showing the relationship between corpus-level similarity metrics and average translation quality (ChrF and COMET). Each plot corresponds to one of the following corpus-level measurements: **Jaccard Similarity** (lexical overlap), **POS Distance** (cosine distance between part-of-speech distributions), and **Semantic Alignment** (average of sentence cosine similarity between corpus). Spearman's ρ is shown for each metric, indicating the strength and direction of correlation.

level metrics that capture complementary aspects of similarity in texts:

- **Lexical overlap** (using (Jaccard similarity Jaccard, 1901) for corpus-level analysis and token overlap for prompt-level analysis): it measures vocabulary overlap across examples to capture whether they share key medical terms, and thus belong to the same domain and register. High overlap indicates coherence in subject matter.

- **Structural similarity** (cosine difference of part-of-speech distributions) (Liu et al., 2021): Part-of-speech distributions reflect grammatical choices; their cosine difference approximates whether examples adopt similar interpersonal stances and modes of medical communication.

- **Semantic alignment** (cosine similarity of sentence embeddings): Compares sentence embeddings to assess whether the overall meaning of the examples aligns. We used a different sentence embedding model from that used in the selection method, specifically the one proposed by (Reimers and Gurevych, 2019).

To perform this analysis, we included additional corpora for n-shot sampling to provide more data for corpus-level analysis: translations of documents related to public health and disease prevention across different languages within the European Union (ECDC, European Centre for Disease Prevention and Control, Greer, 2012); diverse datasets created during the COVID-19 period, including a set of Wikipedia documents related to health (Wikipedia Health); a database containing European Union law and other public documents generated during COVID-19[6]; and TICO-19 for non-European languages (Anastasopoulos et al., 2020). Finally, we included a general-domain corpus, Tatoeba[7]. While several of these texts share the same domain (medical), they differ in register, ranging from policy documents (EU public documents) to encyclopedic health texts and public health advisories. All corpora were extracted using the OPUS platform (Tiedemann, 2012).

We first examine corpus-level characteristics to understand how to select sample pools for ICL and to determine which aspects of domain and register are the most impactful when choosing a sample

[6]Extracted from https://elrc-share.eu/

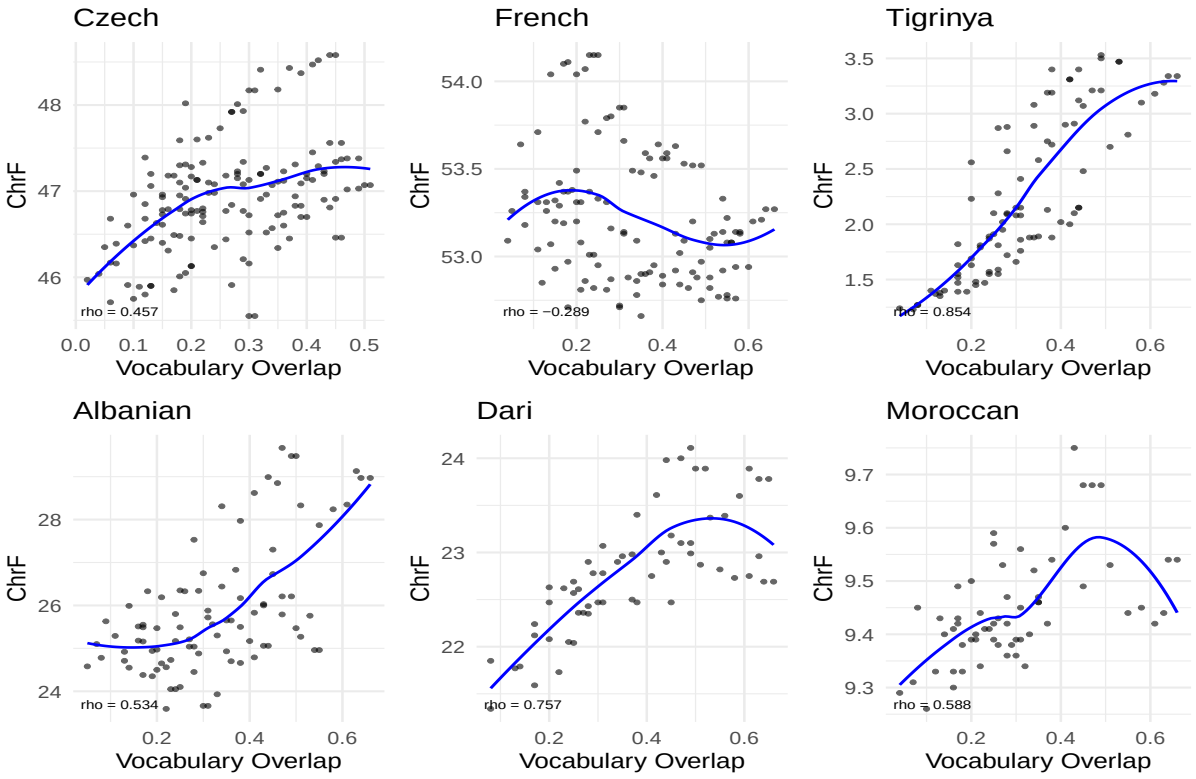

Figure 6: Scatterplots showing the relationship between prompt-level similarity metrics and average translation quality. Each plot corresponds to one of the following prompt-level measurement for **Vocabulary Overlap** (lexical overlap). Spearman's ρ is shown for each metric, indicating the strength and direction of correlation.

pool. We then analysed prompt-level examples[8] to evaluate the effect of their linguistic characteristics on translation quality. To identify which aspects of register matter most, we examined the relationship between linguistic features and evaluation scores, checking how strongly each feature–such as vocabulary overlap, grammatical similarity, and semantic similarity–correlated with ChrF and COMET using Spearman rank correlation.

We selected language pairs in which POS tagging and embedding-based metrics for the source language were supported and for which the neccesary corpora were available. Specifically, we used English paired with six languages: two high-resource languages (French and Czech) and four low-resource languages (Tigrinya, Albanian, Moroccan Arabic, and Dari), selected based on the availability of medical corpora.[9]

[8]When multiple examples were provided for in-context learning, we calculated the mean; maximum scores were also tested but showed lower correlation with translation quality according to Pearson's ρ.

[9]According to the OPUS platform, English–Tigrinya has 6,142 sentences in the COVID medical domain; English–Dari has 3,071; English–Albanian has 389; and English–Moroccan Arabic has none.

In the next section, we describe the results collected during our experiences to answer RQ4, divided by corpus and prompt levels of analysis.

5.1 Results

Corpus-level Analysis At the corpus level, the similarity measures (lexical, syntactic, semantic) are the same for all sentences within a given sampling and test dataset, as they are calculated over the full example set, while translation quality varies between prompts. To avoid inflating the number of independent observations, we averaged the translation quality scores for all sentences in the same sampling and test dataset configuration and used these aggregated values in the analysis. This ensures that each configuration is counted once, and the results reflect real differences between configurations rather than repetition of identical feature values.

Figure 5 illustrates the corpus-level analysis between the translation automatic scores and the corpus-level metrics for lexical overlap. The results show that lexical overlap strongly correlates with COMET ($\rho = 0.698$), but not with ChrF, suggest-

ing that COMET is more sensitive to lexical content alignment. POS distance shows negative correlations with both metrics, especially with COMET, indicating that structural divergence between examples and test sets degrades ICL performance. Semantic alignment correlates moderately with both ChrF ($\rho = 0.294$) and COMET ($\rho = 0.247$), confirming that semantically coherent prompts are beneficial, although their predictive power is lower than the lexical alignment for COMET.

Prompt-level Analysis To assess the effect of samples register and domain from the prompt on translation quality, we first calculated the Spearman's ρ correlation between the translation quality scores and the linguistic features between the samples and the input sentence – vocabulary overlap, grammatical similarity, and semantic similarity.

Figures 6, 11, 12 show that translation quality–measured by ChrF and COMET–correlates with lexical, syntactic, and semantic similarity between the input and the selected examples. Spearman correlations indicate that low-resource languages such as Tigrinya, Dari, Moroccan Arabic, and Albanian exhibit the strongest correlations across all three similarity types, while higher-resource languages display more selective patterns. The ANOVA analysis, which includes the number of examples and the selection method as fixed effects, confirm these trends, with semantic similarity often producing the largest effect in translation quality for low-resource languages, and syntactic similarity dominating in Czech. η^2 analysis further reveals the unique contribution of each feature: semantic similarity explains the largest share of variance in most low-resource languages (e.g., 4–10% in Albanian and Moroccan Arabic), whereas in French lexical similarity accounts for 13–15% and in Czech syntactic similarity explains up to 21.7% of variance in ChrF. Together, these results show that the relative importance of lexical, syntactic, and semantic alignment is language-dependent.[10]

6 Conclusions

This study shows that, in multilingual medical machine translation, the domain and register of in-context examples are the most influential factors affecting translation quality. Partial η^2 analysis confirms that aligning the n-shot register and domain with the test input yields substantially greater improvements than increasing the number of examples. In practice, a small, well-chosen set of domain-relevant shots often yields higher translation quality scores than a larger set of examples sampled from other domains or registers.

Sentence-level analysis of lexical, syntactic, and semantic similarity confirms that the most predictive features vary by language. In low-resource language pairs, all three similarity types correlate strongly with translation quality, while in higher-resource languages pairs such as English to Czech and French, syntactic and semantic similarity dominate. Semantic similarity is the most consistent predictor across languages.

These results suggest that prompt engineering for ICL should prioritise register and domain alignment, and adapt exemplar selection criteria to the characteristics of the language pair rather than applying the same similarity heuristics.

Acknowledgements

This work is part of the PROPICTO project, funded by the Swiss National Science Foundation (N°197864) and the French National Research Agency (ANR-20-CE93-0005). We would also like to thank the three reviewers for their careful suggestions, which helped improve this work.

Limitations

This study has several limitations. First, all experiments were conducted using a single LLM, which constrains the generalisability of the findings to other model families, training paradigms and sizes. We hypothesize that larger models could reach better translation quality, which we leave for future work. Second, the linguistic similarity features—lexical, syntactic, and semantic—were computed using specific operationalisations (e.g., Jaccard similarity, POS distribution cosine distance, sentence embedding cosine similarity). They represent only one way of quantifying similarity, and alternative feature definitions or embeddings might yield different rankings of predictive importance. Moreover, corpus-level features were constant within each configuration, which required aggregation to avoid artificially statistical significance; this design limits the granularity of the corpus-level analysis. The linguistic evaluation was limited to a fixed set of high- and low-resource languages in the medical domain, meaning that

[10] Type–token ratio was negatively correlated with both metrics in nearly all languages, suggesting that higher lexical diversity in prompts tends to reduce translation quality.

results may not generalise to other languages. Finally, while ChrF and COMET provide complementary perspectives on translation quality, incorporating human evaluation for adequacy and fluency would strengthen the validity of the results. Furthermore, the evidence gathered in this work provides practical insights into the factors influencing translation quality as measured by automatic metrics. However, these findings do not indicate whether the translations are sufficiently accurate for practical use without introducing potential risks. Future work will involve evaluating clinical risks, following the approach of Mehandru et al. (2023).

A Example Translation Corpora

Table 2 illustrates a typical sentence from our medical dialogue dataset in French, English, and Spanish. As seen in the example, the translations are target-oriented and adapted to the communicative context: the English version uses an idiomatic rendering ("ringing noise in your ears"), while the Spanish version employs an equivalent ("zumbidos") rather than a literal calque of the French source term. This reflects the dataset's design guidelines, which emphasized the audience awareness and freedom of reformulation.

Language	Sentence
French	Pendant combien de jours avez-vous pris des médicaments contre les acouphènes ?
English	How many days did you take medicine to help with the ringing noise in your ears for?
Spanish	¿Durante cuántos días ha estado tomando medicamentos contra los zumbidos?

Table 2: Example of a medical dialogue sentence in three languages.

```

Figure 7: Prompt structure for in-context learning, illustrated for English-to-French text translation. The prompt provides an instruction with output schema, a few example input-output pairs in JSON format, and then the test input demarcated by special tokens.

We use Mistral-7B-Instruct v0.3, a 7-billion parameter decoder-only LLM, as the backbone. This model was chosen because at the time of experimentation it was one of the stronger openly-available instruction-tuned models. Notably, Mistral-Instruct is predominantly trained on English and lacks dedicated support for many of our languages (e.g. Tigrinya), making it a good stress-test for ICL. We access the model via HuggingFace Transformers, running in half-precision (fp16) with FlashAttention optimization for efficiency. Generation is done greedily (no sampling) to ensure deterministic outputs for a given prompt.

We construct a prompt template that includes an instruction section, a few example translation pairs, and then the input to translate. The instruction defines the task (e.g., "Translate from language X to language Y and output in a JSON format"). We enforce a JSON output schema to ensure the model's output is structured correctly. An example prompt (for English-to-French translation) is shown in Figure 7. The prompt begins with a task description and output schema specification (the schema indicates that the output should be a JSON with a "translation" field containing a string). It then says: "Here are some examples:" followed by N example pairs. Each example is formatted as:

[source language]: [source text example]

[target language] JSON: "translation": "[target text example]"

After listing the N examples, the prompt has a separator and then the actual input to be translated, marked clearly (e.g., by <<< >>>). The model is expected to produce only the JSON translation for the input without additional commentary. We found that including the language names (as in the figure) helps the model produce the output in the correct language, especially since the model is multi-lingual only through prompting. This prompt format was kept consistent in all experiments to focus on the content of examples rather than prompt wording.

C Effect of Factors on Translation Quality

Figures 9, 8 and 10 show the detailed results for the effect of the number of examples and the selection method across test sets by langauge. Each subfigure presents ChrF scores for examples drawn from different registers (BM25, LASER, RANDOM). Statistical significance between registers is indicated in the plots. These results complement the main findings in Section 4.1, providing per-dataset and per-method breakdowns that were summarised in the main text.

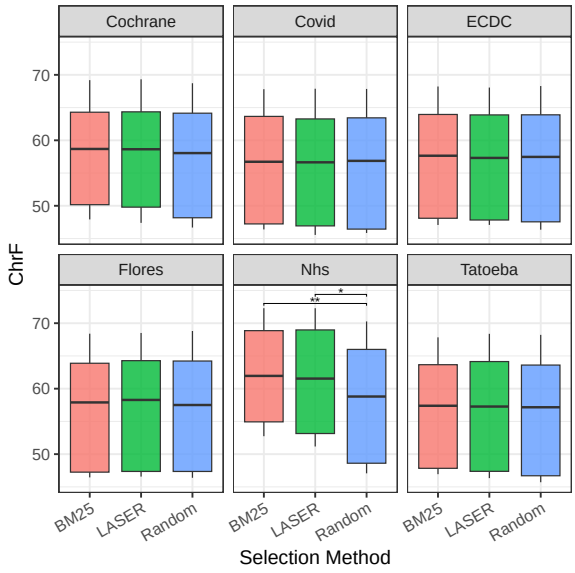

Figure 8: Effect of selection method on translation quality across different test datasets tested in NHS24. ChrF and COMET scores are shown for in-context examples drawn from different selection methods (BM25, LASER, RANDOM) on the different domain examples. Statistical significance among results is indicated by *** when $p < 0.001$, ** when $p < 0.01$ and * when $p < 0.05$.

D Linguistic Evaluation

Figures 11 and 12 present the full scatterplots for the relationship between prompt-level similarity metrics and average translation quality. Each figure corresponds to one similarity feature:

- Figure 11: **POS Distance** (cosine distance between part-of-speech distributions).
- Figure 12: **Semantic Alignment** (cosine similarity between sentence embeddings).

Spearman's ρ is shown for each plot, indicating both the strength and direction of the correlation. These figures provide the complete visual evidence underlying the correlation values reported in Section 5.

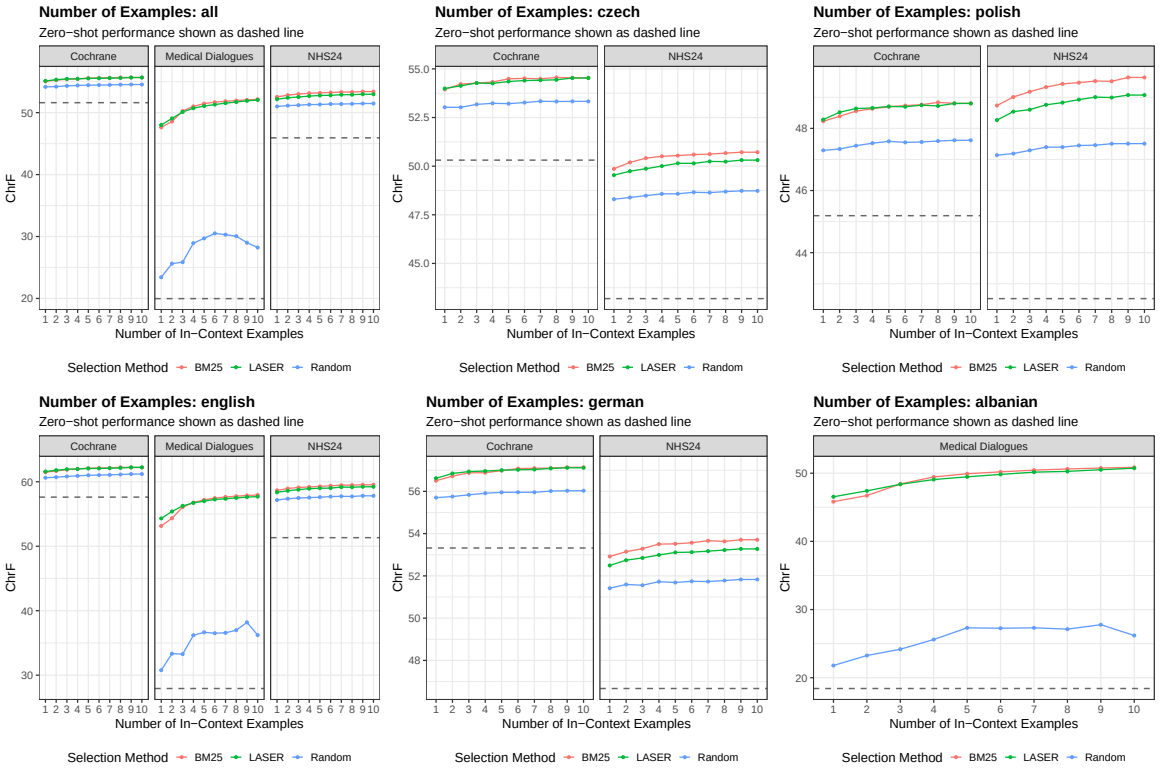

Figure 9: Effect of number of examples and selection method per test data. ChrF scores are shown for in-context examples drawn from different registers using three selection methods (BM25, LASER, RANDOM). Statistical significance between registers is indicated.

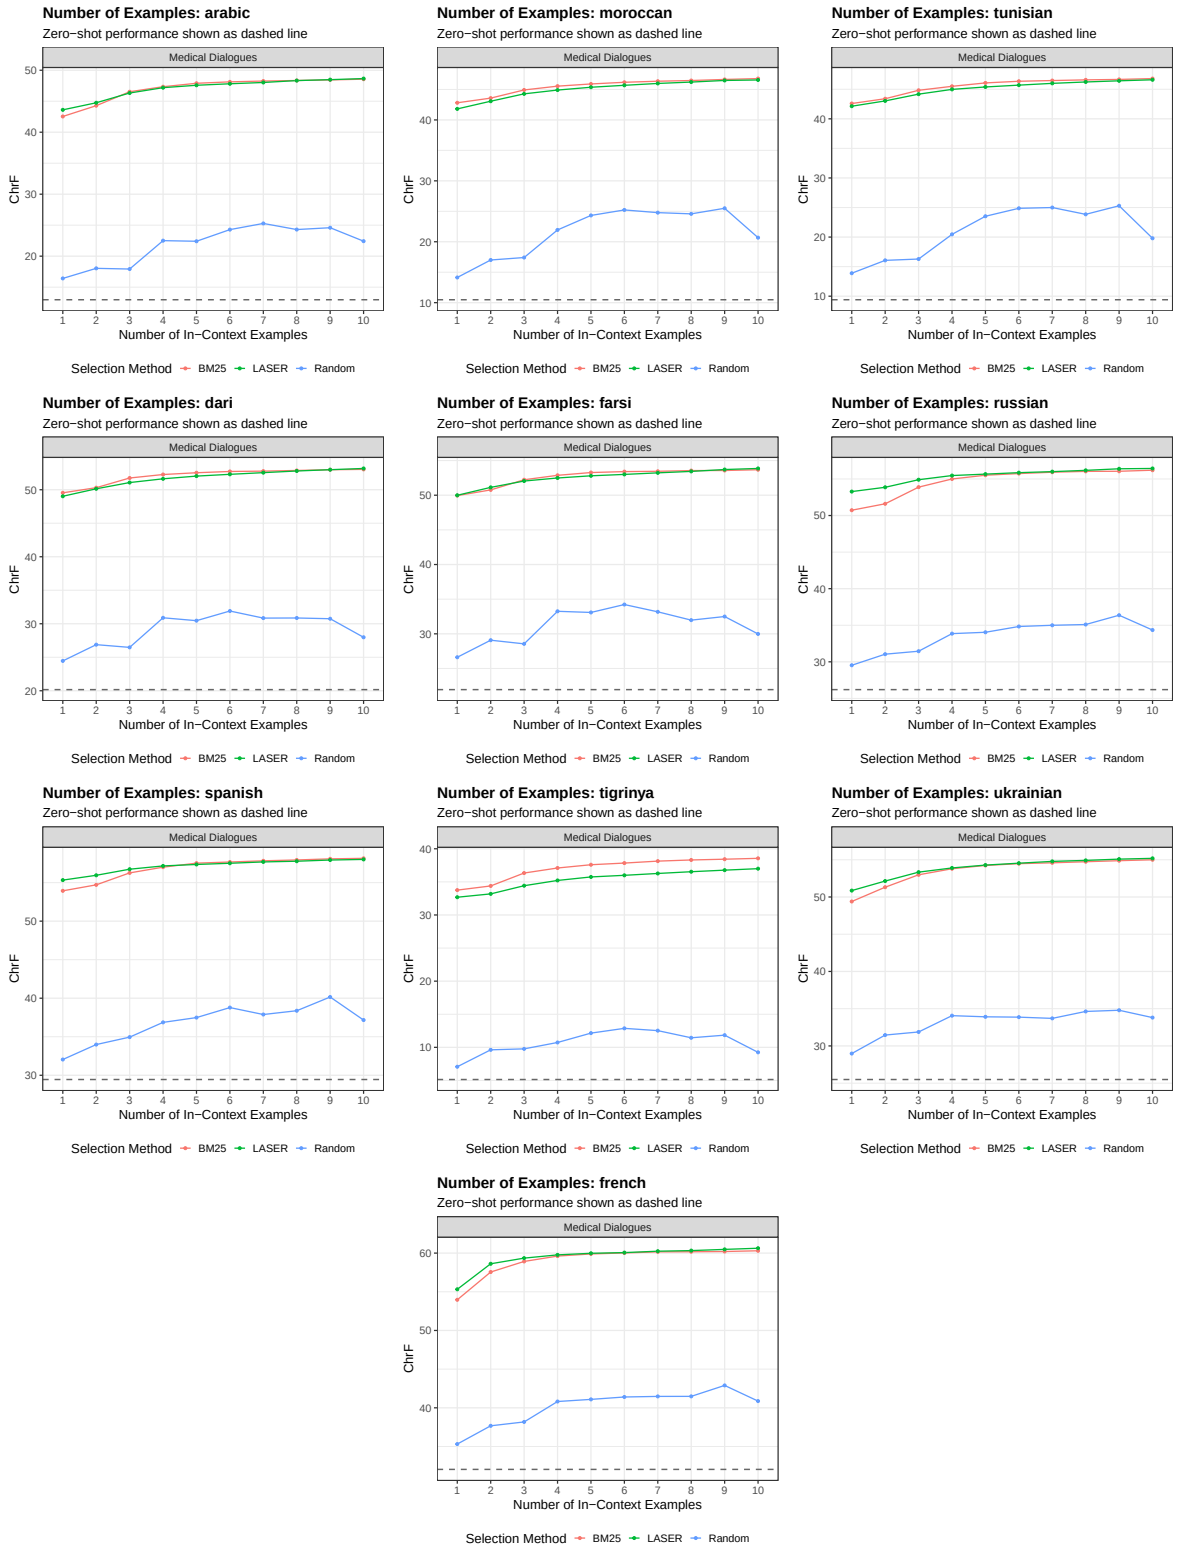

Figure 10: Effect of number of examples and selection method per test data. ChrF scores are shown for in-context examples drawn from different registers using three selection methods (BM25, LASER, RANDOM). Statistical significance between registers is indicated.

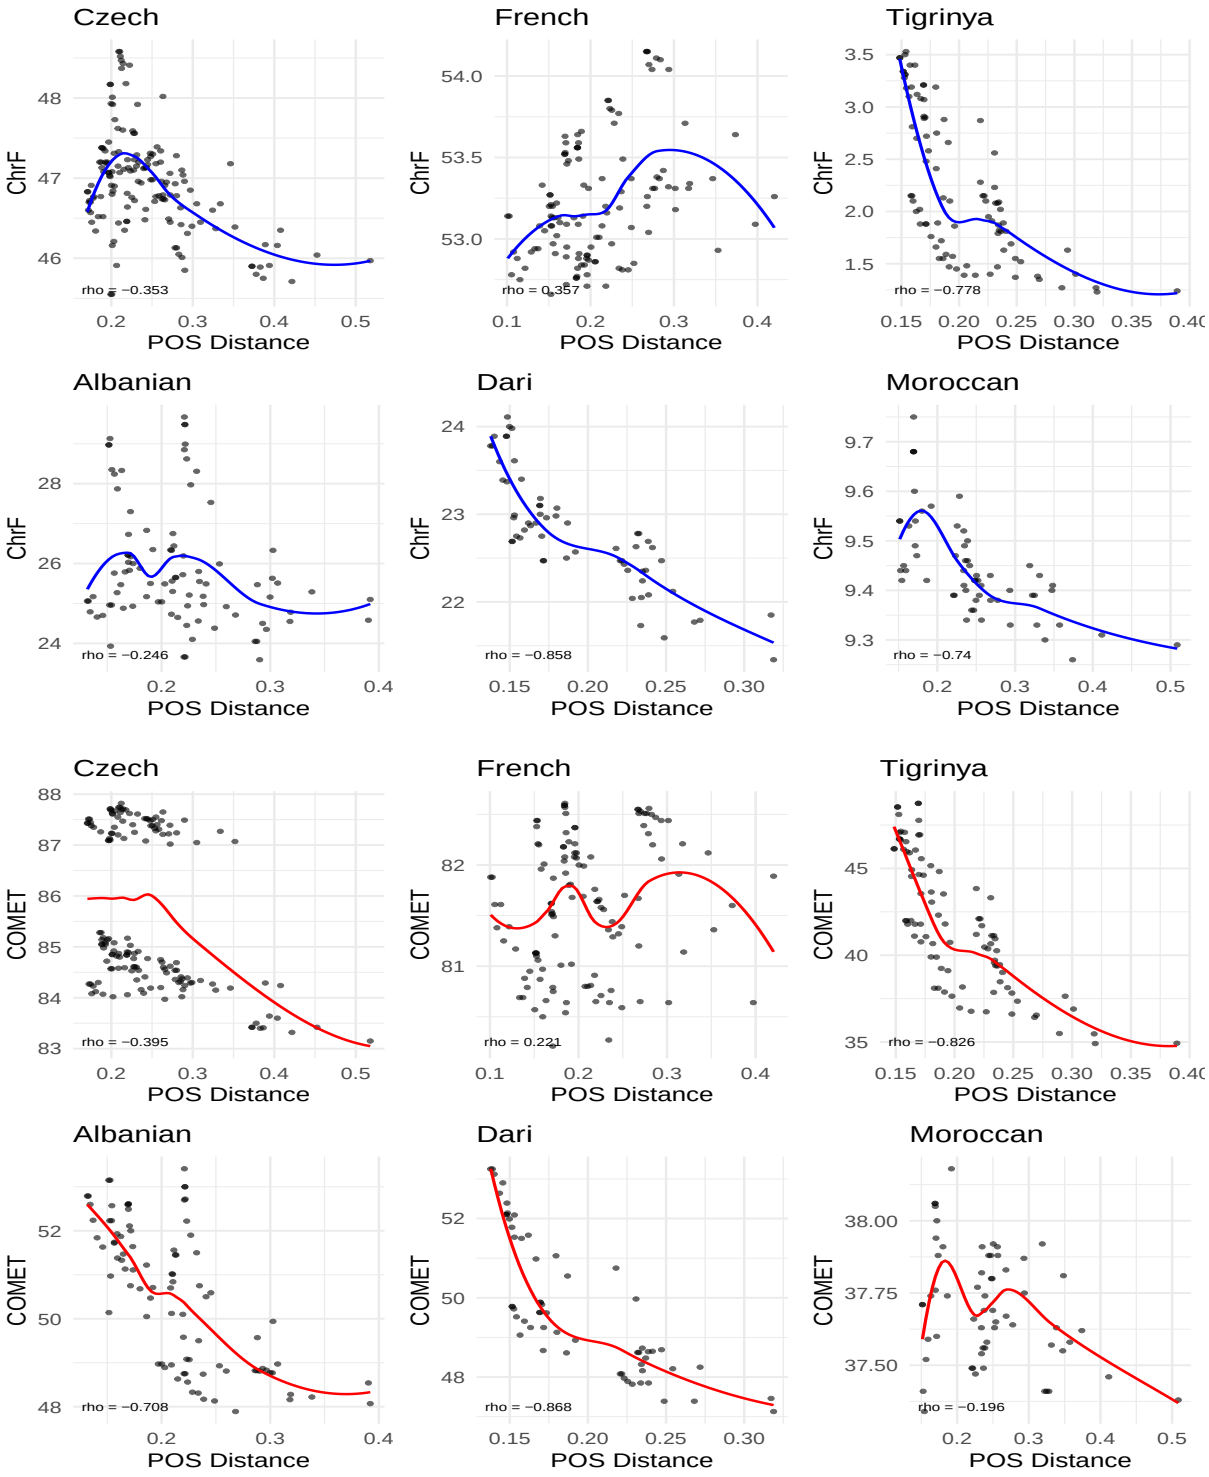

Figure 11: Scatterplots showing the relationship between prompt-level similarity metrics and average translation quality. Each plot corresponds to one of the following prompt-level measurements **POS Distance** (cosine distance between part-of-speech distributions). Spearman's ρ is shown for each metric, indicating the strength and direction of correlation.

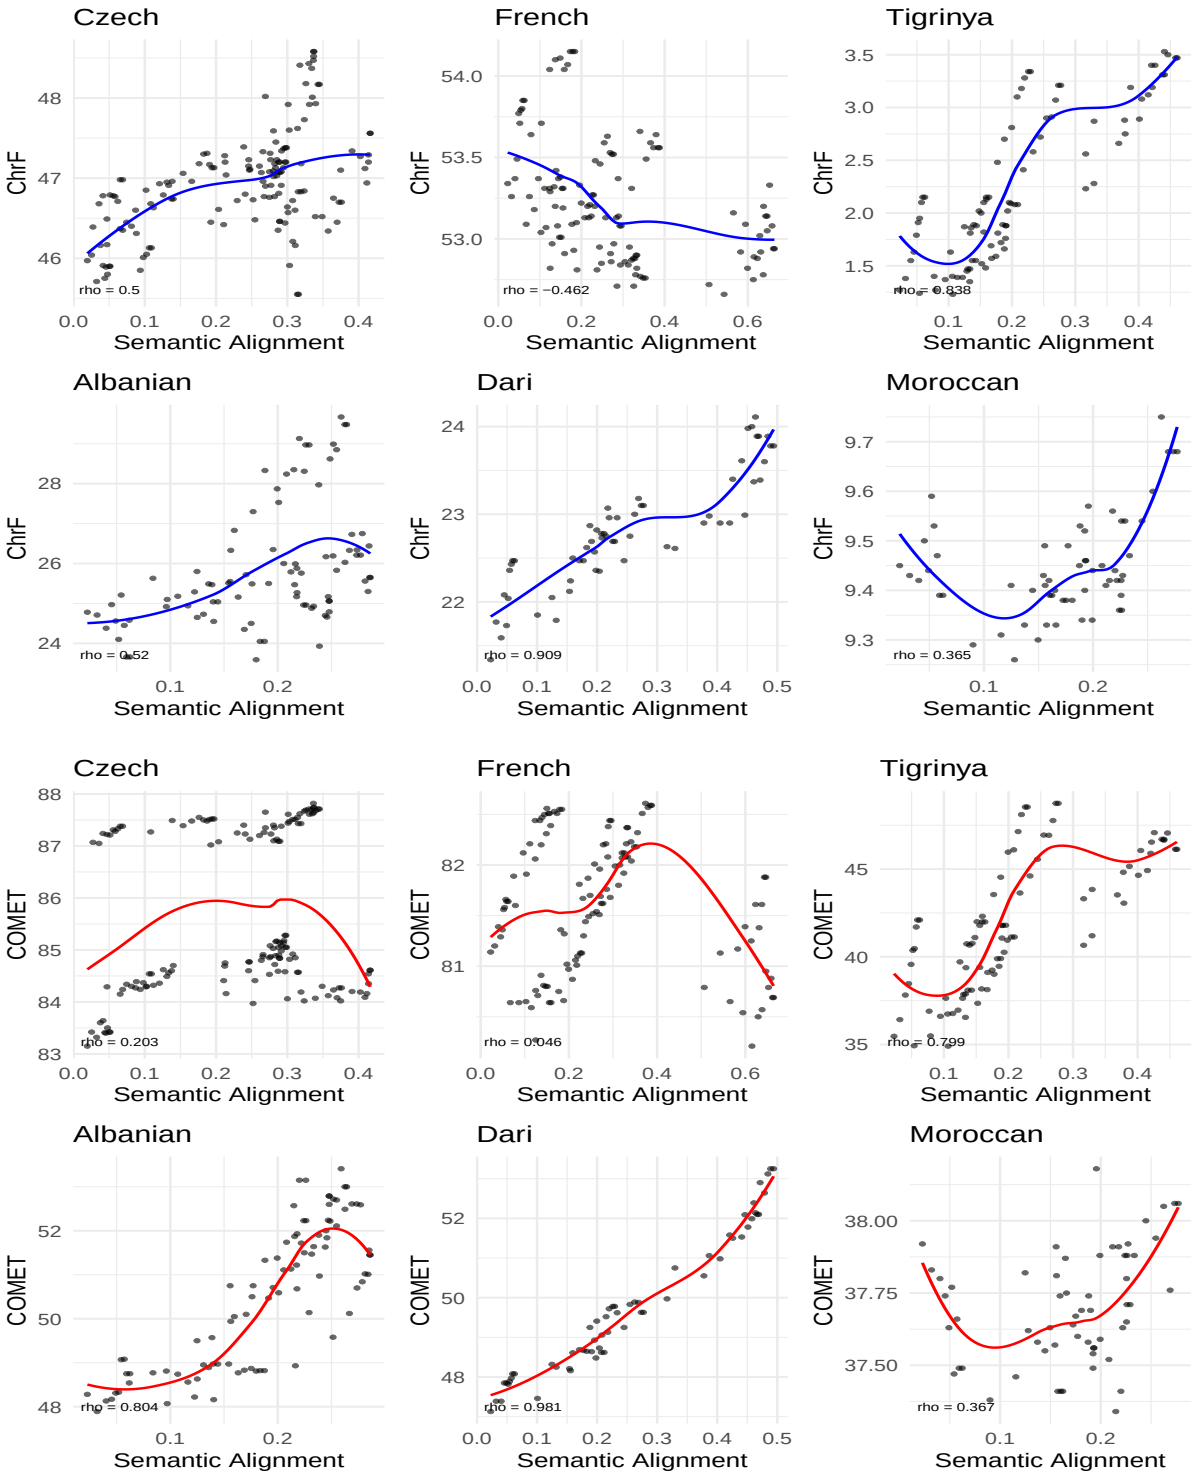

Figure 12: Scatterplots showing the relationship between prompt-level similarity metrics and average translation quality. Each plot corresponds to one of the following prompt-level measurements for **Semantic Alignment** (cosine similarity between sentence embeddings). Spearman's ρ is shown for each metric, indicating the strength and direction of correlation.

Character-Aware English-to-Japanese Translation of Fictional Dialogue Using Speaker Embeddings and Back-Translation

Ayuna Nagato **Takuya Matsuzaki**
Tokyo University of Science

Abstract

In Japanese, the form of utterances often reflect speaker-specific character traits, such as gender and personality, through the choise of linguistic elements including personal pronouns and sentence-final particles. However, such elements are not always available in English and a character's traits are often not directly expressed in English utterances, which can lead to character-inconsistent translations of English novels into Japanese. To address this, we propose a character-aware translation framework that incorporates speaker embeddings. We first train a speaker embedding model by masking the expressions in Japanese utterances that manifest the speaker's traits and learning to predict them. The resulting embeddings are then injected into a machine translation model. Experimental results show that our proposed method outperforms conventional fine-tuning in preserving speaker-specific character traits in translations.

1 Introduction

Neural machine translation (NMT) has made remarkable progress in recent years. However, translating fictional narratives, such as novels, still poses substantial challenges. Prior work has pointed out difficulties such as preserving long-range coherence, maintaining consistent tone across chapters, and handling figurative or culturally specific expressions (Thai et al., 2022; Liu et al., 2023; Karpinska and Iyyer, 2023). One of the less-studied issues is the preservation of character-specific linguistic style, especially in the translation of dialogue.

This problem becomes particularly apparent when translating from English into Japanese. Japanese dialogue often encodes rich speaker characteristics – such as gender, personality, and social status – through a variety of linguistic devices, including first- and second-person pronouns, honorifics, and sentence-final particles. In contrast, English dialogue tends to be less explicit in expressing such traits. As a result, standard translation models often produce Japanese utterances that contradict the original speaker's identity, leading to unnatural or inconsistent character portrayals.

One major obstacle in addressing this issue is the scarcity of high-quality bilingual dialogue corpora in the literary domain. To overcome this, we employ a back-translation (Sennrich et al., 2016) strategy: we first translate a large collection of Japanese novels into English using a high-performing neural MT system. This enables us to construct a large-scale pseudo-parallel corpus of Japanese-English fictional dialogue, which serves as the foundation for training our models.

While fine-tuning translation models on such in-domain dialogue can partially alleviate the problem, it is insufficient to capture the nuanced stylistic variation required for faithful character portrayal. We hypothesize that explicitly modeling the speaker's identity can help resolve this issue.

In this work, we propose a character-aware translation model that integrates speaker embeddings into the translation process. These embeddings are learned from Japanese utterances by masking the expressions that manifest the speaker's traits and training the model to predict them, capturing latent speaker traits in a data-driven way. We inject these embeddings into a Transformer-based translation model and fine-tune it on bilingual literary dialogue data. Experimental results show that our approach produces translations that better preserve speaker-specific character traits compared to conventional fine-tuned baselines.

The contributions of this paper are as follows:

- We introduce a novel speaker embedding model tailored to Japanese dialogue.
- We incorporate these embeddings into a neural translation model.
- We utilize back-translated Japanese-English

Proceedings of the Tenth Conference on Machine Translation, pages 180–190
November 8-9, 2025

novel data to overcome the lack of existing bilingual corpora.

- We demonstrate both qualitative and quantitative improvements in preserving character consistency in Japanese translations.

2 Background: Character Expressiveness in Japanese Utterances

Japanese is a language rich in surface-level variation that reflects the speaker's social identity, personality, and emotional stance. In spoken language, particularly in literary dialogue, this variation is often encoded through the choice of **personal pronouns**, **honorific expressions**, and **sentence-final particles**. These elements do not simply convey information but actively construct the speaker's character. In this section, we outline each of these linguistic mechanisms and explain how they contribute to speaker characterization in Japanese.

2.1 Personal Pronouns

Unlike English, Japanese personal pronouns vary widely depending on the speaker's gender, formality, and social distance. Even within first- and second-person references, different pronouns evoke distinct speaker personas.

For example, for the first-person pronoun "I", speakers may choose from:

- 私 **(watashi)** : neutral or formal
- 僕 **(boku)** : typically used by polite males
- 俺 **(ore)** : rough or masculine tone
- あたし **(atashi)** : casual and feminine

and many more.

For second-person references:

- あなた **(anata)** : formal or neutral
- おまえ **(omae)** : rough, informal, sometimes aggressive
- あんた **(anta)** : casual, often used by women
- きみ **(kimi)** : gentle, sometimes condescending depending on context

2.2 Sentence-Final Particles

Sentence-final particles such as よ **(yo)**, ね **(ne)**, の **(no)**, ぞ **(zo)**, and わ **(wa)** play a key role in expressing pragmatic and emotional nuance.

- よ **(yo)** : adds emphasis or confidence
- ね **(ne)** : invites agreement or shared understanding
- の **(no)** : softens a statement, often used by female speakers
- ぞ **(zo)**, ぜ **(ze)** : express strong masculine emphasis
- わ **(wa)** : indicates a feminine or classical tone depending on usage

2.3 Honorifics and Politeness Levels

Japanese exhibits a highly stratified system of honorifics, including respectful, humble, and polite forms. These levels express not only social hierarchy but also character traits in literary dialogue.

Politeness can be expressed by an auxiliary verb or a light verb:

- です **(desu)**/ます **(masu)** : basic politeness
- ございます **(gozaimasu)** : highly respectful
- くださる **(kudasaru)** : humble expressions

as well as the choice of a verb:

- 食べる **(taberu)** ↔召し上がる **(mesiagaru)** : normal ↔polite form of "eat"
- 言う **(iu)** ↔おっしゃる **(ossyaru)** : normal ↔polite form of "say"

2.4 Variation in Utterances Reflecting Speaker Character

The above linguistic features often appear together, shaping the overall tone and personality of the speaker. Table 1 shows different utterances of "Who are you?" that reflect various speaker identities through the use of pronouns, honorifics, and sentence-final particles.

Although all the examples convey the same core meaning, the speaker's personality, social stance, and emotional intensity vary drastically. In English–Japanese translation of literary dialogue, these nuances have to be properly differentiated by the

Table 1: Examples of speaker-dependent utterance variation in Japanese

Utterance	Pronoun	Honorifics	Final Particle	Character Impression
あなたはどなた**ですか**？	あなた (anata)	です (desu)	か (ka)	Formal, respectful
おまえ、誰だ？	おまえ (omae)	none	none	Rough, masculine
あんた、誰**よ**？	あんた (anta)	none	よ (yo)	Strong-willed female
きみは誰な**の**？	きみ (kimi)	none	の (no)	Friendly, gentle

choices of linguistic features according to the character, even if the source English expression is the same. Conventional systems often produce translations that fail to align with the character's original persona. This motivates our approach to incorporate speaker embeddings into translation to better preserve character-specific traits.

3 Method

Figure 1 illustrates the architecture used for constructing speaker embeddings and utilizing them in English-Japanese translation. We detail the method in what follows.

3.1 Speaker Embedding Construction

To incorporate speaker-specific characteristics into the translation process, we construct a speaker embedding model trained on Japanese literary dialogue. The aim is to learn embeddings that capture the personality traits expressed in each character's speech. The training proceeds as follows:

Step 1: Creating a Japanese-English Parallel Corpus Due to the scarcity of parallel corpora of Japanese and English novels, we create a pseudo-parallel corpus by translating 13,772 Japanese novels from Aozora Bunko[1] into English. We translated these novels by using a Transformer-based large model trained on JParaCrawl v3 (Morishita et al., 2022). This pseudo-parallel corpus is also used in the training of the speaker-aware translation model described in Section 3.2.2.

Step 2: Speaker Identification Using Stanford CoreNLP (Manning et al., 2014), we extract speaker-utterance pairs and the sentences where the subject is one of the speakers from the English translations. Specifically, we extract (i) utterances and their speakers through quote attribution, and (ii) declarative sentences where one of the speakers in a novel is marked as the subject (nsubj). These English sentences are then aligned with their Japanese counterparts to create bilingual dialogue pairs.

Step 3: Speaker-Sensitive Masking We mask parts of each Japanese utterance that tend to encode speaker-specific traits using the following rules:

- **Pronouns (1st and 2nd person):** Tokens tagged as "pronoun" by MeCab morphological analyzer (Kudo et al., 2004) are replaced with [MASK].
- **Sentence-final particles:** Tokens tagged as "sentence-final particle" are masked.
- **Honorific expressions:** Polite or honorific expressions, including verbs and sentence-final copulas such as です (desu) and ます (masu) are masked. If none of these forms are present at the sentence end, an empty [MASK] token is inserted to maintain output consistency.

Step 4: Embedding Extraction To obtain the embedding of speaker X, all utterances by X and the sentences with X as the subject are extracted from an English novel, concatenated using [SEP] as separators, truncated to 512 tokens, and input to English BERT [2]. The resulting [CLS] token embedding is used as the speaker's embedding vector.

Step 5: Training the Speaker Embedding Model Masked Japanese utterances are input to Japanese BERT [3]. Each output token vector is combined with the speaker's English BERT embedding by vector addition and passed through the language modeling head to predict the masked tokens. Cross-entropy loss is computed only at masked positions. Figure 2 presents an overview of Step 4 and 5. All components—Japanese BERT, English BERT, and the language modeling head—are jointly fine-tuned.

For consistency with the downstream translation model, we also fine-tune the speaker embedding model using the aligned NICT corpus described in Section 3.2.2.

[2] https://huggingface.co/google-bert/bert-base-uncased

[3] https://huggingface.co/tohoku-nlp/bert-base-japanese-v3

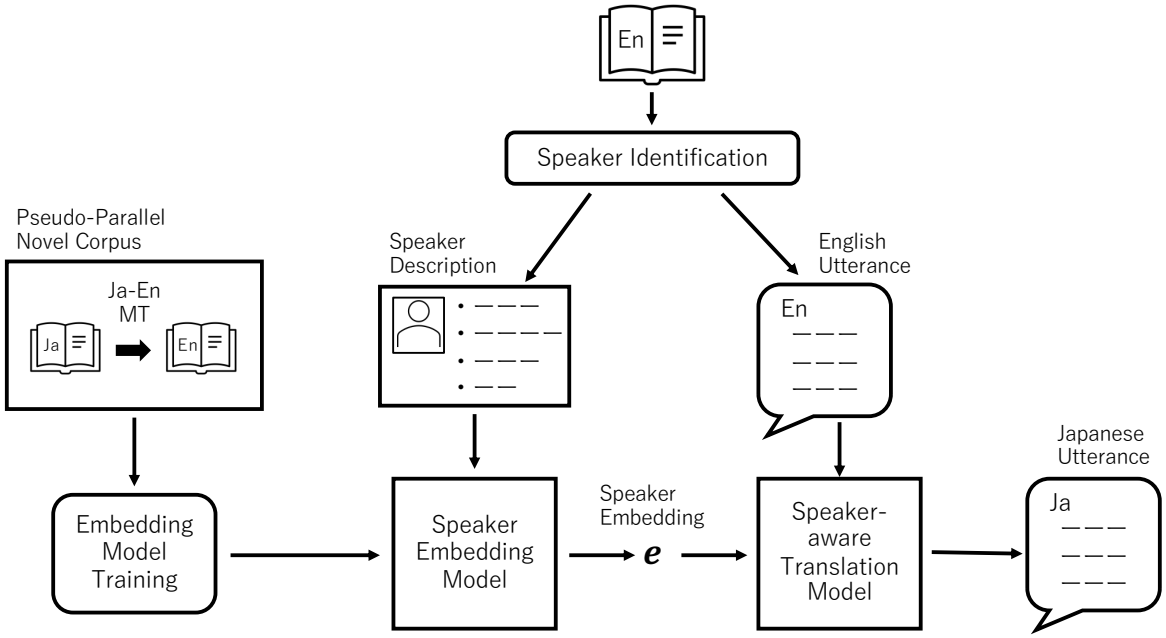

Figure 1: Overview of our proposed method.

For optimization, we used AdamW with hyperparameters of $\beta_1 = 0.9, \beta_2 = 0.999, \epsilon = 10^{-8}$, and learning rate of 10^{-5}. The batch size was set to 32. We chose the model achieved minimum loss on the validation set within five epochs.

3.2 Speaker-Aware Translation Model

3.2.1 Model Architecture

Our translation model adopts a Transformer encoder-decoder architecture. To incorporate character-specific style into the output, we inject speaker embeddings into the decoder. Specifically, the speaker embedding is added to the hidden states of the decoder's last layer before the final linear projection:

$$z_i' = z_i + e_s$$

where z_i is the decoder hidden state at time step i, and e_s is the speaker embedding vector. This additive integration enables the model to condition generation on speaker traits such as personality or social role.

3.2.2 Training Procedure

We employ a three-stage training process designed to balance general translation quality with speaker-sensitive stylistic control. These stages are: (1) pretraining of a general-domain English-to-Japanese model, (2) training on back-translated literary dialogue, and (3) fine-tuning on sentence-aligned, human-translated dialogue from novels.

Pretraining on JParaCrawl (English to Japanese) We initialize our model using a Transformer-based large model trained on JParaCrawl v3 (Morishita et al., 2022), in the English-to-Japanese direction. This model provides a strong general translation foundation but does not incorporate speaker-specific information. It serves as the backbone for subsequent adaptation.

Training with Back-Translated Literary Dialogue As described in Section 3.1, we utilize a pseudo-parallel corpus of Japanese novels and their translations to English. We use this back-translated dataset—composed of Japanese original dialogue and its English translation—to fine-tune our English-to-Japanese translation model with speaker embeddings. The Japanese side contains rich stylistic expressions, and the English side provides automatically extracted speaker labels via quote attribution and syntactic parsing.

This stage allows the model to learn how speaker-specific stylistic features in Japanese correspond to the more neutral English dialogue, and how to generate speaker-aware Japanese output based on speaker embeddings.

For optimization, we used Adam with hyperparameters of $\beta_1 = 0.9, \beta_2 = 0.98, \epsilon = 10^{-8}$, and learning rate of 5×10^{-5}. The batch size was set to 6000 tokens. We trained up to 20k updates and averaged the last eight checkpoints for the final model.

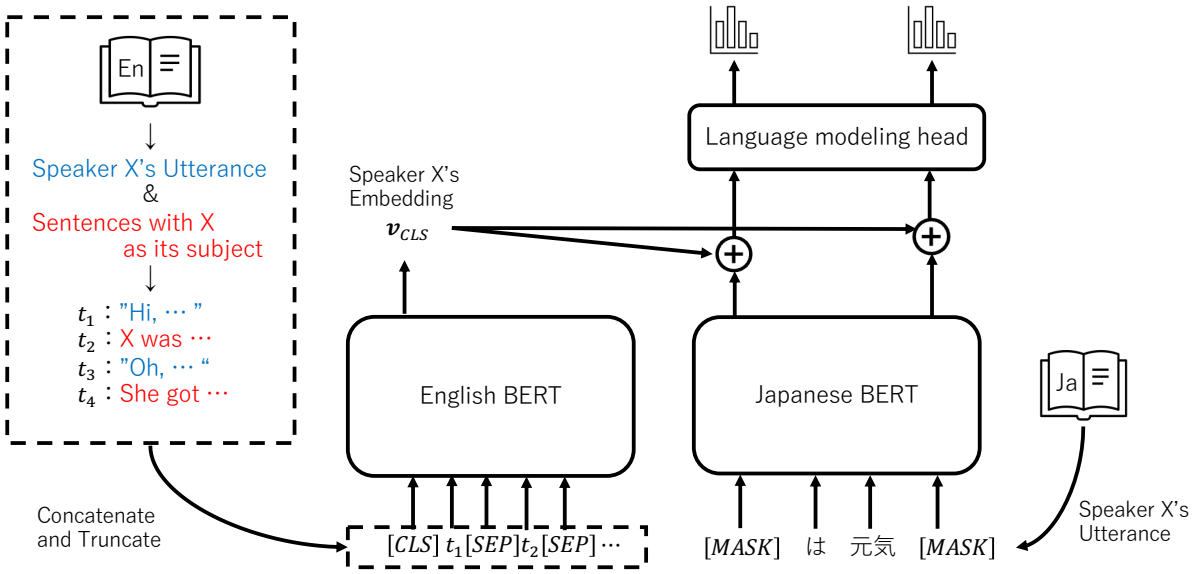

Figure 2: Architecture of the speaker embedding model. The masked Japanese input is processed by Japanese BERT, while the speaker embedding from English BERT is integrated during token prediction.

Fine-Tuning with Sentence-Aligned Modern Dialogue Although the back-translated Aozora data is rich in stylistic variation, it tends to reflect older literary styles. To adapt the model to contemporary Japanese, we fine-tune it using a small set of manually sentence-aligned English-Japanese novel data that was developed by Utiyama and Takahashi (2003) and is distributed by the National Institute of Information and Communication Technology (NICT). We henceforth call this data the NICT corpus. It mostly consists of modern fictional texts aligned at the sentence level, but without explicit speaker annotations.

We extract speaker information automatically using Stanford CoreNLP on the English side, as described in Section 3.1, and generate speaker embeddings using our trained embedding model. This final step improves fluency, modernity, and alignment with contemporary character dialogue styles.

For optimization, we used Adam with hyperparameters of $\beta_1 = 0.9, \beta_2 = 0.98, \epsilon = 10^{-8}$, and a smaller learning rate of 10^{-5} to avoid overfitting on the limited NICT corpus. The batch size was set to 2000 tokens. We trained up to 2k updates and averaged the last three checkpoints for the final model.

Data Splits All training, validation, and test sets for the English-to-Japanese translation consist exclusively of utterances from dialogue segments, with narrative text excluded (except as the input to the speaker embedding model). For both the back-translated Aozora corpus and the aligned NICT corpus, we split the data into training, validation, and test sets in an 8:1:1 ratio. Importantly, the split is done on a per-work basis (i.e., by novel title) to avoid information leakage across sets. Furthermore, to ensure corpus independence, we exclude from the Aozora corpus any works that are also included in the NICT corpus.

4 Experiments

This section presents a comprehensive evaluation of the proposed speaker-aware translation model. We first conduct qualitative and quantitative manual analyses to assess how incorporating speaker embeddings affects character-sensitive translation aspects such as pronoun choice and sentence-final particles. Next, a case study on a single character from a literary work examines consistency in character voice over multiple utterances. Additionally, we perform automatic evaluation using BLEU, ChrF, and COMET-22 scores on dialogue-heavy test data to quantify improvements over baseline models. Finally, we analyze the learned speaker embeddings via Principal Component Analysis (PCA) to interpret the linguistic and stylistic features captured in the embedding space.

Together, these evaluations demonstrate the effectiveness of integrating speaker embeddings in enhancing the fidelity and expressiveness of literary dialogue translation.

4.1 Quantitative Analysis: Manual Evaluation of Speaker-Sensitive Translation

To qualitatively and quantitatively evaluate the impact of incorporating speaker embeddings, we conducted a manual analysis of sampled outputs. From the 1,436 utterances in the NICT test set, we randomly selected 150 utterances and compared translations produced by two systems:

- **Baseline**: A standard Transformer model pretrained on JParaCrawl v3 and fine-tuned on back-translated Aozora data followed by fine-tuning on the NICT corpus.
- **Proposed**: The same model architecture and training procedure, but augmented with speaker embeddings during training and inference.

We evaluated each output along five criteria:

- **Pronouns**: Whether first- and second-person pronouns exactly matched the reference translation (surface differences such as 私 (watashi) vs わたし (watashi) were treated as equivalent).
- **Sentence-final particles**: Whether sentence-final particles exactly matched the reference translation.
- **Honorific usage**: Whether honorific or polite expressions were used when the reference translation employed them.
- **Intra-utterance consistency**: Whether a single utterance maintained consistent character traits (e.g., not mixing 僕 (boku) and 私 (watashi)).
- **Translation errors**: Whether the output contained critical errors such as omissions, repetitions, or untranslated segments.

The results are summarized in Table 2. For pronouns, sentence-final particles, and honorifics, we report accuracy (percentage of exact matches with the reference). For consistency and translation errors, we report the number of problematic utterances out of the 150 sampled.

Manual evaluation results, as shown in Table 2, demonstrate several notable improvements brought by our proposed speaker-aware translation model.

First, the accuracy of pronoun translation significantly increased from 25.6% in the baseline to 61.6% in our model. This suggests that incorporating speaker embeddings greatly improves the model's ability to select appropriate first- and second-person pronouns, which are crucial in reflecting character-specific traits. Similarly, accuracy on sentence-final particles improved from 40.5% to 52.5%, despite the strict criterion of requiring exact matches. In fact, our manual inspection revealed that some minor mismatches—such as わ (wa) vs. よ (yo) or だ (da) vs. ぞ (zo) —still produce utterances with similar character impressions, implying that the model's improvement may be underrepresented by exact matching metrics alone.

Interestingly, performance on honorific forms remained unchanged (28.1% accuracy in both models). One possible explanation is that honorific expression tends to depend more on the social relationship between the speaker and the hearer, rather than on the speaker's character identity alone. This highlights a potential limitation of our speaker-only embedding approach in capturing such pragmatic nuances.

The number of consistency errors —-such as inconsistent use of personal pronouns within the same utterance—- decreased from seven to zero. This indicates that the proposed model contributes to maintaining character consistency at the utterance level. Furthermore, the number of critical translation errors, including untranslated segments and repeated phrases, was reduced from four to zero.

Taken together, these findings support the effectiveness of integrating speaker embeddings in improving character-sensitive aspects of translation, especially for pronoun and sentence-final particle choices, while also enhancing consistency of character traits.

4.2 Case Study: Fatty Coon in *The Tale of Fatty Coon*

To further analyze the effect of our method on maintaining the consistency of character's traits, we conducted a case study on Fatty Coon, the protagonist of *The Tale of Fatty Coon* by Arthur Scott Bailey. This character is portrayed as an energetic young boy raccoon, often using casual language such as ぼく (boku) and sentence-final particles like よ (yo) in the Japanese translation.

Out of 74 utterances attributed to Fatty Coon (based on CoreNLP speaker tagging), 9 were misattributed. We excluded these and manually analyzed

Table 2: Manual evaluation results on 150 randomly sampled utterances from the NICT test set. Accuracy is reported for categorical items (pronouns, sentence-final particles, honorifics), and raw counts are reported for consistency errors and critical translation errors.

Model	Pronouns	Final Particles	Honorifics	Consistency Errors	Translation Errors
Baseline	25.6% (32/125)	40.5% (98/242)	28.1% (9/32)	7	4
Proposed	**61.6% (77/125)**	**52.5% (127/242)**	28.1% (9/32)	**0**	**0**

the remaining 65 utterances.

We found that the baseline model frequently produced outputs that were inconsistent with the character's personality. Specifically, 29 out of the 65 utterances (44.6%) included language that was too formal or feminine, such as the use of 私 (watashi) or sentence-final particles like わ (wa), or even polite verb forms. In contrast, our proposed method produced consistent outputs aligned with the character's casual and boyish tone in nearly all cases, with only 9 utterances showing mismatches (e.g., use of honorifics).

Table 3 shows representative examples. In each case, the proposed method produces translations that are closer to the reference translation and consistent with the intended persona of Fatty Coon.

4.3 Automatic Evaluation on NICT Dialogue Segments

To complement our manual evaluation, we conducted automatic evaluation using BLEU (Papineni et al., 2002), ChrF (Popović, 2015), and COMET-22 (Rei et al., 2022) on the NICT test data, comprising 1,436 Japanese utterances. We report BLEU scores computed using `sacreBLEU` with `--tokenize=intl` option. COMET is a neural-based metric trained to predict human direct assessment scores, and has been shown to correlate more strongly with human evaluation than surface-overlap metrics such as BLEU (Rei et al., 2020).

Table 4 provides the results. The absolute BLEU and ChrF scores appear low, especially compared to typical scores reported in general domain English-to-Japanese translation. However, our task differs significantly in both content and style: the data is literary dialogue, which contains diverse speaker-specific expressions, idiosyncratic phrasing, and multiple valid translations. In such settings, surface-form overlap metrics like BLEU often underestimate translation quality (Toral and Way, 2018; Mathur et al., 2020; Thai et al., 2022).

Despite the limitations of these metrics in capturing speaker-specific style or consistency, the proposed method outperforms both the base model and the fine-tuned baseline by a noticeable margin on both BLEU and ChrF. This suggests that introducing speaker-aware information helps produce translations that better align with the reference utterances even in automatic evaluation metrics. In the case of BLEU score, the larger gain compared to the fine-tuned baseline also supports our hypothesis that speaker traits contribute to reducing ambiguities in character-driven translation.

In addition, the COMET-22 scores also show that our proposed method achieves the highest performance among the compared systems (0.802 vs. 0.778 for the baseline). This further supports that incorporating speaker information not only improves surface-level similarity but also yields translations that are semantically closer to human references, in line with human judgments of adequacy.

To assess the reliability of these improvements, we conducted paired bootstrap resampling tests. BLEU differences between the baseline and our proposed model were not statistically significant ($p = 0.14$). However, both ChrF ($p < 0.01$) and COMET ($p < 0.05$) confirmed that the improvements of the proposed model over the baseline are statistically significant. These results suggest that while BLEU may underestimate gains in this task, stronger metrics such as ChrF and COMET provide more robust evidence that speaker-aware information improves translation quality.

Nonetheless, given the nature of the task, we emphasize that manual evaluation and qualitative analysis (as described in the previous subsections) provide a more reliable assessment of character expressiveness and speaker consistency in translation.

4.4 Speaker Embedding Visualization via PCA

To investigate the structure of the learned speaker embeddings, we apply Principal Component Analysis (PCA) to the speaker vectors extracted from the test portion of the back-translated Aozora corpus. This test set was held out during model training.

We first applied our trained speaker embedding model to the machine-translated English versions

Table 3: Example translations of utterances by Fatty Coon. The proposed method produces outputs more consistent with the character's persona.

Source	Reference	Baseline	Proposed
"I'd like to eat all the corn in the world."	世界中のとうもろこしを全部食べちゃいたい**よ (yo)**。	世界中のとうもろこしをみんな食べてみたい**わ (wa)**。	世界中のとうもろこしがみんな食べたい**よ (yo)**。

of the test set novels. Each character's English utterances were concatenated and processed using BERT to produce a fixed-size speaker embedding, as described in Section 3.1. As a result, we obtained embeddings of 6,449 speakers.

We then performed PCA on these embeddings and analyzed the first principal component. Table 5 lists the top and bottom 10 characters based on their scores on the first principal component, along with their associated works and authors. We found that characters with high component scores tend to be female, while those with low scores tend to be male.

This interpretation is supported by examining the masked tokens in their utterances (Figure 3). Tokens like わ (wa), の (no), あなた (anata), and あたし (atashi) appear frequently in the utterances of characters with high PCA scores—expressions that are stereotypically feminine in Japanese. In contrast, utterances from characters with low PCA scores more often contain ぞ (zo), おまえ (omae), and おら (ora), which are typically masculine expressions.

Moreover, we observe that characters with similar component scores often come from the same literary work or author. This pattern suggests that the speaker embeddings encode not only individual character traits but also stylistic patterns associated with particular authors.

These results indicate that our speaker embedding space captures interpretable dimensions related to gendered language use and authorial style in literary dialogue.

5 Discussion

The proposed speaker-aware translation model showed improvements in preserving speaker-specific linguistic traits. However, several limitations and potential directions for future work have emerged.

Accuracy of Speaker Attribution. In this study, we relied on speaker attribution results from Stanford CoreNLP. As observed in the case study of "Fatty Coon", speaker misattribution occurred in 9 out of 74 utterances. These errors can directly affect the quality of the speaker embeddings, potentially leading to unnatural or inconsistent translations.

Effect of Character Description Length on Embedding Quality. To construct speaker embeddings, we used English character descriptions—specifically, sentences where the character was the subject and the character's utterances—from the beginning of each work. These sentences were concatenated until reaching the maximum input length of the English BERT model. As a result, the amount of contextual information varied depending on how much text was available for each character. We have not yet conducted a systematic analysis of how the amount or content of these character-descriptive sentences affects the quality of the embeddings or the final translation output. Investigating the impact of description length and exploring methods to prioritize more informative sentences (e.g., those rich in personality cues) may help enhance consistency,

Table 5: Top and bottom characters on the first PCA component

Bottom (Low PC score)			Top (High PC score)		
Speaker	Gender	Work	Speaker	Gender	Work
Kasuke	Male	“Irefuda” by Kikuchi Kan	Kuroe	Female	“Charako-san” by Hisao Juran
Koshu	Male	“Dai-bosatsu toge” by Nakazato Kaizan	her	Female	“Charako-san” by Hisao Juran

Yamada	Male	“My Private Taiheiki” by Yoshikawa Eiji	Madam	Female	“The Shadowless Criminal” by Sakaguchi Ango

especially for characters with limited text.

Limitations of Back-Translation Quality. One challenge we observed is that the back-translation process used to construct the training data—specifically, translating Japanese to English and then back to Japanese—sometimes produces unnatural Japanese sentences. In our pipeline, the major source of noise stems from the Japanese-to-English translation step. When this translation is inaccurate, it leads to poor-quality pseudo-parallel data, which in turn affects the quality of the final English-to-Japanese translation model. While using manually curated parallel data would be ideal, such data is extremely limited, especially for literary dialogue. Future work may improve the overall quality by employing stronger Japanese-to-English translation models, or by integrating automatic quality filtering mechanisms to reduce the impact of noisy samples.

6 Related Work

6.1 Speaker Attribution in Narrative Texts

Speaker attribution—the task of identifying who is speaking in a given utterance—is a crucial preprocessing step for speaker-aware translation. In narrative texts such as novels, explicit speaker tags are often absent, requiring automatic identification based on linguistic cues. For English texts, tools such as Stanford CoreNLP provide heuristic-based speaker tagging, but they often fail in the presence of figurative or indirect speech.

Speaker attribution in Japanese poses additional challenges due to frequent subject omission, flexible word order, and the use of sentence-final particles that vary by speaker. Ishikawa et al. (2024) addressed this by leveraging grammatical and contextual features to estimate speaker identity in Japanese novels. Zenimoto and Utsuro (2022) proposed a method for identifying the speakers of quoted utterances in Japanese novels using a gender classification model.

6.2 Machine Translation for Literary Texts

Discourse-level literary translation remains one of the most demanding tasks in natural language processing. Unlike general-domain texts, literary works require models to handle complex semantic phenomena such as figurative language, long-range dependencies, character voice, and culturally grounded expressions (Pang et al., 2025). These aspects place high demands on translation systems, which must not only be accurate but also preserve subtle stylistic and narrative consistency.

While recent progress in large language models (LLMs) has enabled strong performance on many NLP tasks, training or fine-tuning models specifically for literary translation remains costly and resource-intensive. In response to these challenges, the WMT2023 Shared Task on Discourse-Level Literary Translation was launched, highlighting the need for models that go beyond sentence-by-sentence translation (Wang et al., 2023). Results from the shared task demonstrated that even state-of-the-art systems struggle to maintain coherence, tone, and character consistency across longer texts. These findings suggest that further advances are needed in integrating discourse-level information and stylistic modeling, particularly for literature.

7 Conclusion

This paper proposed a speaker-aware machine translation framework aimed at preserving character-specific expressions in Japanese literary dialogue. By constructing speaker embeddings from English descriptions of each character and incorporating them into the translation model, our method promotes more consistent and personality-aligned outputs.

We evaluated our approach using the NICT English-Japanese translation alignment dataset. Manual analysis showed that our method improves the consistency of personal pronouns and sentence-

final particles, which are strongly associated with character identity. However, the use of honorifics did not improve as clearly, likely because honorific usage depends more on social context—such as the relationship between the speaker and hearer—than on character traits alone.

In future work, we plan to explore the integration of situational context (e.g., dialogue participants and relationships), adopt higher-quality translation models, and refine our speaker recognition pipeline to further enhance the character consistency and fluency of literary dialogue translation.

Abstract

End-to-End Speech Translation (E2E-ST) is the task of translating source speech directly into target text bypassing the intermediate transcription step. The representation discrepancy between the speech and text modalities has motivated research on what is known as *bridging the modality gap*. State-of-the-art methods addressed this by aligning speech and text representations on the word or token level. Unfortunately, this requires an alignment tool that is not available for all languages. Although this issue has been addressed by aligning speech and text embeddings using nearest-neighbor similarity search, it does not lead to accurate alignments. In this work, we adapt Dynamic Time Warping (DTW) for aligning speech and text embeddings during training. Our experiments demonstrate the effectiveness of our method in bridging the modality gap in E2E-ST. Compared to previous work, our method produces more accurate alignments and achieves comparable E2E-ST results while being significantly faster. Furthermore, our method outperforms previous work in low resource settings on 5 out of 6 language directions. [1]

1 Introduction

End-to-End Speech Translation (E2E-ST) is the task of translating speech in a source language directly into text in a target language. E2E-ST gained success and attention as an alternative to cascaded solutions where an Automatic Speech recognition (ASR) and a Machine Translation (MT) models are combined (Tang et al., 2021; Ye et al., 2022; Fang et al., 2022; Ouyang et al., 2023; Zhou et al., 2023; Le et al., 2023; Zhang et al., 2024, 2025). Cascaded solutions benefit from abundant ASR and MT data but might suffer from error propagation and high latency, which can be solved by E2E-ST.

However, training E2E-ST models is not straightforward due to the representation discrepancy between the speech and text modalities. Previous work has achieved state-of-the-art results by aligning speech and text representations at the word or token level, either using an alignment tool (Ouyang et al., 2023; Fang et al., 2022) or by generating the alignment automatically during training (Zhou et al., 2023; Zhang et al., 2023b). The closest to our work is Cross-modal Mixup via Optimal Transport (CMOT), which uses optimal transport for finding speech and text alignments. Although CMOT achieves state-of-the-art results, it does not guarantee producing monotonic alignments or ensure that each text token is assigned to at least one frame. This contradicts the expected structure of speech-text alignment and can lead to noisy alignments. Furthermore, CMOT introduces a significant training time overhead.

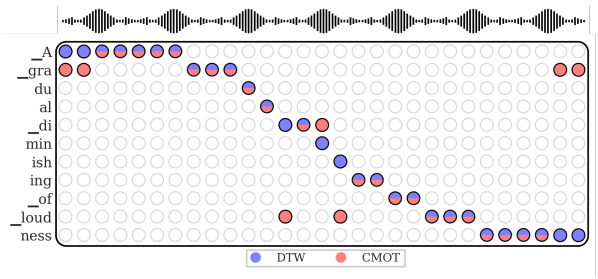

Figure 1: We show an example alignment from DTW (Ours) vs. CMOT. The figure shows that unlike CMOT, DTW guarantees generating monotonic alignments and that all tokens are aligned. In contrast, CMOT failed to align the tokens "min" and "ish" to any frames.

In this work, we introduce **DTW-Align**, a method for aligning speech and text embeddings during training using an adaptation of Dynamic Time Warping (Sakoe and Chiba, 1978). Figure 1 shows an example alignment generated using DTW-Align and CMOT, which illustrates that our method generates monotonic alignments and guarantees that all tokens are aligned, while CMOT does not. We demonstrate the effectiveness of our method

Proceedings of the Tenth Conference on Machine Translation, pages 191–199
November 8-9, 2025

in bridging the modality gap with mixup training (Fang et al., 2022; Zhou et al., 2023). Similarly to previous work (Zhou et al., 2023), we train on a mixup of aligned speech and text representations, however, instead of discretely selecting either a speech or a text embedding, we linearly interpolate speech and text embeddings (Zhang et al., 2018). Our experiments show that our method is faster and produces more accurate alignments. Furthermore, it achieves comparable results to CMOT on 6 language directions from the CoVoST2 dataset, while training significantly faster. We also evaluate our method in a low resource setting where training can be more vulnerable to alignment noise, and we show that our method leads to a statistically significant improvement over CMOT in 5 out of 6 language directions.

2 Related Works

Bridging the Modality Gap: The discrepancy between the source and target modalities (i.e. speech and text respectively) has motivated multiple works on what is termed bridging the modality gap (Liu et al., 2019; Han et al., 2021; Fang et al., 2022), where the goal is to build a shared semantic space between the speech and text modalities. Aligning speech and text either based on an alignment tool (Fang et al., 2022; Ouyang et al., 2023) or dynamically during training (Zhang et al., 2023b; Zhou et al., 2023) was shown to achieve state-of-the-art results. Our work goes in this direction, by improving the accuracy and speed of aligning speech and text during training.

Mixup: Mixup is a common data augmentation strategy (Zhang et al., 2018; Jin et al., 2025). In E2E-ST, it is applied for bridging the modality gap (Fang et al., 2022; Zhou et al., 2023), where the model is trained on a discrete mixup of speech and text representations. Mixup training in E2E-ST requires an alignment between speech and text that can be generated using an alignment tool (Fang et al., 2022). Zhou et al. (2023) alleviate the need for an alignment tool by aligning speech and text representations using optimal transport. Our approach is similar to (Zhou et al., 2023), where we generate the alignments dynamically during training. However, instead of discretely mixing speech and text representations, we apply mixup as a linear interpolation.

DTW: DTW is an algorithm for measuring similarity between two sequences of varying length (Sakoe and Chiba, 1978). Due to this property, it has been widely applied to speech data (Juang, 1984; Furtuna, 2008; Muda et al., 2010), and also more specifically in the context of aligning speech and text sequences (i.e. forced alignment). For example, Aeneas (Pettarin, 2017) aligns speech and text utterances by transforming the text utterances into speech, then uses DTW to align the synthetic and original speech sequences. Kürzinger et al. (2020) uses an algorithm that resembles DTW by using dynamic programming and backtracking to find the optimal alignment based on Connectionist Temporal Classification (CTC) probabilities. In this work, we adapt DTW to dynamically align speech and text based on their embeddings.

3 Method

3.1 Architecture

Inspired by previous work in E2E-ST (Fang et al., 2022; Zhou et al., 2023), our model consists of two main components, a speech encoder, and a translation encoder-decoder. The translation encoder-decoder is a standard transformer model that can be decomposed into 3 components: a text embedding layer, an encoder that inputs either speech or text embeddings, and a decoder that generates the target sentence.

3.2 DTW for Aligning Speech and Text Representations

DTW can be used to compute similarities between two sequences of variable length along time. This is achieved by finding an optimal path between the two sequences, or the path that leads to their maximum similarity. The time dimension of the two sequences is said to be *warped*. In our case, when aligning speech and token embeddings, we only warp the token time dimension to have a one-to-many relationship from speech to token embeddings. We start by computing the cosine similarity between each speech embedding $t \in [0; N-1]$ to each token $j \in [0; M-1]$, then we use the similarity matrix $S \in \mathbb{R}^{N \times M}$ to compute a trellis matrix T of the same dimension:

$$T_{t,j} = \begin{cases} S_{t,j} & t = 0, j = 0 \\ -\infty & t = 0, j > 0 \\ +\infty & t > N - M, j = 0 \\ S_{t,j} + T_{t-1,j} & t > 0, j = 0 \\ \max(T_{t-1,j}, T_{t-1,j-1}) & \\ \quad + S_{t,j} & t > 0, j > 0 \end{cases} \quad (1)$$

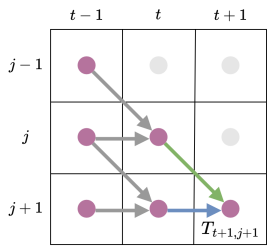

Figure 2: An illustration of the possible alignment paths. Each frame is assigned to only one token, while a token can be assigned to multiple frames.

The last step is backtracking, where we traverse the trellis starting from the last frame and token to find the optimal path, or the path with maximum similarity, which eventually represents the alignment a from speech to text tokens. We assign the last token to the last frame $a_{N-1} = M - 1$, and we traverse as follows:

$$a_t = \begin{cases} M-1 & t = N-1 \\ a_{t+1} - 1 & T_{t,a_{t+1}-1} > T_{t,a_{t+1}} \\ a_{t+1} & \text{else} \end{cases} \quad (2)$$

Figure 2 shows an illustration of the possible alignment paths. We can see that when backtracking from $t+1, j+1$ we can either go to the previous token j if $T_{t,j} > T_{t,j+1}$ or stay on token $j+1$ otherwise, which guarantees monotonicity. The constraints in the trellis matrix guarantee that all tokens are aligned to at least one frame, since the diagonal is filled with $-\infty$ during the trellis computation, when backtracking, this guarantees that we move to $j-1$ when $j \geq t$.

By fully vectorizing both the trellis computation and backtracking, our implementation achieves a much faster alignment.

3.3 Mixup Training

Given a sequence of speech representations generated using the speech encoder $f = [f_0, f_1, ..., f_{N-1}]$ and a sequence of text embeddings generated using the text embedding layer $e = [e_0, e_1, ..., e_{M-1}]$, our method generates an alignment $a = [a_0, a_1, ..., a_{N-1}]$ as described in §3.2. Finally, we apply mixup similarly to previous work (Zhou et al., 2023):

$$m_i = \begin{cases} f_i & p > p^* \\ e_{a_i} & else \end{cases} \quad (3)$$

where p^* is the mixup probability which controls how much text embeddings we introduce into the speech manifold, and p is sampled from a uniform distribution $\mathcal{U}(0, 1)$. We term this discrete mixup. We further introduce interpolation mixup (Zhang et al., 2018), where instead of selecting a speech or text embedding based on probability p^*, we use p^* as a mixup coefficient to linearly interpolate speech and text embeddings:

$$m_i = (1 - p^*).f_i + p^*.e_{a_i} \quad (4)$$

We argue that interpolation mixup can be more robust to alignment noise since the speech embeddings are not entirely replaced as in discrete mixup, but they are softly down-weighted. Therefore, even in the presence of alignment noise, the model still has access to the correct speech embeddings. Furthermore, it can be more data efficient, since all the speech and text token embeddings are included in training, rather than selecting one or the other.

3.4 Training Objective

We train with similar training objectives as CMOT (Zhou et al., 2023) to ensure fair comparison. The ST training corpus is denoted as $D = (s, x, y)$, where s is the speech input, x is the transcription, and y is the translation. In the first stage, the translation encoder-decoder is pre-trained on transcription-translation pairs using cross entropy:

$$\mathcal{L}_{MT} = -\mathbb{E}_{x,y} \log P(y|x) \quad (5)$$

The second stage is multi-task fine-tuning with ST and MT tasks using cross entropy:

$$\begin{aligned} \mathcal{L}_{ST} &= -\mathbb{E}_{s,x,y} \log P(y|s) \\ \mathcal{L}_{MT} &= -\mathbb{E}_{s,x,y} \log P(y|x) \end{aligned} \quad (6)$$

Furthermore, to bridge the modality gap between speech and text representations, we train with Kullback-Leibler (KL) divergence between the output probability distribution under mixup input m, and the output distribution of the ST task, as well as with the output distribution of the MT task:

$$\begin{aligned} \mathcal{L}_{KL_{m \leftrightarrow s}} = \mathbb{D}_{KL}(P(y|s)||P(y|m)) + \\ \mathbb{D}_{KL}(P(y|m)||P(y|s)) \end{aligned} \quad (7)$$

$$\begin{aligned} \mathcal{L}_{KL_{m \leftrightarrow x}} = \mathbb{D}_{KL}(P(y|x)||P(y|m)) + \\ \mathbb{D}_{KL}(P(y|m)||P(y|x)) \end{aligned} \quad (8)$$

Therefore, the final loss is:

$$\mathcal{L} = \mathcal{L}_{ST} + \mathcal{L}_{MT} + \lambda.(\mathcal{L}_{KL_{s \leftrightarrow m}} + \mathcal{L}_{KL_{x \leftrightarrow m}})/2 \quad (9)$$

where λ is a hyperparameter weight to control the KL losses.

4 Experiments

4.1 Dataset

We conduct our experiments on CoVoST-2 dataset (Wang et al., 2020), a large multilingual ST dataset that is based on Common Voice project (Ardila et al., 2020). CoVoST-2 covers translation from 21 source languages to English and from English to 15 target languages, and it contains speech, transcription and translation triplets. In this work, due to computational resources, we focus on 6 language directions: En-De, En-Ca, En-Ar, De-En, Fr-En, and Es-En. These directions are selected to ensure a balanced number of En-X and X-En directions. Furthermore, all languages selected are high resource with a minimum of 97 hours of training data and are of varying linguistic distance from English.

4.2 Experimental Setup

Pre-processing:
For speech input, we use the raw 16 bit 16kHz mono-channel audio. We filter out examples with a number of frames higher than 480k or less than 1k. For the text input, we remove punctuation, then we tokenize using a uni-gram SentencePiece model (Kudo and Richardson, 2018) with a vocabulary of 10k that is shared between the source and target languages.

Model:
Our model is composed of a speech encoder and a translation encoder-decoder. For the speech encoder, we use a pre-trained base HuBERT model (Hsu et al., 2021) for En-X language directions, and mHuBERT-147 (Zanon Boito et al., 2024) (a multilingual version of HuBERT base model) for X-En language directions. To shrink the audio representations over the time axis, we stack 2 1-dimensional convolution layers of kernel size 5, stride size 2, padding 2, and hidden dimension 1024. For the translation encoder, we use 6 transformer encoder layers. For the translation decoder, we use 6 transformer decoder layers. Each transformer layer is comprised of 512 hidden units, 8 attention heads, and 2048 feed-forward hidden units.

Training:
We train our model in two stages, first we pre-train the translation encoder-decoder on CoVoST2 transcription-translation pairs. We train with a learning rate of 1e-4, a maximum of 33k tokens per batch, and for a maximum 100k steps. We early stop training if the loss doesn't decrease for 10 epochs. During the second stage, we fine-tune the speech encoder and translation encoder-decoder with a learning rate of 1e-4, a maximum of 16M audio frames per batch, and we train for 40k steps. For CMOT, NFA-Align and DTW-Align, we train with a mixup probability $p^* = 0.2$ and a KL weight $\lambda = 2.0$.

The MT models are trained using one A100 GPU and ST models are trained using one H100 GPU. We use Fairseq [2] (Ott et al., 2019) for the implementation.

Evaluation:
We average the last 10 epoch checkpoints for evaluation, and generate with a beam size of 5. We use SacreBLEU (Post, 2018) to compute detokenized case-sensitive BLEU score (Papineni et al., 2002). We also use SacreBLEU to measure statistical significance using paired approximate randomization (Riezler and Maxwell, 2005).

Low Resource Setting:
All the languages in our experiments are considered high resource with at least 97 hours of training data, therefore, to evaluate our method in a low resource setting, we simulate a low resource scenario by sampling 10 hours of ST training data and 1 hour of development data for each language directions. During training, we use the same hyperparameters but we early stop if the loss did not decrease on the development set for 10 epochs. Our goal is to demonstrate how noise in the alignment has a more pronounced effect in low-resource ST scenarios. Therefore, we use a simulated low-resource setting with the same languages and training setup to avoid any confounding effects that would arise from using a different dataset.

4.3 Main Results

Baselines:
We experiment with the following models:
HuBERT-Transformer: Composed of speech encoder and translation encoder-decoder trained for ST.
CMOT: HuBERT-Transformer trained by using CMOT alignment for discrete mixup training.
NFA-Align: Using word level alignments from NeMo Forced Aligner (NFA) [3] which was shown to achieve state-of-the-art results in terms of alignment accuracy (Rastorgueva et al., 2023) for mixup training.
DTW-Align-Discrete (Ours): Using DTW for

Table 1: BLEU score results on CoVoST2 test set. The table shows that CMOT, DTW-Align, and DTW-Align-Discrete achieve the best results against other baselines. †: indicates results reported in the original work (the rest of the baselines are trained in this study)

generating alignments and training with discrete mixup (Equation 3) similar to CMOT.

DTW-Align (Ours): Using DTW for generating alignments and training with interpolation mixup (Equation 4).

5 Results and Discussion

Table 1 shows the results of our method and baselines, and results of previous work that was evaluated on the CoVoST2 dataset. The results show that consistent with previous studies (Fang et al., 2022), the baseline HuBERT-Transformer remains a competitive baseline, even outperforming previous work that uses more complex techniques. Furthermore, CMOT, DTW-Align-Discrete and DTW-Align achieve the best results overall. Although we train under similar settings and we do not optimize our method differently, we achieve similar results to CMOT. Surprisingly, NFA-Align which uses NFA to align speech and text lags slightly behind on average (i.e. 0.1 BLEU), this suggests that in a high resource setting, and with a low mixup probability the effect of noise in the alignment is less evident.

5.1 Alignment Accuracy and Training time

Table 2 shows that our method produces more accurate alignments with a significant increase of 19% in alignment accuracy. Furthermore, our method is more than 33 times faster in terms of execution time, which is concretely manifested in the staggering difference in training time between CMOT and DTW-Align (i.e. 14:20:53 and 6:48:14 respectively). As a reference, HuBERT-Transformer baseline training time is 6:32:53, which means that our method improves the performance over this baseline (by an average of 1.2 BLEU points) without the drawbacks of the significant training time overhead that CMOT suffers from. Therefore, although our method achieves similar results to state-of-the-art CMOT in high resource settings, it offers a significant advantage in terms of training time. In Section 6, we show that due to the improved alignment accuracy, our method is more robust both in low resource settings and under higher mixup probability values.

Method	Accuracy ↑	Execution Time ↓	Train Time ↓
CMOT	26%	97.89	14:20:53
DTW-Align	**45%**	**2.91**	**6:48:14**

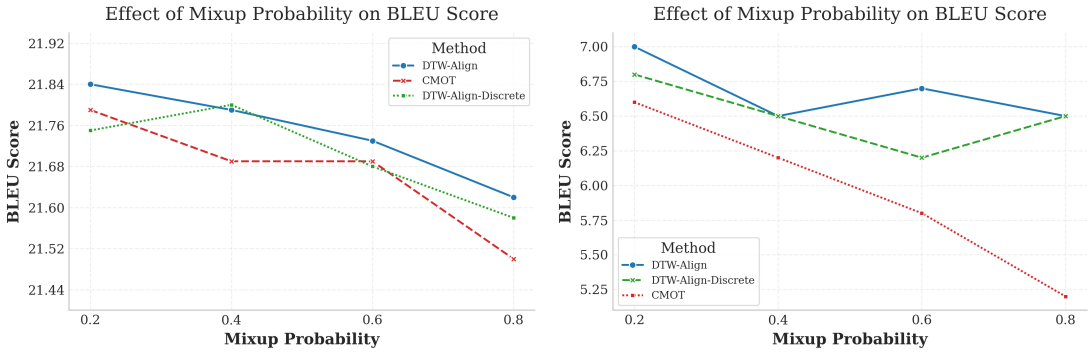
Table 2: We show the accuracy of alignments against NFA, and the execution time on CoVoST2 En-De dev set, plus the training time on En-De train set. DTW-Align is significantly faster and more accurate than CMOT.

6 Analysis

Although our method substantially outperfroms CMOT in terms of alignment accuracy, it does not yield improvements in ST performance. We attribute this to two factors: the amount of training data, which makes training more robust under noise and the low mixup probability value, which is set to 0.2. In §6.1 we measure the performance of CMOT, DTW-Align-Discrete and DTW-Align in a simulated low resource scenario of 10h per lan-

Model	En-De	En-Ca	En-Ar	De-En	Fr-En	Es-En	Avg.
HuBERT-Transformer	6.4	8.7	2.2	1.8	3.2	2.9	4.2
CMOT	6.6	9.6	2.7	2.8	8.5	7.5	6.3
DTW-Align-Discrete	6.8**	9.6	2.8	2.7	**8.6**	7.9**	6.4
DTW-Align	**7.0****	**9.8****	**3.1****	**2.9***	**8.6**	**8.0****	**6.6**

Table 3: BLEU score results on CoVoST2 test set in the low resource setting. The table shows that on overall DTW-Align-Discrete and DTW-Align on overall achieve better results than CMOT, with DTW-Align achieving the best results overall. *, ** indicate whether the improvement over CMOT is statistically significant with $p < 0.05$ and $p < 0.01$ respectively.



(a) En-De

(b) En-De Low Resource

Figure 3: The BLEU score of CMOT and DTW-Align under different mixup probabilities on En-De (Figure 3a) and En-De Low Resource (Figure 3b). DTW-Align is more robust to higher mixup probabilities than CMOT even with discrete mixup. This can be explained by noise in CMOT alignments.

guage direction, and in §6.2 we ablate the mixup probability value.

6.1 Low Resource Setting

Models can be more vulnerable to the negative effects of alignment noise in low resource scenarios. To study this, we compare the performance of CMOT, DTW-Align-Discrete and DTW-Align in a low resource setting of 10h of ST training data and 1h of development data. Table 3 shows the results over the 6 language directions in our experiments. Overall, DTW-Align-Discrete achieves better results than CMOT, with the improvements on En-De and Es-En being statistically significant. Furthermore, DTW-Align achieves the best results, with statistically significant improvement over CMOT on 5 language directions out of 6. These results show that combining the alignment accuracy of DTW and the robustness of interpolation mixup yields the best performance in low resource settings. Although our method performs on par with CMOT in high-resource settings, it offers an increase in performance in low resource ones, where effects of noise on CMOT are more pronounced. Finally, we find that the improvement of DTW-Align over HuBERT-Transformer has doubled (i.e. from 1.2 to 2.4 BLEU points), which demonstrates the advantage of mixup training in low resource settings.

6.2 Mixup Probability

We perform an ablation study on the effect of increasing the mixup probability p^* of CMOT, DTW-Align-Discrete and DTW-Align as shown in Figure 3 on En-De in high (Figure 3a) and low resource setting (Figure 3b). Results indicate that higher mixup probabilities lead to lower performance but the performance degradation is more significant in the case of CMOT, especially in the low resource setting, where training is more vulnerable to noise. This demonstrates that using DTW for aligning speech and text representations is more robust to the mixup probability hyperparameter, especially in low resource scenarios.

7 Conclusion

We introduce a method that eliminates the requirement for an external forced alignment tool by dynamically aligning speech and text embeddings

during training based on Dynamic Time Warping (DTW). Compared to state-of-the-art approaches, our method matches or exceeds BLEU score results while being significantly faster. We further demonstrate that using DTW-Align is more robust and data efficient in low resource settings. In addition, compared to HuBERT-Transformer baseline, our method improves performance by 1.2 and 2.4 BLEU points in high and low resource settings respectively with minimal overhead in the training time. Finally, unlike CMOT, our method can produce both token and word level alignments, which makes it compatible with previous work that requires word level alignments (Fang et al., 2022; Ouyang et al., 2023; Nguyen et al., 2025), therefore, it can bring a boost to the ongoing efforts on bridging the modality gap in E2E-ST or other speech-to-text tasks.

Limitations

Our work considers the following limitations:

Previous work shows that using external MT data for pretraining the translation encoder-decoder improves downstream ST performance. In our experiments, however, we only use internal CoVoST2 data for pretraining because of resource limitations.

Moreover, our work requires speech transcriptions, which might not be available for all languages. Future work can explore using transcriptions from an ASR model potentially extending the method's applicability to a wider range of languages.

Finally, CoVoST2 is an English centric dataset with English as the source or target language in all directions. Evaluating the accuracy and effect of speech and text alignment on other language directions would be valuable for future research.

Acknowledgments

Abstract

To improve the translation quality of "black-box" machine translation (MT) systems, we focus on the automatic editing of source texts to be translated. In addition to the use of a large language model (LLM) to implement robust and accurate editing, we investigate the usefulness of targeted editing, i.e., instructing the LLM with a text span to be edited. Our method determines such source text spans using a span-level quality estimator, which identifies actual translation errors caused by the MT system of interest, and a word aligner, which identifies alignments between the tokens in the source text and translation hypothesis. Our empirical experiments with eight MT systems and ten test datasets for four translation directions confirmed the efficacy of our method in improving translation quality. Through analyses, we identified several characteristics of our method and that the segment-level quality estimator is a vital component of our method.

1 Introduction

In the last decade, the quality of machine translation (MT) outputs has been significantly improved as a result of the advancements of neural MT (NMT) and large language models (LLMs) and the accumulation of parallel data in the community. A number of new techniques for further improving translation quality, i.e., reducing translation errors, have been presented at conferences; however, proprietary MT services have tended to remain state of the art, presumably thanks to undisclosed technologies and massive in-house data. Such "black-box" systems are, in general, difficult to adapt for users' niche use cases in which texts with specific content domains or text styles are to be translated.

To obtain better translations using black-box MT systems, several strategies have been proposed. One such strategy is "pre-editing," i.e., editing given source texts to improve their translation by an MT system of interest. Although studies on automatic pre-editing have long been conducted (§2), two issues remain. First, existing methods have only limited editing ability. Various types of source text editing can potentially improve its translatability (Miyata and Fujita, 2017, 2021). However, in past studies, researchers have addressed only specific linguistic complexities or performed the regeneration of entire texts indiscriminately. Another issue is that researchers have performed pre-editing without referring to the actual translation generated by the MT system, despite the proven effectiveness of editing source text with reference to actual translation errors (Uchimoto et al., 2006; Resnik et al., 2010). Different MT systems have different error tendencies; thus, editing expressions that the MT system can translate well would result in new translation errors.

In this study, we automate "targeted source text editing" using (a) quality estimation models to determine what to edit on the basis of the translation errors caused by a target MT system and to search for a better translation and (b) LLMs to realize various types of editing as in Ki and Carpuat (2025). In our method (§3), a given source text is translated by the MT system, and errors in the output are identified by a span-level quality estimator. Then, using an LLM, our method edits the source text with a text span annotated as the source of the severest translation error. Guiding the editing process with a trigger error does not guarantee that the MT system can translate the edited text better (Miyata and Fujita, 2017, 2021). Thus, our method searches for a better translation by repeating text editing and MT, relying on a segment-level quality estimator.

Our empirical experiments with eight MT systems and ten test datasets for four translation directions confirmed the efficacy of our method in improving translation quality (§5). Our analyses

[*] This work was done during an internship of the first author at NICT.

Proceedings of the Tenth Conference on Machine Translation, pages 200–219
November 8-9, 2025

also revealed several characteristics of our method, including the diverse impact depending on the MT system and dataset, the necessity of improving the segment-level quality estimator, and controlled editing realized by tailored instruction (§6).

2 Previous Work

MT systems and services have gradually pervaded our lives, and have been incorporated into the human-centered translation production process adopted by translation/language service providers (ISO/TC37, 2017). Before they became sufficiently practical, researchers examined several approaches to human–MT interaction. Uchimoto et al. (2006) proposed the editing of source texts motivated by translation errors; the method was later named "targeted paraphrasing" by Resnik et al. (2010). Inspired by previous studies on targeted paraphrasing, Miyata and Fujita (2017, 2021) conducted manual investigations into the pre-editing strategy for exploiting black-box services based on statistical and neural MT. Through incrementally performing source text editing in four content domains referring to MT outputs, they found that most (80%–100%) of the source texts could eventually be edited so that they will lead to no translation errors and that human editors have performed diverse types of edits, not only limited to paraphrasing, that can improve translation quality.

Automatic "pre-editing" methods, which have been studied for three decades, can be classified into two groups. The first group focuses on specific linguistic phenomena that are difficult to translate, such as low frequency words, subject ellipsis, and long sentences, and avoids them relying on a set of rewriting rules based on morpho-syntactic information, corpus statistics, and neural language models (Shirai et al., 1993; Kim and Ehara, 1994; Yamaguchi et al., 1998; Shirai et al., 1998; Yoshimi, 2001; Mirkin et al., 2013; Štajner and Popovic, 2016; Štajner and Popović, 2018; Koretaka et al., 2023). However, each of these methods only covers a specific type of editing, among the diverse promising ones. Early methods are difficult to replicate for other source languages because of their heavy reliance on hand-crafted rules and resources.

Another line of research has attempted to regenerate entire source texts by regarding the task as monolingual translation and applying data-driven sequence-to-sequence decoding methods (Sun et al., 2010; Nanjo et al., 2012; Mirkin et al., 2013; Mehta et al., 2020). The performance of this approach is dominated by the characteristics and quantity of training parallel data. Since no parallel data have been specifically tailored for the purpose of pre-editing, except for small collections for manual analyses and evaluation, researchers have used monolingual parallel data that exhibit other monolingual tasks, such as text simplification and text revision, or synthetic parallel data generated by back-translating bilingual parallel data and round-trip translation of monolingual data. This approach has been proven effective for rule-based and statistical MT systems (Sun et al., 2010; Nanjo et al., 2012; Mirkin et al., 2013); in contrast, it does not necessarily work for NMT systems (Koretaka et al., 2023). Recently, Ki and Carpuat (2025) examined the utility of LLMs for source text editing. They compared several editing strategies and identified that the instruction for text simplification and selection based on quality estimation are effective.

Unlike manual investigations (Miyata and Fujita, 2017, 2021), both of the aforementioned groups of methods do not refer to the translation errors caused by the MT system of interest. Although a linguistically motivated pre-edit should be helpful in general, excessive editing of translatable expressions would introduce new translation errors.

3 Targeted Source Text Editing

Unlike existing "pre-editing" methods, we propose the editing of given source texts to avoid actual translation errors that the target MT system makes, i.e., the automation of the manual investigation process (Miyata and Fujita, 2017, 2021). Algorithm 1 shows the overall procedure of our method.

Given a source text src_0, our method first translates it using an MT system of interest T, and evaluates the quality of the generated hypothesis hyp_0 with reference to src_0 using a quality estimator Q. The pair of hyp_0 and its score initializes the best result (steps 1–3). The open list of errors to be edited is also initialized with translation errors in hyo_0 identified by an error detector E (steps 4–5).

Then, for pre-defined iterations N or until no errors remain (step 7), our method repeats the following steps: (a) identify the severest error and corresponding source text span (steps 8–9, §3.1), (b) edit the identified source span (step 10, §3.2), (c) translate the edited source text and evaluate the new hypothesis (steps 11–12, §3.3), and (d) search for the best translation (steps 8, 13–17, §3.4).

Algorithm 1: Proposed Error-Informed Source Text Editing Method.

Input : Original source text src_0, Translator T, Quality estimator Q, Error detector E, Maximum iteration N, Aligner A, Paraphraser P
Output : Best translation $best\_hyp$

1 $hyp_0 = T.translate(src_0)$
2 $best\_score = Q.evaluate(src_0, hyp_0)$
3 $best\_hyp = hyp_0$
4 $errs = E.detect\_errors(src_0, hyp_0)$
5 $cands = [\langle src_0, hyp_0, errs\rangle]$ `// open list`
6 $i = 1$
7 **while** $i < N \wedge cands \neq [\,]$ **do**
8 $\quad \langle src, hyp, err\rangle, cands = select\_one\_error(cands)$
9 $\quad src^{ann} = A.propagate\_error(src, hyp, err)$
10 $\quad src_i = P.paraphrase(src^{ann})$
11 $\quad hyp_i = T.translate(src_i)$
12 $\quad score_i = Q.evaluate(src_0, hyp_i)$
13 $\quad$ **if** $score_i > best\_score$ **then**
14 $\quad\quad best\_score = score_i$
15 $\quad\quad best\_hyp = hyp_i$
16 $\quad\quad errs = E.detect\_errors(src_i, hyp_i)$
17 $\quad\quad cands.append(\langle src_i, hyp_i, errs\rangle)$
18 $\quad i = i + 1$
19 **return** $best\_hyp$

3.1 Identification of the Source Text Span

In general, a translation hypothesis can contain multiple errors derived from dispersed source text spans. Following the incremental amelioration approach (Miyata and Fujita, 2017, 2021), we focus on the severest error and corresponding source text span (steps 8–9) in each iteration.

To this end, we rely on an error detector or a span-level quality estimator E, which identifies error spans with a severity score (steps 4 and 16). E may not jointly detect source text spans each corresponding to an error in the hypothesis. We thus identify such spans by aligning the source text tokens and those in the hypothesis using an aligner A (step 9). Then, we determine the source span that aligns with the severest error. Other tuples of an error span, its corresponding source text span, and its severity score are stored in the open list (steps 5 and 17) for future iterations (§3.4).

3.2 Targeted Text Editing Using an LLM

Given a source text annotated with a text span, our method then attempts to edit the span. Since the annotated span can be linguistically diverse, from a single symbol or word to the entire source text, we require a robust editor that can realize diverse types of text editing without introducing linguistic errors and semantic changes.

To perform such monolingual text editing, we use a decoder-only LLM, assuming that it has learned diverse linguistic phenomena from massive text data and is well-instructed for various text-editing tasks. In addition to the source text and the text span to be edited, it would be useful to instruct the LLM on the text editing task, such as its sub-steps and constraints, with some examples if possible. To better control its output, instructing the LLM with prompt formatting through few-shot examples is a promising approach (He et al., 2024). However, we need to prepare countermeasures against irregular outputs, such as control sequences and an off-target format.

3.3 Translation and Evaluation

The edited source text src_i is translated by the MT system T (step 11), and the quality of the generated hypothesis hyp_i is evaluated by the quality estimator Q (step 12). Text editing is not necessarily successful; it may fail to edit the annotated error source, thereby resulting in semantic drift in src_i and/or severer errors in hyp_i. Therefore, the quality is evaluated with respect to the original source text src_0 rather than the corresponding source text src_i as in Ki and Carpuat (2025).

3.4 Search for the Best Translation

We search for a better translation through repeating targeted source text editing, hypothesis generation with the MT system, and quality assessment. Given the high computational cost for LLM-based text editing, it is not feasible to traverse the entire search space. Therefore, we conduct depth-first search as in past manual investigations (Miyata and Fujita, 2017, 2021): our method performs source text editing greedily as long as quality improves. If an edit is confirmed to be detrimental by the quality estimator, it discards the edited text and selects the second severest error of the previous version of the source text. If no error remains, it backtracks to one more previous version of the source text. This is implemented in the "`select_one_error()`" function (step 8).

4 Preliminary Experiments

We determined the detailed settings using a small set of Japanese-to-English translation examples and one MT system. Henceforth, resources used in our experiments, including datasets, pre-trained model checkpoints, and tools, will be presented in this manner. See Appendix A for their details.

For this purpose, we used an NMT model pre-trained on JParaCrawl (Morishita et al., 2022) (the big model) and four sets of Japanese–English parallel data: (a) the development data of ASPEC (Nakazawa et al., 2016) (abstracts of scientific papers), (b) the test data of WMT22 (Kocmi et al., 2022) (mixture of several domains), (c) the test data of MTNT (Michel and Neubig, 2018) (users' posts on social media), and (d) the development data of the Kyoto Free Translation Task (benchmark splits of the Japanese–English Bilingual Corpus of Wikipedia's Kyoto Articles; henceforth, KFTT). First, we translated the Japanese side of these datasets into English using the MT model and Fairseq (Ott et al., 2019), and detected translation errors using a span-level quality estimator, XCOMET-XL (Guerreiro et al., 2024). We then randomly extracted 25 text pairs from each dataset that contained at least one "critical" or "major" error. Referring only to the sampled 100 ($= 25 \times 4$) text pairs, we determined the details of our method, including the combination of the span-level quality estimator and word aligner (Appendix C.1), the LLM for source text editing (Appendix C.2), and the prompt template (Appendix B.1).

To identify text spans in the source texts to be edited, our method propagates errors identified by XCOMET-XL, relying on optimal transport implemented by OTAlign (Arase et al., 2023). We determined the alignments between the tokens in the source text and hypothesis using contextual token embeddings obtained by InfoXLM-Base (Chi et al., 2021), uniform distribution as the mass for each token, cosine distance between token embeddings as the cost function, Sinkhorn algorithm, and 0.1 as the weight for the entropy-based regularizer.

For source text editing, we used Llama-3.1-Swallow-70B-Instruct-v0.1 (henceforth, Llama-Swallow) (Fujii et al., 2024), an LLM trained on massive text data of the source language, i.e., Japanese, and devised a prompt template for it, including the way of specifying the source text span to be edited and providing a one-shot paraphrase example. Such an example was randomly sampled from the 71 paraphrase examples in Japanese taken from a taxonomy of paraphrases.[1] The instruction was formatted by applying a chat template using the Language Model Evaluation Harness.

To select the best translation hypothesis among those derived from different versions of source texts, we also used XCOMET-XL, a reference-free quality estimation metric.

Through the preliminary experiments, we observed that the translation quality achieved by our method saturated up to five iterations (Appendix C). This is fewer than the 5.4–21.8 iterations required to obtain an acceptable translation in a manual investigation (Miyata and Fujita, 2021) because of the limited ability of our method compared with humans. The advancement of each component, as well as their tight integration, should improve the ability of our method.

5 Evaluation

To confirm the efficacy of our method on translation quality, we conducted experiments. Although most components of our method are multilingual, we had only Japanese and English speakers to write prompt templates for source text editing and translation with LLMs. Therefore, we evaluated the applicability of our method on Japanese-to-English (Ja→En), Japanese-to-Chinese (Ja→Zh), English-to-Japanese (En→Ja), and English-to-Chinese (En→Zh) translation directions.

5.1 Settings

5.1.1 Configuration of the Proposed Method

The configuration of our method mostly follows the details that we determined in our preliminary experiments (§4). For both translation error detection and translation quality estimation, we used XCOMET-XL, with one exception: we regarded text spans annotated as "critical," "major," or "minor" as errors, thereby extending the target. We used OTAlign and InfoXLM-Base for propagating erroneous spans to the source text.

Source text editing in our method is a monolingual task. Considering that an LLM trained specifically for the source language should perform better than other LLMs (Appendix C.2), we used Llama-Swallow for the Ja→En and Ja→Zh tasks, and Llama-3.1-70B-Instruct (henceforth, Llama) (Grattafiori et al., 2024) for the En→Ja and En→Zh tasks. We used 71 Japanese and 44 English examples available in the aforementioned paraphrase taxonomy[1] as the pool for the one-shot demonstration. The prompt templates are shown in Appendix B.1.

We set the number of maximum iterations, i.e., N in Algorithm 1, to 5, following our preliminary experiments (§4).

[1] https://paraphrasing.org/paraphrase.html

5.1.2 MT Systems

We applied our method to eight MT systems: four NMT and four LLM-based systems. Although we chose publicly available checkpoints for the sake of reproducibility, we regarded them as black boxes with the aim of simulating applications of our method to proprietary MT systems and services.

The NMT systems were NLLB-200-3B (henceforth, NLLB) (NLLB Team et al., 2022) and three sized-variants of the Ja→En and En→Ja specific models trained on JParaCrawl (Morishita et al., 2022), labeled as small, base, and big.

The four LLM-based MT systems were based on two LLMs, i.e., Llama and Llama-Swallow (see Appendix B.2 for their prompt templates), and two methods for selecting a translation example from a reference parallel corpus. One is BM25 (Robertson and Zaragoza, 2009), implemented in bm25s (Lù, 2024), which searches the parallel corpus for a text pair whose source side is most similar to the given source text. To this end, the source text to be translated and the corresponding side of the parallel corpora were tokenized with MeCab (Kudo et al., 2004) and Moses tokenizer (Koehn et al., 2007) for Japanese and English, respectively. The other method, called "vector," identifies such a text pair relying on sentence embeddings. We used LaBSE (Feng et al., 2022) as the sentence encoder and Faiss (Douze et al., 2024) for search, where we indexed the source side of the parallel corpora using product quantization with the number of subquantizers of 96 and the number of bits per subvector index of 8. As the reference parallel corpora, we used the official training data of WMT23 (Kocmi et al., 2023) consisting of 33.9M and 55.2M text pairs for Japanese–English and Chinese–English pairs, and Japanese–Chinese JParaCrawl (Nagata et al., 2024) consisting of 4.6M text pairs.

5.1.3 Test Datasets

For Ja→En, we used four datasets: [a] the test data of ASPEC (Nakazawa et al., 2016), [b] the test data of WMT23 (Kocmi et al., 2023) (mixture of several domains), [c] the test data of MTNT19 (Li et al., 2019) (users' posts on social media), and [d] the test data of KFTT. For Ja→Zh, we used [e] the test data of ASPEC. For En→Ja, we used four datasets: [f] the test data of the Asian Language Treebank (Riza et al., 2016) (news articles; henceforth, ALT), [g] the test data of WMT23, [h] the test data of MTNT19, and [i] the test data of IWSLT 2017 (Cettolo et al., 2017) (TED talks; henceforth, IWSLT). We also used [j] the test data of IWSLT 2017 for En→Zh.

When these datasets were translated by the target MT systems, 61.6%–96.2% of the resulting translations contained at least one "critical," "major," or "minor" error (see Appendix D for the details). Note that our method processes only these "erroneous test subsets."

5.1.4 Other Methods Compared

We regarded translation of the original source texts, i.e., hyp_0 in Algorithm 1, as the baseline. In addition, we evaluated the following "non-targeted" methods. Unlike ours, they are unaware of the target MT system and attempt to pre-edit source texts irrespective of potential translation errors.

Word-Sub: We replicated the word-substitution method proposed by Koretaka et al. (2023), which generates N-best paraphrases by substituting one word, relying on a masked language model and cosine similarity between word embeddings. We used language-specific BERT models trained through whole-word masking (Tohoku-NLP BERT base Japanese and Google BERT large for English) and FastText word embeddings.

Seq2seq-B: Although it is proven ineffective (Koretaka et al., 2023), we trained a monolingual sequence-to-sequence model for each source language, following Wieting et al. (2017) (see Appendix G for the training details), and obtained N paraphrased texts using the model via beam search with a beam size of 12.[2]

LLM-NT (non-targeted): We obtained N versions of source texts through iterative paraphrasing with an LLM.[3] The only difference from our method is that the source texts were not annotated on the basis of translation errors. We thus derived the prompt templates for Llama-Swallow and Llama from those for our method (Appendix B.1) by removing the step-wise instruction for error-informed text editing while retaining the criteria to meet.

Each of the N paraphrased source texts and the original source text was translated separately by the given MT system, and the best translation among

[2]We also examined nucleus sampling with $top\_p = 0.95$ but it underperformed beam search in most configurations.

[3]With $N = 1$, this is similar to one of the MT-Agnostic rewriting methods examined by Ki and Carpuat (2025).

Table 1: COMET scores for the entire test sets. **Bold** indicates the improvement over the Baseline, underlining so does the best score among all the methods, the "#+" and "#-" columns show the number of test datasets for which the method achieved a significantly better or worse score (marked with "*") than the Baseline, respectively, and the "#w" column presents the number of datasets for which the method achieved the best score for each MT system.

$(N+1)$ hypotheses was selected by XCOMET-XL similarly to our method.[4]

5.1.5 Evaluation Metric

To evaluate the translation quality of MT outputs, we used the COMET score (Rei et al., 2020), specifically with the wmt22-comet-da checkpoint (Rei et al., 2022). We performed paired bootstrap resampling (Koehn, 2004) to test the statistical significance of the score difference from the baseline.

[4]XCOMET-XL achieved consistently better results than mBART used in Koretaka et al. (2023) in our preliminary experiments, although it was substantially slow.

5.2 Results

The COMET scores of all the methods in 74 test configurations are presented in Table 1. For the four NMT systems (the upper half), the LLM-based text editing methods, i.e., LLM-NT and ours, significantly improved translation quality, with only one exception. The word-substitution method also led to a significant gain in roughly 70% of configurations, outperforming the sequence-to-sequence method. For the LLM-based MT systems (the bottom half), the LLM-based text editing methods and the word-substitution method also achieved significant improvements. The word-substitution method

Table 2: COMET scores for the erroneous test subsets (§5.1.3). See Table 1 for text decoration and symbols.

achieved the highest COMET score in more than 50% of configurations, whereas our method lagged behind it and LLM-NT.

Unlike existing non-targeted methods, our method edits only the erroneous test subsets (§5.1.3). Table 2 compares the COMET scores for these subsets, revealing the advantage of our method and diminished impact of the non-targeted methods. Our method achieved the highest COMET score in 34 out of 74 configurations, followed by LLM-NT which won in 28.

From these results, we conclude that the LLMs performed source text editing for MT more robustly and accurately than the existing methods. However, our targeted method is not yet incontestably superior over its non-targeted counterpart, i.e., LLM-NT. For instance, the prompt template developed with Ja→En examples had a minimal or negative impact on the Ja→Zh task, in particular with Llama-Swallow. In contrast, the equivalent prompt template manually translated into English worked fairly well, encouraging future applications of our method to other source languages.

6 Analyses

To better understand the characteristics of our method, we conducted several analyses, focusing on the erroneous test subsets (§5.1.3).

6.1 System-wise and Dataset-wise Impact

We hypothesize that the worse the quality of an MT output for the original source text is, the more

MT System	Ja→En				Ja→Zh	En→Ja				En→Zh
	ASPEC [a]	WMT23 [b]	MTNT19 [c]	KFTT [d]	ASPEC [e]	ALT [f]	WMT23 [g]	MTNT19 [h]	IWSLT [i]	IWSLT [j]
NLLB [1]	-0.381	-0.401	-0.416	-0.388	-0.324	-0.453	-0.540	-0.444	-0.340	-0.359

Table 3: Pearson product-moment correlation coefficients r between the baseline COMET score and its gain achieved by our method. See Appendix D for the number of segments in each configuration.

it should benefit from avoiding underlying translation errors by source text editing. To examine this, we calculated the correlation between the baseline COMET score and its gain. Table 3 summarizes segment-level correlation coefficients. Although there was moderate negative correlation for most configurations, we observed that others, such as the Ja→Zh ASPEC dataset translated by the LLM-based MT systems, did not follow the rule. In general, correlation for the LLM-based MT systems was weaker than those for the NMT systems, except for the two IWSLT tasks, and more diverse over the datasets. This implies that these LLMs had peculiar characteristics. For instance, some of the test datasets might have already been learned by them, unlike the NMT systems.

Figure 1 visualizes the correspondences between the baseline COMET score and its gain for each erroneous test subset. Our method had a stronger correlation than the other methods. One may consider that our method could be less impactful for very accurate MT systems, such as "black-box" proprietary systems. Despite this, we consider that our approach still has potential, because its advancement is orthogonal to the enhancements of those MT systems. For instance, we developed our method using only one NMT system and a small sample of Ja→En sentence pairs (§4), but it worked well for other translation directions (4f–4i) and stronger LLM-based MT systems (e.g., 5g–8i). Through our extensive experiments, we identified configurations where the current form of our method did not work well, such as the two ASPEC and KFTT tasks. We will conduct in-depth analyses to explore the reasons and address them in our future work.

6.2 Quality Estimator

We investigated whether the segment-level quality estimator, i.e., XCOMET-XL, was useful for search-

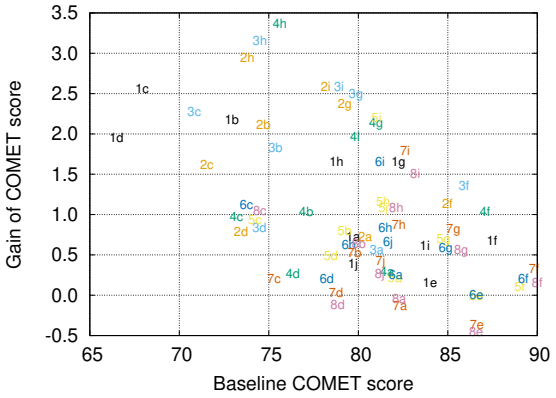

Figure 1: Baseline COMET score for the erroneous test subsets and its gain achieved by our method ($r = -0.522$). "1" to "8" and "a" to "j" are the indices of the MT systems and test datasets, respectively.

ing for the best translation. Figure 2 shows that the estimated quality monotonically improved during the search as intended; 1.91–8.48 and 2.46–11.05 points with $N = 1$ and $N = 5$, respectively. However, the final COMET score shown in Figure 3 did not follow the same trend, even though these two measures correlated well at the segment level in our experiments (0.292–0.762, Appendix E). For instance, in the two configurations where our method significantly deteriorated the COMET score, i.e., the two variants based on Llama-Swallow for the Ja→Zh ASPEC task (7e and 8e shown at top right of Figure 3), the correlation coefficient between the two measures was moderate (0.534 and 0.519). In contrast, the configurations with a weakest correlation, i.e., the JParaCrawl variants applied to the En→Ja IWSLT task (2e–4e, $r = 0.292$–0.296), achieved a 2.0–2.5 COMET point gain.

This discrepancy suggests that the segment-level quality estimator was a vital component, and thus requires further improvements to capture subtle differences between accurate translations.

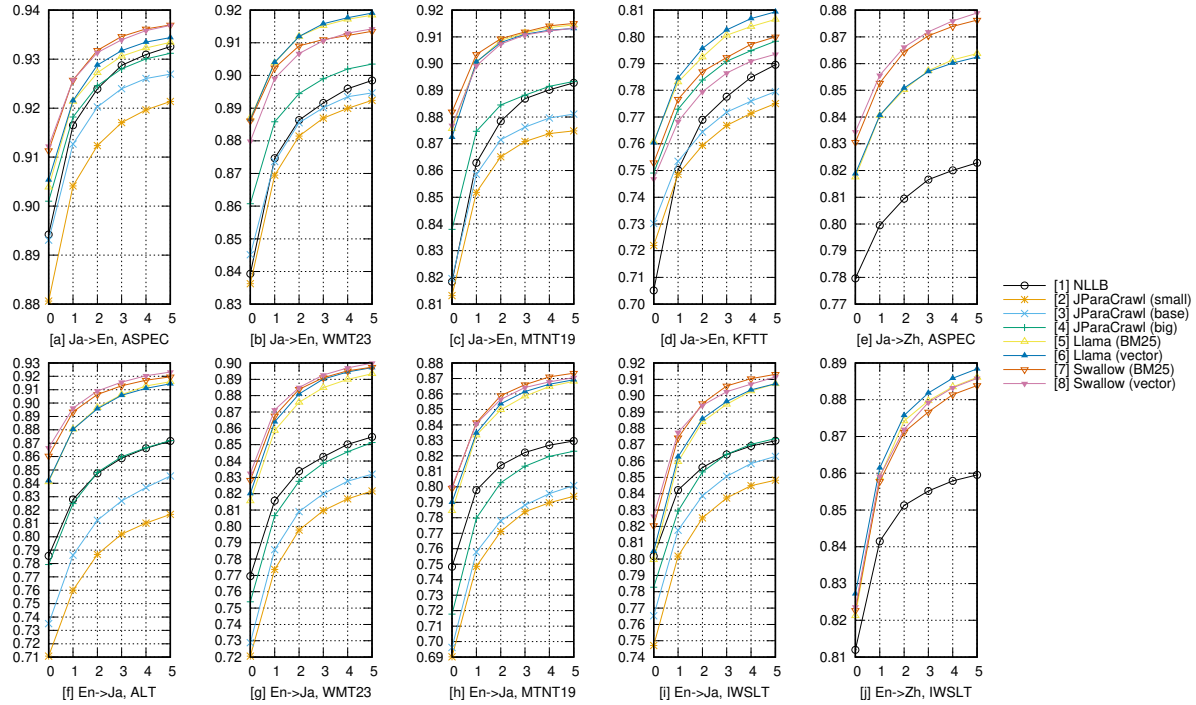

Figure 2: Translation quality estimated by XCOMET-XL without reference at each iteration of our method.

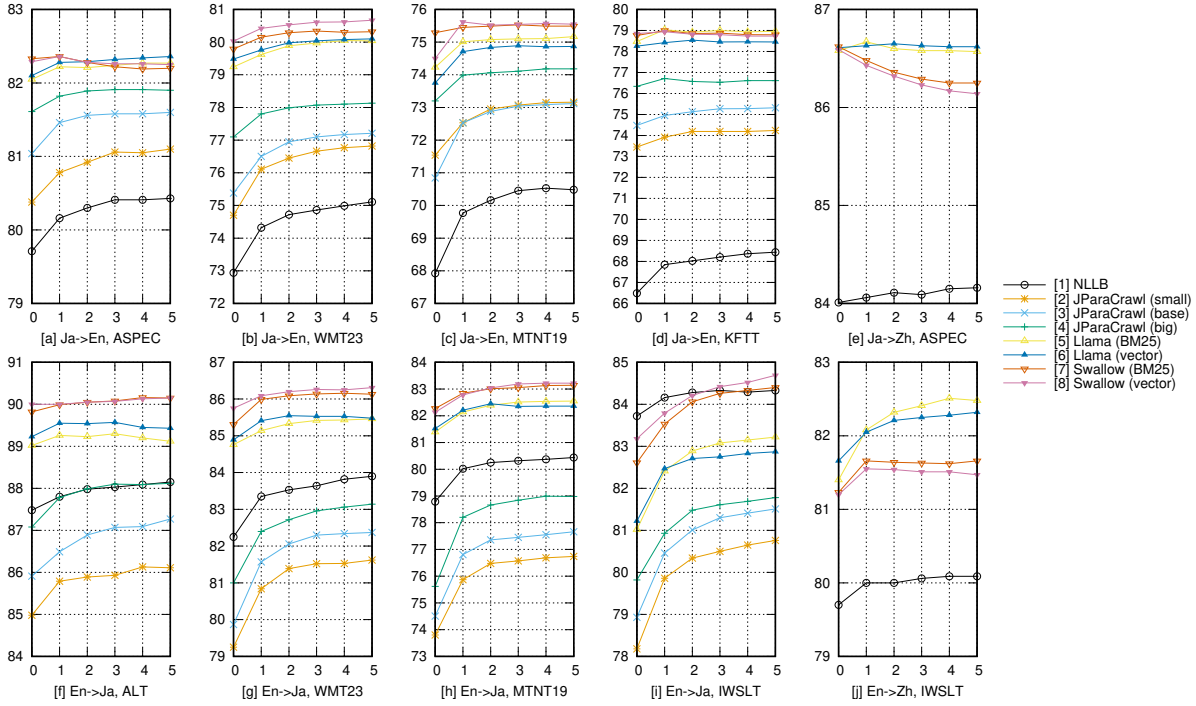

Figure 3: COMET score computed by wmt22-comet-da with a reference at each iteration of our method.

6.3 Source Text Editor

We quantified the degree of text editing performed by each method, with the translation error rate (TER) (Snover et al., 2006) at the dataset level. More specifically, we tokenized Japanese and English texts using MeCab (Kudo et al., 2004) and Moses tokenizer (Koehn et al., 2007), respectively, and computed TER using SacreBLEU (Post, 2018),[5] regarding the original and edited source texts as the reference and hypothesis, respectively.

Figure 4 shows that our method altered 9%–37% of linguistic tokens. The ratio was higher

[5]Signature: nrefs:1|case:lc|tok:tercom|norm:no|punct:yes|asian:no|version:2.5.1

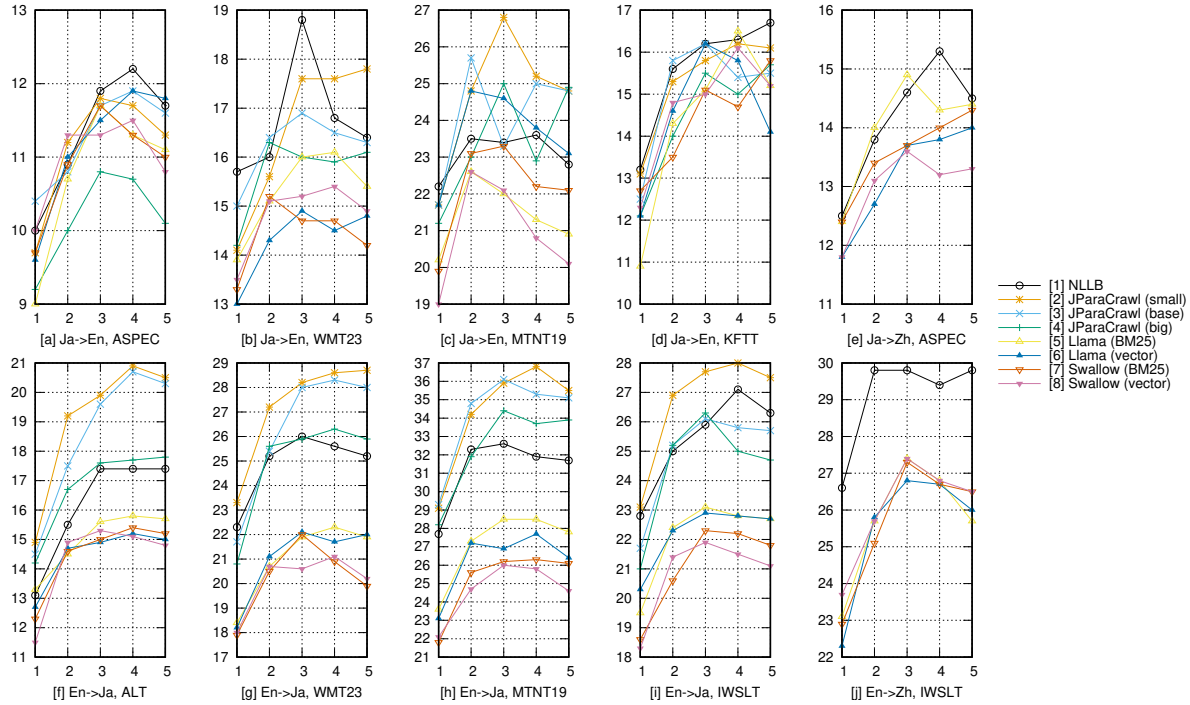

Figure 4: Translation edit rate (TER) between the original source text src_0 and each of its edited versions src_i generated by our method. Because of the search function, src_{i+1} was not necessarily obtained from src_i directly.

than those exhibited by the word-substitution method (9%–19%; Appendix F), except for the two ASPEC tasks (9%–16% vs. 17%–19%), and lower than those performed by the other two non-targeted methods (12%–76% and 19%–68% by the sequence-to-sequence and LLM-NT methods, respectively; Appendix F). We also observed that the ratio varied across the targeted MT systems.

The modest ratio of our method reflects the length distribution of the translation error spans and corresponding source text spans identified by XCOMET-XL and OTAlign. We thus consider that the LLMs properly conformed to the instruction for targeted text editing.

Note that we do not consider the ratio to be a good indicator of better translations.

7 Conclusion

As an approach to exploiting black-box MT systems, we focused on automatic and targeted source text editing. To overcome the two issues that remain in the literature, i.e., the limited ability of editing and unawareness of actual translation errors, we used LLMs, expecting that they would have sufficiently high competence to realize diverse types of edits that can improve translation quality (Miyata and Fujita, 2017, 2021) and a segment-level quality estimator as in a concurrent work (Ki and Carpuat, 2025), and implemented targeted paraphrasing (Uchimoto et al., 2006; Resnik et al., 2010) by harnessing a span-level quality estimator (error detector) and a word aligner.

Our experiments with eight MT systems and ten test datasets for four translation directions confirmed the efficacy of our method in improving translation quality, while the non-targeted counterpart (LLM-NT) also achieved a rivaling performance. Through the analyses, we identified that the impact of our method varied depending on the MT system and dataset, and that the segment-level quality estimator is the vital component that requires further improvements.

Future work includes improving each component of our method, while simplifying and speeding up the whole pipeline. Since our method focuses on source texts that lead to translation errors according to an error detector, applying LLM-NT to other error-free segments will be a straightforward way for improving translation for entire datasets. Only prompt templates are language dependent; hence, we plan to evaluate the applicability of our method to other translation tasks as well as other MT systems, including proprietary ones. We are also interested in assessing the applicability of the proposed method to other text-to-text tasks, including text summarization and text simplification.

Acknowledgments

We would like to thank the anonymous reviewers for their insightful comments and suggestions. A part of these research results was obtained from the commissioned research (No. 22501) by NICT.

Limitations

As observed in our experiments, the gain of the COMET score achieved by our method and competing methods depended on the target MT systems and test datasets. In addition, the COMET score may evaluate the translation quality only from limited perspectives, heavily relying on a single reference translation. Thus, our results do not guarantee the same conclusions for other MT systems, datasets, and translation directions. For instance, our method may not work well for translating from/into low-resource languages, provided that the component models of our method, i.e., quality estimator, error detector, aligner, and paraphraser, have not been trained for those languages and thereby perform less accurately.

We used COMET (wmt22-comet-da) for evaluating the translation quality, following Freitag et al. (2022); they reported that it achieved the highest correlation with human rating among reproducible automatic metrics. However, recent work, such as Agrawal et al. (2024), demonstrated that XCOMET-XL surpassed COMET. Evaluating with XCOMET-XL may lead to different conclusions. The discrepancy between reference-free and reference-based metrics observed in Figures 2 and 3 could be resolved. On the other hand, the use of the same model for search and evaluation may lead to a bias. To confirm the gain in translation quality, human evaluation is indispensable.

We made large efforts to refine the prompt templates for text editing and translation with LLMs. However, there is still room for improvement. While our prompt templates (Appendix B.1) follow the spirit of "targeted paraphrasing" (Uchimoto et al., 2006; Resnik et al., 2010), a concurrent work (Ki and Carpuat, 2025) has demonstrated that the instruction for text simplification results in better translations than instructing on the paraphrasing task. The optimized templates for an LLM may not work well for other LLMs.

LLM-based source text editing requires substantially larger computes than existing methods that do not rely on LLMs. However, we assume that the latency with $N = 5$ and eight NVIDIA Tesla V100 GPUs is acceptable for the existing translation production process (ISO/TC37, 2017), where the manual post-editing step governs latency. We expect that recent advances in smaller language models and model compression will make our approach faster and consequently more feasible.

Ethics Statements

The resulted translations had, on average, a higher quality according to the COMET score. However, translation errors should remain. Therefore, the direct use of MT outputs could mislead potential users.

A Public Resources Used

Table 4 lists the links to the resources, including the datasets, pre-trained model checkpoints, and tools, used in our experiments (Sections 4–6).

B Prompt Templates

B.1 For Targeted Source Text Editing

Figure 5 presents the prompt templates used for our targeted source text editing. To perform this task, we used an LLM that is mainly trained on the language of interest, i.e., Llama-Swallow for Japanese and Llama for English, and provided prompts in the same language. Pairs of double brackets ("{{" and "}}") indicate placeholders. Given a source text to be edited, a tailored prompt is automatically instantiated by filling these placeholders.

B.2 For Translation

Figure 6 presents the prompt templates used for MT. In the same manner as for source text editing, we provided prompts in the language for which the LLM was recently and mainly trained on, i.e., Japanese for Llama-Swallow and English for Llama. The role of double brackets is the same as for source text editing.

C Preliminary Experiments

As described in §4, we explored a better way of determining the source text span to be edited and the LLM used for source text editing, using the sampled set of 100 parallel sentences and the JParaCrawl Japanese-to-English NMT model (big).

C.1 Source Text Span Detection Methods

To confirm the feasibility and impact of determining source text spans to be edited, we compared the following three methods.

Random: This method first specifies the beginning of the source text span randomly, and then the end from the remainder of the source text.

Table 4: Public resources used in our experiments.

Direct: The error detector, XCOMET-XL, annotates only erroneous text spans in the hypothesis. This method examines whether it can directly annotate the source text spans by swapping the source text and hypothesis.

Propagation: A combination of XCOMET-XL for annotating erroneous text spans in the hypothesis and a word aligner, OTAlign, to propagate those spans to the source text.

Figure 7 shows the results with Llama-Swallow for Japanese source text editing (Appendix C.2). The "Propagation" method achieved the highest COMET score with any value of N up to 5, even though it should have involved prediction errors of both the error detector and word aligner. Interestingly, with the "Random" text spans, our method improved the COMET score up to 1.0 point. Even though the "Direct" assessment of the source text led to a higher COMET score than "Random," it lagged behind "Propagation."

We thus chose the "Propagation" method in our experiments in §5, whose prediction could become even more accurate if the two components are improved. In addition, in the literature on translation quality estimation, researchers have attempted to determine source text spans corresponding to translation errors (Specia et al., 2020, 2021; Fomicheva et al., 2021). Although this line of research is out of scope in the recent series of shared tasks, we believe it is worth considering, in particular for promoting source text editing.

C.2 LLMs for Text Editing

A number of LLMs are publicly available, but the extent to which they perform the source text editing task is unknown. We considered that instruction tuning is necessary. Hence, we compared the following four LLMs that differ in the existence of language-specific adaptation and model size.

Llama-Swallow-70B: The Llama model with 70B parameters, continually pre-trained on

```
日本語文の言い換え文を出力してください。
手順は次の通りです。
1. 日本語文の¶¶で囲まれた言い換え対象表現について、同じ意味を持つ異なる表現の言い換え候補を1個から5個挙げてください。
2. 手順1で挙げた言い換え候補の中から、日本語文の¶¶で囲まれた箇所を言い換えるのに、最も適切な候補を1つ選んでください。
3. 日本語文の¶¶で囲まれた箇所を、手順2で選ばれた最適な言い換え候補を使用して置換してください。この際、以下の基準を満たすように文脈に合わせて適切に調整してください。
・文脈に応じて、適切な動詞の活用形や助詞を使うこと。
・元の文の意味を正確に伝えること。
・文法的に正しい構文を持つこと。

```

(a) Prompt template used for Llama-Swallow to edit Japanese source text.

```
Please output a paraphrased sentence for a given English sentence.
The procedure is as follows:
1. For the target expression for paraphrasing marked with ¶¶ in the English sentence, provide 1 to 5 paraphrase candidates with the same meaning and different expressions.
2. Select one among the paraphrase candidates generated in step 1 that is most appropriate for paraphrasing the part marked with ¶¶ in the English sentence.
3. Replace the part marked with ¶¶ in the English sentence with the paraphrase candidate selected in step 2. At the same time, please perform necessary adjustment to make it fit the context while meeting the following criteria.
・Use appropriate conjugation form of words and particles according to the context.
・Convey the original meaning of the sentence accurately.
・Maintain the grammatically correct structure of the sentence.

Input example:
English sentence: {{paraphrase["example_original"]}}
Target expression for paraphrasing: {{paraphrase["example_original_span"]}}
Output example:
{"paraphrased_sentence":"{{paraphrase["example_paraphrase"]}}"}

English sentence: {{paraphrase["annotated_src"]}}
Target expression for paraphrasing: {{paraphrase["propagate_error_span"]}}
```

(b) Prompt template used for Llama to edit English source text.

Placeholder	Content to be filled
paraphrase["example_original"]	Source text of the retrieved example
paraphrase["example_original_span"]	Targeted span in the above text
paraphrase["example_paraphrase"]	Paraphrased text of the retrieved example
paraphrase["annotated_src"]	Source text to be edited
paraphrase["propagated_error_span"]	Targeted span in the above text to be edited

{{source_language}} sentence: {{translation["src"]}}
```

(b) Prompt template used for translation with Llama.

Placeholder	Content to be filled
source_language	Source language (e.g., "Japanese")
target_language	Target language (e.g., "English")
translation["example_src"]	Source text of the retrieved translation example
translation["example_tgt"]	Target text of the retrieved translation example
translation["src"]	Source text to be translated

(c) Placeholders in the prompt templates for translation.

Figure 6: Prompt templates used for translation.

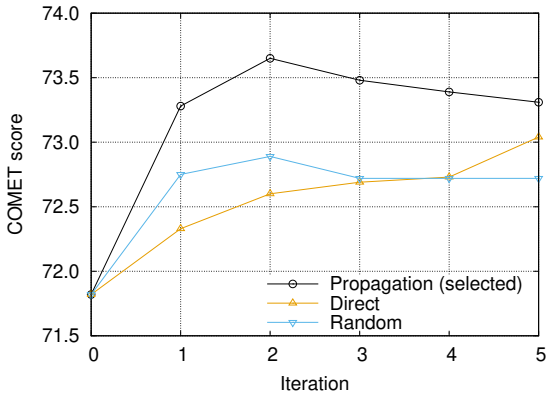

Figure 7: COMET scores achieved by different source text span detection methods.

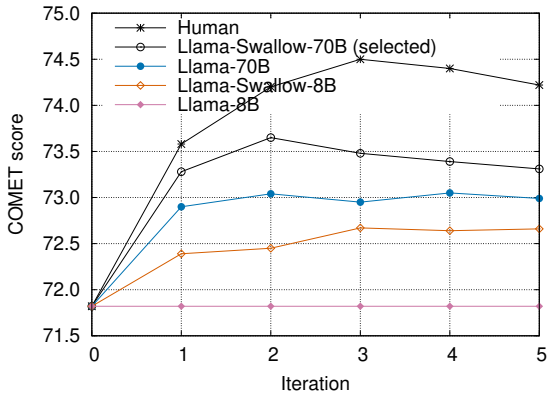

Figure 8: COMET scores achieved by different source text editors.

with any value of N up to 5. When we compared LLMs with the same sizes, Llama-Swallow outperformed Llama, which confirms the benefit of adaptation to the language of interest. We also found that smaller LLMs were not as good as their larger counterpart. Although some coincidences could exist, the non-adapted small LLM, i.e., Llama-8B, did not improve the COMET score at all. Following the results, we used Llama-Swallow-70B for editing source texts in Japanese, and analogously Llama-70B for English (§5.1.1).

At the time of this preliminary experiment, we required a sufficiently large model. However, recent advances in smaller language models will lead to a better balance of cost and benefit.

D Erroneous Test Subsets

Our method attempts to avoid translation errors. Thus, we mainly evaluated and analyzed our method focusing on the erroneous test subsets determined using XCOMET-XL (§5.1.3).

Table 5 summarizes the number of lines containing at least one "critical," "major," or "minor" error when translating with each MT system.

Table 6: Pearson product-moment correlation coefficients r between the COMET gain (wmt22-comet-da, with reference) and QE score gain (XCOMET-XL, without reference) both achieved by the proposed method. See Table 5 for the number of segments in each configuration.

E Correlation between the Estimated Quality and COMET Score

Table 6 summarizes the segment-level correlation coefficients between the gain of the COMET score and the gain of the estimated quality. At a glance, a moderate positive correlation existed for most configurations, and one might consider that this indicates that the estimated quality was beneficial to the search. However, as observed in §6.2, the estimated score does not always help the system make the correct decision.

F Source Text Edit Rate

Figures 9, 10, and 11 show the degree of text editing performed by the word-substitution, sequence-to-sequence, and LLM-NT methods, respectively, measured by TER computed in the same manner as for our method (§6.3). Compared with our method, the word-substitution method led to a lower TER, since it substituted only one word. The other two non-targeted methods indiscriminately affected the entire texts, which led to a substantially larger TER depending mainly on the dataset: the sequence-to-sequence method for Japanese and the LLM-NT method for English. LLM-NT demonstrated a saturation, indicating that it properly followed the instruction for retaining semantics and grammaticality.

G Details of the Sequence-to-Sequence Paraphrasing Models

Only the monolingual sequence-to-sequence pre-editing models were trained by us for our experiments. Our procedure below follows that in a previous study (Koretaka et al., 2023).

First, we generated synthetic monolingual parallel data from the bilingual parallel corpora used for retrieving translation demonstrations (§5.1.2). We randomly sampled text pairs from each corpus, aligning their sizes with the minimum corpus of 4.6M, and translated their non-targeted side into the language on the other side, using M2M100-418M (Fan et al., 2021) and beam search with a beam size of 12. The synthetic monolingual parallel data, 9.2M text pairs for each of Japanese and English, were composed of the pairs of the resulted translation (Ja'←{En,Zh} and En'←{Ja,Zh}) and the corresponding reference translation in the bilingual parallel corpus (Ja–{En,Zh} and En–{Ja,Zh}).

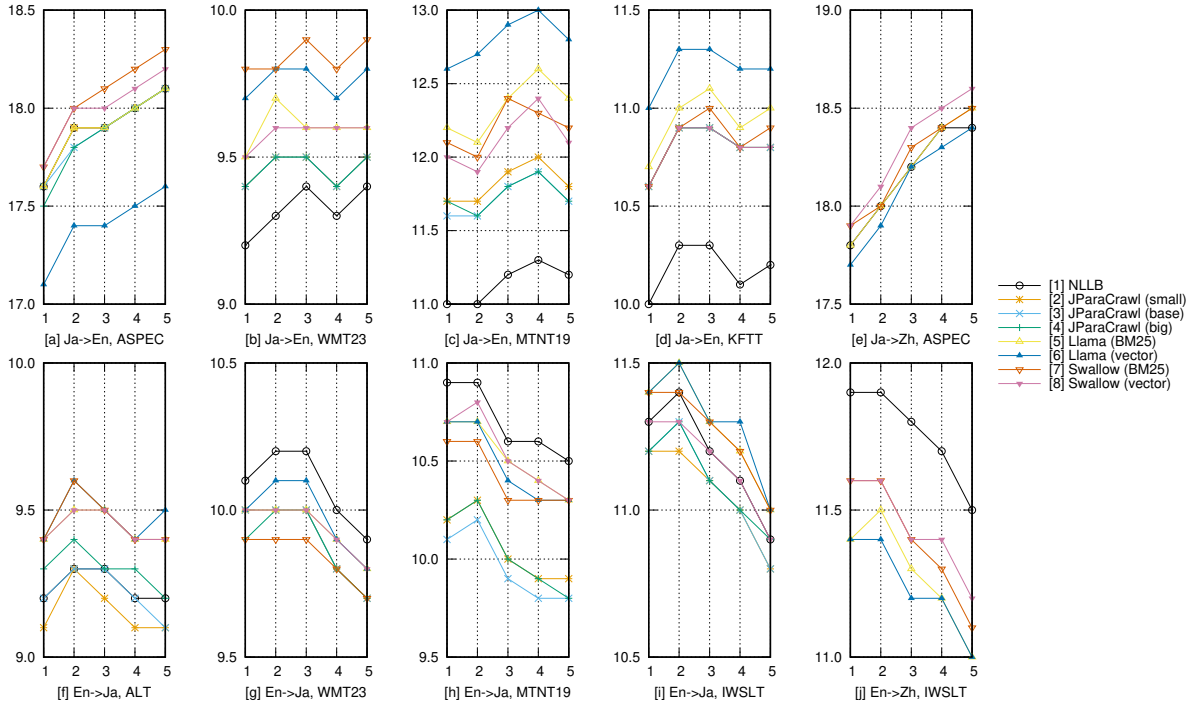

Figure 9: Translation edit rate (TER) between the original source text src_0 and each of its edited versions src_i generated by the Word-Sub method (the five-best outputs).

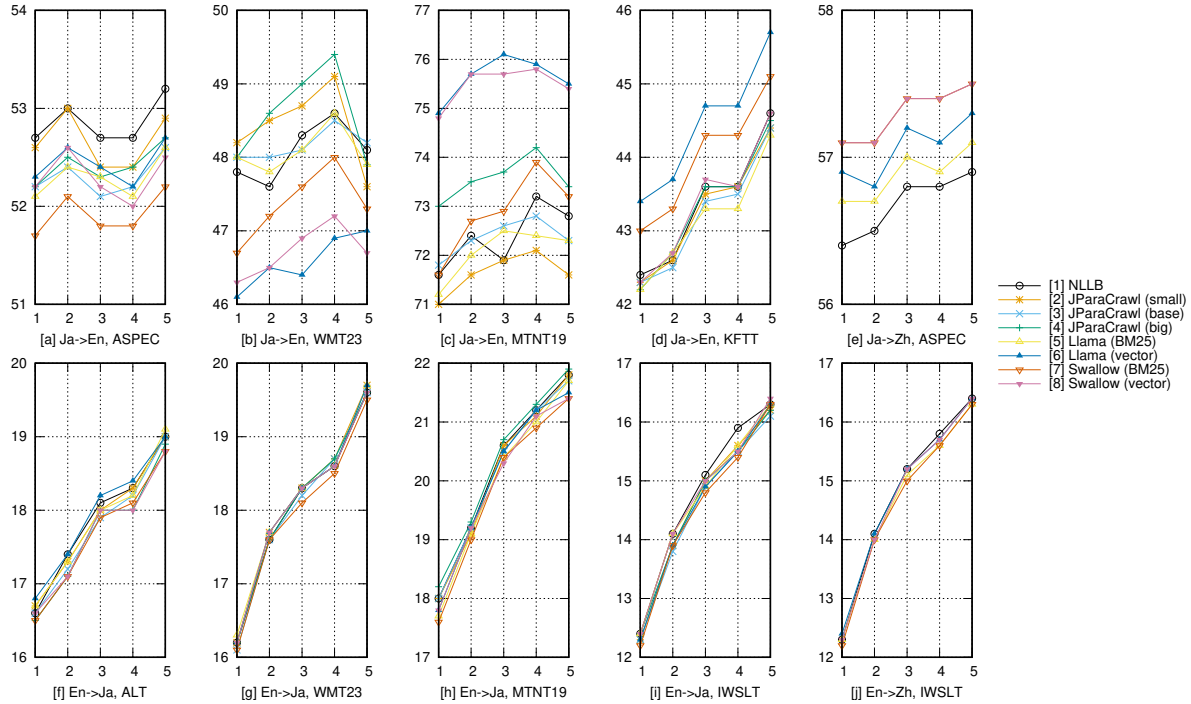

Figure 10: Translation edit rate (TER) between the original source text src_0 and each of its edited versions src_i generated by the Seq2seq-B method (the five-best outputs).

We then trained a Transformer Base model (Vaswani et al., 2017) for each of Japanese and English, regarding the synthetic side as the source, and using a joint vocabulary of 32k sub-words determined using SentencePiece (Kudo and Richardson, 2018) and Fairseq (Ott et al., 2019). We set the training hyper-parameters to the same values as Morishita et al. (2022), except for the number of updates of 60k and the lack of checkpoint averaging.

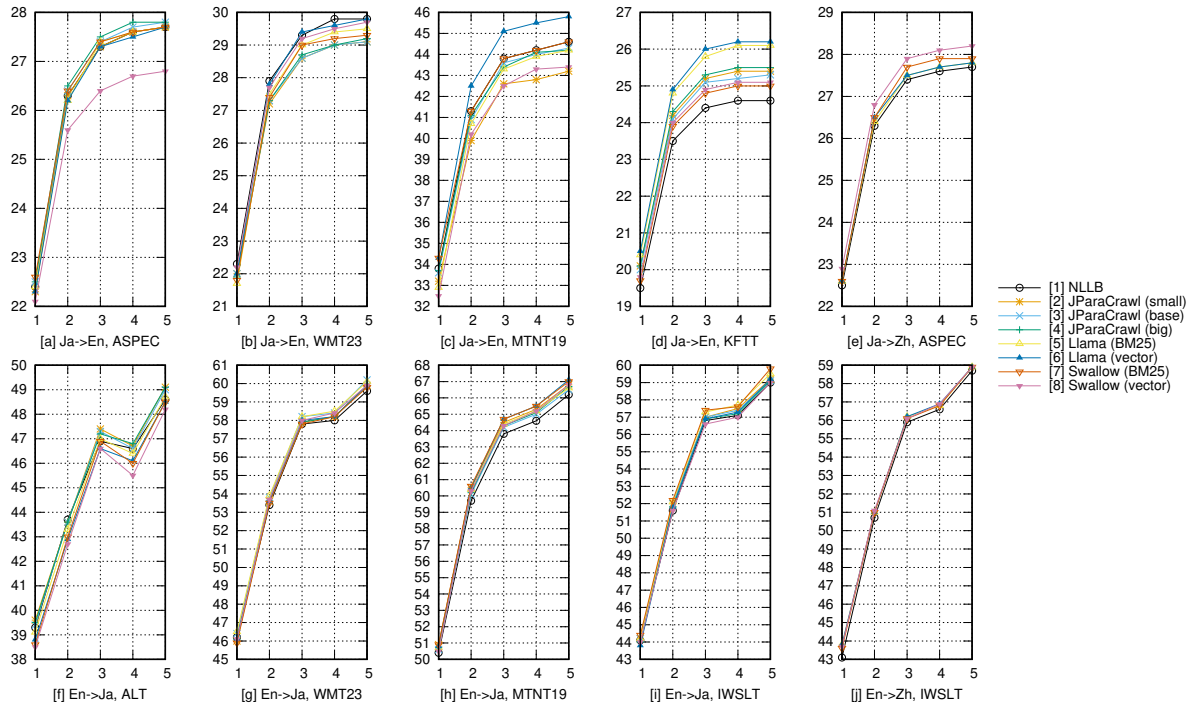

Figure 11: Translation edit rate (TER) between the original source text src_0 and each of its edited versions src_i generated by the LLM-NT method. Because of the iterative nature, src_{i+1} was always obtained from src_i directly.

Self-Retrieval from Distant Contexts for Document-Level Machine Translation

Ziqian Peng[1,2] and **Rachel Bawden**[2] and **François Yvon**[1]
[1]Sorbonne Université & CNRS, ISIR, Paris, France
[2]Inria, Paris, France
{ziqian.peng,francois.yvon}@isir.upmc.fr rachel.bawden@inria.fr

Abstract

Document-level machine translation is a challenging task, as it requires modeling both short-range and long-range dependencies to maintain the coherence and cohesion of the generated translation. However, these dependencies are sparse, and most context-augmented translation systems resort to two equally unsatisfactory options: either to include maximally long contexts, hoping that the useful dependencies are not lost in the noise; or to use limited local contexts, at the risk of missing relevant information. In this work, we study a self-retrieval-augmented machine translation framework (SELF-RAMT), aimed at informing translation decisions with informative local and global contexts dynamically extracted from the source and target texts. We examine the effectiveness of this method using three large language models, considering three criteria for context selection. We carry out experiments on TED talks as well as parallel scientific articles, considering three translation directions. Our results show that integrating distant contexts with SELF-RAMT improves translation quality as measured by reference-based scores and consistency metrics.

1 Introduction

Document-level machine translation (DLMT) is a challenging task, as it requires modeling both short-range and long-range dependencies to maintain the coherence and cohesion of the generated translation. Inter-sentential contexts are indispensable for the handling of phenomena such as co-reference, lexical consistency, textual coherence and cohesiveness, which continue to be challenging for long document translation (Bawden et al., 2018; Maruf et al., 2019; Voita et al., 2019b; Fernandes et al., 2023). Numerous approaches, reviewed in (Maruf et al., 2021; Castilho and Knowles, 2024), have been proposed to integrate these contexts. They include segment concatenation (Tiedemann and Scherrer, 2017; Bawden et al., 2018; Sun et al., 2022), architecture adaptation (Miculicich et al., 2018; Yang et al., 2019; Ma et al., 2020), training strategy optimization (Lupo et al., 2022b; Li et al., 2023; Wu et al., 2024), and multi-pass refinement (Voita et al., 2019a; Yu et al., 2020; Koneru et al., 2024). Past work also shows that various sources of contextual information contribute differently to translation quality; the local source and target context is the main resource for handling anaphoric references and word-sense disambiguation information (Bawden et al., 2018; Gete et al., 2022), whereas the global context, especially on the target side, holds information likely to improve coherence and cohesiveness of the full translated document (Pal et al., 2024).

Recent generative models such as Llama3 (Grattafiori et al., 2024) and GPT4 (OpenAI et al., 2023) can process inputs up to hundreds of thousands of tokens, creating new possibilities for the inclusion of the whole source text, as well as already translated target segments, in the translation context. It however remains an open question whether such architectures, relying on the self-attention-mechanism (Vaswani et al., 2017), are effectively able to identify relevant long-range dependencies and actually improve DLMT (Wang et al., 2024). This is because inter-sentential dependencies can be sparsely distributed within a document, whereas self-attention generates dense patterns spreading out over the entire past text (Tay et al., 2023; Liu et al., 2024). Therefore, most approaches to DLMT still consider a limited context window size, usually up to 1024 tokens or a fixed number of sentences.

In order to capture long-distance dependencies without requiring the attention mechanism to handle overly long contexts, we propose self-retrieval augmentation for machine translation (SELF-RAMT), aiming to take into account both local and global dependencies, regardless of the

Proceedings of the Tenth Conference on Machine Translation, pages 220–240
November 8-9, 2025

document length. In our approach, inter-sentential dependencies are precomputed for the full source document to identify past relevant segments for each translation unit. As soon as they are translated, these segments and their translation become available to inform the subsequent translation choices. In our implementation, which uses large language models (LLMs), such dynamic contexts are taken into account through in-context learning (ICL). Two scenarios are considered: (a) one where in-context examples correspond to correct translations, as in online learning, where the input sentences, once incrementally post-edited by a human translator, become available to revise the model (Álvaro Peris and Casacuberta, 2019),[1] and (b) a fully automatic setup, with imperfect in-context translations, requiring no human intervention. In this context, our main research questions are as follows: (i) how to best identify and retrieve useful context segments, (ii) what improvement to MT quality do these retrieved contexts bring, and (iii) to what extent distant (as opposed to local) contexts actually enhance translation scores. We compare three criteria for context selection (cosine similarity with respect to LaBSE embeddings (COS), Best Match 25 (BM25) and point-wise mutual information (PMI)) and carry out experiments on three LLMs in three language directions (English to German (EN–DE), French (EN–FR), and Chinese (EN–ZH)), analyzing the impact of contexts, especially distant ones. Experimental data includes both TED talks (Cettolo et al., 2012) and a new dedicated parallel test set, MERSENNE, consisting of scientific articles for the EN–FR direction. Scientific articles offer an interesting use case to study term consistency in long document translation. Our investigation reveals that distant contexts retrieved with PMI provide valuable information that increases translation metric scores as well as term consistency. We make our code and data available.[2]

2 Related Work

Document-level MT DLMT research broadly falls into two categories: *Doc2Sent*, which involves translating each sentence individually using intra-document source and/or target context to aid translation, and *Doc2Doc*, which involves translating multiple sentences at once (Popescu-Belis, 2019; Maruf et al., 2021; Castilho and Knowles, 2024). *Doc2Doc* approaches represent a simple strategy for effective context integration, maintaining better consistency and coherence than *Doc2Sent* methods (Li et al., 2020; Sun et al., 2022). However, *Doc2Doc* methods struggle to process very long sequences of sentences, as relevant information is sparse in global contexts (Lupo et al., 2022a; Wang et al., 2023), which can lead to the degradation of translation quality or omitted sentences (Zhuocheng et al., 2023; Li et al., 2023; Peng et al., 2025). To address this problem, several approaches have been explored, including context-aware attention (Maruf et al., 2019; Zheng et al., 2021; Yang et al., 2023), which selects important contexts according to the attention distribution, and dynamic context selection (Kang et al., 2020), which applies a reward model to identify varying numbers of useful context sentences within the local context, constrained by the complexity of reinforced training.

LLM-based DLMT Various LLM-based methods have been proposed for DLMT. Several works explore zero-shot prompting and ICL for *Doc2Doc* MT (Hendy et al., 2023; Karpinska and Iyyer, 2023) and study the best way to train LLMs for DLMT (Xu et al., 2024; Li et al., 2024; Guo et al., 2024; Alves et al., 2024), illustrating the importance of high-quality in-context demonstrations and fine-tuning parallel corpora. LLMs have also been used as post-editors, either through fine-tuning (Koneru et al., 2024; Li et al., 2025; Dong et al., 2025) or prompting for iterative translation refinement (Briakou et al., 2024; Wang et al., 2025a).

When it comes to integrating context, LLMs offer greater flexibility than traditional neural machine translation models. Various multi-aspect prompting techniques have been proposed to enhance the input by incorporating or automatically summarizing relevant information from the context. For instance, DELTA (Wang et al., 2025b) builds a dynamic context for each source sentence, heavily relying on LLM components to extract and assemble relevant information from the available source and target texts (including proper nouns, bilingual summaries of local contexts and relevant past sentences within a predefined context window). However, DELTA is computationally costly (a lot more so than SELF-RAMT), due to the multiple steps required for dynamic context extraction. SENT2SENT++ (Guo et al., 2025) incorporates two types of contexts: a static part, consisting of an au-

[1] We refer to this scenario as *online in-context learning*.
[2] https://anr-matos.github.io/resources.

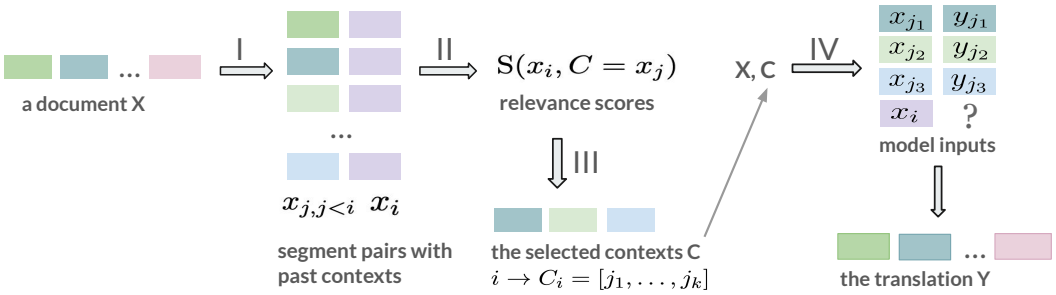

Figure 1: SELF-RAMT framework. It consists of four steps: I. Define the search domain (e.g. the past contexts); II. Compute contextual relevance scores for segments in the search domain; III. Retrieve relevant contexts according to the ranked scores and IV. Integrate the selected contexts to the inputs then generate the translations.

tomatically generated bilingual summary of the full source document, and a dynamic part, composed of the previous source and target sentences. However, the use of static, automatic summaries (a) has the effect of potentially changing the words of the context, which can be detrimental to lexical consistency and (b) does not ensure that the most relevant information is accessible for each source sentence, especially as documents increase in length.

Retrieval-augmented MT Choosing which context to be included in MT can be seen as a type of retrieval-augmented MT. In past works, retrieval-augmented MT systems have mostly been designed to mimic the use of *translation memories* by translators, which has a long history in MT (Kay, 1997). Recent implementations of this idea for neural models encode the target side of relevant example(s) together with the source sentence in an extended translation context (Gu et al., 2018; Bulte and Tezcan, 2019; Xia et al., 2019; Xu et al., 2020; He et al., 2021; Cheng et al., 2022). Variants, relying on both the source and target sides of the retrieved example(s) are proposed by Pham et al. (2020) and Reheman et al. (2023).

LLM-based MT systems seamlessly accommodate examples through in-context learning, where examples of the translation task (the source and target sides of parallel samples) (Radford et al., 2019) are inserted into the prompt. The optimal selection of in-context examples has also been the focus of recent research (Moslem et al., 2023; Vilar et al., 2023; Zhang et al., 2023; Bawden and Yvon, 2023; Agrawal et al., 2023; Cui et al., 2024; Zebaze et al., 2025), also analyzed by Zaranis et al. (2024) and Bouthors et al. (2024).

A key difference with SELF-RAMT is that these methods retrieve examples from external resources, instead of the input sequence, with the aim to find similar examples that can be easily edited. Several retrieval-augmented architectures have also been proposed, e.g., by Rubin and Berant (2024), to retrieve relevant contextual information from very long input documents. These approaches have been evaluated in language modeling tasks, but, to the best of our knowledge, have not yet been applied to MT.

3 Augmenting MT with Self-retrieval

3.1 A Self-retrieval Framework for MT

As illustrated in Figure 1, SELF-RAMT involves translating each segment of an input document X with relevant contexts retrieved within X. It consists of four steps:

I. Defining the Search Domain We consider a Doc2Sent scenario, translating sentences $\mathbf{x}_i$ in a document $X = \langle \mathbf{x}_1 \ldots \mathbf{x}_T \rangle$ using previous context sentences $\{\mathbf{x}_j, j < i\}$ in X.

II. Contextual Relevance Scores We compute contextual relevance scores $\mathrm{S}(\mathbf{x}_i, \mathbf{x}_j)$ of candidate segments $\mathbf{x}_j$ for each $\mathbf{x}_i$, with the aim of improving the consistency and coherence of the resulting translations. Details are in Section 3.2.

III. Context Retrieval For each $\mathbf{x}_i$, $\mathbf{x}_j$ is selected as a contextual segment if $\mathrm{S}(\mathbf{x}_i, \mathbf{x}_j)$ is among the top K relevance scores. Additionally, $\mathbf{x}_j$ is disregarded if $\mathrm{S}(\mathbf{x}_i, \mathbf{x}_j) \leq \tau$, where τ represents the minimum value such that $\mathbf{x}_j$ is relevant to $\mathbf{x}_i$ for score S (see Section 3.2). The resulting list of selected sentences, which we refer to as C_i, constitutes a dynamic context containing up to K sentences.

IV. Context-aware Translation Contextual sentences selected in step III are included as few-shot demonstrations in the LLM prompt in the order

in which they appear in the original text. We use specific prompts for each LLM. Details about the prompt selection and the decoding process are given in Appendix B.

3.2 Context Selection Criteria

Multiple criteria can be used to identify the relevant contextual sentences (reviewed in (Bouthors et al., 2024) for retrieval-based MT). In our approach, contextual relevance is assessed based on source side similarity between segments, which enables us to pre-compute the relevant contexts for all $\mathbf{x}_i$ prior to translation. Our hypothesis is that if $\mathbf{x}_j, j < i$ is sufficiently similar to $\mathbf{x}_i$, then $(\mathbf{x}_j, \mathbf{y}_j)$ will contain useful information when generating $\mathbf{y}_i$. This enables us to vary the retrieval score while keeping the translation infrastructure unchanged. It is therefore simpler than the proposal of Wang et al. (2025b), where contexts are dynamically updated during the generation process. In our experiments, we consider three contextual relevance scores:

COS We compute the cosine similarity between the sentence embeddings using LaBSE (Feng et al., 2022). Only positive cosine similarities are taken into account (i.e. $\tau = 0$).

BM25 We adapt BM25L (Lv and Zhai, 2011), a variant with length normalisation[3] of the Best Match 25 (BM25) relevance score (Robertson and Zaragoza, 2009), which is a go-to method for retrieving lexically relevant segments in large data stores. Implementation details are in Appendix B.2.

PMI To better reflect contextual relevance, we also consider an alternative inspired by the Pointwise Cross-Mutual Information (P-CXMI) (Fernandes et al., 2021, 2023) and the likelihood difference (Shi et al., 2024; Pombal et al., 2024). We identify relevant contexts based on the point-wise mutual information (PMI) between $\mathbf{x}_i$ and $\mathbf{x}_j$, defined as:

$$\mathrm{PMI}(\mathbf{x}_i, \mathbf{x}_j) = -\frac{1}{l_i} \sum_{t=1}^{l_i} \log \frac{P_C(x_{i,t}|x_{i,<t})}{P_C(x_{i,t}|x_{i,<t}, \mathbf{x}_j)},$$

where l_i is the length of $\mathbf{x}_i$. In other words, $\mathrm{PMI}(\mathbf{x}_i, \mathbf{x}_j)$ measures how much the knowledge of $\mathbf{x}_j$ reduces the uncertainty about $\mathbf{x}_i$ for some autoregressive language model P_C. We disregard $\mathbf{x}_j$ if $\mathrm{PMI}(\mathbf{x}_i, \mathbf{x}_j) \leq \tau$ with $\tau = 0$.

[3]Our code uses the Python implementation of Lù (2024).

Baseline We compare these relevance scores to four baselines: (i) Zero-shot, vanilla sentence-level MT, reflecting the basic non-contextual MT ability of LLMs, (ii) Past-K, where the local context is composed of K previous sentences, (iii) Random-K, where we randomly select K past sentences, and (iv) Indep-K (K independent examples generated by an LLM, the same for all sentences). More details are given in Appendix B.

4 Experimental Settings

4.1 Datasets

Our experiments rely on two test sets described below.

IWSLT Following Wang et al. (2025b) and Guo et al. (2025), we take the test sets of IWSLT2017[4] (Cettolo et al., 2012) as our test sets, for three translation directions: English to German (DE), French (FR) and Chinese (ZH), with respectively 10, 12 and 12 TED talks.

MERSENNE Due to the scarcity of long document-level data, we curated a set of 23 published scientific articles and their translations for the EN–FR language pair.[5] These articles are segmented into sentences and aligned into parallel articles. We refer to this test set as MERSENNE. More details on data preparation are given in Appendix A.

Statistics of test sets Table 1 reports the number of full documents and the number of sentences in our test sets. It also includes the average, minimum, and maximum length of sentences in LLAMA tokens, for the source and target languages. The average number of sentences is 119 for TED talks from IWSLT, and 192 for articles from MERSENNE.

4.2 Models and Inference Settings

We evaluate our framework with three open-weight medium-size multilingual LLMs using ICL: Llama3.1-8B-Instruct[6] (LLAMA) (Grattafiori et al., 2024), EuroLLM-9B-Instruct[7] (EUROLLM) (Martins et al., 2024, 2025), and Qwen2.5-7B-Instruct[8] (QWEN) (Qwen et al., 2025). These models do

not contain IWSLT nor parallel articles from MERSENNE in their pre-training data. Our experimental pipelines relies on vLLM (Kwon et al., 2023), an efficient framework for text generation. Decoding is performed with a beam width of 5 and a maximum number of new tokens of 256. To determine the impact of K (the maximum number of selected contexts), we vary K from 0 to 6. Regarding context selection, we compute PMI using LLAMA. For the Indep-K baseline, we generate 6 examples in the style of TED talks again using LLAMA. More details regarding the experimental setup are in Appendix B.

4.3 Metrics for DLMT

To evaluate general translation quality, we primarily rely on COMET (Rei et al., 2022) and its document-level variant (d-COMET) (Vernikos et al., 2022), with the reference-based model `wmt22-comet-da`. We also report BLEU[9] (Papineni et al., 2002) and SLIDE (Raunak et al., 2024) with `wmt22-cometkiwi-da` with a window size of 8 sentences and a stride of 6. For lexical consistency, we compute Lexical Translation Consistency Ratio (LTCR) (Lyu et al., 2021; Wang et al., 2025b) for proper nouns annotated using spaCy[10] and aligned using awesome-align (Dou and Neubig, 2021). We also conduct case studies to examine the effectiveness of SELF-RAMT.

5 Examining Context Selection Strategies

In this section, we aim to answer the following questions: (a) how effective are the context selection scores to identify relevant contexts? and (b) how similar are the retrieved segments when retrieval is performed in the source text or in the target text? As discussed above, generating coherent texts ideally requires taking the target context into account. As only the source text is initially available, it is important to verify that source-based retrieval is a reliable substitute for target-based retrieval, simulated using the oracle reference.

Method To assess the context selection criteria for their sensitivity to coherence, we challenge their ability to distinguish sentences extracted from the same documents from other noise segments. Starting with a set of document pairs (X^1, X^2) both containing n sentences in the same language, we randomly shuffle sentences from X^1 with those of X^2, resulting in a combined document $X^{1,2}$. We then retrieve, from the first $2n-1$ segments of $X^{1,2}$, the K most relevant segments for the last sentence ($\mathbf{x}_{2n}$), using each relevance score, and compute the extraction error rate r, defined as the proportion of selected sentences that do not belong to the same document as $\mathbf{x}_{2n}$. For a set of N documents $\{X_l^{1,2}, l = 1 \dots N\}$, from which we retrieve the K context sentences $\{c_{l,1}, \dots, c_{l,K}\}$ for each $\mathbf{x}_{2n}$, r is computed as follows:

$$r = \frac{\sum_{l=1}^{N} \sum_{j=1}^{K} \mathbb{I}(\mathrm{doc}(c_j) \neq \mathrm{doc}(\mathbf{x}_{2n}))}{N \times K},$$

where $\mathrm{doc}(\mathrm{c})$ returns the document index of its input segment c.

[9] We use SacreBLEU (Post, 2018) with signature: nrefs:1|case:mixed|eff:no|tok:13a|smooth:exp|version:2.4.0. We use the default zh tokenizer for translations into Chinese.

[10] https://spacy.io/usage

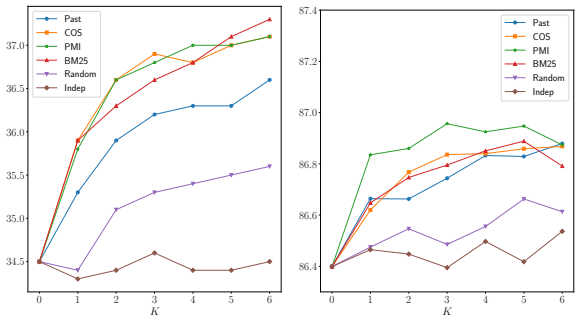

Figure 2: BLEU (left) and s-COMET (right) scores for IWSLT EN–FR translated using EuroLLM, with source and reference as contexts, for K from 0 to 6.

To compare the relevance scores computed using source and target texts, we also compute Kendall's τ (Kendall, 1938, 1945) between the relevance ranking respectively induced on the source and target texts, and average over the N documents. Finally, we also report the cover rate, defined as the ratio of context sentences c_j recognized by retrieval using both $X^{1,2}$ and $Y^{1,2}$, which is the reference translation of $X^{1,2}$, among all selected contexts retrieved from $Y^{1,2}$.[11]

MergedTED We artificially construct shuffled documents $X^{1,2}$ and their translations $Y^{1,2}$ from the 12 EN–FR talks from IWSLT. We consider the first 30 sentences of each talk as a pseudo-document, and include all 66 possible pairs as (X^1, X^2).[12] We refer to the resulting corpus as MergedTED.

Results For question (a), Table 2 reports the extraction error rate for COS, PMI and BM25, derived from MergedTED. We observe that, with the exception of PMI, error rates are quite high: already for $K = 1$, about 12% (resp. 22%) of the sentences retrieved by COS (resp. BM25) do not belong to the same talk as the focus sentence. In comparison, PMI error rates increase more slowly with the value of K. Regarding (b), we note that the error rates computed in the target language (FR) are only slightly higher than in the source (EN). Table 3 reports the cover rates of contextual segments selected in $X^{1,2}$ and in $Y^{1,2}$. Using the source document, the context criteria identify around half of the relevant contexts determined with the reference target document. Regarding the ranking of potential contexts, Kendall's τ between the relevance scores derived from the source and the reference are 0.55, 0.45 and 0.55 for COS, PMI and BM25 respectively. These results provide an empirical support of our main hypotheses, in particular they confirm that we can effectively perform context selection by only looking at the source side of the input documents, yet identify relevant dependencies on the target side.

[11] For the cover rate, we only count segments appearing in the same document as $\mathbf{x}_{2n}$.

[12] We consider 10 different shuffled versions for each pair (X^1, X^2), then report the average r and Kendall's τ.

6 Results and Analyses

6.1 MT quality with SELF-RAMT

The Impact of K To determine the optimal value for K and the best relevance criteria, we examined the BLEU and s-COMET scores for K from 0 (i.e. Zero-shot) to 6, with pairs of source and reference as contexts. Figure 2 displays representative results with the EN–FR translation of IWSLT using EuroLLM, where the context-augmented translations perform better than Random-K and Indep-K. Furthermore, compared to s-COMET, BLEU scores distinguish better translations using selected contexts from Past-K, indicating that these contexts lead to greater lexical similarity between the translations and the references. For a trade-off between quality and complexity, we take $K = 3$ for the following experiments and analysis.

Comparing Relevance Scores We perform context-aware evaluations on IWSLT, reported in Table 4. The results show that all reference-based metrics, including BLEU, s-COMET, and d-COMET, classify PMI as the best or the second-best relevance score for all models and translation directions. In contrast, SLIDE scores are less conclusive, ranking PMI as the top-2 best systems 7 out of 9 times. This suggests that PMI performs better than COS and BM25. LTCR only prefers PMI for EN–FR, while for EN–DE and EN–ZH, baseline methods give higher scores. This highlights a small issue with this metric, when we use the oracle reference as context. Assume that the MT engine translates the first instance of a term x as y_1, different from the reference version (y_2); then, for all the subsequent instances of the same term, we may retrieve the translation of the first instance (y_2), making the system more inclined to generate the same translation (y_2), which is what we want. This will introduce a discrepancy between the first instance (y_1) and the remaining ones, which will be penalized by LTCR. By comparison, the baseline system may appear more consistent.

Table 6: Results for IWSLT (source and MT as contexts) using EuroLLM. * indicates significant gains as in Table 4.

Note that this problem does not arise when we retrieve automatic translations, where we see the benefits of SELF-RAMT more clearly.

The evaluation results for MERSENNE and IWSLT translated with reference and automatic translations as context (using EuroLLM) are given in Tables 5 and 6. These results lead to the same conclusion that PMI is a good criterion for retrieving relevant past segments. As the LTCR scores rank the context selection methods differently across test sets, we conduct a follow-up case study presented in Section 6.3, which better highlights the contribution of selected contexts to term consistency. The complete scores for all MT systems are in Tables 11 and 12 in Appendix C.

6.2 Analysis of Context Contribution

Distance Contexts are Retrieved Contextual information plays a crucial role in DLMT. To analyze the contribution of relevant contexts (especially distant ones) to the translation quality, we bin sentences according to the distance (in number of sentences) to their most distant selected context. For example, all selected contexts of sentences in the group 0–20 are retrieved from the past 20 sentences, while there are contexts more distant than 64 sentences for members of the group 64–256.

We then measure the ratio between the effective number of contexts occurring within a given interval (e.g., $20 - 40$) and the maximal possible number of contexts in that interval.[13] This analysis

[13]Which depends on the sentence position in a document: sentences in the initial paragraphs only have access to a re-

Range	rand. nb	rand. ratio	COS nb	COS ratio	PMI nb	PMI ratio	BM25 nb	BM25 ratio

64-128	995
128-320	570

Table 8: Retrieval statistics with respect to the distance between the translated sentence and selected contexts, for sentences appearing after the 20^{th} sentence. Selection is performed with PMI and $K = 3$, for IWSLT (left) and MERSENNE (right).

is performed for the TED talks test set (IWSLT), for $K = 3$. We exclude from the analysis the first 40 sentences in each document, as the context they can access is limited. The corresponding statistics are in Table 7.

We observe that about half of the retrieved contexts are in the past 20 sentences, while a sizable portion of contexts are chosen in more distant part of the document (in the $20 - 80$ range); more remote sentences, with a distance larger than 80 are also frequently selected. There is a clear variance between relevance scores: COS retrieves closer segments on average, whereas PMI and BM25 are more likely to extract more remote sentences.

Distant Contexts Matter For each group of sentences, we now compare the translations generated with PMI and with the baseline methods. Table 8 reports the corresponding retrieval statistics for these experiments, where we again group sentences by their position index in the source text.

Translation scores are in Table 9, where we compute the d-COMET difference between baselines and PMI-based retrieval. The upper part of Table 9 shows that, for translations of IWSLT with

stricted contexts, while sentences occurring in the last position have a much larger set of contextual segments to chose from.

SRC	The hemihedria is, moreover, non-superposable.
REF	L'hémiédrie est, en outre, non superposable.
0-shot	La hemihedrie est, en outre, non superposable.
Past	De plus, l'hémimorphie n'est pas superposable.
PMI	De plus, l'hémiédrie n'est pas superposable.

Figure 3: Translations of the 72^{nd} sentence of a MERSENNE article, using EUROLLM with MT as target-side context. The correct translations of "hemihedria" are underlined.

SRC: And he found a match.
REF: 结果找到了一个配对！ *(a match)*
0-shot: 他找到了合适的人。*(an appropriate person)*
Past: 他找到了匹配的物品。*(a matched object)*
PMI: 他找到了匹配的物种。*(a matched species)*

The contexts of PMI:
English: It turns out that different species have slightly different structures of collagen, so if you get a collagen profile of an unknown bone, you can compare it to those of known species, and, who knows, maybe you get a match.
Chinese: 事实证明，不同物种的胶原蛋白结构略有不同，因此如果你得到一块未知骨头的胶原蛋白谱，你可以将其与已知物种的胶原蛋白谱进行比较，谁知道，也许能找到匹配。
English: So she shipped him one of the fragments, FedEx.
Chinese: 于是她通过联邦快递把其中一块碎片寄给了他。
English: LN: And he processed it, and compared it to 37 known and modern-day mammal species.
Chinese: LN: 他对它进行了处理，并将其与 37 种已知和现代哺乳动物进行了比较。

Figure 4: EN–ZH translations of the 45^{th} sentence from an IWSLT talk, using EUROLLM with MT as target-side context. PMI retrieves relevant contexts for "a match" that corresponds to a specie (see Figure 7 in Appendix C for more details.)

source and reference as contexts, integrating remote contexts selected by PMI leads to better translation quality than Zero-shot, Random and Past. The bottom part reports the results for translations with source and automatic translations as contexts. In this setting, translation using EUROLLM with PMI is still better than Zero-shot, Random and Past, with lesser performance gains. In contrast, for QWEN, PMI appears to do less well than Past. The performance of LLAMA depends on the language pair, PMI being best only for EN–ZH translations.

We report a similar analysis in Table 10 for MERSENNE corpus. The results show that PMI outperforms Zero-shot and Random for all models using reference or automatic translations as target side context. In all cases except four, PMI is better than Past in d-COMET, especially for QWEN.

6.3 A Case study: Lexical Consistency

We illustrate the benefits of retrieving relevant contexts for the adequate translation in context-dependent cases. A first example is in Figure 4: to translate *a match*, which corresponds here to a

Table 10: Average differences between the d-COMET of translations using PMI and three baselines. From top to bottom these are: zero-shot (sent), random (rand), past (past). We only consider all sentences occurring past the 20^{th} sentence in MERSENNE articles, and take into account the maximum distance between the selected contexts and the current sentence. * marks significant difference with p-value < 0.05.

matched species, PMI retrieves the relevant contexts and generates the correct translation, while Zero-shot translates it as "an appropriate person" and Past considers it as a matched object. Complementary details and another Chinese example are presented in Appendix C.

Distant contexts are necessary to ensure lexical consistency, especially when translating full articles, and we do observe some evidence for improved translation consistency. For example, in one particular MERSENNE article, the term *hemihedria* appears 12 times,[14] with a consistent French reference translation *hémiédrie*. Table 3 shows the translation of the 72^{nd} sentence using EUROLLM taking source and MT as context.

PMI achieves consistent translation for this term, while Past fails due to the absence of remote contexts, resulting in 11 translation errors with 4 variants. Zero-shot translates them into 6 different forms with only one correct translation, despite its high LTCR score.

Figure 8 and Figure 9 in Appendix C provide the contexts selected using PMI for the 72^{nd} and the 159^{th} sentences respectively, including the sentences in lines 51 and 58 that contain the term *hemihedria*.

7 Conclusion

To achieve better document-level machine translation for extra long documents, we propose the SELF-RAMT framework. By retrieving relevant sentences in a local translation memory composed

[14] Lines 26, 39, 51, 53, 56, 58, 72, 78, 89, 122, 159, 160.

of sentences that have already been translated, and possibly post-edited, in the same document, we expect to generate translations that are globally more consistent. We carry out experiments to translate full TED talks and a novel parallel corpus consisting of scientific articles, using three LLMs with in context learning, to integrate the retrieved past contexts.

We further analyze the influence of distant contexts on translation quality, according to their distance from the current sentence. Our findings show that incorporating distant contexts, selected using context criteria such as PMI, can be useful for better lexical consistency. Distant context also seem to improve the general translation quality, as measured by reference-based scores.

Limitations

In this work, we only considered three open-weight models, excluding close-source models such as GPT4 (OpenAI et al., 2023) the use of which makes results difficult, if possible at all, to reproduce for scientific purposes. The translation of low-resource languages is not included in our experiments, although our framework could be beneficial in that scenario. In our experimental settings, we process each document sentence per sentence, defining the translation unit and the contextually relevant sentences based on this predefined segmentation. Segmenting and processing input documents in larger chunks, made of several consecutive sentences, is left for future work. Our evaluation was based mainly on derivatives of BLEU and COMET metrics, with a variant of LTCR and some case studies. While we reckon that some better metrics should be applied to better reflect document translation quality, measuring for example, the consistency and coherence of the translated text, we also can only regret that such standard evaluation metrics have not yet developed nor adopted by the community.

Ethics Statement

This work has conducted experiments and analysis using open source models, tools, and corpus. We see no ethical problem with this study.

Acknowledgments

This work was supported by the French national agency (ANR) as part of the MaTOS project under reference ANR-22-CE23-0033.[15] Rachel Bawden was also partly funded by her chair position in the PRAIRIE institute funded by ANR as part of the "Investissements d'avenir" programme under reference ANR19-P3IA-0001. The authors wish to thank Célia Vaudaine and Caroline Rossi for giving access to the MERSENNE corpus. The authors are also grateful to the anonymous reviewers for their insightful comments and suggestions, and to Paul Lerner and Lichao Zhu for their review and feedback on a preliminary draft of this work.

A Mersenne

Due to the scarcity of complete parallel scholarly documents, we constructed MERSENNE, which consists of 23 articles in English and their translation into French prepared by the Mersenne Center.[16] Nineteen of them report recent research in the geosciences domain and the remaining four belong to the chemical sciences. The translations are human post-edits of an initial machine-translated version.

For each article, we first convert the curated html page to plain texts using `pandoc`.[17] Extra empty lines and the symbol xa0 are removed before normalizing the texts to the NFC[18] format through `unicodedata`.[19] We then extract the article from the processed plain text, excluding equations and tables, which are reserved for future exploitation. We segment the texts into sentences and align the sentences to parallel articles. For sentence segmentation, we use Trankit (Nguyen et al., 2021) as it recognizes lists of citations well. Our alignment tool is derived from BertAlign (Liu and Zhu, 2022), which supports many-to-many alignments. All the alignments matched with an empty string were checked and manually adjusted whenever needed.

[16] https://www.centre-mersenne.org/

[17] https://pandoc.org/

[18] Normalization Form Canonical Composition.

[19] https://docs.python.org/3/library/unicodedata.html

We subsequently evaluated the aligned sentence pairs using TransQuest (Ranasinghe et al., 2020). All alignment scores were above 0.75, suggesting that sentence alignment is mostly correct and that all aligned sentences can be kept. Statistics regarding the MERSENNE parallel articles can be found in Table 1.

B Experimental Details

This section presents details about the inference settings, the computation of relevance scores, and the prompt patterns for ICL.

B.1 Inference

In our experiments, we obtain automatic translations through ICL using vLLM (Kwon et al., 2023) in bfloat16. We set the beam width to 5 and the temperature to 0. The minimum and maximum number of new tokens are 1 and 256 respectively.

For the decoding process, we propose a multi-turn decoding algorithm to access the incrementally generated target-side contexts. This involves translating the i^{th} sentences of all documents from the same batch in parallel, and updating the pre-selected contexts for the $(i+1)^{th}$ sentences with the generated translations. When contexts comprise source texts and reference translations of past sentences, we integrate them in the LLM prompts and decode them all at once.

Regarding context selection, we compute PMI scores for source texts using LLAMA, performing compuations in bfloat32 for IWSLT and in bfloat16 for MERSENNE and MERGEDTED.

B.2 Implementation of BM25L

In practice, given a document X, we preprocess each sentence,[20] then compute the term frequency and the inverse document frequency (IDF) for each term in the whole document. We also precomputed an IDF for terms from the training split of IWSLT-2016 (Cettolo et al., 2012)[21] for the EN–FR language pair. Therefore, the IDF of a term in X is replaced by the precomputed values if available.

B.3 Prompt Patterns

We integrate the bilingual context for DLMT in a few-shot template for ICL. As all our MT engines are instruction-tuned, we use the chat template. Regarding prompt design, we empirically tested the performance of the Past-K baseline using different prompt patterns on the IWSLT TST2010 and TST2011 test sets, for $K \in \{2, 6\}$. After disregarding some patterns that lead to over-generation, we selected the prompt templates in Figure 6, where we integrate the few-shot contexts into system prompts for EUROLLM and LLAMA, and into user prompts for QWEN.

For each sentence, we apply the prompt pattern without context to perform zero-shot translation. For the Indep-K baseline, we maintain K-shot demonstrations for all sentences. In practice, we generate 6 examples in the style of TED talks using LLAMA,[22] then integrate the first K examples as K-shot demonstrations.

C Complementary Evaluation Results

Translation Quality Based on the complete evaluation scores for IWSLT with source and automatic translations as contexts (see Table 11), and MERSENNE (see Table 12), we can confirm that in general PMI performs better than COS and BM25, as discussed in Section 6.1. On the other hand, we also observed that the performance of LLAMA is worse than EUROLLM. This quality degradation has a strong influence on DLMT using multi-turn decoding.

Case Study In this section, we provide additional examples that illustrate the need to integrate remote contexts for term consistency when translating long documents, and relevance criteria such as PMI can identify such contexts. This analysis is complementary to the one in Section 6.3. For example, a consistent translation of the term *hemihedria* in the 159^{th} sentence of a MERSENNE article requires contexts more distant than the past 30 sentences, and contexts with the K highest PMI scores include these relevant but remote sentences (see Figure 9). Figure 5 displays another example that contextual information from the past 10^{th} sentence is required for the consistent translation of "the High Arctic".

Figure 7 gives complementary information for the example in Figure 4, including the two successive sentences of the source sentence to be trans-

[20] The preprocessing consists of lowercasing, stop-word removal and stemming using PyStemmer: https://pypi.org/project/PyStemmer/.

[21] https://wit3.fbk.eu/2016-01

[22] We use the following chat template integrated in the system prompt "You are a good translation assistant!" and the user prompt "Give six few-shot examples to assist the translation from English to {tgt_lang} in the style of TED talks."

Using Encipherment to Isolate Conditions for the Successful Fine-tuning of Massively Multilingual Translation Models

Carter Louchheim, Denis Sotnichenko, Yukina Yamaguchi and Mark Hopkins
Williams College
Williamstown, MA

Abstract

When fine-tuning massively multilingual translation models for low-resource languages, practitioners often include auxiliary languages to improve performance, but factors determining successful auxiliary language selection remain unclear. This paper investigates whether syntactic similarity or lexical overlap is more important for effective multilingual fine-tuning. We use encipherment to create controlled experimental conditions that disentangle these confounded factors, generating novel languages with identical syntax but no lexical overlap, and conversely, languages that preserve lexical overlap. Through extensive NLLB-200 fine-tuning experiments across Europarl and AmericasNLP datasets, we demonstrate that lexical overlap is the dominant factor. Syntactically identical auxiliary languages provide negligible benefits (< 1.0 ChrF), while languages with significant lexical overlap provide substantial improvements (> 5.0 ChrF), with effectiveness strongly correlated to KL-divergence between token distributions ($r = -0.47$, $p < .001$). Our findings provide clear guidance: when selecting auxiliary languages for multilingual fine-tuning, prioritize lexical overlap over syntactic similarity.

1 Introduction

A popular modern approach to low-resource machine translation is the fine-tuning of massively multilingual encoder-decoder transformers (Vaswani et al., 2017). For example, the top two entrants in the AmericasNLP 2023[1] Shared Task on Machine Translation into Indigenous Languages (which solicits systems that translate Spanish into Indigenous American languages) both used this technique (Ebrahimi et al., 2023). The teams from the University of Sheffield (Gow-Smith and Sánchez Villegas, 2023) and the University of Helsinki (De Gibert et al., 2023) fine-tuned distillations of Meta's NLLB-200 model (Costa-Jussà et al., 2022) simultaneously on all eleven language pairs of the shared task.

Simultaneous training on a set of related language pairs (as opposed to training a separate system per language pair) has frequently been reported to yield performance benefits (Aharoni et al., 2019; Maillard et al., 2023). One survey (Ranathunga et al., 2023) on low-resource machine translation claims: "This is mainly due to the capability of the model to learn an interlingua (shared semantic representation between languages)". But when the parent model (as in the case of NLLB-200) has already been pre-trained on 200 language pairs, when (and why) does it remain beneficial to simultaneously fine-tune on multiple language pairs? What do the fine-tuning languages learn from each other?

In the context of multilingual language modeling, investigators have focused on two candidates: syntax and lexicon. According to a recent review (Philippy et al., 2023): "In previous research, syntax has been suggested as potentially the most important linguistic contributor for better cross-lingual transfer."[2] The same article also reports that "lexical overlap is particularly important when the pre-training corpus for the source language is small or when the word order between the source and target languages is dissimilar," but concludes that "lexical overlap is not a sufficient standalone factor to explain cross-lingual transfer."

An obstacle to drawing definitive conclusions is the difficulty of isolating the confounding factors of shared syntax and lexicon – related languages typically share both. In this work, we use **encipherment** to disentangle these factors. Encipher-

[1] These two systems were the baselines for the 2024 edition of the shared task, and continued to be the top systems for most language pairs. The Sheffield system was used as the baseline for the 2025 shared task, and maintained its superiority.

[2] The review, however, hypothesizes that the impact of syntax "may be overestimated" due to shortcomings in the research methods.

Proceedings of the Tenth Conference on Machine Translation, pages 241–252
November 8-9, 2025

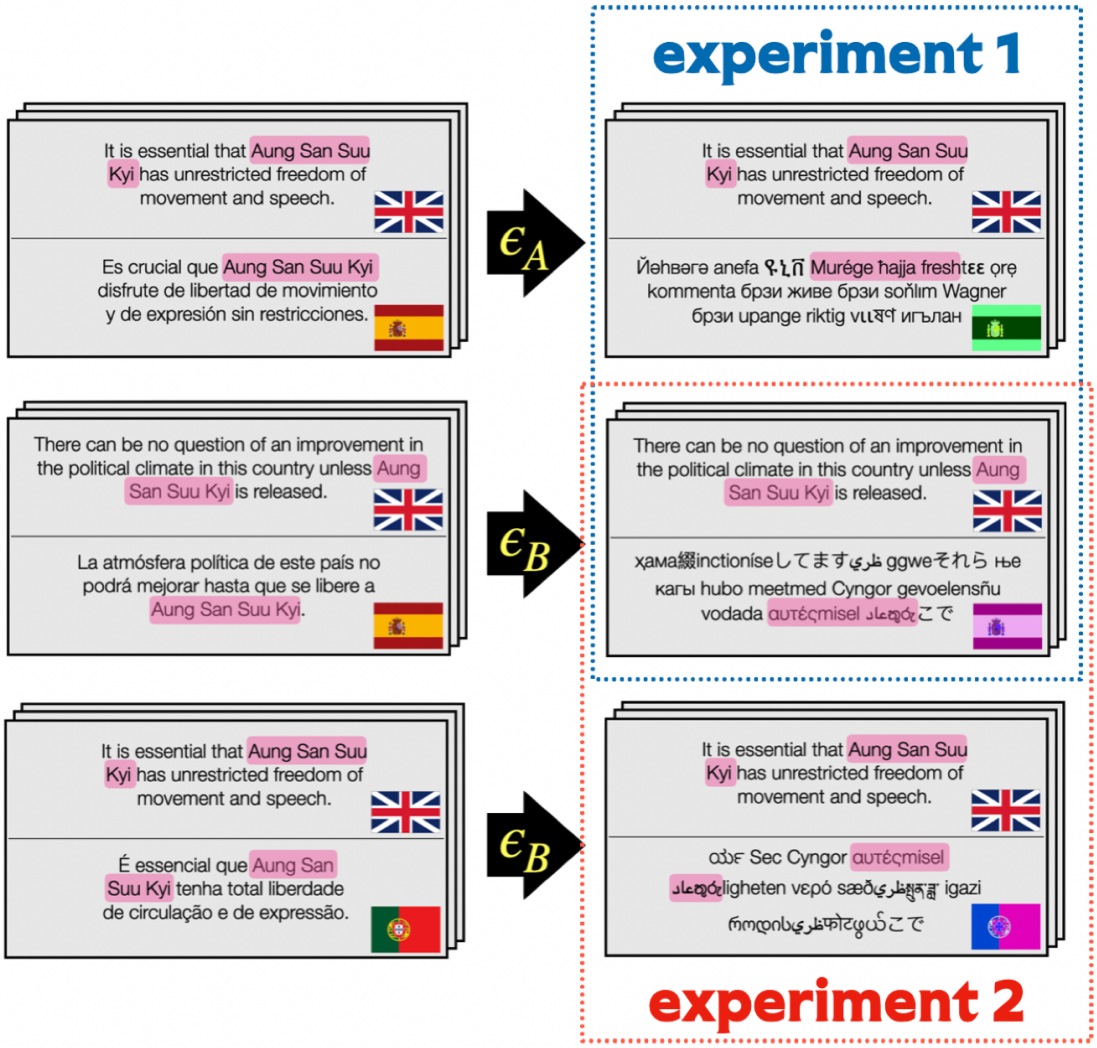

Figure 1: We use encipherment to create statistically realistic languages that are unseen by pre-trained translation models, affording experimental control over the often-confounded factors of syntactic and lexical overlap. For the top two rows, we apply different encipherments to disjoint subsets of English-Spanish Europarl, creating two novel languages with identical syntax but no lexical overlap. For the bottom two rows, we apply the same encipherment to disjoint subsets of English-Spanish and English-Portuguese Europarl, creating two novel languages that preserve the lexical overlap between Spanish and Portuguese.

ment allows us to generate statistically realistic languages that have not been previously included in translation model pre-training, while also providing experimental control:

1. We can produce syntactically identical languages with no lexical overlap. Figure 1 (top two rows) shows an example where two English-Spanish corpora are enciphered using different encipherments (ϵ_A and ϵ_B), producing two languages that are syntactically identical but lexically distinct.

2. We can produce novel languages that preserve cross-lingual lexical overlap. Figure 1 (bottom two rows) also shows an example where an English-Spanish corpus and an English-Portuguese corpus are enciphered using the same encipherment (ϵ_B), producing two languages that preserve the lexical overlap between Spanish and Portuguese.

The goal of this paper is to provide practical guidance to those seeking to build translation engines for low-resource languages. Specifically, when fine-tuning a massively multilingual translation model like NLLB-200, how should one select auxiliary languages to include in the fine-tuning (or should one include them at all)? We ultimately arrive at the following recommendations:

- **Recommendation 1:** Lexical overlap is the

most important factor to consider. If there is a low relative entropy (KL-divergence) between the token distribution of two source or target languages, then you can get considerable performance benefits from multilingual fine-tuning.

- **Recommendation 2:** Even if you can find an auxiliary language with extreme grammatical similarity to your low-resource language of interest, the performance benefits of multilingual fine-tuning (attributable to common syntax) are liable to be negligible.

Bottom line: When choosing auxiliary languages for the multilingual fine-tuning of massively multilingual translation models, focus on languages with high lexical overlap with your low-resource language of interest.

2 Related Work

Neural Machine Translation

Zoph et al. (2016) approached low-resource neural machine translation by leveraging a "parent" model (pre-trained on a high-resource language pair) to train a "child" model (for a low-resource language pair). Nguyen and Chiang (2017) and Kocmi and Bojar (2018) streamlined this process so that it could be succinctly described as follows (Kocmi and Bojar, 2018): "We train the parent language pair for a number of iterations and switch the training corpus to the child language pair for the rest of the training, without resetting any of the training (hyper)parameters."

Ensuing work studied conditions resulting in successful transfer from a parent to a child model. Among this work, Dabre et al. (2017) explored several parent-child combinations and reported that "transfer learning done on a X-Y language pair to [a] Z-Y language pair has maximum impact when Z-Y is resource-scarce and when X and Z fall in the same or linguistically similar language family." Lin et al. (2019) trained gradient-boosted decision tree models to predict synergistic parent/child language pairs, and observed that dataset size and word overlap were the most common splitting features. Aji et al. (2020) determined that the "inner" transformer layers were more crucial to transfer than the embedding layer, and noted that even using a simple copy model as the parent had performance benefits over training from scratch. This earlier work focused on parent models that were trained on a single language pair.

Over the past few years, the trend has been to pre-train massively multilingual translation models (Aharoni et al., 2019; Costa-Jussà et al., 2022) by simultaneously training on many language pairs. Focusing on the pragmatics of this training paradigm, Shaham et al. (2023) studied "interference," i.e. when multilingual pre-training underperforms bilingual pre-training. They concluded that the main cause of interference is when the model size is too small relative to the available training data. Tan and Monz (2023) used a linear regression model to determine factors that predict the zero-shot X→Y translation performance (where neither X nor Y is English) of multilingual models trained exclusively on English-centered language pairs. Our focus is on fine-tuning massively multilingual parent models for a low-resource language pair, specifically the factors that promote synergistic multilingual fine-tuning. We also believe we are the first work in this space to use encipherment as an instrument to de-confound the factors of syntactic similarity and lexical overlap.

Multilingual Language Modeling

It was quickly observed (Lin et al., 2019; Pires et al., 2019) that pre-trained multilingual encoder-only language models like mBERT (Devlin et al., 2019) could be fine-tuned on certain tasks (like named entity recognition or textual entailment) using monolingual supervision (typically English supervision), and only suffer minor performance degradation when applied zero-shot to other languages from the pre-training corpus. Several papers have studied this phenomenon (Dufter and Schütze, 2020; K et al., 2020; Lauscher et al., 2020; Ahuja et al., 2022; Deshpande et al., 2022; de Vries et al., 2022; Wu et al., 2023) – enough to have merited a survey paper (Philippy et al., 2023). Among these papers, K et al. (2020) used the most similar methodology to ours. To determine the impact of lexical overlap on cross-lingual transfer, they pre-trained two versions of BERT: one on English and Hindi[3] and another on "fake English" and Hindi, where "fake English" was derived from English by shifting the Unicode encoding of each character by a fixed constant. They concluded that lexical overlap plays only a minor role in cross-lingual transfer for textual entailment and named entity

[3]They also conducted this experiment with Russian instead of Hindi.

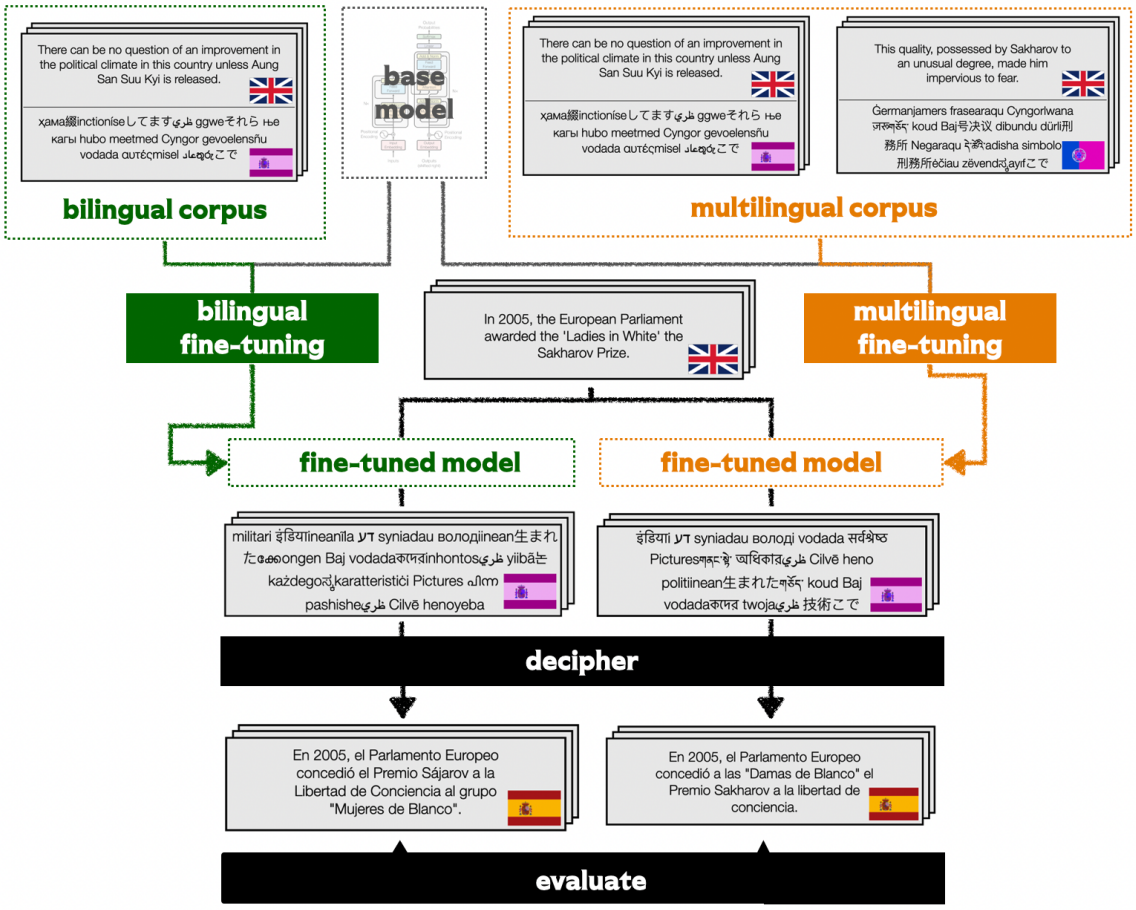

Figure 2: Overview of an experiment trial: a base model is fine-tuned using one or more enciphered bitexts. The resulting model is evaluated by translating held-out test sets, then deciphering and scoring the translations.

recognition. Also relevant to our approach is the work of Wu et al. (2023), who used "controlled studies" to investigate the factors contributing to the success of cross-lingual transfer learning – for instance, they perform artificial syntactic manipulations before fine-tuning on the GLUE dataset (Wang et al., 2018).

3 Preliminaries

This paper uses the following formalisms to describe enciphered parallel corpora.

Let $\mathcal{T}$ and $\mathcal{L}$ be finite alphabets that respectively correspond to a token vocabulary[4] and a set of language ids (e.g. `eng_Latn`, `rus_Cyrl`, etc.). Let $\mathcal{T}^*$ be the set of all sequences of tokens from $\mathcal{T}$.

Define a *parallel corpus* as a function $\pi : D \mapsto \mathcal{T}^*$, where $D \subset \mathcal{L} \times \mathbb{Z}^+$ and $\forall (l_1, i), (l_2, i) \in D$, $\pi(l_1, i)$ and $\pi(l_2, i)$ have the same meaning (i.e. they are translations of one another).

Define an *encipherment* ϵ as a permutation[5] of token vocabulary $\mathcal{T}$, i.e. a bijection $\epsilon : \mathcal{T} \mapsto \mathcal{T}$. For a token sequence $\pi(l, i) = \langle t_1, ..., t_k \rangle$ from parallel corpus π, denote the ϵ-enciphered sequence as $\pi_\epsilon(l, i) = \langle \epsilon(t_1), ..., \epsilon(t_k) \rangle$.

We extract a *bitext* from parallel corpus π using the following notation:

$$\hat{\pi}(l, l', \epsilon, \epsilon', I) = \{(\pi_\epsilon(l, i), \pi_{\epsilon'}(l', i) \mid i \in I\}$$

where $l, l' \in \mathcal{L}$ are language ids, ϵ, ϵ' are encipherments, and $I \subset \mathbb{Z}^+$ is a finite set of indices.

4 Experiment Design

Figure 2 provides an overview of our experiment design. Each experiment involves K bitexts ex-

[4]Throughout this paper, we assume a fixed token vocabulary. Namely, the token vocabulary we use in all our experiments is the NLLB-200 (Costa-Jussà et al., 2022) token vocabulary.

[5]One might worry that a translation model could simply learn to invert the permutation, but previous experimental work (Aji et al., 2020) suggests "that the [transformer] model is incapable of untangling [an] embedding permutation."

tracted from parallel corpus π:

$$\hat{\pi}(l_1, l'_1, \epsilon_1, \epsilon'_1, I_1)$$
$$\hat{\pi}(l_2, l'_2, \epsilon_2, \epsilon'_2, I_2)$$
$$\vdots$$
$$\hat{\pi}(l_K, l'_K, \epsilon_K, \epsilon'_K, I_K)$$

The index sets $I_1, \ldots, I_K$ are pairwise disjoint.

We use these bitexts to train several translation models:

- **bilingual fine-tuning**: For each bitext $\hat{\pi}(l_k, l'_k, \epsilon_k, \epsilon'_k, I_k)$, we fine-tune model M_k from pre-trained model M_{base}.
- **multilingual fine-tuning**: We use the entire collection of bitexts to simultaneously fine-tune a single model M_{multi} from pre-trained model M_{base}. During training, we sample evenly from the bitexts.

We fine-tune each model using a batch size of 64 for a maximum of 60,000 training steps. Validation is performed every 500 steps, and training is terminated early if the validation loss does not decrease for five consecutive evaluations. We use the Adafactor optimizer (Shazeer and Stern, 2018), as implemented in the Transformers library (Wolf et al., 2020), with a fixed learning rate of 1×10^{-4}, disabling both parameter scaling and relative step sizing. Gradient clipping is applied with a threshold of 1.0, and a weight decay of 1×10^{-3} is used for regularization. We adopt a constant learning rate schedule with warm-up, increasing the learning rate linearly over the first 1,000 steps.

We evaluate the resulting models by translating held-out test sets, then deciphering the translations and scoring them using standard machine translation metrics (e.g. BLEU (Papineni et al., 2002) and ChrF (Popović, 2015)). Because one of the languages in our experiments is polysynthetic, we report results using ChrF, but the choice of metric does not affect the experimental conclusions. We run 5 trials for each of the following training bitext sizes: 1024, 2048, 4096, 8192, and 16392 (so 25 trials in total). A bilingual fine-tuning trial consists of a fine-tuning for each bitext – the resulting systems are then evaluated and their scores are averaged. A multilingual fine-tuning trial is a single fine-tuning over all bitexts – the resulting system is then evaluated on each language pair, and these scores are averaged.

5 Base Models

We focus on fine-tuning NLLB-200 models (Costa-Jussà et al., 2022). These models were trained on a large-scale multilingual corpus covering 200 languages, using a transformer-based encoder-decoder architecture, following the general design of the M2M-100 model (Fan et al., 2021). Several distillations of this model are provided, including a 600M parameter model (6 encoder/decoder layers, 768 hidden size, 12 attention heads) and a 1.3B parameter model (12 encoder/decoder layers, 1024 hidden size, 16 attention heads). To increase experimental throughput, our experiments focus on the 600M parameter model.

6 Datasets

This section describes the parallel corpora that we use in our experiments.

Europarl

The Europarl Parallel Corpus (Koehn, 2005) is a set of sentence-aligned proceedings from the European Parliament covering sessions from 1996 to 2011. It spans 21 European languages, with each language contributing approximately 60 million words across 30 million aligned sentence fragments. We preprocess the corpus to eliminate repeated sentences.

AmericasNLP

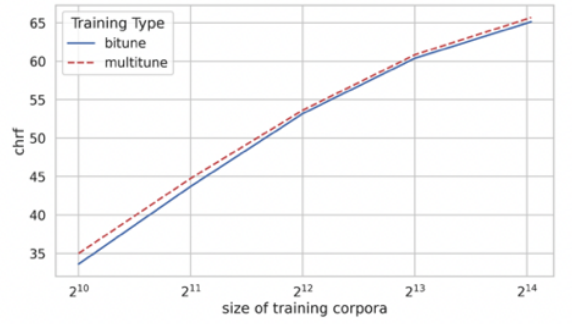
Referenced in the introduction, the AmericasNLP Workshop solicits systems that translate Spanish into Indigenous American languages. They provide official training corpora for these language pairs. In 2025, the workshop introduced Spanish → Wayuunaiki as a new language pair (Prieto et al., 2024). Wayuunaiki is "an Arawakan language spoken in northern Colombia and Venezuela, primarily by the Wayuu community, with about 420,000 speakers. It is an agglutinative language with a predominant SOV word order." (De Gibert et al., 2025)

7 Experiment 1: The Impact of Syntactic Similarity on the Success of Multilingual Fine-tuning

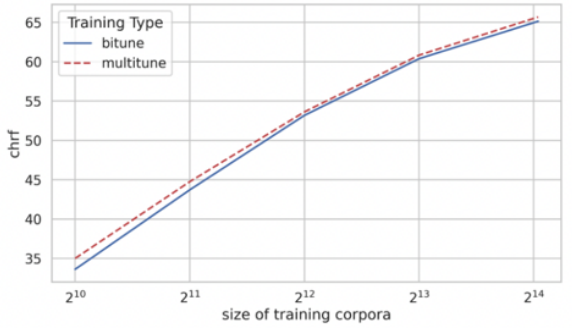
7.1 Syntactic Similarity of Target Languages

For our first set of experiments, we construct a scenario in which we have target languages with no lexical overlap but identical syntax (i.e. the top two rows of Figure 1). Specifically, we extract the

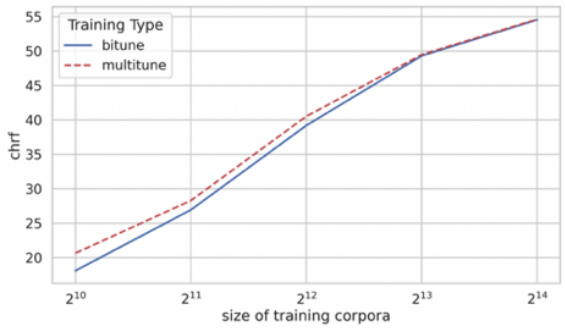
base model	corpus	source	target (enciphered)
nllb-200(600M)	europarl	english	spanish-ε1 spanish-ε2



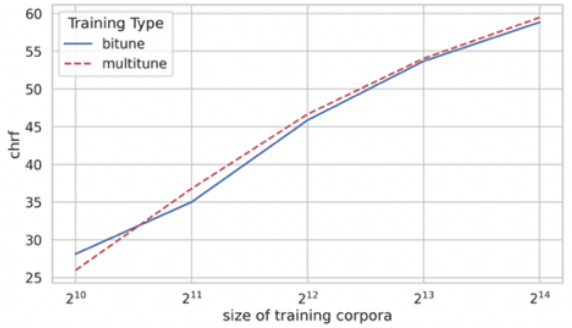
base model	corpus	source (enciphered)	target
nllb-200(600M)	europarl	spanish-ε1 spanish-ε2	english



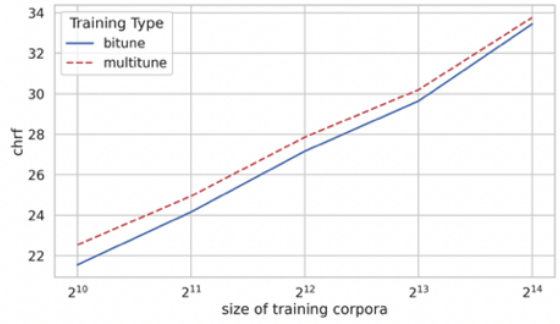
base model	corpus	source	target (enciphered)
nllb-200(600M)	europarl	english	czech-ε1 czech-ε2



base model	corpus	source (enciphered)	target
nllb-200(600M)	europarl	czech-ε1 czech-ε2	english



base model	corpus	source	target (enciphered)
nllb-200(600M)	anlp	spanish	wayuunaiki-ε1 wayuunaiki-ε2



base model	corpus	source (enciphered)	target
nllb-200(600M)	anlp	wayuunaiki-ε1 wayuunaiki-ε2	spanish

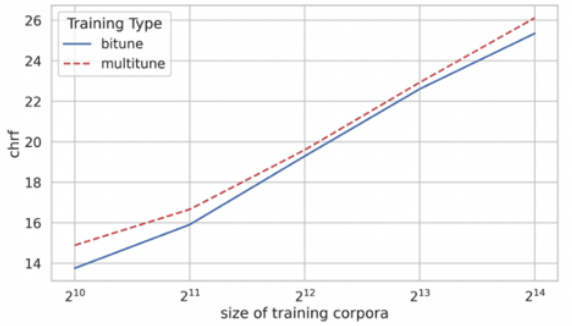


Figure 3: Experiment 1 results. Multilingual fine-tuning using two lexically distinct but syntactically identical languages provides only marginal improvement over bilingual fine-tuning of each language independently. While more pronounced for Wayuunaiki (whose unenciphered analogue is not part of the NLLB-200 pre-training corpus), the benefits are still minor (< 1.0 ChrF).

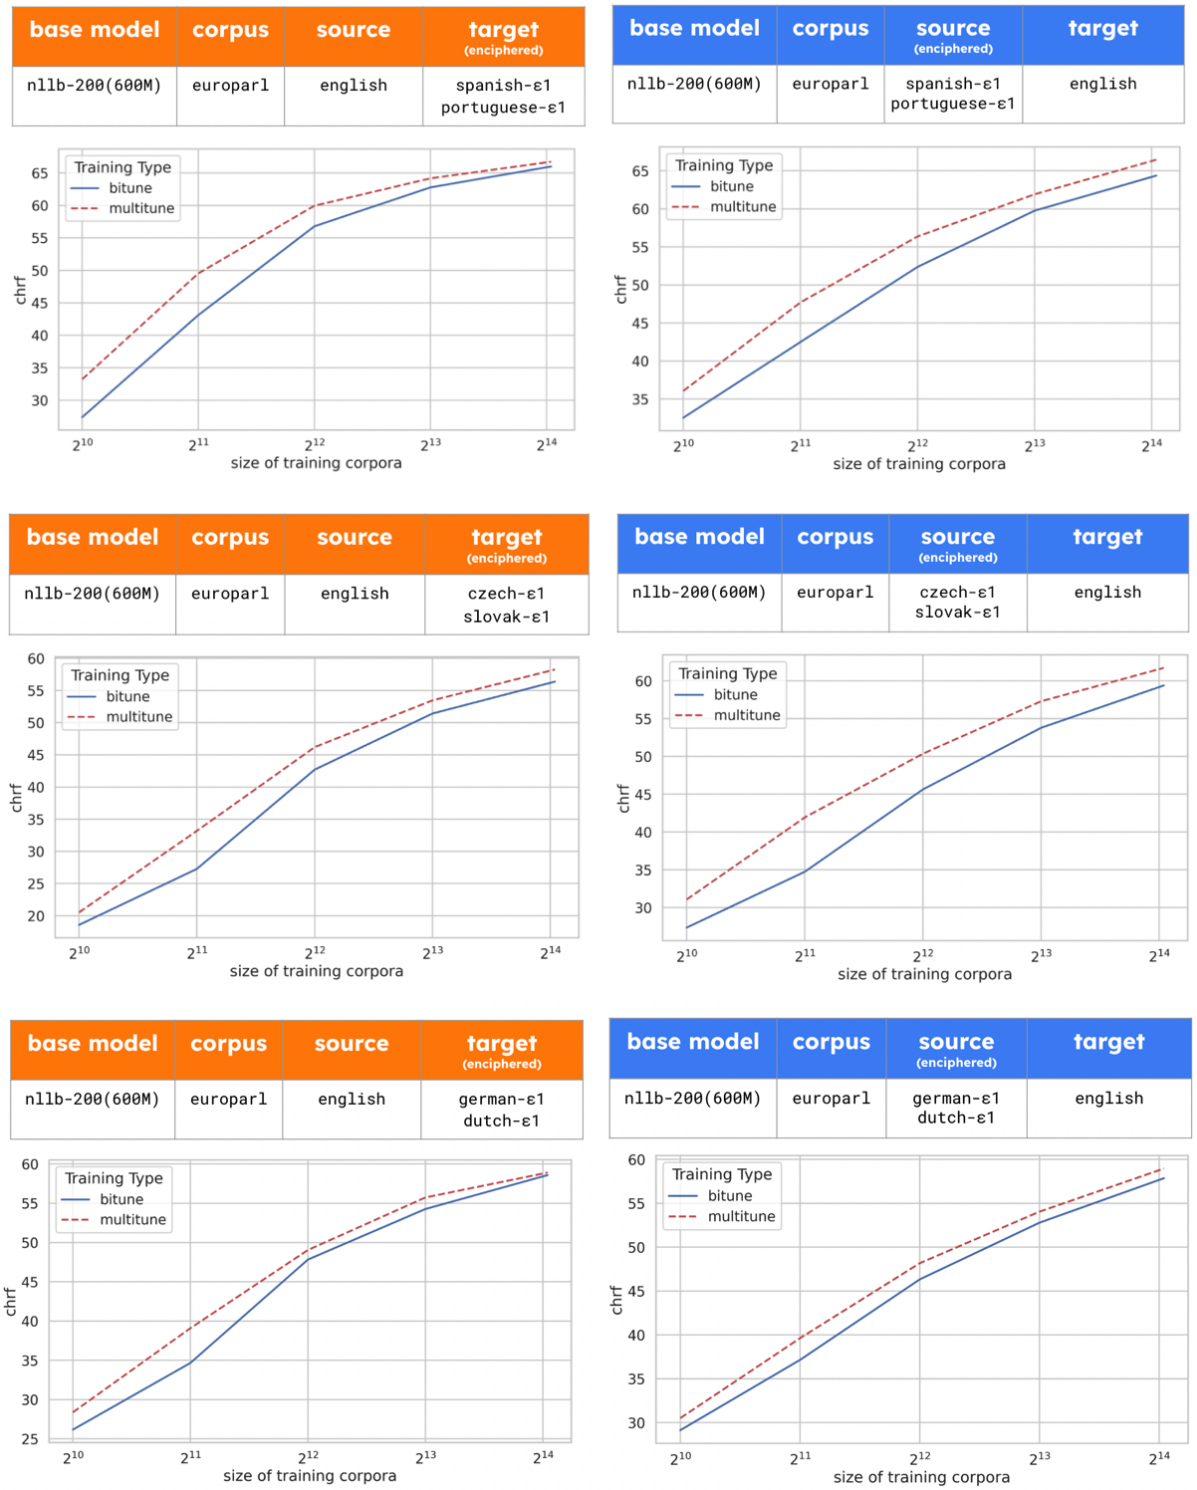

Figure 4: Experiment 2 results. Multilingual fine-tuning using two enciphered languages that preserve lexical overlap can provide significant improvement ($>$ 5.0 ChrF at certain data sizes) over bilingual fine-tuning of each language independently.

following k bitexts from parallel corpus π:

$$\hat{\pi}(l, l', \epsilon^0, \epsilon'_1, I_1)$$
$$\hat{\pi}(l, l', \epsilon^0, \epsilon'_2, I_2)$$
$$\vdots$$
$$\hat{\pi}(l, l', \epsilon^0, \epsilon'_k, I_k)$$

Here (and henceforth), ϵ^0 denotes the identity function (i.e. no encipherment occurs, since the encipherment maps each token to itself). Note that we have constructed k target languages with identical syntax but distinct lexicons. During fine-tuning, we freeze the encoder to eliminate the confounding impact of encoder domain adaptation to the source language.

7.2 Syntactic Similarity of Source Languages

Analogously, we construct a scenario in which we have **source** languages with no lexical overlap but identical syntax, i.e., we extract the following k bitexts from parallel corpus π:

$$\hat{\pi}(l, l', \epsilon_1, \epsilon^0, I_1)$$
$$\hat{\pi}(l, l', \epsilon_2, \epsilon^0, I_2)$$
$$\vdots$$
$$\hat{\pi}(l, l', \epsilon_k, \epsilon^0, I_k)$$

This time, we have constructed k source languages with identical syntax but distinct lexicons. During fine-tuning, we freeze the **decoder** to eliminate the confounding impact of decoder domain adaptation to the target language.

7.3 Results

We conducted these experiments using the following language pairs:

- Target Side Encryption: English $\rightarrow$ {Spanish, Czech, Wayuunaiki}
- Source Side Encryption: {Spanish, Czech, Wayuunaiki} $\rightarrow$ English

Figure 3 shows results from this set of experiments. Multilingual fine-tuning generally shows little advantage over bilingual fine-tuning, even though the two target languages are syntactically identical (they are both encipherments of the same language). Only in the case of Wayuunaiki, a language whose family (Arawak) was not represented in the original NLLB-200 training set, do we observe a small benefit from multilingual fine-tuning. This suggests that even in the best-case scenario – where we can find an auxiliary language with nearly identical syntax to our low-resource language of interest – the benefits of multilingual training (in the absence of lexical overlap) is minor.

Conclusion: Syntactic similarity of the source or target languages appears to have little impact on the effectiveness of multilingual fine-tuning.

8 Experiment 2: The Impact of Lexical Overlap on the Success of Multilingual Fine-tuning

8.1 Lexical Overlap of Target Languages

The only difference between this experiment and Experiment 1 is that we extract the following k bitexts from parallel corpus π:

$$\hat{\pi}(l, l'_1, \epsilon^0, \epsilon', I_1)$$
$$\hat{\pi}(l, l'_2, \epsilon^0, \epsilon', I_2)$$
$$\vdots$$
$$\hat{\pi}(l, l'_k, \epsilon^0, \epsilon', I_k)$$

We use different languages but the same encipherment, so that shared tokens remain shared after encipherment (see the bottom two rows of Figure 1). This produces unseen languages that have the same amount of lexical overlap as their unenciphered analogues. Again, we freeze the encoder during fine-tuning to eliminate the confounding impact of encoder domain adaptation to the source language.

8.2 Lexical Overlap of Source Languages

We also construct a scenario in which we have unseen **source** languages that have the same amount of lexical overlap as their unenciphered analogues, i.e., we extract the following k bitexts from parallel corpus π:

$$\hat{\pi}(l'_1, l, \epsilon', \epsilon^0, I_1)$$
$$\hat{\pi}(l'_2, l, \epsilon', \epsilon^0, I_2)$$
$$\vdots$$
$$\hat{\pi}(l'_k, l, \epsilon', \epsilon^0, I_k)$$

During fine-tuning, we freeze the **decoder** to eliminate the confounding impact of decoder domain adaptation to the target language.

8.3 Results

For these experiments, we used English as the unenciphered language l. As the enciphered

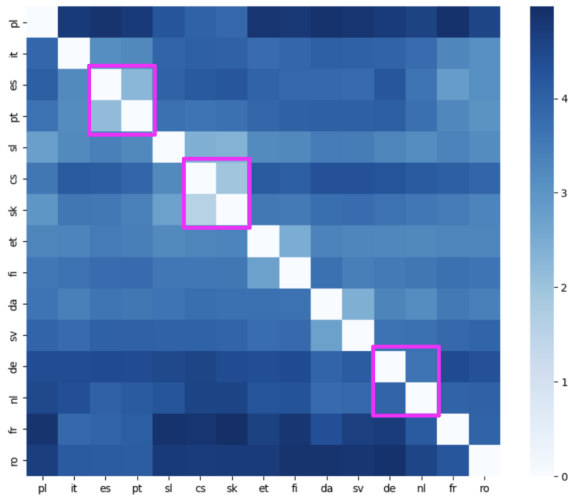

Figure 5: KL-divergence heatmap between Europarl languages. The heatmap shows the KL-divergence between token distributions for all pairs of Latin script languages in the Europarl corpus. Lighter colors indicate lower KL-divergence (greater lexical overlap). The magenta boxes highlight language pairs used in Experiment 2: Spanish-Portuguese (KL $\approx$ 2.26), Czech-Slovak (KL $\approx$ 1.96), and German-Dutch (KL $\approx$ 3.63). This visualization helps explain why Spanish-Portuguese and Czech-Slovak multilingual fine-tuning show greater benefits than German-Dutch, as their lower KL-divergence values indicate higher lexical overlap.

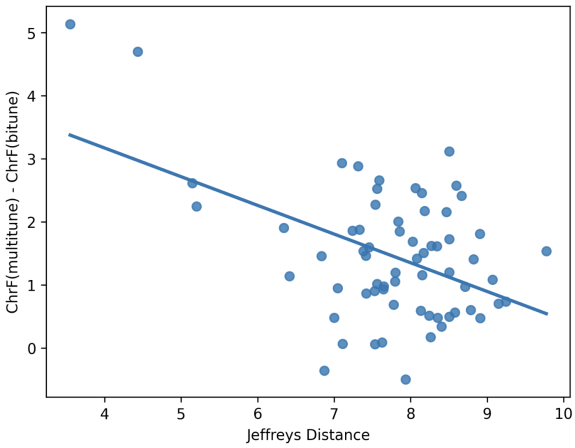

Figure 6: Relationship between lexical overlap and multilingual fine-tuning effectiveness. The scatter plot shows the ChrF improvement (multilingual minus bilingual fine-tuning) versus the Jeffreys distance between token distributions for all pairs of non-English Latin script languages in Europarl. Each point represents a single trial of Experiment 2 with bitext size 4096. The negative correlation (r = -0.47, p < .001) demonstrates that languages with greater lexical overlap (lower Jeffreys distance) benefit more from multilingual fine-tuning, supporting the conclusion that lexical overlap is the primary factor driving successful auxiliary language selection.

language combinations, we used three pairs of geographically-proximate European languages (which we assumed would have significant lexical overlap):

- l'_1 = Spanish and l'_2 = Portuguese
- l'_1 = Czech and l'_2 = Slovak
- l'_1 = German and l'_2 = Dutch

Figure 4 shows the results of these experiments. Under these conditions, multilingual fine-tuning substantially outperforms bilingual fine-tuning, often by more than five ChrF points. Given that Experiment 1 showed little benefit to incorporating syntactically similar languages during multilingual fine-tuning, it would appear that the observed benefits are mainly attributable to the lexical overlap.

However, the multilingual fine-tuning of English $\leftrightarrow$ German and English $\leftrightarrow$ Dutch is notably less effective than the others. To explain this difference, we computed the KL-divergence between the token distributions of all Europarl languages that use Latin script (see Figure 5). The KL-divergence from Spanish to Portuguese (approximately 2.26) and from Czech to Slovak (approximately 1.96) is considerably smaller than the KL-divergence from German to Dutch (approximately 3.63).

To assess the general impact of lexical overlap on the effectiveness of multilingual training, we conducted a single trial of Experiment 2 (using bitext size 4096) for every pair (l'_1, l'_2) of non-English Latin script languages in Europarl. Figure 6 plots the ChrF delta between multilingual and bilingual fine-tuning, versus the Jeffreys distance (additive symmetrization of KL-divergence) between languages l'_1 and l'_2. There is a moderate, statistically significant negative correlation ($r(63) = -0.47$, $p < .001$), suggesting that lexical overlap is a significant determining factor in the effectiveness of multilingual fine-tuning.

9 Conclusion

This work addresses a fundamental question in low-resource machine translation: when fine-tuning massively multilingual models like NLLB-200, which factors determine the success of multilingual fine-tuning with auxiliary languages? Through controlled experiments using encipherment to disen-

tangle syntactic similarity and lexical overlap, we provide empirical evidence that lexical overlap is the primary driver of performance improvements. Our key findings are:

- Syntactic similarity provides minimal benefit: Even when auxiliary languages share identical syntax with the target language, multilingual fine-tuning shows little advantage over bilingual approaches. The benefits are most pronounced (but still minor) only for languages from families not represented in the pre-training corpus.
- Lexical overlap drives substantial improvements: Languages that share vocabulary can provide significant performance gains (> 5.0 ChrF in many cases), with effectiveness inversely correlated to the KL-divergence between token distributions.

The encipherment methodology introduced here also provides an experimental framework for future research on cross-lingual transfer, allowing researchers to control for confounding factors that typically make it difficult to isolate the impact of different linguistic properties.

Future work should explore whether these findings generalize to other massively multilingual models, investigate optimal methods for measuring and maximizing lexical overlap, and examine whether the relative importance of syntax versus lexicon changes with different model architectures or pre-training objectives.

Abstract

Multilingual toxicity detection remains a significant challenge due to the scarcity of training data and resources for many languages. While prior work has leveraged the *translate-test* paradigm to support cross-lingual transfer across a range of classification tasks, the utility of translation in supporting toxicity detection at scale remains unclear. In this work, we conduct a comprehensive comparison of translation-based and language-specific/multilingual classification pipelines. We find that translation-based pipelines consistently outperform out-of-distribution classifiers in 81.3% of cases (13 of 16 languages), with translation benefits strongly correlated with both the resource level of the target language and the quality of the machine translation (MT) system. Our analysis reveals that traditional classifiers outperform large language model (LLM) judges, with this advantage being particularly pronounced for low-resource languages, where `translate-classify` methods dominate `translate-judge` approaches in 6 out of 7 cases. We additionally show that MT-specific fine-tuning on LLMs yields lower refusal rates compared to standard instruction-tuned models, but it can negatively impact toxicity detection accuracy for low-resource languages. These findings offer actionable guidance for practitioners developing scalable multilingual content moderation systems.

1 Introduction

Detecting instances of toxic, abusive, or hateful content at scale is a challenging problem with important, real-world implications for content moderation. In a multilingual setting, however, toxicity detection is often rendered particularly difficult due to a paucity of labeled data for lower-resourced languages. In parallel, recent years have seen the scaling up of machine translation (MT) systems to cover a vast array of world languages (e.g., NLLB-Team et al., 2022), offering a potential pathway toward leveraging cross-lingual transfer for improved multilingual toxicity detection.

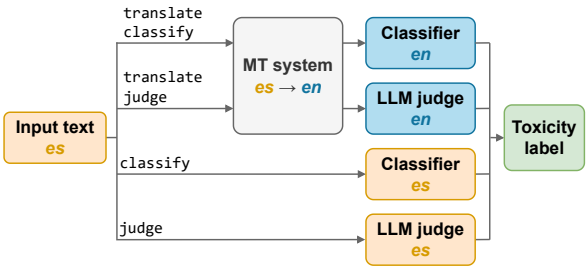

Figure 1: Across 17 languages, we evaluate toxicity detection using translation-based pipelines (`translate-classify`, `translate-judge`) against classifying in the original language (`classify`, `judge`). In this example, text in Spanish (es) is optionally translated to English (en) before classification.

In monolingual non-English settings, cross-lingual transfer has already proven useful for toxicity detection (Eskelinen et al., 2023; Kobellarz and Silva, 2022), aligning with broader analyses of translation's utility for cross-lingual transfer across a range of classification tasks (Artetxe et al., 2023; Etxaniz et al., 2023b; Ponti et al., 2021). Specifically, Artetxe et al. (2023) compare *translate-test* (translating a sample before zero-shot classification) against *translate-train* (translating a sample before classification with a classifier *finetuned on translation data*) and find that *translate-test* is competitive as long as translation quality is sufficient.

While cross-lingual classification has been widely studied in other NLP tasks, toxicity detection presents distinctive challenges that warrant separate investigation. Toxic language is culturally and contextually grounded, with expressions, slurs, and taboos that often lack direct equivalents across languages, making transfer more brittle than for semantically simpler labels. Online toxicity also frequently involves code-switching, orthographic

[*]Joint first author

Proceedings of the Tenth Conference on Machine Translation, pages 253–268
November 8-9, 2025

variation, and deliberate obfuscation, which may be less common in other tasks. Moreover, toxicity labels are inherently subjective and shaped by cultural norms, leading to potential label drift when transferring across languages. These factors, combined with the high stakes of moderation errors, make cross-lingual transfer in toxicity detection both consequential and scientifically challenging.

In this work, we present an empirical exploration of translation for multilingual toxicity detection, through the lens of the practitioner for whom labeled data may be unavailable—a particularly common scenario when working with lower-resourced languages—by comparing translation-based pipelines against a variety of off-the-shelf multi- and monolingual classifiers. Across 27 pipelines spanning five MT systems and nine toxicity classifiers—including both traditional classifiers and large language model (LLM) judges—we evaluate the benefit of cross-lingual classification in 17 languages with varying levels of resources.

Our results suggest that leveraging translation is an effective method for multilingual toxicity detection (§4.1), with benefits scaling in line with increasing language resources and MT system quality (§4.2). Motivated by these results, we study the issue of refusal rates and its mitigation via MT supervised finetuning (MT-SFT), as well as the downstream effect of MT-SFT on toxicity detection performance (§4.3). Finally, we explore classifying using LLM judges and compare them to traditional toxicity classifiers (§4.4). We conclude with practical recommendations for deploying multilingual toxicity detection systems at scale.

2 Related work

2.1 Multilingual toxicity detection

Multilingual toxicity detection is widely used in cases like content moderation or faithful translation (e.g. Costa-jussà et al., 2023). Prior work has either trained models using multilingual corpora of labeled training data (e.g. Hanu, 2020), or sought to exploit cross-lingual transfer via monolingual finetuning of multilingual foundation models (e.g. XLM-ROBERTa; Conneau et al., 2020a). Multilingual evaluation datasets exist for toxicity detection (e.g. Kivlichan et al., 2020; Gupta, 2021) alongside those used for text detoxification (Dementieva et al., 2024b, 2025). In this work, we evaluate a representative sample of off-the-shelf traditional classifiers, including cross-lingual, and both mono- and multilingual classifiers, across a wide variety of languages.

2.2 Cross-lingual classification

Early approaches to cross-lingual classification relied on bilingual lexicons and statistical methods to project documents into a shared feature space (Rapp, 1995; Dumais et al., 1997; Gliozzo and Strapparava, 2006). The introduction of cross-lingual word embeddings (Mikolov et al., 2013; Faruqui and Dyer, 2014; Ammar et al., 2016) enabled models trained in one language to be applied to others through a shared vector space. Prior to multilingual encoders, transfer was typically achieved via MT, either by translating the training data into the target language (*translate-train*) or by translating inputs into the source language at inference (*translate-test*) (Wan, 2009; Prettenhofer and Stein, 2010).

Multilingual sentence encoders such as LASER (Artetxe and Schwenk, 2019) and mBERT (Devlin et al., 2019) demonstrated the feasibility of direct zero-shot transfer without translation. XLM (Lample and Conneau, 2019) introduced translation language modeling to improve alignment, and XLM-R (Conneau et al., 2020b) showed consistent gains from scaling model and data size. Artetxe et al. (2020) provided a systematic comparison of translate-train and translate-test, while Etxaniz et al. (2023a) revisited translate-test with modern neural MT, finding it competitive for low-resource and distant languages.

Recent work explores large multilingual LLMs (Muennighoff et al., 2022) and parameter-efficient adaptation methods (Pfeiffer et al., 2020), aiming to combine the flexibility of fine-tuning with the scalability of zero-shot prompting.

3 Methods

We evaluate the performance of toxicity detection *pipelines*, where a pipeline comprises a binary toxicity classifier and an optional MT system. In many languages—and particularly for lower-resourced languages—labeled data for toxicity detection is unavailable, precluding the training and deployment of specialized classifiers and motivating the consideration of translation-based pipelines. As such, we are principally interested in comparing pipelines in the following three regimes:

`classify (ID)` An untranslated, in-distribution (ID) sample is classified in the source language

Language Code	Language	FineWeb-2 Docs	Dataset	No. Samples
am	Amharic	280,355	Amharic Hate Speech (Ayele et al., 2023)	1,501
ar	Arabic	57,752,149	L-HSAB (Mulki et al., 2019)	5,846
de	German	427,700,394	GermEval 2018 (Wiegand et al., 2018)	3,398
es	Spanish	405,634,303	Jigsaw Multilingual (Kivlichan et al., 2020)	8,438
fr	French	332,646,715	Jigsaw Multilingual (Kivlichan et al., 2020)	10,920
he	Hebrew	13,639,095	OffensiveHebrew (Hamad et al., 2023)	500
hi	Hindi	20,587,135	MACD (Gupta et al., 2022)	6,728
it	Italian	219,117,921	Jigsaw Multilingual (Kivlichan et al., 2020)	8,494
kn	Kannada	2,309,261	MACD (Gupta et al., 2022)	6,587
ml	Malayalam	3,406,035	MACD (Gupta et al., 2022)	5,170
pt	Portuguese	189,851,449	ToLD-Br (Leite et al., 2020)	21,000

ta	Tamil	5,450,192	MACD (Gupta et al., 2022)	6,000
te	Telugu	2,811,760	MACD (Gupta et al., 2022)	6,000
th	Thai	35,949,449	Thai Toxicity Tweet Corpus (Sirihattasak et al., 2018)	2,794
tr	Turkish	88,769,907	Jigsaw Multilingual (Kivlichan et al., 2020)	14,000
uk	Ukrainian	47,552,562	TextDetox 2024 (Dementieva et al., 2024a)	5,000

Table 1: Toxicity datasets used per language, including number of samples, and number of documents in FineWeb-2 as a measure of language resourcedness.

using a classifier trained on data from the same distribution (e.g., evaluating a classifier on French social media posts that has been trained on French social media posts).

`classify (OOD)` An untranslated, out-of-distribution (OOD) sample is classified in the source language using a classifier trained on data from a different distribution (e.g., evaluating a classifier on French video comments that has been trained on French social media posts).

`translate-classify` The sample is translated into English using an MT model before being classified in English, using a toxicity classifier that supports English. No evaluated classifiers have been trained on translated data.

While we expect finetuned classifiers to exhibit the strongest performance while operating ID, it is relative to the far more common OOD scenario (i.e., where no suitably finetuned classifier is available to process the source language) that we expect `translate` pipelines to offer significant utility.

3.1 Evaluation

We evaluate various pipeline implementations across several languages and datasets, each of which comprise text samples x_i and gold toxicity labels y_i. Each pipeline, given a sample, produces a continuous score corresponding to toxicity.

Pipeline performance To avoid the need for thresholding, we evaluate pipeline performance via the Area Under the Receiver Operating Characteristic curve (AUC), which provides a continuous measure of how well the pipeline can separate toxic from non-toxic samples. The AUC is defined as:

$$\text{AUC} = \int_0^1 \text{TPR}(t)\, d\text{FPR}(t)$$

where $\text{TPR}(t)$ and $\text{FPR}(t)$ are the true positive and false positive rates at threshold t.

When comparing pipelines, we typically evaluate the benefit of using one pipeline over another by way of change in AUC. For two pipelines, P_A and P_B,

$$\Delta\text{AUC}(P_A, P_B) = \text{AUC}(P_A) - \text{AUC}(P_B)$$

We evaluate all possible combinations of pipeline and dataset where the supported pipeline language matches the dataset's language.

Language resources We evaluate the role of language resourcefulness on pipeline performance, where we roughly approximate the number of available resources using the amount of documents available in FineWeb2 (Penedo et al., 2025), a large-scale dataset of web text sourced from various CommonCrawl snapshots.

Translation system quality Following standard practice (e.g., Kocmi et al. 2024), we additionally evaluate the quality of translations into English using the CometKiwi-DA-XL (Rei et al., 2023) quality estimation model, evaluated on the BOUQuET (Omnilingual MT Team et al., 2025) dataset.

NLLB 200 3.3B (NLLB-Team et al., 2022)	NMT

Table 3: Translation systems evaluated in this work.

3.2 Datasets

We curate a set of ten toxicity benchmarks for evaluating pipeline performance, spanning 17 languages, where each dataset comprises samples of text with gold labels indicating toxicity. Benchmarks were identified via searching related work on toxicity detection and by searching the Hugging Face datasets catalog. We limited our search to only datasets comprising natural human data, and to those where the gold labels are produced by human annotators, such that datasets comprising model-generated or otherwise synthetic text or labels were discarded. Datasets were restricted to those with a permissive license, where data provenance was clearly indicated, and where the data is readily-accessible online. This resulted in the following benchmarks: Amharic Hate Speech (Ayele et al., 2023); GermEval 2018 (German; Wiegand et al. 2018); Jigsaw Multilingual (Spanish, French, Italian, and Turkish partitions only; Kivlichan et al. 2020); L-HSAB (Levantine Arabic; Mulki et al. 2019); MACD (Hindi, Kannada, Malayalam, Tamil, and Telugu; Gupta et al. 2022); Offensive-Hebrew (Hamad et al., 2023); ToLD-Br (Brazilian Portuguese; Leite et al. 2020); Russian Language Toxic Comments (Belchikov, 2019); Thai Toxicity Tweet Corpus (Sirihattasak et al., 2018); and TextDetox 2024 (Ukrainian partition only; Dementieva et al. 2024a). See Table 1 for full details.

Across all datasets, only the test partition is used for evaluation. Where a toxicity classifier is trained on data that includes one of our benchmark's training partitions, we consider that classifier to be operating ID. Otherwise, as the classifier has been trained on data unlike the benchmark, we consider it to be operating OOD. See Table 2 for the training data used to produce each classifier.

For the purposes of our evaluation, we intentionally avoid drawing a distinction between toxicity detection and and hate speech detection. While hate speech and toxic or offensive are distinct concepts (Davidson et al., 2017; Waseem et al., 2017)—with hate speech typically being interpreted as directed toward a specific group (Davidson et al., 2017; Röttger et al., 2021)—in practice, most evaluation datasets use the terms toxicity, abusive or offensive language, and hate speech almost interchangeably (Fortuna et al., 2020; Banko et al., 2020). As a result, we consider datasets spanning toxicity and hate speech detection, and expect minimal difference in findings between tasks.

3.3 Toxicity classifiers

We consider eight open-source toxicity classifiers, including English-language, non-English monolingual, and multilingual, all of which are available on Hugging Face. See Appendix A.1 for selection

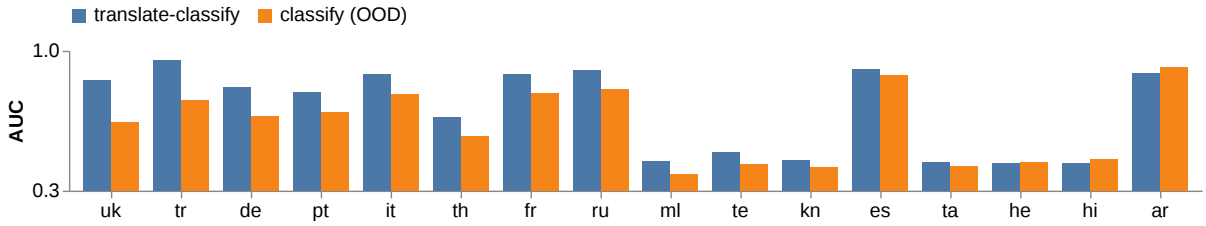

Figure 2: AUC of best possible `translate-classify` pipeline (over all combinations of translation systems and English toxicity classifiers) and best possible `classify (OOD)` pipeline (over all OOD toxicity classifiers). **The `translate-classify` approach wins across 13 out of 16 evaluated languages.**

criteria and Table 2 for full details of all classifiers considered.

All classifiers evaluated make use of pretrained Transformer-based encoder models as a backbone, such as BERT (Devlin et al., 2019), DistilBERT (Sanh et al., 2020), ROBERTa (Liu et al., 2019), or the multilingual XLM-ROBERTa (Conneau et al., 2020a), some of which have undergone additional fine-tuning on language specific corpora, such as Russian RuBERT (Kuratov and Arkhipov, 2019). All classifiers are then finetuned on a portion of labeled toxicity data, such as detailed in §3.2.

3.4 Translation systems

For `translate-classify` pipelines, we translate samples into English with a translation system before classifying the translations with an English-supporting classifier. We evaluate four different translation systems (see Table 3), including both encoder-decoder MT systems (NMT) and decoder-only (i.e., LLM) translation systems. In the NMT category, we use NLLB 200 3.3B (NLLB-Team et al., 2022). We evaluate three LLM systems (two open-weights and one behind-API): Llama 3.1 8B Instruct (Grattafiori et al., 2024), Gemma 3 4B Instruct (Gemma Team et al., 2025) and GPT-4o (OpenAI, 2024). The following prompt is used to produce the translations:

```
Translate the following sentence from
    ↪ {{lang}} into English. Respond
    ↪ only with the translation into
    ↪ English, without any additional
    ↪ comments.
{{sentence}}
```

4 Experiments

4.1 Translated pipelines often win

We compare the AUC of the best `translate-classify` pipeline (the best possible combination of translation system and toxicity classifier) against the best possible `classify` pipeline (the best toxicity classifier that supports each language).

Results In Fig. 2, we evaluate `translate-classify` in the common scenario where a language-specific finetuned toxicity classifier is unavailable, i.e., where classifiers are operating OOD with respect to either their source language or training domain, `classify (OOD)`. We observe that in such a scenario, the best `translate-classify` pipeline outperforms the best `classify (OOD)` pipeline across 13 of 16 languages considered (81.3%). Reducing a degree of freedom by using a fixed classifier, `distilbert-base-multilingual-cased-toxicity`, `translate-classify` still outperforms `classify` in 12 of 16 languages (75%; see Fig. S1).

In Fig. 3 we evaluate translated pipelines in scenarios where a language-specific finetuned classifier *is* available (`classify (ID)`), though we note that this is far from the case for the majority of languages. Here, `translate-classify` still offers a robust baseline, outperforming finetuned `classify (ID)` pipelines across three out of seven languages. See Table S1 for full results over all languages.

4.2 Translation benefit scales with resources

Next, we explore which factors determine the success of `translate-classify` pipelines. To allow for consistent comparison across languages and control for variability in classifier performance, we now limit ourselves to two fixed classifiers: for `translate-classify` we use the English classifier, `toxic-bert`, while for `classify` we use our most multilingual classifier, `distilbert-base-multilingual-cased-toxicity`. We evaluate the role of language resourcefulness and translation quality on change in AUC between pipelines, as specified in §3.1.

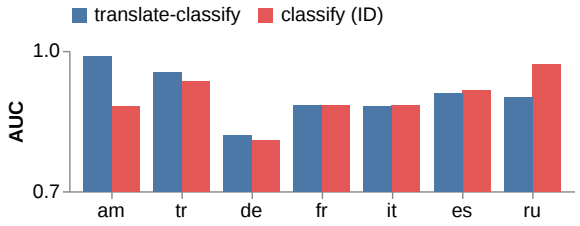

Figure 3: AUC of best possible `translate-classify` pipeline (over all combinations of translation systems and English toxicity classifiers) and best possible `classify (ID)` pipeline (over all ID toxicity classifiers). **The `translate-classify` approach still wins across three of seven languages where in-distribution finetuned classifiers are available.**

Results In Fig. 4, we observe that the relative benefit of `translate-classify` over `classify`, as measured by the change in AUC, is higher for better-resourced languages. This is consistent across four different translation systems, including both LLM and NMT systems. After fixing the best performing classifiers, we notice that the relative benefit of translation for some languages is affected, suggesting the framework is susceptible to model selection to maximize gains.

Similarly, in Fig. 5 we see that the relative benefit of `translate-classify` increases with the quality of translations in each language, across both LLM and NMT systems. We note a higher sensitivity to both language resourcefulness and translation quality for the NMT system, NLLB, compared with LLM systems.

4.3 MT-SFT reduces refusal and improves performance

When using safety-tuned LLMs for translation, a we noticed that key risk is *refusal*: the model declines to translate inputs containing harmful or toxic content, which can severely limit coverage in toxicity detection. We examine whether finetuning for MT can mitigate this problem by comparing two `translate-classify` pipelines: (1) `translate-classify (Llama 3)`, which uses translations from a standard instruction-tuned LLM (Llama 3.1 8B Instruct), and (2) `translate-classify (+TowerBlocks/MT)`, which uses translations from the same base model after supervised finetuning (MT-SFT) on the TowerBlocks/MT dataset (Alves et al., 2024) (see Appendix A.2 for details). Both pipelines feed translations to a fixed English-only classifier, `toxic-bert`, to isolate translation effects, and are compared against a direct multilingual `classify` pipeline using `distilbert-base-multilingual-cased-toxicity`.

Refusal detection We use `Minos` (Suphavadeeprasit et al., 2025) to assign each translation output $y_i = T(x_i)$ a refusal probability $P_r(y_i)$. The refusal rate is defined as:

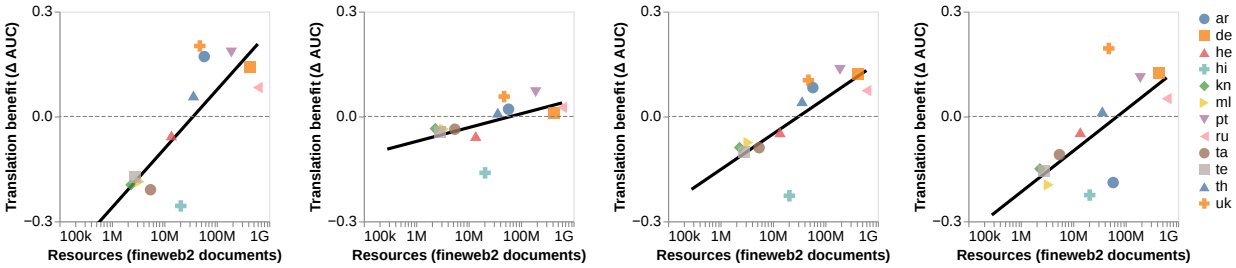
$$\mathrm{R}(T) = \frac{1}{N}\sum_{i=1}^{N}[P_r(T(x_i)) > 0.95],$$

where a 0.95 threshold minimizes false positives. For two systems T_A and T_B, the difference in refusal rates is:

$$\Delta\mathrm{R}(P_{T_A}, P_{T_B}) = \mathrm{R}(P_{T_A}) - \mathrm{R}(P_{T_B}).$$

Refusal results As shown in Fig. 8, `translate-classify (+TowerBlocks/MT)` reduces refusal rates in *every* language compared with `translate-classify (Llama 3)`. The reduction scales approximately log-linearly with language resources (Fig. 9a), indicating that MT-SFT particularly benefits high-resource languages where refusals are rarer but still impactful. Lower refusal means more toxic content is actually processed by the classifier, directly improving pipeline coverage.

Human verification of refusal mitigation To validate both the accuracy of our automated refusal detection and the effectiveness of MT-SFT in addressing refusals, we conducted a targeted human annotation study. For each dataset, we randomly sampled up to 5% of the content flagged as refusals by the base Llama 3.1 8B Instruct model, with a minimum of 10 examples per dataset. Annotators manually verified whether each flagged case was indeed a refusal, then examined translations of the same inputs generated by the MT-finetuned model. As shown in Table 4, the refusal detector achieved perfect true positive rates for Thai, German, and Ukrainian, and high —though not perfect— accuracy for Malayalam and Levantine Arabic, where some false positives were observed. Importantly, the MT-finetuned model produced valid translations for *all* annotated examples, yielding a true negative rate of 100% across every language in the sample. This confirms that, at least for the languages tested, MT-SFT can completely eliminate refusals observed in the base instruction-tuned model, turning previously blocked content into usable inputs for the downstream classifier.



(a) GPT-4o (b) Llama 3.1 8B Instruct (c) Gemma 3 4B Instruct (d) NLLB

Figure 4: Change in AUC (i.e., translation benefit) between `translate-classify` pipelines with a fixed English classifier, `toxic-bert`, and `classify` pipelines with a fixed multilingual classifier, `distilbert-base-multilingual-cased-toxicity`, as a function of language resources, over four translation systems **(a)** GPT-4o, **(b)** Llama 3.1 8B Instruct, **(c)** Gemma 3 4B Instruct, and **(d)** NLLB. **Translation benefit is increased for higher resourced languages.**

(a) Llama 3.1 8B Instruct (b) NLLB

Figure 5: Change in AUC (i.e., translation benefit) between `translate-classify` pipelines and `classify` pipelines, as a function of English translation quality measured by `CometKiwi-DA-XL`, over two translation systems **(a)** Llama 3.1 8B Instruct, and **(b)** NLLB. **Translation benefit increases with translation quality for both LLM-based and NMT systems.**

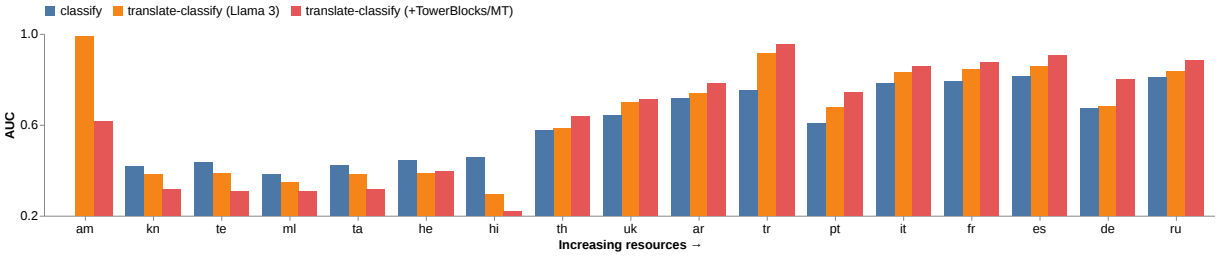


Figure 6: AUC of `translate-classify (Llama 3)` and `translate-classify (+TowerBlocks/MT)` using a fixed English classifier, `toxic-bert`, and a `classify` pipeline using a fixed multilingual classifier, `distilbert-base-multilingual-cased-toxicity`. **Using a finetuned LLM for translation improves pipeline performance for higher-resourced languages.**

MT-SFT improves performance for high resource languages In addition to lowering refusals, MT-SFT also improves classification accuracy. In Fig. 6, `translate-classify (+TowerBlocks/MT)` achieves higher AUC than `translate-classify (Llama 3)` for 11 of 17 languages, with gains concentrated in high-resource settings. When measured against the multilingual `classify` baseline, `translate-classify (+TowerBlocks/MT)` shows even stronger sensitivity to language resource availability (Fig. 7).

4.4 LLM judges underperform on lower-resourced languages

Given the strong performance of LLMs across a range of tasks, we additionally compare pipelines based on traditional classifiers vs. zero-shot LLM judges.

Specifically, we analyze the performance of

Name	TPR (`Llama 3.1`)	TNR (`+TowerBlocks/MT`)
TH	100%	100%
DE	100%	100%
UK	70%	100%
ML	75%	100%
AR	40%	100%

Table 4: Analysis of human annotations of refusal predictions, showing True Positive Rate (TPR) of Llama 3.1 8B Instruct (`Llama 3.1`) and the True Negative Rate (TNR) of the same model finetuned on TowerBlocks/MT (`+TowerBlocks/MT`). **Refusal detection is highly accurate for Thai, German, and Ukrainian. Even for Malayalam and Levantine Arabic where the refusal detector produces some false positives, the finetuned model never refuses.**

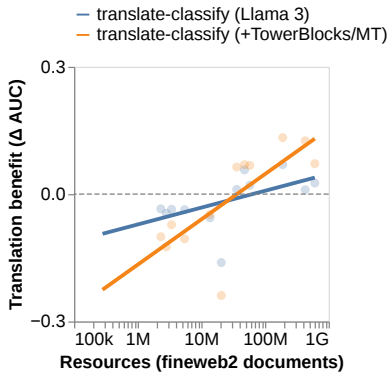

Figure 7: Change in AUC (i.e., translation benefit) of `translate-classify (Llama 3)` and `translate-classify (+TowerBlocks/MT)` pipelines with a fixed English classifier against a fixed `classify` pipeline with a fixed multilingual classifier, as a function of language resources. **The `translate-classify (+TowerBlocks/MT)` pipeline performance is more sensitive to available language resources.**

two judge-based pipelines: (1) `judge`, where an LLM is prompted to classify untranslated samples, and (2) `translate-judge`, where the LLM is prompted to classify samples that have been translated into English. The judge in both cases is Llama 3.1 8B Instruct with the following custom prompt, where `{{sample}}` is either the translated or original sample according to pipeline:

```
You are a toxicity classifier. Classify
    ↪ the following text as toxic or
    ↪ not toxic. Respond with 'toxic'
    ↪ or 'not toxic' with no other
    ↪ comments or explanation.
Text: {{sample}}
Classification:
```

Translations are also produced using Llama 3.1 8B Instruct. We compare both judge pipelines against a `classify` pipeline based on the overall best English classifier, `toxic-bert`, coupled again with Llama 3.1 8B Instruct for fair comparison. We evaluate all pipelines using accuracy as opposed to AUC, as the LLM judge emits only a label, rather than a continuous score.

Results Figure 10 illustrates notable patterns in the comparative performance of `translate-judge` and `judge` pipelines. Across all languages, translation-based approaches narrowly outperform their untranslated counterparts; however, this advantage becomes pronounced in low-resource settings, where `translate-judge` completely dominates, outperforming `judge` in 6 out of 7 low-resource languages. Similarly, `translate-classify` pipelines provide a slight overall edge compared to both `judge` and `translate-judge`, but the margin is especially significant for low-resource languages, where `translate-classify` overwhelmingly wins (again in 6 out of 7 cases). These results further indicate that multilingual capabilities in LLMs are not homogeneously distributed: while MT models demonstrate broader multilingual reach, toxicity classification performance by LLMs is markedly less consistent across lower-resource languages.

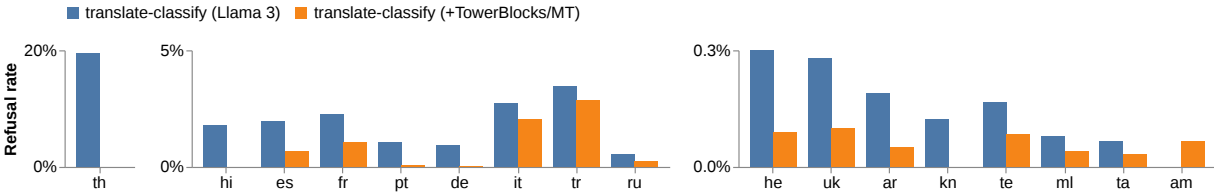

Figure 8: Translation refusal rate of `translate-classify (Llama 3)` and `translate-classify (+TowerBlocks/MT)` pipelines. Note three separate scales for legibility. **Using a finetuned LLM for translation reduces refusal rates.**

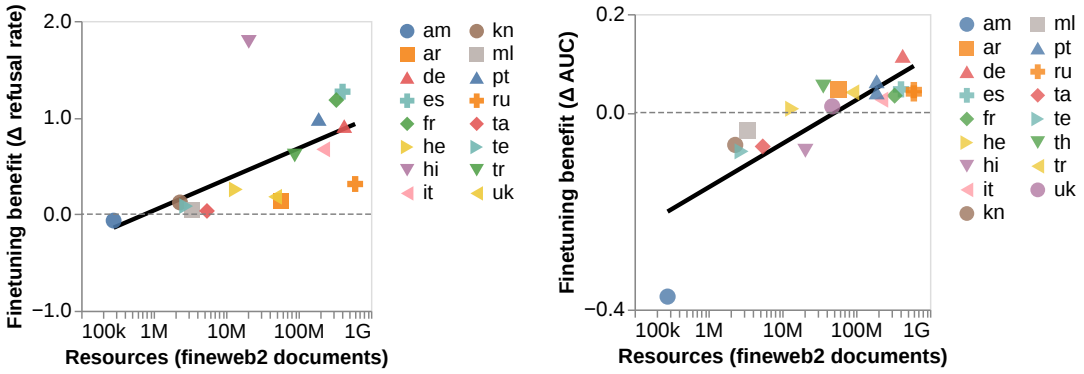

(a) Δ refusal

(b) Δ AUC

Figure 9: Change in **(a)** translation refusal rate and **(b)** AUC of a `translate-classify (+TowerBlocks/MT)` pipeline against a `translate-classify (Llama 3)` pipeline, both with a fixed English classifier, `toxic-bert`, as a function of language resources. **The benefit of using a finetuned LLM for translation, in terms of both refusal rates and improved performance, increases for with language resources.**

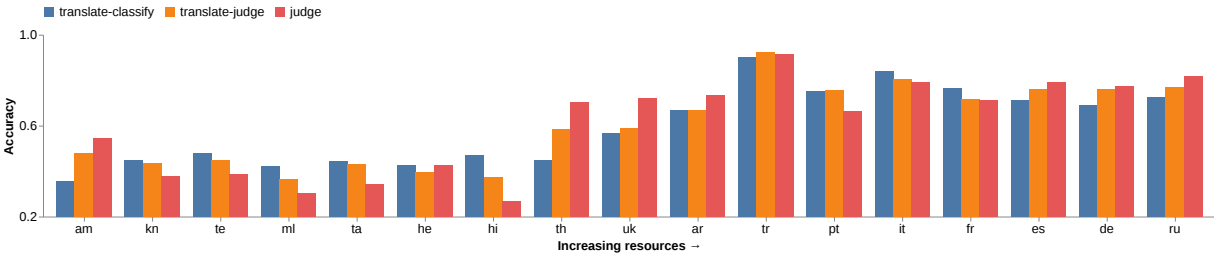

Figure 10: Accuracy of `translate-judge`, `judge`, and `translate-classify` with a fixed English classifier, `toxic-bert`, all using a Llama 3 for translation. **Translation with traditional classifiers outperforms LLM judges for most lower resourced languages.**

5 Discussion

Across ten benchmarks spanning 17 languages, our analysis suggests that translation-based approaches can be successfully leveraged to support multilingual toxicity detection at scale. Specifically, we observe that `translate-classify` pipelines outperform `classify (OOD)`, a non-finetuned classifier operating OOD (i.e., an off-the-shelf model) in the majority of cases, and can even occasionally outperform `classify (ID)`, dedicated finetuned classifiers evaluated ID. The relative benefit of using `translate-classify` over `classify` pipelines increases with both a language's available resources and the quality of the translation system. This may suggest that while translation may be an effective strategy *in general*, it does have the potential to increase performance disparities between better- and worse-resourced languages. We additionally note that using an MT-finetuned LLM for translations can further drive up pipeline performance, in part, by reducing refusal rates, but that this benefit appears to be reserved for higher-resourced languages. Finally, we evaluate the utility of an LLM judge approach over traditional (e.g., BERT-based) classification, finding that in lower-resourced languages,

`translate-classify` consistently outperforms.

Practical recommendations We make four practical recommendations for practitioners looking to deploy multilingual toxicity detection at scale.

1. At the very least, `translate-classify` pipelines using traditional classifiers and LLM-based translation should be considered a robust baseline.

2. If fine-tuning on dedicated data is unavailable, a `translate-classify` pipeline is likely to provide a strong first choice of model, particularly in languages where translation quality is high.

3. If operating on a higher-resourced language, making use of an MT-finetuned LLM may offer some performance improvements over a standard instruction-tuned LLM, particularly in the scenario where refusal rates can be reduced.

4. Unlike many other NLP tasks, an LLM judge demonstrates only a limited performance advantage on select higher-resourced languages when compared to traditional (e.g., BERT-based) classifiers.

Limitations

While we approach multilingual toxicity detection through the lens of a practitioner making a choice between available, off-the-shelf pipeline components, this does limit our ability to analyze the role of specific finetuning details. For example, in contrast with previous work (Artetxe et al., 2023) that has contrasted cross-lingual transfer pipelines where the classifier was finetuned on either the original domain or the outputs of the translation system, we only make use of publicly-available classifiers which may be finetuned on different numbers of samples or different domains, and none of which are finetuned on translations. However, given the performance improvements offered by the `translate-classify` pipeline *without finetuning on translations*, we might expect a translation-finetuned classifier to further benefit the `translate-classify` approach.

As we note in §3.2, our work is also potentially limited by shifts in data distribution between languages. In order to identify broad trends across many languages with different levels of resources, we draw samples from different constituent datasets. These datasets, however, are drawn from different domains (e.g., social media vs. WikiMedia talk pages) with labels produced using different annotation schemas (e.g., identifying hate speech vs. toxicity). As a result, our conclusions should be interpreted as indicative of general trends about the relative utility of translation, rather than individual claims about how well translation may function on any given language. This limitation could be overcome with access to additional highly-multilingual datasets of labeled toxicity data.

A Additional methods

A.1 Toxicity classifier selection

We evaluate on a sample of toxicity classifiers that are publicly-available on Hugging Face. We reviewed classifiers that matched the search terms "toxic" and "toxicity", selecting those that supported either English or one or more of the 17 languages analyzed. Classifiers were limited to those that were permissively-licensed, with clear data provenance (to allow for distinguishing between ID and OOD performance), and substantial community engagement (as measured by downloads and likes). See Table 2 for all classifiers evaluated.

A.2 MT finetuning an LLM

We used Llama 3.1 8b Instruct as our baseline model and finetuned it for 5 epochs with the MT split from Towerblocks 0.2, a multi-task, multilingual SFT dataset. We employed the AdamW optimizer with a learning rate initialized to 1×10^{-6}, β_1 and β_2 coefficients set to 0.9 and 0.95 respectively, and a weight decay of 0.1. We used a cosine annealing learning rate scheduler configured with a final learning rate scaled to 0.2 times the initial rate and a total of 1,000 warmup steps.

B Additional results

In Table S1 we present the detailed results behind Figs. 2 and 3, showing the performance of the best-possible `translate-classify`, `classify (OOD)`, and `classify (ID)` pipelines over all languages. In Tables S2 to S4 we present the corresponding best-performing translation system and classifier combinations for `translate-classify`, `classify (OOD)`, and `classify (ID)` respectively.

In Fig. S1, we present a version of Fig. 2 but reducing one degree of freedom: rather than choosing the best-possible combination of translation system and classifier, here we choose the best possible translation system though use a fixed classifier, `distilbert-base-multilingual-cased-toxicity`. In this setting, `translate-classify` still outperforms across 12 of 16 languages.

Abstract

We investigate the tradeoff between adequacy and fluency in machine translation. We show the severity of this tradeoff at the evaluation level and analyze where popular metrics fall within it. Essentially, current metrics generally lean toward adequacy, meaning that their scores correlate more strongly with the adequacy of translations than with fluency. More importantly, we find that this tradeoff also persists at the meta-evaluation level, and that the standard WMT meta-evaluation favors adequacy-oriented metrics over fluency-oriented ones. We show that this bias is partially attributed to the composition of the systems included in the meta-evaluation datasets. To control this bias, we propose a method that synthesizes translation systems in meta-evaluation. Our findings highlight the importance of understanding this tradeoff in meta-evaluation and its impact on metric rankings.

1 Introduction

As translation systems become more sophisticated and widely adopted, the critical challenge of accurately evaluating their performance has come to the forefront, driving significant ongoing research to the developement of more accurate and robust metrics (Chatzikoumi, 2020; Guerreiro et al., 2024). Traditionally, translation evaluation relied on lexical metrics such as BLEU (Papineni et al., 2002) and ChrF (Popović, 2015), which primarily consider the n-gram overlap between the candidate and reference translations. However, these metrics have been shown insufficient for measuring the quality of modern translation systems (Babych and Hartley, 2008; Freitag et al., 2022). In the recent decade, researchers have been exploring the idea of training neural models to measure translation quality (Wieting et al., 2019; Ma et al., 2019; Freitag et al., 2022; Guerreiro et al., 2024), with popular examples including MetricX (Juraska et al., 2023, 2024) and Comet (Rei et al., 2020, 2022a).

Two key aspects of translation quality, long discussed in the community (Pierce and Carroll, 1966; White and O'Connell, 1993; Banchs et al., 2015; Martindale and Carpuat, 2018), are[1]:

- *Fluency*: the grammatical correctness and naturalness of the translation; and
- *Adequacy*: how well the translation conveys the meaning of the source text.

Flamich et al. (2025) demonstrate that an adequacy–fluency tradeoff exists in translation: optimizing for one aspect eventually sacrifices the other. They further introduce measurements to study the severity of this tradeoff at **the level of translation systems**.

The aforementioned tradeoff naturally results in an adequacy–fluency tradeoff at **the level of evaluation metrics**, if we limit our evaluation to a single score: increasing the capability of measuring one aspect eventually comes at the cost of decreasing the capability of measuring the other. It is important to understand this tradeoff and know the position of each metric to avoid undesired biases when optimizing translation systems according to the metric.

In this work, we demonstrate the severity of the adequacy–fluency tradeoff at the evaluation level. We analyze current evaluation setups in WMT (Callison-Burch et al., 2007; Moghe et al., 2025), and show that there is a significant disagreement between adequacy and fluency when ranking systems (Table 1). This directly imposes a severe tradeoff, as a metric can only agree with either adequacy or fluency when comparing discordant system pairs. Subsequently, we empirically analyze several contemporary translation metrics to illustrate their positions within this tradeoff.

More importantly, we show that this adequacy–

[*]Work partially done when the first author was interning at Google.

[1]Different namings and slightly different definitions are used in the literature for these two aspects; however, the main idea remains consistent.

Proceedings of the Tenth Conference on Machine Translation, pages 269–285
November 8-9, 2025

Evaluation Set	Concordance	Discordance
En–De'23	49 (74%)	17 (26%)
Zh–En'23	70 (67%)	35 (33%)
En–De'24	98 (72%)	38 (28%)
En–Es'24	55 (71%)	23 (29%)
Ja–Zh'24	58 (74%)	20 (26%)

Table 1: Concordance and discordance between adequacy and fluency in MQM datasets (§3.1), reported as system pair counts and percentages. Concordance means one system in a pair outperforms the other in both metrics; discordance indicates inconsistent performance across metrics. Notice that 26–33% discordance, although being the minority, is way far from being negligible and imposes a significant tradeoff when the metric quality improves.

fluency tradeoff extends even to **the level of meta-evaluation** (the evaluation of evaluation metrics). Meta-evaluation typically compares the scores of a set of candidates given by a metric to those given by humans (Callison-Burch et al., 2007). We show that the selection of the candidates used during the meta-evaluation significantly influences the identified optimal metric within the tradeoff: if there is a higher variance in the candidates' adequacy than in their fluency, the meta-evaluation will lean toward favoring metrics that prioritize adequacy. Conversely, if the fluency of these candidates shows higher variance, the meta-evaluation will prefer fluency-oriented metrics. This can inadvertently guide the development of evaluation metrics, and thus the development of translation systems, toward a particular bias toward either adequacy or fluency. We propose to synthesize candidates with desired variance in their adequacy and fluency scores to conduct a controlled (balanced) meta-evaluation.

2 Background & Related Work

2.1 Translation Metrics

The evaluation of translation systems is a critical aspect of their development and deployment, and has been researched for years (Tao et al., 2018; Chatzikoumi, 2020). This research has resulted in the development of a variety of metrics (Chauhan and Daniel, 2023; Guerreiro et al., 2024).

Traditional metrics, such as BLEU (Papineni et al., 2002), METEOR (Lavie and Denkowski, 2009), and ChrF (Popović, 2015), compare the output of a translation system against one or more human-created reference translations, only at the surface level (e.g., based on string overlap). While widely adopted for their simplicity, these surface-level metrics are shown to be incapable of measuring the quality of modern, high-quality translation systems (Freitag et al., 2022).

Recent advancements have led to the development of *trained metrics*, which leverage machine learning models to assess translation quality (Wieting et al., 2019; Freitag et al., 2022). These metrics, such as MetricX (Juraska et al., 2023, 2024) and Comet (Rei et al., 2020, 2022a), are often trained on large datasets of human annotations, allowing them to learn more nuanced correlations between system outputs and perceived quality.

Translation metrics can be divided into two categories: *reference-based* and *reference-free*. Reference-based metrics, such as those mentioned previously, rely on access to a trusted reference translation and compare the candidate against the reference to assess quality. Reference-free metrics, also known as Quality Estimation (QE) metrics, directly evaluate the candidate given the source text, without requiring a reference translation (Ito et al., 2025). This capability is particularly valuable in scenarios where human references are scarce or impractical to obtain, offering a more flexible and potentially more accurate evaluation paradigm for contemporary translation systems (Agrawal et al., 2021). MetricX and Comet offer their reference-free versions: MetricX QE (Juraska et al., 2023, 2024) and CometKiwi (Rei et al., 2022b).

In our work, we empirically analyze several contemporary translation metrics to illustrate their positions within the adequacy–fluency tradeoff, providing insights into their strengths and limitations.

2.2 Meta-Evaluation

Meta-evaluation assesses how well a translation evaluation metric correlates with human annotations (Callison-Burch et al., 2007; Macháček and Bojar, 2013). This is traditionally accomplished by computing Pearson, Kendall, and Spearman correlation coefficients (Macháček and Bojar, 2013; Mathur et al., 2020; Freitag et al., 2023), at either the segment[2] level (for individual translation scores) or the system level (for scores averaged per system). More recently, pairwise accuracy (PA; Kocmi et al., 2021) and soft pairwise accuracy (SPA; Thompson et al., 2024) have gained prominence as they directly assess how well a met-

[2]Following the common terminology in the community, we refer to each data sample as a *segment*.

ric aligns with human preferences over pairs of translations (Mathur et al., 2020). Given their popularity, we utilize these two metrics for our analysis and elaborate their formulations below.

Pairwise accuracy. PA assesses whether a metric correctly identifies the better translation (segment level) or the better system (system level) given a pair. Let m and h be the metric and human scores, respectively. PA is formulated as

$$\frac{1}{|\mathcal{P}|} \sum_{i,j \in \mathcal{P}} \mathbb{1}[\text{sgn}(m_j - m_i) = \text{sgn}(h_j - h_i)] \quad (1)$$

where $\mathcal{P}$ is the set of pairs, and sgn is the sign function. Pairs with tied human scores are excluded (Kocmi et al., 2021).

A key challenge for PA at the segment level is to handle tied metric scores. While techniques like tie calibration are employed to address this issue (Deutsch et al., 2023), recent studies (Perrella et al., 2024) indicate that such approaches are not reliable and the matter warrants further investigation. This challenge is minor at the system level, since averaging scores over many translations rarely yields ties. We therefore focus on system-level PA in our work.

Soft pairwise accuracy. SPA is a system-level meta-metric that extends PA by incorporating statistical significance from both human and metric scores. Unlike PA's binary agreement, SPA compares p-values from hypothesis tests to determine if one system is statistically superior. The SPA score is formulated as

$$\frac{1}{|\mathcal{P}|} \sum_{i,j \in \mathcal{P}} (1 - |p(h_j > h_i) - p(m_j > m_i)|) \quad (2)$$

Here, $p(x_j > x_i)$ is the p-value from a permutation test (Welch, 1990) assessing if system j is superior to system i based on scores x. SPA is sensitive to the magnitude of the score differences, reflecting the metric's confidence in its preference, and compares this confidence against that of human judgments.

3 Experimental Setup

3.1 Dataset

The Multidimensional Quality Metrics (MQM) framework provides a standardized and granular guideline for characterizing and classifying errors in translations (Mariana et al., 2015). Instead of being a score-based annotation, the MQM framework annotates translation errors. Each error is annotated as a substring of the translation with a category (such as accuracy, fluency, terminology, and style) and a severity level (usually major, minor, and neutral). This framework enables a diagnostic understanding of translation system performance, as well as more reliable and standardized evaluation scores.

WMT adopts MQM annotations (Freitag et al., 2021a) for human evaluation, producing datasets of detailed translation error annotations. We use this dataset of years 2023 and 2024 in our meta-evaluation and analysis. We reserve data from prior years (2020–2022) for training to avoid leakage. Our setup is consistent with practice in previous studies (Juraska et al., 2024; Rei et al., 2022a) for fair comparison.

It is common to transform MQM annotations into a single score (Freitag et al., 2022, 2023). This involves assigning a specific penalty to each error based on its category and severity (Freitag et al., 2021b). These penalties are then summed across all errors in the translation. We refer to this aggregated value as the *All MQM* score, where a lower score indicates higher quality.

For a more granular analysis, Flamich et al. (2025) categorize MQM errors into adequacy and fluency classes (Tables 8 and 9 in Appendix A), resulting in *Adequacy MQM* and *Fluency MQM* scores for each segment. We use these specialized scores for our tradeoff analysis. We present detailed statistics for our dataset in Appendix B.

3.2 Meta-Metrics

To study the performance of evaluation metrics in the adequacy–fluency tradeoff, we separately assess their ability to measure translation adequacy and fluency. To achieve this, we compute meta-metrics—namely, PA and SPA (§2.2)—with respect to Adequacy MQM and Fluency MQM. In Appendix C, we point out the necessity of including both PA and SPA in such studies due to their potentially different behavior in measuring bias toward adequacy or fluency.

3.3 Translation Metrics in Our Analysis

In our work, we select a set of diverse and widely used metrics to analyze their positions within the adequacy–fluency tradeoff. These metrics include **BLEU** (Papineni et al., 2002) and **ChrF** (Popović,

2015), representing overlap-based metrics; **MetricX** (Juraska et al., 2024) and **Comet** (Rei et al., 2022a), representing trained metrics; and **MetricX QE** and **CometKiwi** (Rei et al., 2023), representing reference-free metrics.

Moreover, we introduce a set of extreme translation metrics designed to measure only adequacy or fluency, which will provide a clearer view of the tradeoff between the two. Specifically, we develop **AdequacyX** and its reference-free variant, **AdequacyX QE**, trained exclusively on MQM errors categorized under adequacy. Likewise, we develop **FluencyX** trained on fluency annotations.

Technically, these trainable metrics adopt the same neural architecture as MetricX (Juraska et al., 2024), and are fine-tuned from an mT5 checkpoint (Xue et al., 2021). Following Juraska et al. (2024), we train these models on MQM annotations (WMT 2022), covering En–De, En–Ru, and En–Zh.[3] AdequacyX and AdequacyX QE are trained to predict Adequacy MQM, while FluencyX is trained to predict Fluency MQM. Unlike Juraska et al. (2024), we exclusively use MQM annotations for fine-tuning, omitting direct assessments (DA) and synthetic data, as these do not offer a clear adequacy–fluency distinction.

It should be noted that AdequacyX QE does not take the reference translation as input as it is a reference-free metric. We further restrict FluencyX to the candidate translation alone (no source or reference), similar to $\text{SENTINEL}_{\text{CAND}}$ in Perrella et al. (2024), given that fluency is considered source-independent.

To have a fair comparison, we also train our own MetricX and MetricX QE variants; they are identical to AdequacyX (QE), except that they predict All MQM scores. The key difference between our variants and the original MetricX (QE) is the exclusion of DA and synthetic data.

Additionally, we include the log-perplexities of a pretrained Gemma model as a fluency measure, following Flamich et al. (2025). We use **Gemma 3 4B** (Gemma Team, 2025) in this work.

4 Analysis: Tradeoff at the Meta-Evaluation Level

In this section, we explore the adequacy–fluency tradeoff at the meta-evaluation level. We first discuss in §4.1 how the tradeoff exists in meta-evaluation, and show that the imbalance in WMT meta-evaluation datasets imposes a bias that favors adequacy-oriented metrics. We argue that this bias consists of both an intrinsic and an extrinsic component, and that we aim to control the latter. In §4.2, we design a metric to quantify the extrinsic bias, and in §4.3, we propose a practical approach to reduce it. Finally we demonstrate in §4.4 the impact of meta-evaluation bias on the ranking of translation metrics by comparing this ranking before and after reducing the meta-evaluation extrinsic bias.

4.1 Understanding the Meta-Evaluation Bias

Translation meta-evaluation compares the ranking of translation systems produced by a given metric against the ranking based on human annotations, which in our case is the All MQM score. In this section, we will show that the All MQM ranking reflects systems' adequacy more than their fluency, leading the WMT meta-evaluation to favor adequacy-oriented metrics.

For simplicity, we assume that All MQM = Adequacy MQM+Fluency MQM.[4] Therefore, the ranking by All MQM (thus the meta-evaluation assessment) is more influenced by the component with higher variance, and we say the meta-evaluation is *biased* toward that component.

As shown in Table 2, Adequacy MQM exhibits a much higher variance than Fluency MQM in system level scores, consequently having a greater influence on the All MQM system ranking and the meta-evaluation system-level assessment. This influence is further demonstrated by the stronger alignment between All MQM and Adequacy MQM in terms of both PA and SPA. The question now is: *Should we embrace this dominance of adequacy, or is it a bias we should mitigate?*

Answering the above question requires noticing that the higher variance of the system-level Adequacy MQM scores, and consequently its greater influence, can be attributed to two possible causes:

- *Intrinsic variation,* which is due to the preference of the MQM framework and annotators. For example, adequacy errors may be generally considered more severe, leading to larger assigned penalties and thus greater variance.
- *Extrinsic variation,* which is due to the choice of translation systems during meta-evaluation. For example, we may select systems that

[3] We limit En–Zh to the conversation, e-commerce, and social domains, in line with Juraska et al. (2024).

[4] Although there are some errors that are not categorized as either adequacy or fluency, they are rare and have minor influence; therefore, we omit them for simplicity.

	Adequacy MQM				Fluency MQM				
	Variance	F-stat	PA	SPA	Variance	F-stat	PA	SPA	$B(\Delta p)$
En–De'23	0.31	36.5	0.98	0.97	0.06	7.0	0.76	0.75	0.08^A
Zh–En'23	0.23	80.6	0.97	0.93	0.03	12.9	0.70	0.74	0.03^A
En–De'24	0.24	13.7	0.88	0.87	0.11	9.5	0.85	0.81	0.04^A
En–Es'24	0.61	26.4	0.96	0.94	0.28	4.6	0.74	0.77	0.13^A

Macro-Avg	0.36	38.5	0.96	0.94	0.12	7.7	0.76	0.76	

Table 2: Adequacy MQM and Fluency MQM statistics across different evaluation sets. The reported statistics include the variance of system-level scores, the (S)PA of the scores with respect to All MQM, the F-statistic, and the B transformation of the difference between the p-values of Adequacy MQM and Fluency MQM. The last two are explained in §4.2.

differ primarily in adequacy, while performing similarly in fluency. This naturally leads to higher system-level variance in Adequacy MQM than in Fluency MQM.

Both of the above factors contribute to the variances of system-level Adequacy MQM and Fluency MQM, which in turn lead to the bias of the meta-evaluation. Therefore, we say that the meta-evaluation bias consists of two components: *intrinsic bias* and *extrinsic bias*.

The intrinsic bias reflects translation experts' beliefs about translation errors. Therefore, we retain intrinsic bias in this study. However, whether the extrinsic bias should be eliminated, retained, or partially kept is debatable and depends on the application. In our study, we aim to avoid it in order to gain a clearer understanding of the adequacy–fluency tradeoff at the evaluation level. In other contexts, one could argue that adequacy assessment should have greater influence on meta-evaluation outcomes, even at the cost of reduced fluency influence. In both cases, the extrinsic bias must first be measured separately from the intrinsic bias.

4.2 Measuring the Extrinsic Bias

To study the extrinsic bias, we propose to compare the F-statistics (Weir and Cockerham, 1984) for Adequacy MQM and Fluency MQM. In each case, the F-statistic is formulated as follows:

$$\text{F-statistic} = \frac{\text{between-system variation}}{\text{within-system variation}} \quad (3)$$

where the numerator and denominator are

$$\text{between-system variation} = \sum_{i=1}^{K} \frac{N \cdot (\bar{s}_i - \bar{s})^2}{K-1} \quad (4)$$

$$\text{within-system variation} = \sum_{i=1}^{K} \sum_{j=1}^{N} \frac{N \cdot (s_{i,j} - \bar{s}_i)^2}{N-K} \quad (5)$$

In our scenario, $s_{i,j}$ is the Adequacy MQM or Fluency MQM score of the candidate translation given by the ith system for the jth segment, $\bar{s}_i$ is the average of all the scores by the ith system, and $\bar{s}$ is the average of all the scores. N and K are the numbers of segments and systems, respectively.

The F-statistic is effective at distinguishing extrinsic variation from intrinsic variation because of how its numerator and denominator are defined. On one hand, the intrinsic variation can be regarded as a multiplicative constant within the s variables; it appears in both the numerator and denominator of Eqn. (3) and thus cancels out. On the other hand, the F-statistic captures extrinsic variation, which is due to the selected systems in the meta-evaluation. It does so by normalizing between-system variation with within-system variation.

Notice that the F-statistic depends on N and K, which makes it difficult to interpret. To this end, we adopt the ANOVA framework (Heiman, 2001) and use p-values to quantify extrinsic variation. We perform this analysis separately for Adequacy MQM and Fluency MQM.

We assume that, within each translation system, scores are independent and normally distributed around that system's mean, and that all systems share the same variance[5]; i.e., $s_{i,j} \overset{\text{iid}}{\sim} \mathcal{N}(\mu_i, \sigma^2)$. Under the null hypothesis that all systems have the same mean ($\mu_1 = \mu_2 = \cdots$), the F-statistic in Eqn. (3) follows an F distribution (Johnson et al., 1995) with degrees of freedom $K-1$ and $N-K$. The right-tail p-values are then given by

[5]ANOVA is robust to moderate variance inequality, so this assumption need only hold approximately (Lowry, 1998–2023). For completeness, we report in Appendix D the results using the variance-inequality-tolerant alternative ANOVA (Welch, 1951), which yield the same conclusions; We prefer the standard approach for its simplicity and greater numerical stability.

	Original	Synthesized by		Adequacy MQM			Fluency MQM

Table 3: Adequacy MQM and Fluency MQM statistics for different meta-evaluation setups, along with the B transformation of the difference between their corresponding p-values, macro-averaged across evaluation sets. Each meta-evaluation setup includes one or more system sets drawn from the original, synthesized-by-adequacy, and synthesized-by-fluency system sets.

$1 - \mathrm{CDF}(\text{F-statistic})$, where CDF denotes the cumulative distribution function of the F-distribution. Converting F-statistics to p-values puts results on a common probability scale, and makes the interpretation independent of N and K. We use this p-value as our measure of extrinsic variation.

As mentioned in §4.1, extrinsic variations of Adequacy MQM and Fluency MQM contribute to their respective variances. An asymmetry in these variations induces a bias of meta-evaluation toward adequacy or fluency, which we term *extrinsic bias*. We quantify this bias by

$$\Delta p = p_{\text{ Adequacy MQM}} - p_{\text{ Fluency MQM}} \quad (6)$$

where $p_{\text{ Adequacy MQM}}$ and $p_{\text{ Fluency MQM}}$ are the respective p-values. A positive Δp indicates bias toward adequacy, a negative Δp indicates bias toward fluency, and $\Delta p = 0$ indicates no bias between adequacy and fluency.

We observe that the range of Δp is typically very small (from 10^{-7} to 10^{-31} in Table 2), even in cases where severe bias is present (as shown in our later analysis). For presentation purposes, we report the degree of bias using $B(\Delta p) = \frac{1}{1-\log|\Delta p|}$, and append a special symbol to indicate which aspect dominates: A for adequacy ($\Delta p > 0$) and F for fluency ($\Delta p < 0$). Note that $B \in [0, 1]$, with a lower B indicating less bias.

We report the B values in Table 2, where we compare the influence of Adequacy MQM and Fluency MQM on the meta-evaluation in five evaluation datasets. Results show a consistent extrinsic bias toward adequacy. We argue that this behavior stems from the particular composition of translation systems in the WMT datasets, and may be controlled by carefully selecting or synthesizing systems with more variance in their Fluency MQM.

4.3 Reducing the Extrinsic Bias

In this subsection, we provide a method to reduce meta-evaluation extrinsic bias. This not only has practical values, but also allows us to better evaluate the adequacy–fluency bias of existing translation evaluation metrics (to be discussed in §5).

We accomplish this by considering additional pseudo-translation systems in the meta-evaluation. In particular, we synthesize two sets of translation systems: one exhibiting extreme variations in system-level Adequacy MQM, and the other in Fluency MQM. This design helps to control the variation in each dimension and thereby reduces extrinsic bias through controlled mixing of candidate translation systems.

Suppose we have K original translation systems. We synthesize K adequacy-oriented systems in the following way: for each segment, we assume that the kth synthesized system generates the kth most adequate translation (according to Adequacy MQM), among the original K translation systems' outputs.[6] It is easy to see that, given the available translation candidates, such K synthesized translate systems exhibit extreme variation in Adequacy MQM at the system level. Likewise, we synthesize K fluency-oriented systems, and in total, we have $3K$ translation systems for meta-evaluation. It is emphasized that our research does not require additional annotation effort, as the above synthesizing process utilizes readily available MQM scores.

Table 3 illustrates how synthesized systems help control the extrinsic bias. The table reports the macro-average of metrics across the five evaluation sets (§3.1).

[6]For segments with tied scores, we rank them randomly.

Rows 2 and 3 represent extreme configurations that maximize the F-statistic for Adequacy MQM and Fluency MQM, respectively. We see that they yield extreme B values, with Row 2 being biased toward adequacy and Row 3 toward fluency. This expected pattern confirms that (1) the B value effectively captures extrinsic bias arising from system selection, and (2) our synthesis method can control such a bias.

We observe that the setup in Row 5 has an overall bias toward adequacy (indicated by higher PA and SPA scores), although the extrinsic bias is toward fluency (indicated by the F annotation). This suggests the existence of intrinsic bias discussed in §4.1, further justifying the need of separately quantifying the intrinsic and extrinsic bias.

We also observe that Rows 6 and 7 yield the lowest B values, and we consider them the most balanced meta-evaluation setups, which will be used in our study of adequacy–fluency tradeoff at the evaluation level in §5.

4.4 The Effect of Meta-Evaluation Bias on Metric Comparisons

In the previous parts, we have demonstrated that the standard WMT meta-evaluation is biased toward adequacy, and we propose to carefully synthesize pseudo-translation systems to control this bias. In this part, we show how the meta-evaluation bias can influence the development of translation metrics.

Table 4 presents how the original WMT setup (Row 1 of Table 3) and *our balanced setup* (Row 6 of Table 3) rank various metrics, using PA and SPA as the meta-metrics.

It is interesting to examine "CometKiwi 22 XXL" and "MetricX (ours)" in detail, shown by the bold lines in Table 4. As seen, CometKiwi 22 XXL consistently and significantly outperforms MetricX (ours) under the original meta-evaluation, which is biased toward adequacy; however, this trend is reversed under our balanced meta-evaluation setup. In §5, we will show that CometKiwi 22 XXL has a considerable bias toward adequacy, whereas MetricX (ours) demonstrates a more balanced behavior. This comparison shows that a metric is favored if its bias in the adequacy–fluency spectrum aligns with that of the meta-evaluation; consequently, the development of translation metrics inherits the bias of the meta-evaluation. Our analysis highlights the importance of studying translation meta-evaluation imbalance.

Metric	Original setup PA	Original setup SPA	Our balanced setup PA	Our balanced setup SPA
AdequacyX	0.881 4	0.866 4	0.847 1	0.833 1
AdequacyX QE	0.885 3	0.873 1	0.834 2	0.824 5

Ja–Zh'24	156 (51%)	149 (49%)

Table 5: Concordance and discordance between adequacy and fluency in our balanced setup, reported as system pair counts and percentages.

5 Analysis: Tradeoff at the Evaluation Level

In this section, we analyze the adequacy–fluency tradeoff at the evaluation level and determine the bias of each metric within this tradeoff. Note that the notion of bias considered here is related to but distinct from that in §4. We say a metric is biased toward adequacy or fluency if it ranks translation systems in a way that is more aligned with the ranking derived solely from that aspect, as measured by the corresponding MQM scores.

To study the aforementioned bias, we would like to separately meta-evaluate the adequacy and fluency of each metric, using the original WMT meta-evaluation setup and our balanced setup described in Row 6 of Table 3.[7] Notice that the latter is a

[7]Although Rows 6 and 7 in Table 3 have similar B values, we prefer the former because it is fully synthesized and has a

Metric	Original setup			Our balanced setup

Table 6: PA breakdown for the original setup and our balanced setup, macro-averaged across five evaluation sets. For each metric, the agreements with Adequacy MQM and Fluency MQM sum to 1, by formulation and because ties between system-level Adequacy MQM and Fluency MQM scores are rare.

synthetic setup, which may not be representative of real-world situations. It is included only for our adequacy–fluency analysis.

From the data statistics in Table 5, we observe an even stronger disagreement between adequacy- and fluency-based system rankings under the balanced setup than under the original setup (Table 1). This is expected, as the balanced setup synthesizes the most- and least-adequate systems, which are unlikely to correspond to the most- and least-fluent systems, and vice versa.

Despite the significant discordance between Adequacy MQM and Fluency MQM, we also observe a large number of concordant cases (i.e., one system outperforms another in both Adequacy MQM and Fluency MQM). This raises a challenge when we separately analyze adequacy and fluency. To address this, we design three experimental protocols, as follows.

5.1 PA Breakdown

In this part, we design an experimental protocol using PA to separately analyze how a metric assesses adequacy and fluency, without being misled by the concordant cases. Since PA counts binary agreements, we may simply exclude concordant cases from our adequacy/fluency analysis.

Specifically, we first split our system pairs into two disjoint subsets based on whether their Adequacy MQM and Fluency MQM are concordant or discordant. Then, for each metric we report:

- PA in concordant cases, measuring the metric's general performance;
- PA with respect to Adequacy MQM in discordant cases, which measures the metric's bias toward adequacy (thus we call it "agreement with Adequacy MQM"); and
- PA with respect to Fluency MQM in discordant cases, which is called "agreement with Fluency MQM."

In Table 6, we present the results macro-averaged[8] across different evaluation sets.[9]

As seen, both BLEU and ChrF achieve more agreement with Adequacy MQM than Fluency MQM. This provides empirical evidence for the belief in the literature that BLEU and ChrF lean toward adequacy (Flamich et al., 2025). On the other hand, FluencyX and Gemma 3 exhibit a stronger bias toward fluency, which aligns with their design. Moreover, All MQM shows a strong alignment with Adequacy MQM in the original setup and a weaker alignment in our balanced setup, confirming our claims in §4 that current WMT meta-evaluation is biased toward adequacy and that such bias is partially mitigated in our balance meta-evaluation setup.

clearer construction. For completeness, we also report results for the setup in Row 7 in Appendix E.

[8] In our preliminary experiments, we also analyzed the micro-averaged results, which led to the same conclusions as those obtained here.

[9] We report results for individual evaluation sets under the original setup in Appendix F, where we observe diverse behaviors by the metrics. This variation may be due to the noise of metric performance, which tends to be smoothed out when averaged across evaluation sets.

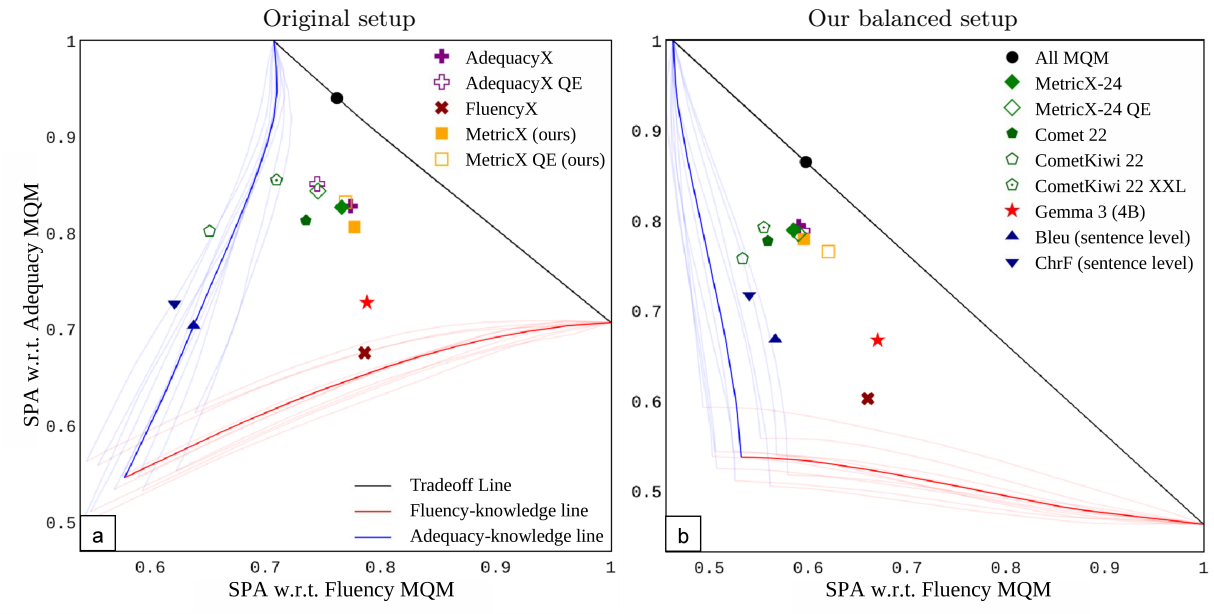

Figure 1: SPA plane using (a) the original setup and (b) our balanced setup. Legends are shared between the two figures. Each shadow line represents the combination of Adequacy MQM or Fluency MQM with a specific random noise instance. The solid red and blue lines are the average of the shadow lines.

Interestingly, FluencyX and Gemma 3 show some alignment with adequacy, despite lacking access to the source texts. This can be explained by two possibilities: (1) These metrics are imperfect and fail to align entirely with Fluency MQM, although designed to do so. (2) When the metrics are trained, they have learned strong prior for adequacy errors (e.g., due to the adequacy–fluency correlation of training segments). This aligns with the findings of Perrella et al. (2024), who show that metrics based solely on candidate translations or source texts can achieve high performance.

For most other metrics, we find that they exhibit stronger alignment with Adequacy MQM than with Fluency MQM. Among them, the MetricX variants display a relatively more balanced behavior than other metrics, including the Comet variants.

Finally, we would like to point out that our analysis sheds light on the position of different evaluation metrics within the adequacy–fluency tradeoff. However, whether a metric should achieve 50%–50% balance or mimicking All MQM (which is highly biased toward adequacy but often treated as the evaluation ground truth) is a task-specific design choice.

5.2 SPA Plane

We also aim to conduct an adequacy–fluency analysis using SPA. However, we cannot mirror the PA breakdown in §5.1, because SPA lacks a binary notion of concordance versus discordance. Instead, we perform qualitative visualization to demonstrate the adequacy–fluency tradeoff of a metric.

Specifically, we design a plot where the x-axis and y-axis represent SPA computed with respect to Fluency MQM and Adequacy MQM, respectively. Each metric is shown as a single point in this space. We then augment the plot with three sentinel lines:

- *Tradeoff line* (the black lines in Figure 1), representing the linear interpolation of Adequacy MQM and Fluency MQM. No system can surpass the tradeoff line.
- *Adequacy-knowledge line* (the blue lines in Figure 1), derived from linear interpolation of Adequacy MQM and random scores (i.e., uniform in the range of Adequacy MQM scores for each segment). The interpolation is accomplished by weighted average of the scores. Points on this line achieve fluency scores solely due to the correlation between Adequacy MQM and Fluency MQM.
- *Fluency-knowledge line* (the red lines in Figure 1), derived from linear interpolation of Fluency MQM and the random score.

The latter two lines are averaged from 10 computations with different random score instances.

These three lines form a triangle-like shape with vertices at Adequacy MQM, Fluency MQM, and pure random noise. A metric's closeness to the tradeoff line indicates its general quality, while its closeness to the other two lines reveals its bias toward adequacy or fluency.

Metric	Unnormalized sensitivity		Normalized sensitivity	
	Adequacy	Fluency	Adequacy	Fluency
All MQM	0.995	0.998	0.882	0.353

Table 7: Normalized and unnormalized sensitivity against adequacy and fluency.

Figure 1 presents the results, also macro-averaged across the evaluation sets in §5.1. The black line illustrates the severity of the adequacy–fluency tradeoff in translation evaluation (given a certain meta-evaluation setup): a larger top-right area indicates a more severe tradeoff, as this area is not reachable. As shown, our balanced setup exhibits a more severe tradeoff, which is consistent with Table 5. Moreover, our balanced setup has a larger angle between the blue and red lines, indicating a lower correlation between the two aspects.

Regarding specific metrics, we observe that FluencyX and Gemma 3 lie close to the fluency boundary (red line), while other metrics (namely, BLEU, ChrF, Comet, and MetricX) are biased toward adequacy. In particular, Comet variants are more biased than MetricX variants. The SPA results are consistent with the analysis using PA (§5.1).

5.3 Sensitivity Analysis

In §5.1 and §5.2, we illustrate the position of each metric in the adequacy–fluency tradeoff by their system-level ranking prediction. Here, we aim to analyze how each metric reacts to an adequacy or fluency error.

We do this by controlling one aspect while varying the other. Take adeqacy as an example. Given a source segment, we consider pairs of translation candidates that share the same Fluency MQM but differ in Adequacy MQM. For a metric, we report $\frac{\Delta \text{ metric score}}{\Delta \text{ Adequacy MQM}}$, averaged over all our translation pairs. This measures the expected change in the metric score per one-point difference in Adequacy MQM.

We also report a normalized version of the above measure by multiplying it with $\frac{\sum \sigma(\text{Adequacy MQM})}{\sum \sigma(\text{metric score})}$, where $\sigma(\cdot)$ is the standard deviation over different candidate translations given a segment, and the sum is taken over all segments. This scaling enables meaningful comparison across metrics with different output scales.

Table 7 reports the results for both adequacy and fluency. Here, we can interpret the bias of a metric by comparing the sensitivity to adequacy and that to fluency. Generally, our findings in previous subsections are also observed in this experiment, except for the normalized sensitivity of FluencyX, which requires further investigation.

Overall, this section provides three analysis protocols (PA Breakdown, SPA Plain, and Sensitivity Analysis) to study the position of different evaluation metrics within the adequacy–fluency tradeoff. Our key findings in this section include: (1) Most of the translation metrics are biased toward adequacy, and (2) For the commonly used MetricX and Comet metrics, the former exhibits a more balanced behavior than the latter. Consistent observations in different protocols cross-validate the reliability of our findings.

6 Conclusion

In this work, we investigate the adequacy–fluency tradeoff in translation. While this tension is well-documented at the level of translation output (Flamich et al., 2025), we show that it also manifests severely at the levels of evaluation and meta-evaluation.

Through empirical analysis of WMT meta-evaluation protocols, we uncover a systematic bias toward adequacy, driven by the composition of meta-evaluation datasets. We also propose a method that can control the balance between adequacy and fluency.

We further analyze the placement of popular translation evaluation metrics along the adequacy–fluency tradeoff and find that most metrics lean toward adequacy.

We argue that the adequacy–fluency tradeoff is a critical yet under-recognized matter in translation evaluation and meta-evaluation. While we do not take a stance on how to deal with such bias, our primary contribution is to raise awareness of this matter within the community.

We discuss future work in Appendix G.

Limitations

Our work provides an extensive investigation of adequacy–fluency trade-offs in the evaluation and meta-evaluation of machine translation. However, it also has limitations.

First, our work is based on MQM data, which includes human evaluation that is inherently noisy. It places limits on the generality of the conclusion we draw in this paper. To mitigate this, we report results macro-averaged over five translation datasets. The results on individual dataset are considerably noisier, as shown in Appendix F.

Second, this study covers only a limited set of language pairs and systems, owing to the limited availability of MQM data. Expanding the evaluation data would yield more robust conclusion.

Third, we only analyze extrinsic bias (caused by the composition of translation systems in meta-evaluation), while not addressing the intrinsic bias (caused by the design of the MQM framework). Studying the intrinsic bias is highly impactful and warrants further efforts.

A Adequacy MQM and Fluency MQM Categorization

As mentioned in §3.1, we consider Adequacy MQM and Fluency MQM separately, following the categorizations provided in Flamich et al. (2025). Table 8 shows the categorization used for En–De, Ja–Zh, and Zh–En. Specially, En–Es follows the categorization in Table 9.

B Dataset Statistics

Table 10 summarizes key statistics for each evaluation dataset in our study.

C PA vs. SPA

In the main paper, we mention that PA and SPA could behave differently, and that it is necessary to consider both PA and SPA in our study. In this appendix, we use a toy example to illustrate the potential disagreement of PA and SPA when assessing whether a metric is biased toward Adequacy MQM or Fluency MQM.

Table 11 shows the details of our example. In this case, PA suggests that the metric is biased toward adequacy, because PA only judges based on the sign. However, SPA suggests the opposite, as it concerns the closeness of the score difference. See §2.2 for details.

Therefore, we use both of the metrics, and design dedicated experiments for them. Luckily, our findings are generally consistent under PA and SPA, suggesting that they are reliable meta-metrics in our study.

D Measuring Extrinsic Bias without Equal-Variance Assumption

In §4.2, for simplicity we assume that all translation systems share the same variance in their Adequacy MQM scores and the same variance in their Fluency MQM scores. In this part, we drop this assumption and use Welch (1951)'s ANOVA approach (which does not require the equal-variance assumption) to calculate F-statistics and B values.

Table 12 reports our results. The findings are consistent with those reported in Table 2 under the equal-variance assumption. We nevertheless prefer the standard approach presented in the main text due to its greater simplicity and numerical stability. Note that we observe undefined p-values in our preliminary experiments for some synthetic datasets in §4.3, if we do not have the assumption.

E Analysis Results for Setup 7

In this section, we present the results of PA Breakdown (§5.1) and SPA Plane (§5.2) based on Setup 7 in Table 3. We include this setup for the sake of completeness, as it closely matches Row 6 (used in our main analysis) in terms of B values. Table 13, Table 14, and Figure 2 present the concordance/discordance ratio, PA Breakdown, and SPA Plane results, respectively, for Setup 7. All our findings based on Setup 6 also hold in this setup.

F Adequacy–Fluency Tradeoff Results on Individual Evaluation Sets

In §5, we report results macro-averaged across five evaluation sets (of different language pairs). In this part, we present the results on each evaluation set.

In Table 15 and Figure 3, we report PA-Breakdown and SPA Planes results based on the original WMT setup, presented separately for each evaluation set. The results exhibit diverse behaviors across evaluation sets. Thus, we perform macro-average in our main paper. The noisy phenomenon requires further investigation.

G Future Work

Our study opens several avenues for future research, discussed below.

Accuracy errors	Fluency errors		Other
Accuracy/Addition	Fluency/Grammar	Style/Archaic or obscure word choice	Other
Accuracy/Creative Reinterpretation	Fluency/Inconsistency	Style/Bad sentence structure	Source issue
Accuracy/Gender Mismatch	Fluency/Punctuation	Style/Unnatural or awkward	
Accuracy/Mistranslation	Fluency/Register	Locale convention/Address format	
Accuracy/Omission	Fluency/Spelling	Locale convention/Currency format	
Accuracy/Source language fragment	Fluency/Text-Breaking	Locale convention/Time format	
Non-translation!	Terminology/Inconsistent	Terminology/Inappropriate for context	

Table 8: Flamich et al. (2025)'s categorization of MQM errors, used for En–De, Ja–Zh, and Zh–En translation directions.

Accuracy errors	Fluency errors		Other
Addition	Capitalization	Date-time format	Other
Agreement	Inconsistency	Lacks creativity	Source issue
Do not translate	Grammar	Measurement format	
Mistranslation	Number format	Punctuation	
MT hallucination	Register	Spelling	
Omission	Unnatural flow	Whitespace	
Untranslated	Word order	Wrong language variety	
Wrong named entity			
Wrong term			

Table 9: Flamich et al. (2025)'s categorization of MQM errors, used for the En–Es translation direction.

Year	2023	2023	2024	2024	2024
Language pair	En–De	Zh–En	En–De	En–Es	Ja–Zh
Mean All MQM	6.17	2.51	2.50	0.58	2.92
Mean Adequacy MQM	3.97	1.62	1.38	0.45	2.55
Mean Fluency MQM	1.99	0.89	1.10	0.13	0.35
Mean non-zero All MQM	10.02	5.20	4.95	3.00	6.00
Mean non-zero Adequacy MQM	9.39	6.21	5.63	3.91	6.38
Mean non-zero Fluency MQM	4.23	2.36	2.82	1.37	2.07
# segments	5520	1954	8766	8722	7840
# segments w/o errors (All MQM = 0)	1350	350	3901	6672	3842
# segments w/ errors (All MQM > 0)	4170	1604	4865	2050	3998
# segments w/ adequacy errors (Adequacy MQM > 0)	2919	891	2738	1393	3354
# segments w/ fluency errors (Fluency MQM > 0)	3149	1250	3462	849	1325

Table 10: Dataset statistics by language pair.

First, we reveal the potential imbalance in the translation meta-evaluation and highlight the importance of understanding this phenomenon (§4). We propose a statistical measure to quantify this imbalance and design a method to control it through data synthesis. However, there is room for improvement in both measuring the imbalance and debiasing the meta-evaluation. In particular, we are interested in exploring theoretical approaches to debiasing the meta-evaluation outputs by normalizing scores in a post hoc manner, without altering the datasets.

Second, we develop dedicated translation metrics, AdequacyX and FluencyX, to independently assess adequacy and fluency (§3.3). We aim to further improve this separation, as it facilitates adequacy–fluency analyses, especially in scenarios where MQM annotations are not available.

Third, as we are now in the era of large language models (LLMs), it is interesting to study the LLM-as-a-judge for translation through the lens of the adequacy–fluency tradeoff, for example, understanding and steering the bias of LLM-as-a-judge.

	Sys 1	Sys 2	Δ
Adequacy MQM	8.0	6.0	+2.0
Fluency MQM	6.0	6.5	−0.5
Metric	6.3	6.0	+0.3

closer

same sign

Table 11: A toy example illustrating potential disagreement between PA and SPA: PA prefers keeping the same sign, whereas SPA prefers the closer one. Here, all numbers are hypothetical for illustration purposes.

	F-statistic		$B(\Delta p)$
	Adequacy	Fluency

Abstract

Existing document-level machine translation resources are only available for a handful of languages, mostly high-resourced ones. To facilitate the training and evaluation of document-level translation and, more broadly, long-context modeling for global communities, we create DocHPLT, the largest publicly available document-level translation dataset to date. It contains 124 million aligned document pairs across 50 languages paired with English, comprising 4.26 billion sentences. By adding pivoted alignments, practitioners can obtain 2500 additional pairs not involving English. Unlike previous reconstruction-based approaches that piece together documents from sentence-level data, we modify an existing web extraction pipeline to preserve complete document integrity from the source, retaining all content, including unaligned portions. After our preliminary experiments identify the optimal training context strategy for document-level translation, we demonstrate that LLMs fine-tuned on DocHPLT substantially outperform off-the-shelf instruction-tuned baselines, with particularly dramatic improvements for under-resourced languages. We open-source the dataset under a permissive license, providing essential infrastructure for advancing multilingual document-level translation.

1 Introduction

The field of natural language processing (NLP) is shifting its focus toward end-to-end, complex tasks, including the domain of machine translation. This increases the demand for techniques and resources beyond the sentence level, with document-level machine translation (DocMT) being a prime example (Maruf and Haffari, 2018; Zhang et al., 2018; Agrawal et al., 2018; Huo et al., 2020). While there is not a single definition of a document, DocMT requires models to translate more than one sentence as a coherent unit rather than isolated segments. This approach is necessary for handling various discourse phenomena: *anaphora, deixis, ellipsis, discourse connectives, grammatical and lexical cohesion* (Maruf et al., 2021), which sentence-level translation typically loses (Müller et al., 2018; Bawden et al., 2018; Voita et al., 2018). Recent long-context large language models (LLMs) are well-suited for this task, as they are usually pre-trained to process thousands of tokens at a time. However, DocMT remains largely unexplored or untested for most languages due to a simple but significant problem: we lack document-level parallel data for both model building and evaluation.

Historically, parallel corpora were mostly constructed in a sentence-oriented manner, using a pipeline that split the text into sentences, aligned them, and then discarded unaligned and multiply-aligned sentences. While a handful of language pairs have some document-level MT resources, the majority of languages have none. This creates two related problems at once: we cannot build DocMT for these languages, and we cannot evaluate DocMT properly. As NLP research moves toward more end-to-end, context-aware applications, this data gap means that most languages get left behind.

We tackle this problem by extracting parallel documents from large web crawls, but our methodology differs from the majority of previous efforts that reconstruct data from sentence pairs after the fact. Instead, we modify the web extraction pipeline itself to preserve document structure from the beginning, retaining documents in their entirety with all original context and non-parallel text. For each language pair, we deliver the aligned documents along with quality-scored sentence alignments and alignment density metrics.

Our effort yielded DocHPLT, a large multilingual document-level translation dataset covering 50 language pairs with English, listed in Appendix A.

★Equal contribution. Public access to DocHPLT: https://huggingface.co/datasets/HPLT/DocHPLT.

Proceedings of the Tenth Conference on Machine Translation, pages 286–300
November 8-9, 2025

The resulting corpus contains 87.8 million documents in English and 50 other languages, 124 million aligned document pairs, and 4.26 billion sentences. A highlight of our work is the focus on medium- and low-resource languages that previous DocMT datasets have overlooked. Practitioners can also use English as a pivot to align up to 2500 extra non-English pairs, expanding the dataset's usefulness beyond English-centric translation.

Using DocHPLT, we conduct extensive experiments with different modeling methods for LLM-based document-level translation. We first try different context sizes for LLM fine-tuning: 1) full document-to-document training with loss calculated on the entire target; and 2) chunk-based training with loss computed on individual segments. These experiments determine the optimal context granularity for our subsequent work. Then, in addition to prompting off-the-shelf instruction-tuned large language models (LLMs) as a baseline, we run monolingual and multilingual fine-tuning using DocHPLT, tested on both seen and unseen languages. The usefulness of our data is reflected empirically: LLMs fine-tuned on our data consistently outperform prompting baselines, showing that practitioners can gain strong performance in DocMT for languages often considered "unsupported" in the machine translation research community.

In summary, our contributions, centred around the DocHPLT resource, are as follows:

- **Scale and diversity:** DocHPLT is the **largest** publicly available document-level translation resource: 124M document pairs for 50 languages paired with English, totaling 4.26B sentences, with extensive medium- and low-resource coverage.
- **Document-first approach**: Instead of piecing together documents from aligned sentence pairs, we preserve complete documents with original structure and unaligned text, enriched with quality metrics such as alignment density and sentence pair-level scores.
- **Empirical validation**: Through LLM experiments on both the internal test set and WMT24++, we establish baselines, test different training strategies, and demonstrate gains in DocMT using our data.

2 Related Work

2.1 Document-Level Translation

Document-level translation aims to process an entire document as a coherent unit, rather than processing each sentence independently. This paradigm leverages the ability of modern neural architectures, lately LLMs, to handle long context, making it particularly effective for capturing document-level discourse structures. Recent work has demonstrated that going beyond sentence-level translation is essential for handling discourse phenomena such as coreference resolution (Müller et al., 2018; Bawden et al., 2018; Voita et al., 2018). The development of dedicated document-level benchmarks further reflects this growing interest in evaluating MT systems in context (Guillou and Hardmeier, 2016; Jwalapuram et al., 2020; Wicks and Post, 2023; Fernandes et al., 2023).

Moreover, a variety of modeling strategies have been proposed for DocMT (Tiedemann and Scherrer, 2017; Maruf and Haffari, 2018; Zhang et al., 2018; Agrawal et al., 2018; Sun et al., 2022), and more recent works adapt LLM-based architectures (Wang et al., 2023; Petrick et al., 2023; Wu et al., 2024; Jin et al., 2024; Ramos et al., 2025; Hu et al., 2025). However, there is still no standard practice in training to ensure effective context handling or in assessing document-level translation. Also, performance gains over strong sentence-level baselines remain inconsistent and not clearly attributable to effective context utilization (Kim et al., 2019). In this work, we try out various context sizes in LLM fine-tuning to establish effective training strategies on DocHPLT.

2.2 Document-Level Translation Data

Although there have been several massive-scale parallel corpus mining efforts (Bañón et al., 2020; El-Kishky et al., 2020; Schwenk et al., 2021; de Gibert et al., 2024; Burchell et al., 2025), document-level data remain limited in size and scope, particularly when extending beyond English-centric or high-resource languages. Moreover, there is little agreement on what constitutes a "document"; definitions vary widely across studies, ranging from short paragraphs to entire articles or books. This lack of standardization, combined with the scarcity of large-scale multilingual document-level corpora, motivates the need for more diverse resources such as the one we present in this work. Before illustrating our data methodology, we survey two typical

methods used in creating document-level translation data.

Reconstruction-based A common strategy to obtain document-level parallel data is to reconstruct from existing sentence-level data. Notably, the sentence-level ParaCrawl (Bañón et al., 2020) has been widely used as a seed for this purpose. Al Ghussin et al. (2023) extracted English–German parallel paragraphs from ParaCrawl, although these are not full-document units. ParaDocs (Wicks et al., 2024) recovered document-level data from ParaCrawl, News Commentary (Kocmi et al., 2023), and Europarl (Koehn, 2005) for German, French, Spanish, Italian, Polish, and Portuguese, all paired with English. Similarly, Pal et al. (2024) released a large-scale reconstructed corpus for German, French, Czech, Polish, and Russian—again all paired with English, along with an open-source pipeline for extension to other languages.

Collection-based An alternative approach is to collect or create document-level parallel corpora directly from targeted sources from scratch. Earlier efforts include Europarl based on the proceedings of the European Parliament (Koehn, 2005) and OpenSubtitles from movie and TV subtitles (Lison and Tiedemann, 2016), but these essentially consist of "spoken" documents, where the former is divided into speeches and the latter into films/shows. Literary works have also been a popular origin. Jiang et al. (2022) introduced a Chinese–English corpus based on web novels, where each chapter, with a median of 30 sentences, is treated as a document. Thai et al. (2022) created PAR3 by aligning machine and human translations of 118 novels across 19 languages at the paragraph level. Jin et al. (2024) constructed JAM from 160 English-Chinese novel pairs with chapter-level alignment. More recently, Alabi et al. (2025) created AFRIDOC-MT, a document-level translation corpus sourced from IT news and health articles and manually translated from English. By covering Amharic, Hausa, Swahili, Yorùbá, and Zulu, it extends DocMT data to medium and lower-resourced languages. Wastl et al. (2025) scraped a Swiss online news outlet to create 20min-XD, a French-German dataset. Such data, directly derived from resources intended to be document-aligned, is high-quality but often limited by languages due to the coverage of the upstream source and/or the cost and effort required.

Key methodological differences in this work Our work gathers document translations from large web crawls, but differs fundamentally from reconstruction-based approaches. As explained later in Section 3, rather than piecing together documents from sentence pairs post-hoc, we modify the document alignment stage of the extraction pipeline to preserve complete document structure from the beginning. This document-first methodology ensures we retain all original content, including unaligned portions, positioning our approach as collection-based at the document level while leveraging existing text crawling and processing infrastructure.

3 DocHPLT

In this section, we explain how we modify and then apply an existing parallel sentence extraction pipeline from ParaCrawl to extract a document-level corpus from a large multilingual web crawl, HPLT.

3.1 Dataset Creation

The starting point for our dataset creation is 15TB of cleaned web documents derived from the Internet Archive[1] and CommonCrawl[2] released as version 2 of the HPLT corpus (Burchell et al., 2025). In the preparation of HPLT, the document text was extracted from HTML using Trafilatura (Barbaresi, 2021) and language-classified using openLID (Burchell et al., 2023). In this work, a *document* is defined as *the full text content retrieved from archive snapshots of a specific URL.*

To extract a parallel corpus of documents, we use a modified version of the ParaCrawl extraction pipeline (Bañón et al., 2020). The original pipeline is sentence-oriented, i.e. it produces a sentence-aligned corpus and discards unaligned sentences. But because the pipeline runs document alignment followed by sentence alignment in separate stages, we are able to intervene to produce document-oriented data. We extract and record each pair of aligned documents, then map the unfiltered sentence alignments back into their source documents. This document-first methodology ensures we retain all document content, even unaligned portions, to provide richer context than traditional parallel corpora.

BF: Bifixer, **BC**: Bicleaner, **BA**: BLEUalign. Higher values indicate better alignment and translation quality.

Figure 1: An example of good, bad (in blue), and multi-way alignments for English-Catalan docs.

Document structuring We transform each document into a hierarchical XML representation that preserves its internal structure. Paragraphs are split by newline characters and maintain their original boundaries, while the text of each paragraph is segmented into sentences using the Loomchild Segmenter (Miłkowski and Lipski, 2011). Every structural element receives a unique identifier with paragraphs, such as `<P id="4">`, and sentences, such as `<s id="4.3">`. This structured representation allows us to track alignments at both document and sentence levels while retaining all content from the original HPLT documents.

Content-based deduplication Since our initial collection contains multiple temporal snapshots of the same URLs, we implement a content-based deduplication strategy. First, within each language-specific collection, we remove duplicates, using the URL together with the full text as the key. This ensures we keep only unique document versions for each URL. Second, we perform global deduplication, based on the URL and text as the key, across all English documents from the 50 language pairs, consolidating them into a single collection. This is necessary because the same English document may appear in multiple language pairs (e.g., the same English page aligned to both Basque and Catalan translations). After deduplication, we have a clean collection of unique documents for each of the 50 source languages and a single, unified collection for all English documents, ensuring each unique document version appears exactly once while preserving all alignment relationships.

We deliberately preserve duplicate content across different URLs and retain near-duplicates within the same URL. This design choice maximizes research flexibility by allowing downstream users to apply filtering strategies suited to their particular use cases. Additionally, duplicate content from different URLs preserves valuable metadata, particularly the source URL, which may indicate different domains, publication contexts, or content distribution patterns. Near-duplicates also represent meaningful content variations such as updates, revisions, or editorial differences. Deduplicating content only for each language separately results in a 3.3% drop in our document count from the original DocHPLT corpus (see Appendix A).

Alignment verification and generation The ParaCrawl pipeline originally used MinHash (Broder, 1997) to deduplicate similar sentences, grouping them and assigning the same quality scores regardless of their source documents. We modify this step to remove MinHash deduplication entirely, instead maintaining all original texts and tracking which documents they came from. This allows us to preserve the complete document structure while still computing alignment quality scores—BLEUalign (Sennrich and Volk, 2010), Bicleaner, and Bifixer (Ramírez-Sánchez et al., 2020)—for each sentence pair. The document in Figure 1 illustrates examples of good, bad, and multi-way alignments along with their corresponding quality scores. We then map each alignment back to its specific source and target documents, maintaining the document-sentence relationships throughout the process. For any document that had multiple versions with the same URL, we explicitly

check that every sentence referenced in an alignment link actually exists in the final XML file to ensure it references the correct version(s). The output follows the standard `cesAlign` XML format[3], where each alignment links specific sentence IDs between source and target documents along with their quality scores.

MultiDocHPLT by pivoting via English As a "bonus" data release, English can be used as a pivot language to derive a corpus beyond the English-centric pairs. This enables the modeling and evaluation of DocMT between two non-English languages. The process is straightforward: if a document in a language and another document in another language are both aligned to the same English document, then we assume a direct alignment between the two documents. We pivot the sentence alignments in a similar way.

3.2 Data Statistics

In this section, we present the statistics of our English-centric dataset. We provide full tables in Appendix A: Table 7 details total documents and sentences per language, while Table 8 reports alignment statistics for each language pair. Specifically, for each language pair, we report the number of aligned document pairs (#doc pairs), the total number of alignments (#alignments), the average number of sentences per aligned document (avg #aligns./#docs), document length ratio calculated as the average number of sentences in English relative to the target language (avg #sent_en/#sent_xx), number of sentences per document (#sent/#docs), and the average alignment scores.

Across all language pairs, DocHPLT contains 87.8 million unique documents with 4.26 billion total sentences, averaging 48.6 sentences per document. The English collection dominates with 47.5 million documents (2.67 billion sentences), while individual non-English languages range from Japanese with 4 million documents (164 million sentences) down to Xhosa with 22 thousand documents (996 thousand sentences). These documents form 124 million aligned document pairs, with an average of 14.8 sentence-level alignments per document pair. Document coverage varies significantly: Japanese-English and Turkish-English each contribute over 11 million aligned document pairs, respectively, while under-represented languages like Sinhala-English (123 thousand document pairs), Uzbek-English (157 thousand document pairs), and Xhosa-English (44 thousand document pairs) have substantially smaller collections.

We observe considerable variations in document length ratios between aligned pairs, ranging from 3.91 (Malayalam-English), where the English documents are typically longer, to 0.84 (Arabic-English). Additionally, the average Bicleaner scores vary significantly, with language pairs like Arabic-English (0.700) demonstrating relatively high-quality alignments, whereas pairs such as Maltese-English (0.293) display substantially lower average alignment quality.

Alignment density Furthermore, we calculate alignment density (AD), which is defined as the proportion of aligned sentence pairs between two documents relative to the length of the longer document. Formally, given two documents D_{src} and D_{tgt}, with $|D_{\text{src}}|$ and $|D_{\text{tgt}}|$ denoting their respective sentence counts, the alignment density is computed as

$$AD = \frac{\text{\# of aligned sentence pairs}}{\max(|D_{\text{src}}|, |D_{\text{tgt}}|)} \quad (1)$$

Alignment density ranges between 0 (no aligned pairs) and 1 (perfect sentence-level coverage) if alignments are strictly one-to-one; however, since our alignment procedure allows one-to-many and many-to-one mappings, values above 1 are also possible. This feature may reveal the quality and the characteristics of the documents: an AD of exactly 1 could suggest that the documents were machine-translated (at the sentence level), whereas a very low AD might imply that they were accidentally matched, possibly due to high-frequency phrases or placeholders.

We observe considerable variation in AD across language pairs, e.g., Welsh-English (cy-en) and Afrikaans-English (af-en) show notably high average alignment densities (0.426 and 0.446, respectively), compared to languages like Farsi, Malayalam, and Marathi, where alignments are much sparser (0.153, 0.151, and 0.150, respectively). While some language pairs exhibit higher or lower densities, these scores are better understood relative to other scores rather than absolute terms.

We did not observe any consistent correlation between automatic quality metrics (BicleanerAI and CometKiwi) and AD values. Future work should investigate more carefully how AD should be interpreted and framed.

4 Experiments and Findings

In order to test the usefulness of our dataset, we apply it to the task of fine-tuning LLMs for MT. Our first set of experiments tests different context lengths for this fine-tuning to see how much performance is affected by using the larger document contexts that DocHPLT enables. We then compare this best-performing fine-tuned configuration against off-the-shelf instruction-tuned models on the same test set. Finally, we investigate monolingual and multilingual fine-tuning for DocMT on DocHPLT. In the following sections, the notation of "src-trg" refers to the src-to-trg translation direction.

Languages We test translation from English into a total of 10 languages, chosen for their diversity in script, typology, and resource availability, as well as their inclusion in WMT24++ (Deutsch et al., 2025) (for testing) and CometKiwi (Rei et al., 2022) (for filtering). The languages are Arabic (ar), Catalan (ca), Hindi (hi), Estonian (et), Persian (fa), Finnish (fi), Icelandic (is), Korean (kr), Malayalam (ml), and Urdu (ur). It is worth noting that generating non-English is usually harder for LLMs compared to generating English.

Data processing We preprocess the documents for training by removing those with an AD below 0.3 or a document-averaged Bicleaner score below 0.3. We then discard unaligned segments in either source or target, and merge segments in a one-to-many alignment into a single segment. Finally, we filter data using CometKiwi (Rei et al., 2022) with SLIDE (Raunak et al., 2023): a window of 3 and a slide of 1. We retain document pairs with a CometKiwi score in the top 25$^{\text{th}}$ percentile for every language. This is to ensure that only high-quality parallel documents are used for training or evaluation.

Model training and inference We perform supervised fine-tuning (SFT) on Qwen2.5-7B-Instruct (Qwen et al., 2025) and Llama-3.1-8B-Instruct (Grattafiori et al., 2024) with LoRA, rank 16 and alpha 32 (Hu et al., 2022), using the `open-instruct` toolkit[4]. Unless stated otherwise, our models are fine-tuned on 1000 documents per language, due to compute constraints. Our hyperparameters are listed in Appendix B. At test time, we always translate an entire source document in a single pass. LLM's chat template is always applied. All prompt information is detailed in Appendix C.

en-is	492
en-ko	497
en-ml	473
en-ur	486

Table 1: Test sizes after de-near-duplication (decontamination); always 500 for unseen language pairs.

Evaluation set We conduct evaluations on two test sets: a held-out set from DocHPLT and WMT24++, selected for their overlapping language coverage. We construct DocHPLT test by randomly sampling 500 documents per language from the CometKiwi-filtered corpora. We de-contaminate on the English side by computing Jaccard similarity over bigrams and removing any test document with a similarity above 0.8 to any training document. This ensures that our evaluation is not biased towards training on *similar* documents. The final test sizes are shown in Table 1.

Metrics We compute BLEU[5] (Papineni et al., 2002) and chrF++[6] (Popović, 2017) by treating each hypothesis document and reference document as a single string, and then averaging these scores across all documents. Our metric choice avoids the need for sentence-level alignment, which DocMT outputs do not guarantee. We note that while neural metrics such as COMET or LLM-as-a-judge are generally more reliable at the sentence level, their effectiveness in our document-level setting remains uncertain due to limited empirical validation, context support, and language coverage.

4.1 How much context do document-level models need?

Existing research on DocMT with LLM adopts distinct strategies to process data. Some approaches operate on a sentence level but use previous translations as context (Wu et al., 2024), some methods process fixed-size chunks (Alabi et al., 2025; Wicks et al., 2024; Post and Junczys-Dowmunt, 2024), translating each chunk separately, and some perform full document-to-document translation (Ramos et al., 2025). We start our experiments by training models using varying context lengths

to find the best configuration.

Setup We build en-xx models for five target languages separately: Finnish, Icelandic, Korean, Malayalam, and Urdu. We fine-tune two open-source LLMs: Qwen2.5-7B-Instruct and Llama-3.1-8B-Instruct. We fine-tune each model under five different context configurations: sentence-level (chunk 1, no context), chunks of 2, 5, and 10 sentences, as well as full document-to-document (doc2doc) training. For chunk-based training, we compute the loss only on target segments while providing source context. The total number of tokens is kept constant for all languages, despite the different data formats.

Results Our experiments in Table 2 reveal a clear and consistent pattern on the DocHPLT test set: measures of translation quality systematically improve as the input size increases from a single sentence to a 10-sentence chunk. As shown in the table, fine-tuning with 10-sentence chunks almost universally delivers the best performance across models, directions, and metrics. The gains are particularly dramatic for lower-resource pairs, such as en-is, where the BLEU score for Llama-3.1-8B-Instruct jumps from a sentence-level performance of 6.51 to 32.07. Nonetheless, full document-to-document training consistently underperforms the 10-sentence chunking strategy. This indicates that while substantial context is crucial, training LLMs on entire documents still poses challenges. This is consistent with Peng et al. (2025)'s findings that LLM-based translation degrades on longer documents.

However, we cannot observe a clear trend for WMT24++ regarding the training context size. The results are inconsistent, and the benefits of larger context windows are less clear. In several cases, smaller context windows or even simple sentence-level fine-tuning outperform the larger-context models, such as Qwen2.5-7B-Instruct on en-ml and en-ur. We hypothesize that the performance difference is due to document length variation as a domain bias. WMT24++ documents have roughly half the average number of tokens com-

Table 4: Results from prompting instruction-tuned (IT) LLMs and those further fine-tuned (FT) on DocHPLT.

pared to DocHPLT (Table 3), so most WMT24++ documents fit within a small chunk size. This creates a mismatch where training on larger chunk sizes is unnecessary or harmful, as longer contexts rarely occur in WMT24++.

These results show that the optimal context strategy for document-level translation is not absolute but is dependent on the test data characteristics. Based on our findings, we establish a training chunk size of 10 for all subsequent experiments.

4.2 Does fine-tuning on DocHPLT help document-level translation?

One key indicator of the usefulness of a data resource is whether practitioners can create better models using it. Although the origin of our data is web crawls, which may have been consumed by LLM pre-training, the parallelism signals are new in DocHPLT and not accessible through pre-training. Thus, in this section, we compare the results of fine-tuning LLMs to prompting baselines.

Setup We compare our fine-tuned models with the best-performing data configuration of chunk size 10 to their corresponding off-the-shelf instruction-tuned models. Evaluation is done on held-out DocHPLT test sets and WMT24++.

Results Table 4 shows that fine-tuning on DocHPLT produces notable improvements across nearly all settings, with gains inversely proportional to language resource levels. On DocHPLT test, lower-resourced languages see bigger jumps, e.g., in BLEU: 10.42 to 32.54 for Icelandic, 3.05 to 12.20 for Malayalam, and 3.79 to 11.11 for Urdu, whereas gains are more modest for higher-resourced languages, e.g., 11.01 to 13.87 for Finnish. On WMT24++, baseline prompting performance is generally poor, often below 6 BLEU, and improvements from fine-tuning persist but are smaller in absolute terms. This may be attributed to WMT24++'s domain mismatch (e.g., social and speech) with DocHPLT.

Our results suggest that off-the-shelf instruction-tuned models may already contain knowledge for these medium to low-resourced languages, yet fine-tuning on DocHPLT consistently improves performance across these languages. This underscores the value of our DocHPLT, which is the *first* to cater to those languages in this task. Nonetheless, we note that a higher performance does not necessarily indicate higher data quality—it may also be a result of greater exposure to a given language or to document-level input and output. A causal analysis will be useful, but for most of the languages we study, there is no suitable alternative data to compare to at the moment.

4.3 Does multilingual training improve over monolingual models?

While our monolingual fine-tuned models achieve significant gains over prompting baselines, deploying and maintaining separate models for each language presents scalability drawbacks. Furthermore, multilingual LLM fine-tuning may offer performance advantages over monolingual tuning (Chen et al., 2024). To test whether our multilingual DocHPLT can be exploited for cross-lingual transfer in training, in this section, we build and assess multilingual models. Particularly, we test on both seen and unseen languages to determine whether benefits extend beyond training languages.

Setup We compare three data configurations: a monolingual FT approach and two multilingual FT settings, resulting in three models:

- Mono_{1K}: a monolingual FT data approach that uses 1000 documents per language.

Table 6: Results from prompting instruction-tuned (IT) LLMs and multilingual fine-tuning for *unseen languages*.

- Multi_{1K}: a multilingual setting that uses 1000 documents combined, with 200 from each of the 5 languages, intended to match the total size for monolingual FT.

- Multi_{5K}: another multilingual setting that uses 5000 documents in total, with 1000 from each language, intended to match the size for each language in monolingual FT.

All models are trained with consistent hyperparameters as in Appendix B. We stick to our best-performing data configuration of chunk size 10.

We evaluate those models on DocHPLT and WMT24++ for all 5 training languages and 5 additional unseen languages: Arabic (ar), Catalan (ca), Estonian (et), Hindi (hi), and Persian (fa). These unseen languages are selected for their linguistic and/or script relation with the training languages.

Results Table 5 compares multilingual to monolingual FT, showing that multilingual advantages are model-dependent. For Qwen2.5-7B-Instruct, Multi_{5K} outperforms Mono_{1K} and Multi_{1K} consistently, whereas Llama-3.1-8B-Instruct displays a mixed pattern. Taking a closer look at the languages, Icelandic and Malayalam always improve with multilingual training, regardless of the LLM. In Table 6, for unseen languages, we see that the off-the-shelf IT models are usually better than multilingual fine-tuning.

In general, multilingual fine-tuning produces inconsistent results: it improves DocMT performance over monolingual fine-tuning for some LLMs, but we find almost no zero-shot cross-lingual transfer. Our observations from a small-scale multilingual experiment warrant further investigation by scaling the model choices and sizes,

as well as the number of languages which is supported by DocHPLT.

5 Conclusion

We introduced a pipeline to derive a document-level corpus with rich metadata and presented the outcome, DocHPLT, the largest publicly available document-level translation dataset with 124 million aligned document pairs across 50 languages paired with English. The utility of our massively multilingual dataset has been demonstrated through experiments: fine-tuning LLMs on our data improved over prompting baselines, and multilingual training surpassed monolingual models, though zero-shot transfer to unseen languages remained challenging. Our experiments also revealed challenges in DocMT: full document-to-document training and generalization to other document domains. Future work may use DocHPLT data for further investigations such as large-scale training, data filtering, data synthesis, and DocMT metric study.

C Prompts

C.1 Overview

We use the same prompt for SFT and during inference for both off-the-shelf instruction-tuned and fine-tuned models. LLM's chat template is always applied.

We illustrate chunk-based translation and full document-to-document translation using the task of English to Catalan translation.

C.2 Chunk-based translation

Template (chunk size 2):

> Translate the following source segment from [SOURCE LANGUAGE] into [TARGET LANGUAGE].
>
> [SOURCE LANGUAGE]: [SOURCE TEXT]
>
> [TARGET LANGUAGE]: [TARGET TEXT]

Example:

> Translate the following source segment from English into Catalan.
>
> English: Online workshops are organized every month. The results will be shared with the community.
>
> Catalan: Cada mes s'organitzen tallers en línia. Els resultats es compartiran amb la comunitat.

C.3 Document-to-document translation

Template

> Translate the following source document from [SOURCE LANGUAGE] into [TARGET LANGUAGE].
>
> [SOURCE LANGUAGE]: [SOURCE DOCUMENT]
>
> [TARGET LANGUAGE]: [TARGET DOCUMENT]

Example:

> Translate the following source document from English into Catalan.
>
> English: Our proposals with you in mind. We suggest.... Castelló d'Empúries is situated in the heart of the Aiguamolls Natural Park. Stay at a house in the historic center of Castelló d' Empúries Check opening times and escape from the hustle and bustle of the city with a visit you will love. A weekend to explore Empordà by bike. Here you will also find events, fairs and festivals that are held close to Hostal Casa Clara.
>
> Catalan: Les nostres propostes pensades per a vosaltres. Us suggerim... Castelló d'Empúries està situat al bell mig del Parc Natural dels Aiguamolls. Les teves vacances en una casa al centre històric de Castelló d'Empúries Consulta els horaris i fes una visita que t'encantarà i et farà desconnectar del brogit de ciutat. Un cap de setmana en bicicleta per conèixer l'Empordà. Aquí també hi trobaràs esdeveniments, fires i festes populars que es fan prop de l'Hostal Casa Clara

SONAR-SLT: Multilingual Sign Language Translation via Language-Agnostic Sentence Embedding Supervision

Abstract

Sign language translation (SLT) is typically trained with text in a single spoken language, which limits scalability and cross-language generalization. Earlier approaches have replaced gloss supervision with text-based sentence embeddings, but up to now, these remain tied to a specific language and modality. In contrast, here we employ language-agnostic, multimodal embeddings trained on text and speech from multiple languages to supervise SLT, enabling direct multilingual translation. To address data scarcity, we propose a coupled augmentation method that combines multilingual target augmentations (i.e. translations into many languages) with video-level perturbations, improving model robustness. Experiments show consistent BLEURT gains over text-only sentence embedding supervision, with larger improvements in low-resource settings. Our results demonstrate that language-agnostic embedding supervision, combined with coupled augmentation, provides a scalable and semantically robust alternative to traditional SLT training.[1]

1 Introduction

Sign languages (SLs) are inherently visual and culturally embedded. Each SL has evolved independently and is closely tied to the communities and spoken languages of its region. As a result, most sign language translation (SLT) datasets are built around a *single* sign–spoken language pair (e.g., DGS→German), which makes it difficult to scale models across languages or to combine datasets. Training a system for a new target language typically requires a separate model and fresh parallel data collection.

Historically, SLT systems have relied on manually provided *gloss supervision* (Camgoz et al., 2018), discrete word-like labels whose design and availability are language-, culture-, and region-specific. Even *gloss-free* SLT approaches assume that sign inputs should be supervised by text from the co-occurring spoken language, keeping the learning signal tied to a single language (Gong et al., 2024; Wong et al., 2024; Chen et al., 2024; Hamidullah et al., 2022) and limiting cross-dataset reuse and generalization.

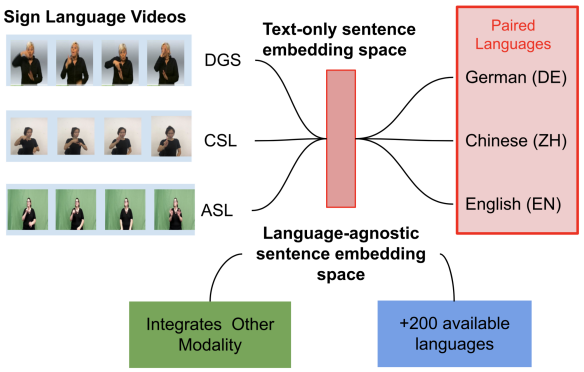

Figure 1: Text-only vs. language-agnostic sentence embedding supervision.

Recent work by Hamidullah et al. (2024) has reduced the reliance on glosses by supervising SLT with *text-based sentence embeddings*. This yields better semantic alignment, but the embeddings remain modality-specific and typically require dataset-specific fine-tuning. Furthermore, compared to large pre-trained models that exploit vast text corpora, these text-only embeddings show limited cross-lingual transfer and reduced robustness. This raises the key question: *Can language-agnostic, multimodal sentence embedding supervision replace text-only alignment in SLT?* We hypothesize that **language-agnostic, multimodal sentence embeddings** can reduce the residual dependence on text. Concretely, we build on SONAR (Duquenne et al., 2023), a pretrained multilingual and multimodal embedding space that jointly rep-

[1]We release the code, models, and features to facilitate further research. Github repository: https://github.com/DFKI-SignLanguage/sonar-slt.git; Huggingface: https://huggingface.co/mtmlt

Proceedings of the Tenth Conference on Machine Translation, pages 301–313
November 8-9, 2025

resents text and speech. SONAR embeddings are claimed to be language-agnostic. Our approach aligns sign representations directly with language-agnostic semantic vectors, thereby decoupling supervision from any specific spoken language and removing the need for glosses. Our model integrates multiple modalities and supports direct supervision across all 200 languages covered by SONAR (see Figure 1). In contrast to prior systems that relied on additional stages or separate models for multi-target translation, our method enables *direct* translation into multiple languages within a single model.

A major obstacle for SLT is the scarcity of annotated data. Recent work on self-supervised pre-training from unannotated or anonymized data (Rust et al., 2024) has shown promise in addressing this challenge. This motivates our second question: *Can target-language augmentation further alleviate data scarcity and enhance robustness, particularly when combined with video augmentation?*

Our **coupled multiple target language and video perturbation augmentation** strategy addresses these challenges by combining (i) *target-language augmentation*, which pairs each sign sample with parallel sentences in multiple languages, and (ii) *video augmentation*, which perturbs the visual stream through spatial, temporal, and photometric transformations. These augmentations are complementary: multiple target-language augmentation strengthens semantic supervision without requiring new sign recordings, while video augmentation improves the invariance of the sign encoder. Together, they yield a more robust SLT model and provide a scalable, semantically grounded alternative to traditional training, unifying supervision across languages and modalities while reducing dependence on language-, culture-, and region-specific annotations. In all, our contributions can be summarized as:

- **Language-agnostic supervision.** We align signs to a multilingual, multimodal embedding space, removing reliance on language-specific text or glosses.
- **Coupled augmentation.** We jointly apply multilingual target augmentation and video perturbations to improve robustness and reduce data scarcity.
- **Direct multilingual decoding.** Our model translates into multiple spoken languages in a single step, without pivots or extra fine-tuning.
- **Open-source resources.** We release a Hugging Face–compatible *visual extension of* SONAR and model port to enable reproducibility and further work.

2 Related Work

2.1 Sign Language Representation

Traditional SLT systems rely on glosses —textual labels that represent signs— as an intermediate representation. MSKA-SLT (Guan et al., 2025) remains a strong baseline using glosses, reporting ∼29 BLEU on PHOENIX-2014T (Camgoz et al., 2018). However, glosses are neither universal nor standardized: they are tightly coupled to specific languages, cultures, and regions. Moreover, producing gloss annotations is highly time-consuming, requiring expert linguistic knowledge (Müller et al., 2023b).

In parallel, gloss-free SLT has emerged, enabling training on weakly annotated datasets exceeding 1,000 hours for some sign languages (Uthus et al., 2023).[2] Hamidullah et al. (2024) aligns sign language videos with sentence-level text embeddings. This supervision avoids feeding long, fine-grained frame sequences to the decoder, thereby reducing redundancy in video features, lowering the need for aggressive masking, and encouraging learning at the sentence-semantic level. While intermediate supervision of visual blocks is common in multimodal models, compressing video into a sentence-level embedding before decoding improves semantic grounding and flexibility in target text generation. Nevertheless, current approaches (Hamidullah et al., 2024; Gueuwou et al., 2025b) remain limited by their reliance on *text-only* embedding spaces with restricted language coverage, constraining augmentation and cross-sign transfer.

2.2 Large Language Models in SLT

Complementary approaches leverage large language models (LLMs). SignLLM (Gong et al., 2024) discretizes videos into tokens and prompts a frozen LLM; Sign2GPT (Wong et al., 2024) feeds pseudo-glosses to XGLM, reporting ∼22 BLEU on

[2] A *weakly annotated dataset* provides only coarse or noisy supervision. For instance, YouTube-ASL datasets are collected from online videos where annotations rely solely on automatically generated or the provided subtitles, without manual realignment, leading to potential inaccuracies and temporal misalignments.

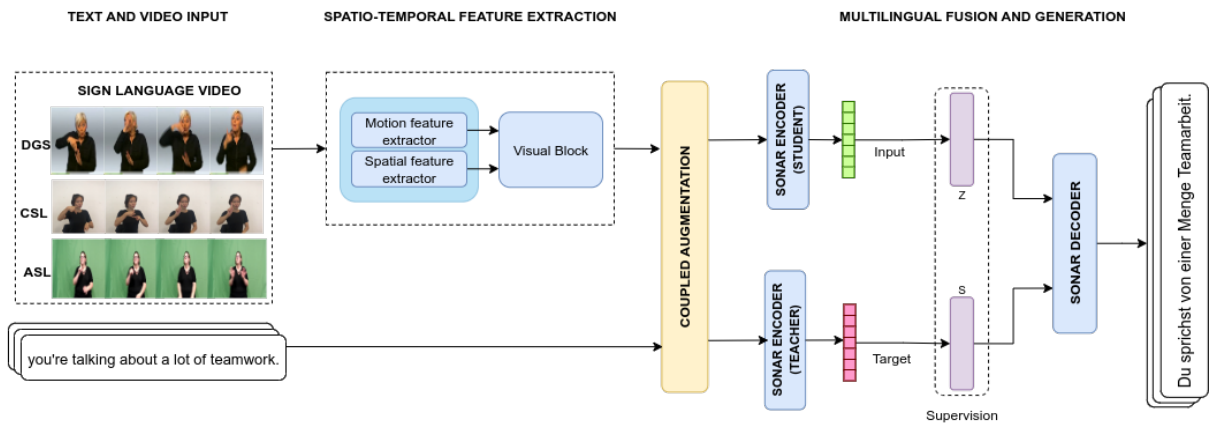

Figure 2: Overall architecture of our SONAR-SLT model. Visual inputs are processed through spatial and spatio-temporal encoders, fused using (Hwang et al., 2025) and encoded into a semantic vector aligned with multilingual sentence embeddings.

PHOENIX-2014T and ∼15 BLEU on CSL-Daily. SpaMo (Hwang et al., 2025) employs a straightforward approach that extracts spatial and motion features from sign language videos and utilizes a low-rank adapter to fine-tune an LLM for sign language translation. Chen et al. (2024) introduced FLa-LLM, a two-stage, gloss-free framework that first pre-trains the visual encoder and then fine-tunes a pre-trained LLM for the downstream SLT task. These methods inherit LLM fluency but are largely monolingual and require substantial tokenization and training overhead. In contrast, our PEFT-based SONAR adapters maintain multilinguality without retraining a large decoder on discretized video tokens. More recent work has explored large-scale pre-training to improve sign language understanding, with Uni-Sign (Li et al., 2025) proposing a unified generative framework that treats downstream tasks as SLT and incorporates prior-guided fusion.

2.3 Multilingual SLT Datasets and Models

Despite these advances, large-scale multilingual datasets (Uthus et al., 2023; Yazdani et al., 2025b) remain scarce and noisy. Crawled web data increases coverage but introduces label and alignment errors that current models struggle to absorb, leading many studies to focus on a single language or a small set of cleaner corpora. Additionally, performance often varies widely even within the same language due to differences in feature pipelines and recording conditions.

Multilingual SLT models also remain in their early stages. MLSLT (Yin et al., 2022) covers ten European sign languages via a routing mechanism, while JWSign (Gueuwou et al., 2023) scales to 98 languages with language-ID tokens. More recently, Sign2(LID+Text) (Tan et al., 2025) incorporated token-level language identification with a CTC loss, achieving competitive results. In addition, Yazdani et al. (2025a) explored continual learning for multilingual SLT. Recent work applies heavy pre-processing (Gueuwou et al., 2025b,a), sometimes obscuring whether improvements arise from better SLT modeling or dataset-specific engineering. Both gloss-based and gloss-free methods perform best when signer distance, camera setup, and motion characteristics closely match training conditions.

3 Methodology

3.1 System Overview

We propose **SONAR-SLT**, a modular SLT framework that decouples *semantic understanding* from *text generation*. As illustrated in Figure 2, the system first maps an input sign language video into a multilingual, multimodal semantic space, and then (optionally) decodes from this space into a chosen spoken language. This design allows training on heterogeneous sign language datasets, supports multilingual supervision, and removes the need for gloss annotations. A detailed architecture is presented in Appendix A.1 and summarized in the next subsections.

3.2 Visual Feature Extraction and Encoding

The first stage maps raw video frames into a compact visual embedding. Let $x = (f_1, \ldots, f_T)$ denote a sign language video of T frames. We extract per-frame spatial features $\mathbf{s}_t$ with ViT (Dosovitskiy

et al., 2020) and spatio-temporal motion features $\mathbf{m}_t$ with VideoMAE (Tong et al., 2022). These are fused through a lightweight block (1D Conv followed by a multi-layer perceptron) $\mathcal{F}$ (Hwang et al., 2025):

$$\mathbf{h}_t = \mathcal{F}(\mathbf{s}_t, \mathbf{m}_t), \qquad t = 1, \ldots, T. \tag{1}$$

A Transformer-based encoder $\mathcal{E}_v$ contextualizes the sequence:

$$\mathbf{z}_{1:T} = \mathcal{E}_v(\mathbf{h}_{1:T}). \tag{2}$$

Finally, temporal pooling (mean or attention) produces a global visual embedding $\mathbf{z} \in \mathbb{R}^d$:

$$\mathbf{z} = \mathrm{Pool}(\mathbf{z}_{1:T}). \tag{3}$$

3.3 Semantic Alignment

Next, we align sign-derived embeddings with multilingual textual embeddings. We adopt a pretrained multilingual, multimodal sentence encoder $\mathcal{E}$ (i.e., SONAR). Given a reference sentence y, we obtain its semantic embedding:

$$\mathbf{s} = \mathcal{E}_{txt}(y) \in \mathbb{R}^d. \tag{4}$$

The visual encoder is trained to align $\mathbf{z}$ with $\mathbf{s}$. Alignment can be done via a squared ℓ_2 loss as per (Duquenne et al., 2023; Hamidullah et al., 2024):

$$\mathcal{L}_{\text{sem}} = \|\mathbf{z} - \mathbf{s}\|_2^2. \tag{5}$$

We also consider a cosine similarity loss,

$$\mathcal{L}_{\cos} = 1 - \frac{\langle \mathbf{z}, \mathbf{s} \rangle}{\|\mathbf{z}\|_2 \, \|\mathbf{s}\|_2}, \tag{6}$$

used either alone ($\mathcal{L}_{\text{sem}} = \mathcal{L}_{\cos}$) or combined with the MSE above:

$$\mathcal{L}_{\text{sem}} = \alpha \|\mathbf{z} - \mathbf{s}\|_2^2 + \beta \mathcal{L}_{\cos}, \qquad \alpha, \beta \geq 0. \tag{7}$$

Target-language augmentation. To enforce language-agnostic supervision, each reference sentence is paired with K translations $\{y^{(k)}\}_{k=1}^K$ (from the embedding decoder). At each iteration, one translation $y^{(k)}$ is sampled and encoded as $\mathbf{s} = \mathcal{E}_{txt}(y^{(k)})$.

3.4 Multilingual Generation from the Semantic Vector

We then decode into natural language from the semantic embedding. A pretrained decoder $\mathcal{D}$ from SONAR generates text from a semantic vector and a target language token ℓ. Conditioned on the sign-derived and semantically text-aligned (Section 3.3) embedding $\mathbf{z}$, the decoder is trained with teacher forcing:

$$\mathcal{L}_{\text{ce}} = -\sum_{t=1}^{T_y} \log p_\theta(y_t \mid y_{<t}, \mathbf{z}, \ell). \tag{8}$$

3.5 Auto-Encoding (Decoder Anchoring)

To keep the decoder aligned to the pretrained semantic space, we introduce an auto-encoding step. Specifically, the decoder reconstructs the target sentence directly from its text-derived embedding $\mathbf{s}$:

$$\mathcal{L}_{\text{ae}} = -\sum_{t=1}^{T_y} \log p_\theta(y_t \mid y_{<t}, \mathbf{s}, \ell). \tag{9}$$

This mirrors SONAR's original training and prevents drift, while the visual encoder learns to project videos into the same space.

3.6 Optional Contrastive Alignment

We optionally strengthen alignment through a symmetric InfoNCE loss (van den Oord et al., 2018). For a batch $\{(\mathbf{z}_i, \mathbf{s}_i)\}_{i=1}^N$, we define similarity as $\mathrm{sim}(\mathbf{a}, \mathbf{b}) = \frac{\mathbf{a}^\top \mathbf{b}}{\tau}$ (temperature $\tau > 0$, optional ℓ_2 normalization). The corresponding loss is:

$$\mathcal{L}_{\text{nce}} = \frac{1}{2N} \sum_{i=1}^{N} \left[-\log \frac{\exp(\hat{\mathbf{z}}_i^\top \hat{\mathbf{s}}_i / \tau)}{\sum_{j=1}^N \exp(\hat{\mathbf{z}}_i^\top \hat{\mathbf{s}}_j / \tau)} - \log \frac{\exp(\hat{\mathbf{s}}_i^\top \hat{\mathbf{z}}_i / \tau)}{\sum_{j=1}^N \exp(\hat{\mathbf{s}}_i^\top \hat{\mathbf{z}}_j / \tau)} \right]. \tag{10}$$

3.7 Joint Training Objective

The final loss combines all components:

$$\mathcal{L}_{\text{joint}} = \lambda_{\text{sem}} \mathcal{L}_{\text{sem}} + \lambda_{\text{ce}} \mathcal{L}_{\text{ce}} + \lambda_{\text{ae}} \mathcal{L}_{\text{ae}} + \lambda_{\text{nce}} \mathcal{L}_{\text{nce}}, \tag{11}$$

with non-negative weights λ_i (setting $\lambda_{\text{nce}} = 0$ disables the contrastive term).

3.8 Cross-Lingual and Multi-Sign Dataset Fusion

Finally, we leverage the language-agnostic semantic space for dataset fusion. Because supervision is defined independently of any specific spoken language, videos from different sign languages can be trained jointly with textual supervision in *any* available language. For example, German sign language

Dataset	Language	Domain	#Videos	#Sent.	Vocab.	Split (train/dev/test)
PHOENIX-2014T	DGS → German	Weather Forecast	∼7k	∼8k	∼3k	7,096 / 519 / 642
CSL-Daily	CSL → Chinese	Daily Communication	∼20k	∼25k	∼5k	18,401 / 1,078 / 1,057

Table 1: Characteristics of the datasets used in our experiments.

videos annotated in German can be re-aligned with English, French, or Chinese translations via $\mathcal{E}$, allowing unified training across datasets such as PHOENIX-2014T and CSL-Daily. This enables direct multi-target translation without glosses and facilitates fusion of heterogeneous sign-language corpora.

4 Experiments

4.1 Datasets

We evaluate our approach on the following datasets:

- **PHOENIX-2014T** (Camgoz et al., 2018): German Sign Language (DGS) weather forecast videos with parallel German text.
- **CSL-Daily** (Zhou et al., 2021): A Chinese Sign Language (CSL) corpus tailored for sign-to-Chinese SLT, emphasizing interactions in daily communication contexts.

Statistics of both datasets are summarizes in Table 1.

4.2 Evaluation Metrics

We evaluate our method following (Müller et al., 2022; Müller et al., 2023a), using BLEU[3] (via SacreBLEU (Post, 2018)) for lexical overlap, ROUGE (Lin, 2004)[4] for recall-oriented n-gram overlap, and BLEURT (Sellam et al., 2020)[5] for semantic quality.

4.3 State-of-the-art Systems

We evaluate our method against several strong recent state-of-the-art systems within the gloss-free paradigm. CSGCR (Zhao et al., 2021) improves SLT accuracy and fluency through three modules: word existence verification, conditional sentence generation, and cross-modal re-ranking for richer grammatical representations. GFSLT-VLP (Zhou et al., 2023) leverages vision–language pretraining, while FLa-LLM (Chen et al., 2024) adopts a two-stage gloss-free pipeline that first pre-trains the visual encoder and then fine-tunes a pre-trained LLM for SLT. Sign2GPT (Wong et al., 2024) maps visual inputs to pseudo-gloss sequences and decodes them with GPT-style language modeling, whereas SignLLM (Gong et al., 2024) discretizes sign features into visual tokens to prompt a frozen LLM. SEM-SLT (Hamidullah et al., 2024) aligns sign language videos with sentence embeddings and serves as the foundation of our work. For multilingual settings, Sign2(LID+Text) (Tan et al., 2025) combines token-level sign language identification with a CTC objective to generate spoken text.

4.4 Implementation Details

• **Feature Extraction.** We begin by processing each sign language video $x = \{f_1, f_2, \ldots, f_T\}$ as a sequence of T RGB frames. From each frame, we extract:

- **Spatial Features (s_t):** Using a Vision Transformer (ViT (Dosovitskiy et al., 2020)) pretrained on ImageNet.
- **Motion Features (m_t):** Using VideoMAE (Tong et al., 2022).

These features are then fused via the visual fusion block $\mathcal{F}$ from SpaMo to yield a joint representation h_t for each timestep.

• **Training the visual block (LoRA).** We train the visual block using LoRA with:

- **LoRA:** $r = 16,\ \alpha = 32$
- **Batching:** batch size 4, gradient accumulation 2, on 8 GPUs in parallel
- **Loss weights:**
  - $\lambda_{\text{ce}} = 0.1$ (auxiliary soft translation signal)
  - $\lambda_{\text{sem}} = 1.0$ (primary objective)
  - $\lambda_{\cos} = 2.7$ (stabilizes angular alignment)
  - $\lambda_{\text{nce}} = 0.0$
  - $\lambda_{\text{mse}} = 7000.0$ (strong magnitude regularizer)

[3] `BLEU|nrefs:1|bs:1000|seed:16|case:mixed|eff:no|tok:13a|smooth:exp|version:2.4.0`

[4] `ROUGE|L|nrefs:1|tok:13a|case:mixed|version:1.5.5`

[5] BLEURT v0.0.2 using checkpoint BLEURT-20.

Because our model operates on embedding vectors with small magnitudes, the MSE loss can rapidly fall to $\sim 10^{-5}$ even when cosine similarity remains suboptimal. Empirically, we observed that **cosine and MSE only begin to correlate at** $\sim 10^{-6}$. Optimizing cosine alone often stalls, as MSE ceases to decrease, while optimizing MSE alone improves fidelity but does not guarantee angular alignment. To address this, we up-weight MSE to maintain shrinkage and retain a non-negligible cosine term to enforce directional consistency. We also experimented with InfoNCE, but under our effective batch size (with few hard negatives) it led to slower convergence and negligible improvements and we do not use it in our final experiments.

• **Sentence embedding pooling.** The original SONAR pools by running a shallow decoder: it feeds a special token (the EOS id in `M200M100`) as input and uses the encoder outputs as hidden states; the first decoder output is taken as the sentence embedding. During the Visual Block training, we adopt this approach with a shallow decoder initialized from the first three SONAR decoder layers and train it only for pooling. This supplies language context during pooling, while the incoming features themselves are language-agnostic (from another modality). Text generation is then conditioned on the target language.

• **Visual representation.** We adopt the best-performing visual representation strategies reported in prior work, noting that optimal choices vary across datasets. To ensure comparability in our multi–sign language experiments, we restrict evaluation to datasets with similar video settings and select the strongest corresponding model. The SpaMo Visual Block performs best with global, high-quality cues e.g., high-resolution videos with a moderate signer–camera distance (CSL-Daily), or lower-resolution videos where the signer is close and centered (PHOENIX-2014T). Consequently, we conduct multilingual experiments on CSL-Daily and PHOENIX-2014T.

• **Training the translation model with visual features.** We train the end-to-end translation system (with the Visual Block or the fused spatial+motion features) using the **same LoRA configuration** as above.

- **Batching & schedule:** batch size 8 on a single GPU
  - **CSL-Daily:** cosine learning-rate schedule with a peak LR of 3×10^{-4}
  - **PHOENIX-2014-T (monolingual):** constant LR (we found it more stable)
- **Text augmentation.** To expand the datasets using NLLB (NLLB Team, 2024), we machine-translate the target texts into three high-resource languages (English, French and Spanish) using the `facebook/nllb-200-distilled-600M` model.
- **Video augmentation.** Coupled with the target-language augmentation, we also perturb the input videos so that each training instance is presented with both linguistic and visual variability. At each iteration, one augmented variant is sampled. In this work we restrict ourselves to:
  - `frame_mask_ratio` $= 0.2$
  - `frame_dropout_prob` $= 0.2$
  - `add_noise_std` $= 0.04$
  - `shuffle_window` $= 3$

5 Results and Analysis

5.1 Comparative Analysis

We compare our approach with other gloss-free methods on both PHOENIX-2014T and CSL-Daily datasets in Table 2. Our method shows a clear advantage on the semantics-oriented BLEURT metric. It reaches a **BLEURT of 0.545**, outperforming the sentence-based supervision model using text-only sentence embedding (SEM-SLT). BLEURT uses a BERT-based scorer and is designed to capture meaning and fluency, unlike BLEU and ROUGE, which primarily measure n-gram overlap. Moreover, our model outperforms previous monolingual and multilingual systems on CSL-Daily in terms of BLEU and achieves comparable results on PHOENIX-2014T.

• **Observed gaps.** We observe a decrease in BLEU compared to the SEM-SLT system, which is expected since our model is not fine-tuned on sign-language text. Our language-agnostic, sentence embedding-based supervision preserves semantics without requiring fine-tuning on specific dataset: it goes beyond surface n-gram matching to produce translations that are contextually accurate, grammatically correct, and cross-lingually robust. Part

Method	PHOENIX-2014T			CSL-Daily

Table 2: Comparison of SONAR-SLT with other gloss-free models on PHOENIX-2014T and CSL-Daily (metrics: BLEU, BLEURT, ROUGE (RG)). Unreported metrics are left blank; SONAR-SLT sets the best reported BLEURT on PHOENIX-2014T and remains strongly competitive with several LLM-based baselines on both datasets.

Resource	Language	BLEU
High	Spanish (es)	22.3
	French (fr)	22.6
	English (en)	21.6
Low	Turkish (tr)	13.1
	Malagasy (mg)	11.8
	Persian (fa)	8.7

Table 3: SONAR-SLT performance across target languages in both high- and low-resource settings on PHOENIX-2014T, reported using BLEU scores.

of the remaining gap stems from dataset capture conditions. Our feature extractor (Hwang et al., 2025) is tuned for global cues and can be less accurate in cases where fine-grained articulations, such as facial expressions and finger movements, are critical. Recent top systems address this with keypoint-based representations and extensive preprocessing (Gueuwou et al., 2025b), which help preserve these fine-grained details.

• **Multilingual and multi–sign language.** We evaluate target-side augmentation, where language translations are included in training. Results for both low- and high-resource languages on PHOENIX-2014T are presented in Table 3. In our experiments, we augmented the target set in training with three high-resource languages—French, Spanish, and English—while the model was evaluated on other unseen languages. Using this augmented target set yields a modest improvement over training with a single target language. However, we observe a gap in performance between high- and low-resource languages, which primarily stems from lower reference translation quality in the low-resource languages.[6] The narrow domain of PHOENIX-2014T can also introduce dataset-specific idiosyncrasies, complicating fair comparisons.

Table 4 shows that pre-training on concatenated multi-sign corpora followed by monolingual fine-tuning proves most effective. In contrast, joint multi-sign fine-tuning risks resembling another full training run without yielding substantial gains. In our experiments, we first pre-train on the combined data and then fine-tune monolingually, consistent with (Hamidullah et al., 2024); post-fine-tuning performance remains largely unchanged (see Table 4, mono vs. multilingual setup). Differences in dataset capture conditions still matter—for example, methods that rely solely on global visual features can underperform when fine-grained articulations, such as hand or facial details, are crucial. Pipelines that integrate keypoints with extensive preprocessing (Gueuwou et al., 2025b) help mitigate such losses and achieve stronger results.

5.2 Multitask Learning Effect on the Visual Block

The effect of sentence-embedding supervision is strongest when the Visual Block is still learning feature representations. Once the block has converged—or is pretrained—the additional impact of cosine or MSE objectives diminishes. This occurs because cross-entropy loss often remains rel-

[6] Reference translations were obtained using `facebook/nllb-200-distilled-600M` model.

Type	Variant	PHOENIX-2014T			CSL-Daily		
		BLEURT	BLEU	RG	BLEURT	BLEU	RG
Multi	VB pretrained	**0.523**	21.52	41.10	**0.561**	**16.23**	**42.29**
	VB scratch	0.508	21.38	**42.03**	0.472	14.68	42.12
	VB frozen	0.516	**21.56**	41.39	0.549	16.06	41.95
Mono	VB pretrained	**0.545**	**22.01**	40.52	**0.558**	**16.07**	**42.13**
	VB scratch	0.490	19.79	39.95	0.447	14.14	40.59
	VB frozen	0.520	21.56	**41.44**	0.529	15.70	41.79

Table 4: SONAR-SLT results for the Visual Block (VB) variants under Multilingual and Monolingual settings on PHOENIX-2014T and CSL-Daily. Metrics include BLEURT, BLEU, and ROUGE (RG); best scores per dataset/metric are in bold.

atively high (above 2–3), while MSE rapidly falls to $\mathcal{O}(10^{-5})$ and cosine similarity saturates around ~ 0.3.

In contrast, introducing the auto-encoding loss provides a second cross-entropy signal, which exerts a stronger influence on the Visual Block. Here, intermediate supervision continues to be beneficial, and the auto-encoding objective itself accelerates convergence. We consistently observed this effect in CSL-Daily and in the augmented translation setup on PHOENIX-2014T.

5.3 Qualitative and Semantic Error Analysis

• **Qualitative analysis.** Table 5 shows examples of two contrasting outcomes: cases where the model accurately captures the intended meaning and cases where it fails. When contextual understanding is incomplete, the decoder frequently compensates by generating fluent continuations via next-token prediction. This behavior is characteristic of SLT systems that rely on pretrained language models as decoders: they can mask weaknesses in semantic grounding by producing outputs that are coherent but only partially faithful to the source. As a result, improvements in BLEU may reflect the decoder's ability to recover plausible sentences rather than true gains in sign-to-text comprehension. Therefore, exact sequence matching metrics such as BLEU are insufficient and in some cases misleading for evaluating translation quality in SLT.

Language-specific tendencies. We deep into the analysis of two languages: German, a language trained with original data and French, a language trained via machine translation augmentation.

- **German:** Errors often arise from compound nouns, flexible word order, and embedded clauses, leading to partial omissions, attribute reordering, or unnatural compounds. When alignment is uncertain, the model may insert generic stock phrases or repetitions.

- **French:** Our analysis shows more frequent noun substitutions, agreement mismatches, and text modality shifts (e.g., hedging with *"sont possibles"*). Register differences from determiners or prepositions are also common. Incorrect date and numeric substitutions occur more frequently than in German, likely due to segmentation differences in temporal expressions.

• **Semantic analysis.** Surface-form scores vs. meaning preservation. We observe a systematic mismatch between surface-form metrics (e.g., BLEU) and semantic adequacy (BLEURT) across both German and French. Outputs with only moderate n-gram overlap can still be semantically faithful, while some high-scoring predictions contain factual errors.

Semantically near correct and correct paraphrases (German). As illustrated by the green-highlighted examples in Table 5, incorrect lexical or numeric substitutions leave most of the remaining meaning intact (e.g., date shifts: *"Sonntag, den neunzehnten Dezember"* → *"Sonntag, den siebzehnten August"*; temperature adjustments: *"sechs Grad an den Alpen"* → *"neun Grad am Alpenrand"*). We also observe benign stylistic reformulations (*"es gelten entsprechende Warnungen"* → *"es bestehen Unwetterwarnungen"*) and word-order changes without semantic effect (*"aus Südwest bis West"* → *"aus West bis Südost"*).

Semantically near correct and correct paraphrases (French). Similarly, the first green-highlighted examples show structural or modality shifts that preserve much of the remaining meaning,

German (DGS weather domain)
Ref (DE): Sonntag, den neunzehnten Dezember. *EN: Sunday, the nineteenth of December.* **Pred (DE):** Sonntag, den siebzehnten August. *EN: Sunday, the seventeenth of August.*
Ref (DE): sechs Grad an den Alpen. *EN: Six degrees in the Alps.* **Pred (DE):** neun Grad am Alpenrand. *EN: Nine degrees on the edge of the Alps.*
Ref (DE): Höhenlagen Süddeutschlands. *EN: High-altitude areas of southern Germany.* **Pred (DE):** Küsten. *EN: Coasts.*
French (weather domain)
Ref (FR): vingt-huit août. *EN: Twenty-eighth of August.* **Pred (FR):** vingt-cinq novembre. *EN: Twenty-fifth of November.*
Ref (FR): Des rafales orageuses de l'ouest. *EN: Stormy gusts from the west.* **Pred (FR):** Des rafales orageuses sont possibles. *EN: Stormy gusts are possible.*
Ref (FR): Risque d'inondation. *EN: Risk of flooding.* **Pred (FR):** Avertissements météorologiques violents. *EN: Severe weather warnings.*

Table 5: German and French examples —two semantically near correct paraphrases (green) and one semantically incorrect output (red), with English translations.

such as date substitutions (*"vingt-huit août"* → *"vingt-cinq novembre"*), modality changes (*"Des rafales orageuses de l'ouest"* → *"Des rafales orageuses sont possibles"*), or expanded phrasing (*"Également orages sur la mer du Nord"* → *"Il y a également des orages sur la mer du Nord"*).

Semantically incorrect outputs, true errors (French and German). The red-highlighted rows in Table 5 illustrate errors such as topic drift (predicting wind instead of temperature), incorrect locations (*"Höhenlagen Süddeutschlands"* → *"Küsten"*; *"sud-est"* → *"nord"*), system inversions (*"Hoch"* ↔ *"Tief"*; *"haut"* ↔ *"profonde"*), hallucinated entities, or incorrect hazard categories (*"Risque d'inondation"* → *"Avertissements météorologiques violents"*).

Overall, as in other machine translation tasks, n-gram metrics penalize near or even fully legitimate paraphrases and sometimes fail to capture serious factual errors. Robust SLT evaluation requires *semantic* metrics that explicitly reward meaning preservation while penalizing distortions or hallucinations.

Implications. Evaluation and model development for multilingual SLT should be language-aware. In practice, one should combine semantics-focused metrics with targeted, language-specific checks (e.g., temporals and agreement in French; word order and compounding in German) to obtain fair comparisons and actionable diagnostics.

6 Conclusion

We presented a scalable SLT framework that breaks the traditional close dependency between sign and spoken languages in training data and system development. By aligning sign language videos with multilingual, multimodal sentence embeddings from SONAR, our approach yields a language-agnostic semantic representation that generalizes across both sign languages and spoken targets. This reduces reliance on language-model priors and prioritizes visual grounding and SLT-specific grammar over surface-level text patterns.

Experiments show that language-agnostic supervision enables robust translation even under sign–target mismatches. Multilingual text augmentations, combined with visual augmentation, improves performance on PHOENIX-2014T despite limited data. Ablations further confirm the advantages of this approach in preserving semantic adequacy.

Current evaluation practices often emphasize surface overlap rather than meaning. Future work should develop metrics aligned with semantic similarity and extend supervision to low-resource sign languages and continuous signing in the wild.

Limitations

Our main limitation lies in the visual feature extractor rather than the model architecture itself. We used a pre-existing visual block to avoid evaluation bias, which restricted us to datasets with compatible video settings (CSL-Daily and PHOENIX-2014T) and excluded larger corpora such as How2Sign or YouTube-ASL. As a result, our approach focuses on preserving semantics rather than maximizing exact sentence matches.

Machine translation for data augmentation might induce unintended cultural mistakes that go beyond literal translation. The evaluation on non-human translated datasets also limits the strength of the conclusions for low-resourced languages.

Acknowledgments

A Appendix

A.1 Detailed Architecture

Figure 3 shows the details of our system architecture as explained in Section 3.

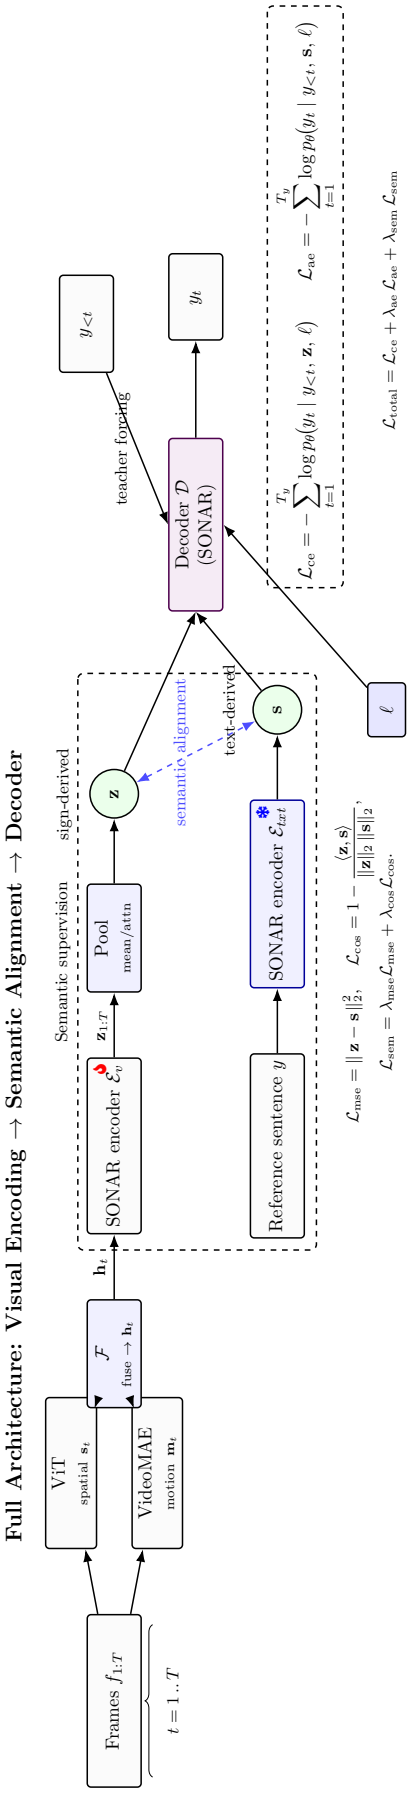

Figure 3: Detailed architecture without the contrastive term (NCE loss).

A.2 Porting SONAR from NLLB Fairseq to Huggingface.

SONAR is officially supported in fairseq, but only its text encoder is available on Hugging Face. To enable full conditional generation, we ported both the encoder and decoder weights from the original SONAR checkpoints into `M200M100`, extending the earlier encoder-only port provided by the NLLB team. In particular, we transferred the decoder weights directly from fairseq, validated their functionality, and released the complete model for public use. The resulting `M200M100ForConditionalGeneration` can now be loaded end-to-end and fine-tuned directly.

A.3 Additional Qualitative Results

GAMBIT+: A Challenge Set for Evaluating Gender Bias in Machine Translation Quality Estimation Metrics

Abstract

Gender bias in machine translation (MT) systems has been extensively documented, but bias in automatic quality estimation (QE) metrics remains comparatively underexplored. Existing studies suggest that QE metrics can also exhibit gender bias, yet most analyses are limited by small datasets, narrow occupational coverage, and restricted language variety. To address this gap, we introduce a large-scale challenge set specifically designed to probe the behavior of QE metrics when evaluating translations containing gender-ambiguous occupational terms. Building on the GAMBIT corpus of English texts with gender-ambiguous occupations, we extend coverage to three source languages that are genderless or natural-gendered, and eleven target languages with grammatical gender, resulting in 33 source–target language pairs. Each source text is paired with two target versions differing only in the grammatical gender of the occupational term(s) (masculine vs. feminine), with all dependent grammatical elements adjusted accordingly. An unbiased QE metric should assign equal or near-equal scores to both versions. The dataset's scale, breadth, and fully parallel design, where the same set of texts is aligned across all languages, enables fine-grained bias analysis by occupation and systematic comparisons across languages.

1 Introduction

While gender bias in machine translation systems is widely acknowledged and has been widely documented, the biases in the translations of gender-ambiguous terms, such as occupational titles, is a topic relatively unexplored, which has lately gained some traction (Mastromichalakis et al., 2025). These biases are often reflected in the disproportionate assignment of a gender (e.g. masculine forms) to occupations when the gender of the subject is unknown. While overall much research has focused on bias in MT outputs, comparatively little attention has been paid to the potential gender biases of automatic quality estimation metrics. Recent studies suggest that QE metrics, which are intended to provide an objective measure of translation quality, can also exhibit systematic biases (Zaranis et al., 2024). However, existing analyses on gender-ambiguous inputs are typically limited by datasets with short texts, typically sentence-level, a restricted variety of occupations, and a limited range of language pairs.

To address these limitations, we introduce GAMBIT+[1], a large-scale challenge set specifically designed to evaluate gender bias in QE metrics when translating gender-ambiguous occupational terms. Our dataset extends the original GAMBIT corpus[2] (Mastromichalakis et al., 2025) of English texts with gender-ambiguous occupations to include three source languages—English (a natural-gendered language), Turkish and Finnish (both genderless languages)—and eleven target languages with grammatical gender: Arabic, Czech, Greek, Spanish, French, Icelandic, Italian, Portuguese, Russian, Serbian, and Ukrainian. This results in 33 source–target language pairs, covering a wide spectrum of linguistic typologies and providing a rich resource for cross-linguistic analysis of gender bias in QE.

For each source text, we provide two target versions differing only in the grammatical gender of the occupational term (masculine vs. feminine). All necessary adjustments for grammatical correctness, such as gendered adjectives, are applied consistently across both versions. An unbiased QE metric should assign equal or near-equal scores to the two versions, as there is no indication of gender in the source text. Unlike prior work, which often aggregates bias analysis across all occupations or texts in general, GAMBIT+ explicitly tracks the occupational terms mentioned in each text and links them to ISCO-08 codes (hereafter, ISCO codes) [3]. This enables fine-grained, occupation-level

analyses and facilitates the study of stereotypical patterns, as previous studies have shown that certain occupations are more likely to be translated in a gendered manner according to societal stereotypes (Mastromichalakis et al., 2025; Menis-Mastromichalakis et al., 2025).

The parallel design of the dataset ensures that all source texts are aligned across target languages and both gendered versions, enabling consistent and controlled benchmarking of QE metrics. With this resource, researchers can investigate not only overall tendencies of QE systems but also nuanced, occupation-specific, and cross-lingual patterns, providing a more comprehensive understanding of how gender bias manifests in translation evaluation.

As part of the challenge set subtask of the shared task on Automated Translation Quality Evaluation Systems at WMT 2025 (Lavie et al., 2025), GAMBIT+ was used to evaluate a set of established QE metrics as well as participant submissions to the shared task. This allowed us to benchmark the performance of different metrics in a controlled, fine-grained setting and to assess how gender bias manifests in real-world QE systems. In this paper, we present and discuss the results of these evaluations, highlighting both systematic tendencies and occupation-specific patterns, and providing insights into the current limitations and strengths of existing QE approaches with respect to gender fairness.

2 Related Work

Gender bias in Machine Translation has been widely documented, revealing persistent disparities influenced by societal norms, model design choices, and deployment contexts (Savoldi et al., 2021; Vanmassenhove, 2024; Savoldi et al., 2024; Menis-Mastromichalakis et al., 2025; Mastromichalakis et al., 2025). Numerous studies have examined the prevalence and consequences of such biases across languages, cultural settings, and MT architectures (Rescigno et al., 2020; Paolucci et al., 2023; Farkas and Németh, 2022; Ghosh and Caliskan, 2023; Kostikova et al., 2023; Piazzolla et al., 2023), underscoring the need for robust evaluation and mitigation. A particularly relevant line of work focuses on occupational bias in MT, where stereotypes associated with specific professions affect translation choices (Gorti et al., 2024; Tal et al., 2022; Mastromichalakis et al., 2025). Related efforts in other NLP tasks have explored gender ambiguity in Question Answering (Parrish et al., 2022; Li et al., 2020) and coreference resolution (Rudinger et al., 2018; Zhao et al., 2018; Kotek et al., 2023). In MT, proposed strategies for handling ambiguity include generating all grammatically correct gendered translations (Garg et al., 2024), and disambiguating inputs before translation (Vanmassenhove et al., 2018). Resources supporting these investigations range from knowledge graphs (Mastromichalakis et al., 2024) to multilingual benchmarks and challenge sets (Currey et al., 2022). Mitigation strategies have included model fine-tuning, data balancing, and adaptive learning (Saunders and Byrne, 2020; Escudé Font and Costa-jussà, 2019; Costa-jussà and de Jorge, 2020), as well as gender-neutral translation approaches (Piergentili et al., 2023a; Lardelli and Gromann, 2023) and benchmarks for evaluating them (Piergentili et al., 2023b; Lardelli et al., 2024; Gkovedarou et al., 2025). A central element in all these efforts is evaluation, since quality estimation metrics determine what counts as a "good" translation and thus influence MT system development.

While several studies have examined whether evaluation metrics for natural language generation exhibit social biases—such as Qiu et al. (2023), who compared n-gram- and model-based metrics, Sun et al. (2022), who quantified different bias types, and Gao and Wan (2022), who measured race and gender stereotypes—very few works have explored gender bias in MT QE metrics. One exception is Zaranis et al. (2024), which conducted a multifaceted analysis of QE methods and demonstrated that the metrics themselves can be biased, potentially perpetuating the very stereotypes they are used to assess.

A key limitation of existing work on gender bias in QE is the lack of suitable datasets, particularly for studying gender ambiguity. Many challenge sets, such as WinoMT (Stanovsky et al., 2019) and MT-GenEval (Currey et al., 2022), focus on cases where gender can be resolved via coreference or other contextual cues. The MuST-SHE corpus (Bentivogli et al., 2020) similarly contains audio and textual cues that reveal gender (e.g., speaker's voice, pronouns, named entities). Conversely, datasets containing true gender ambiguity (Rudinger et al., 2018; Zhao et al., 2018) are often limited in language coverage, consist of isolated sentences, and lack occupational diversity, restricting fine-grained analysis. In contrast, our challenge set builds on GAMBIT (Mastromichalakis et al., 2025), where occupational mentions are inherently gender-ambiguous and no gold-standard gendered translation

classifying occupations endorsed by the International Labour Organisation (ILO). It provides a hierarchical structure that categorizes jobs into four levels of increasing granularity, using a digit-based coding system. More details: https://ilostat.ilo.org/methods/concepts-and-definitions/classification-occupation/

exists. This enables us to test whether QE metrics assign different scores to two theoretically equivalent translations differing only in the grammatical gender of the occupation, offering a controlled setting for investigating metric bias in ambiguous contexts.

3 Challenge Set Creation

The creation of the challenge set, GAMBIT+, was grounded in the GAMBIT dataset (Mastromichalakis et al., 2025), which covers all ISCO occupations (all 4-digit codes) and contains the corresponding ISCO codes and names, with English texts distributed evenly across five formats: short stories, brief news reports, short statements, short conversations, and short presentations, in which the given occupation appears. In these texts, the gender of the occupation is not explicitly indicated. For example, in the sentence "The professor delivered an engaging lecture on generation modification by the auditorium", shown in Table 1, the occupation "professor" is mentioned without any linguistic cues that would reveal its gender.

In GAMBIT+, these gender-neutral English sentences were translated into gendered target languages, producing parallel masculine and feminine versions of each sentence while preserving all other aspects of the translation. In addition, we extended the source language coverage to include genderless languages such as Turkish and Finnish, alongside English, ensuring a diverse and balanced dataset. In total, the challenge set comprises 29,415 source instances (9,805 each of the three source languages), which were translated into 11 target languages, resulting in 323,565 triplets, each consisting of the source sentence with a masculine and a feminine translation. Table 1 presents an example from the GAMBIT+ dataset with the data from GAMBIT and the corresponding entries created for the Challenge Set. Specifically, the following sections describe the generation process for producing these translations and the evaluation procedure applied to assess and ensure the high quality of the resulting dataset.

3.1 Generation

Gendered Languages. The construction of the challenge set for gendered languages was based on the English texts from the GAMBIT dataset in which the gender of the occupation was ambiguous. These sentences served as the source material for the initial stage of the process. An LLM[4] was subsequently instructed to translate each sentence into the target language, specifically translating the occupation into a given gender form (e.g., masculine). Following this, a separate interaction with the same model was initiated, ensuring that no conversational history from the first stage was preserved, and the model was instructed to take the translated text and produce a variation in the target language that preserved the text exactly, modifying only the gender of the occupation from the initial to the alternate form (e.g., feminine respectively).

This process yielded three aligned versions for each source sentence:

1. the original English text s containing a gender-ambiguous occupation,
2. the translation with the occupation in its masculine form t_{male}, and
3. the translation with the occupation in its feminine form t_{female}.

The masculine and feminine translations were constructed to be semantically and lexically identical, differing only in the gender marking of the occupation and the dependent grammatical elements. There were a few cases where the masculine and feminine variations were identical in some target languages, mostly due to the morphology of the source text and the grammatical restrictions of the target languages. All such examples were discarded from all languages (so if the masculine and feminine translations were identical in at least one language, this text was removed from all languages) in order to keep the challenge set consistent, and the texts in all languages aligned. After filtering, we retained 8,771 samples per language pair, resulting in a total of 289,443 samples in the GAMBIT+ dataset.

Genderless Languages. For genderless languages, a similar approach was applied. In this case, the model was instructed to translate the original text into the genderless target language without introducing any linguistic cues that might imply a specific gender for the occupation. This step was designed to avoid subtle cases where unintended gender hints could arise, even in languages without grammatical gender. Since in those languages there is no grammatical gender, the second step that generated the gendered variation in gendered languages was not applied.

By following this procedure, we obtained aligned texts across multiple languages, comprising source languages with gender-ambiguous occupations and target languages with matched masculine and feminine translations for the same occupations, as shown

in the example of Table 1. The model used for the generation is Claude Sonnet 3.5 v2 [5].

3.2 Evaluation

Ensuring that the translations differed solely in the gender marking of the occupation, while remaining otherwise semantically equivalent, was a central requirement of the data creation process. However, adherence to this constraint could not be assumed, even though the model had been explicitly prompted to preserve all other aspects of the source text. To verify compliance, an additional evaluation was conducted in an LLM-as-a-judge approach (Gu et al., 2024). A different and more capable model[6], namely Claude Sonnet 3.7 [7], was provided with two texts: the translation in the masculine form and the translation in the feminine form. The model was instructed to analyse the two sentences and determine whether the only difference between them was the gender of the occupation, or whether additional semantic or structural differences were present. This evaluation was carried out for all language-pair combinations using 10% of the dataset due to computation constraints, and the results are reported in Table 2.

As we can see, in almost all cases the accuracy is above 90%, indicating a high quality of generated data. Additionally, we manually reviewed around 100 samples of the "errors" identified by the LLM judge to further investigate the issues. In most cases, the errors flagged by the judge were not truly errors but rather stemmed from minor variations in dependent gram-

matical elements, which should indeed be adjusted to match the gender changes of the occupation. Such differences often led the judge to conclude that the outputs were not aligned, revealing a certain oversensitivity in the evaluation. As a result, when the metric marked something as incorrect, it was not necessarily a substantive error, whereas we observed that when it marked something as correct, this judgment was indeed accurate. Consequently, the reported numbers are likely stricter than the actual performance.

The prompts used for data generation and evaluation are provided in Appendix A.

4 Evaluation Setup & Analysis Approach

For the evaluation, we prepared a dataset in which each entry consisted of a source text (s) in one of three source languages (English, Turkish, Finnish) and, for each target language, two corresponding hypotheses: one where the occupation appeared in the translated masculine form (t_{male}) and another where it appeared in the translated feminine form (t_{female}). The two hypotheses were constructed to differ solely in the grammatical gender marking of the occupation, with all other aspects of the sentence kept identical. This dataset was then provided by the shared task organizers to the participating teams, who ran their metrics and returned their scores for each hypothesis in every source–target language pair, while the organizers themselves used a set of baseline metrics on our dataset too. These returned results form the basis of the subsequent analysis. The source languages were 3 (English, Turkish, Finnish) and the target languages were 11 (Arabic, Czech, Greek, Spanish, French, Icelandic, Italian, Portuguese, Russian, Serbian, Ukrainian), leading to a total of 33 distinct source–target language pairs.

The organizers returned results for 11 evaluation metrics, 3 baseline metrics (sentinel-cand (Perrella et al., 2024), sentinel-src (Perrella et al., 2024), and COMETKiwi22 (Rei et al., 2022)), and 8 submissions (UvA-MT (Wu and Monz, 2025), rankedCOMET (Maharjan and Shrestha, 2025), MetricX-25-QE (Juraska et al., 2025), MetricX-25 (Juraska et al., 2025), baseCOMET (Maharjan and Shrestha, 2025), Polycand-1 (Züfle et al., 2025), Polycand-2 (Züfle et al., 2025), and Polyic-3 (Züfle et al., 2025)). All metrics, except for UvA-MT, were run on the complete set of 33 source-target language pairs. The UvA-MT metric was evaluated only with English as the source language, covering all corresponding target languages. sentinel-src relies exclusively on the input, which results in identical scores being assigned to both gendered forms; therefore, it is excluded from our subsequent analyses

5 Results and Discussion

5.1 Experimental Setup

Let $M(s,t) \in [\min(M), \max(M)]$ be a translation quality metric, where s denotes the source text, t the translated text, and $M(s,t)$ returns a real-valued score within the metric's range. Our goal is to quantify the variation in M when the translations differ *only* in the grammatical gender of an occupation, while all other elements of the text remain identical.

For each source sentence s, we consider two translations: t_{male} (masculine form) and t_{female} (feminine form). The *absolute difference* in metric scores is defined as:

$$\Delta_{\text{abs}} = \left| M(s, t_{\text{male}}) - M(s, t_{\text{female}}) \right|. \quad (1)$$

To facilitate comparability across different metrics, we define the *normalized difference* as:

$$\Delta_{\text{norm}}(\%) = \frac{\Delta_{\text{abs}}}{R} \times 100\,, \quad (2)$$

where $R = \max(M) - \min(M)$ is the *range* of the metric and $I = [\,\min(M), \max(M)\,]$ denotes the corresponding interval of observed values. Since in the general case the theoretical bounds of M may be unknown, we instead rely on empirical estimates derived from our evaluation results, using as $\min(M)$ and $\max(M)$ the smallest and largest values observed for each metric on the challenge set. This approach ensures that all metrics are interpreted within a consistent, data-driven scale.

5.2 Results

Table 3 summarizes the performance of all evaluated metrics on our challenge set, reporting both absolute and normalized differences alongside their empirical ranges and intervals. A paired t-test[8] was conducted

Table 3: Absolute and normalized differences for each metric, along with their empirical range R and interval I on the challenge set. Δ_{abs} and Δ_{norm} are reported as averages over all source sentences and language pairs. Baseline metrics are indicated with an asterisk (*).

for each metric and language, showing that all differences between $M(s, t_{\text{male}})$ and $M(s, t_{\text{female}})$ were statistically significant in every case ($p < 0.05$).

All evaluated metrics show a measurable difference between masculine and feminine translations. Notably, the magnitude of these differences, both in absolute and normalized terms, varies considerably across metrics. For example, UvA-MT and rankedCOMET display the largest normalized differences (above 70%), suggesting higher sensitivity to gender variation, whereas metrics such as Polyic-3 and Polycand-2 register much smaller relative changes. While, the empirical ranges R and intervals I differ widely among metrics, reflecting substantial variation in score scales and distributional properties, normalization allows us to fairly compare the different metrics.

Analysis per Language. Table 4 presents the average normalized differences (± standard deviation) across all evaluation metrics for each source–target pair. Across most targets, English as the source leads to higher average differences than Finnish or Turkish. In certain cases, such as Arabic, Czech, Icelandic, Italian, Russian, Serbian, and Ukrainian, the source language changes the difference score substantially (>8%). In contrast, for Greek, Spanish, French, and Portuguese, the results are more stable regardless of the source. This suggests a systematic source-language effect. One possible explanation is that English, as a natural-gendered language, exhibits more extensive gender marking than Finnish or Turkish, which are largely genderless languages, thereby increasing the likelihood that occupational gender associations can be stronger and leak into the evaluation metrics. However, this does not explain why this is not true for all target languages, so further investigation is needed to disambiguate these findings.

When focusing on the target languages, the ranking is stable: Arabic, Russian, and Icelandic yield the highest values; Czech, Italian, Ukrainian, and Serbian follow; French, Greek, Spanish, and Portuguese are consistently lower. This stability across different sources points to target-language characteristics as a dominant factor. Standard deviations parallel the ranking of the averages—larger where averages are higher (especially with English as the source) and smaller where they are lower—indicating greater item-level variability when differences are larger. In high-difference pairs, this variability likely reflects greater diversity in how specific items respond to the different evaluation metrics. Conversely, in low-difference pairs, more uniform behavior is observed across items. Overall, the analysis highlights two main points: while the inherent characteristics of the target language play a dominant role in determining the magnitude of differences, selecting English as the source systematically amplifies these effects, leading to both higher average values and greater variability across samples.

Target \ Source	English	Finnish	Turkish

Table 5: $\Delta_{\text{norm}}(\%)$ per occupation across all evaluated metrics. The occupations referenced in this table are listed in Table 7 along with the respective ISCO codes.

Analysis per Occupation. For this analysis, it is necessary to define not only the *strength* of the effect, captured by the absolute magnitude $\Delta_{\text{norm}}(\%)$, but also its *direction*. Specifically, a "+" is assigned when $\overline{M(s,t_{\text{male}})} > \overline{M(s,t_{\text{female}})}$ (where the overline denotes the mean value), indicating that the metric tends to favor the masculine form, whereas a "–" is assigned when $\overline{M(s,t_{\text{male}})} < \overline{M(s,t_{\text{female}})}$, indicating a tendency to favor the feminine form.

Table 5 presents the top ten occupations with the largest positive and negative normalized differences $\Delta_{\text{norm}}(\%)$ across all evaluated metrics, ranked by their average value across all languages. Occupations are identified using their corresponding ISCO-08 codes, providing a standardized reference for each job category.

The occupations appearing in the positive segment of the table (e.g., ISCO 3151 "Ships' Engineers", ISCO 7126 "Plumbers and Pipe Fitters", ISCO 7542 "Shotfirers and Blasters") are predominantly roles that are culturally and historically associated with men and are often perceived as physically demanding or male-dominated. In contrast, the negative segment features occupations such as ISCO 5241 "Fashion and Other Models", ISCO 5311 "Child Care Workers", and ISCO 3222 "Midwifery Professionals", which are stereotypically viewed as female-oriented professions. This pattern suggests that the evaluated metrics may reproduce gender stereotypes in their outputs, ultimately reinforcing such biases in MT systems.

It is also noteworthy that the magnitude of the positive differences is, in absolute terms, generally greater than that of the negative differences. For example, the tenth-highest positive difference toward the masculine form substantially exceeds the highest negative difference toward the feminine form. This asymmetry indicates an overall tendency of the evaluated metrics to favor masculine forms in translation.

6 Gender Density Analysis

Different human-evaluation approaches of translation penalize errors (such as using the wrong gender) differently: direct assessment applies a conceptual approach, penalizing each error only once (Graham et al., 2017), whereas MQM (Lommel et al., 2013) penalizes every occurrence of the error in a text. To better understand how QE metrics capture gender related aspects, we analyse the correlation between the

Metric	English	Finnish	Turkish
*COMETKiwi22	0.17	0.21	0.22
MetricX-25	0.02	0.09	0.08
MetricX-25-QE	0.06	0.17	0.19
Polycand-1	0.18	0.22	0.22
Polycand-2	0.17	0.21	0.20
Polyic-3	0.12	0.16	0.18
UvA-MT	0.47	—	—
baseCOMET	0.20	0.21	0.22
rankedCOMET	0.09	0.10	0.11
*sentinel-cand	0.02	0.02	0.02

Table 6: Pearson correlation coefficients between gender density and metrics' bias. All metrics show a positive correlation and all correlations are statistically significant ($p < 0.05$). Baseline metrics are indicated with an asterisk (*).

bias metric (normalized difference score $\Delta_{\text{norm}}(\%)$) and gender density in the text. We define *gender density* as the normalized count of gendered words in the text. Since the two texts (t_{male}, t_{female}) are identical except for the gendered words, we calculate the gender density as the proportion of differing words to the average text length (in words):

$$\text{gender density} = \frac{\text{worddiff}(t_{male}, t_{female})}{\text{average}(\text{len}(t_{male}), \text{len}(t_{female}))}$$

As presented in Table 6, we observe a positive correlation between metric bias and gender density for all metrics with varying correlation strength, i.e. *texts with a higher number of gendered words result in more biased metric evaluations*. Among the evaluated metrics, Polycand metrics show the strongest correlations overall to gender density. COMET-based metrics (COMETKiwi22, baseCOMET, rankedCOMET) also show strong correlations, while MetricX-25 and MetricX-25-QE consistently show weak correlations. Sentinel-cand metric shows minimal correlations, suggesting it may be less sensitive to gender density. Detailed correlation plots for each metric are in appendix C. The findings suggest that the metrics apply a cumulative preference and penalty for gender in a text.

7 Conclusions

We presented GAMBIT+, a large-scale, fully parallel challenge set containing paired masculine and feminine translations of gender-ambiguous occupations across 33 source–target language pairs, and used it to benchmark 10 QE metrics. Our evaluation revealed consistent, statistically significant score shifts driven solely by grammatical gender—often more pronounced in certain language pairs and occupations—with a clear overall tendency to favor masculine forms. These findings indicate that current QE metrics are not gender-fair and should be systematically audited and calibrated.

Future work will broaden the scope of our analysis to include a wider range of QE metrics, with a focus on identifying specific characteristics that make them more susceptible to gender bias. We also plan to investigate the interplay between MT systems and QE metrics, exploring how system outputs and metric evaluations align or diverge in terms of gender bias. We also plan to extend GAMBIT+ with translations of varying quality to investigate whether translation quality influences the biases of QE metrics—for example, whether poor translations make gender distinctions more or less apparent due to incorrect gender agreements across the sentence. Finally, we aim to extend the use of GAMBIT+ beyond MT, testing its applicability and value in evaluating gender bias in other natural language generation tasks.

A Prompts

Below is the prompt designed for the translation task. In this context, the variable {gender} can take the value "male" or "female," {occupation} refers to the specific occupation under study as defined by the GAMBIT framework, and {lang} denotes the target language. The prompt instructs the translation model to produce a faithful and semantically equivalent rendering of the source text, adapting all gendered references to match the specified {gender} form for the given {occupation}.

Gendered Translation Prompt

You are an expert professional translator. Translate the following English text into {lang}.

Important instructions:

- Any reference to the word "{occupation}" must be translated using the {gender} form in {lang}.

- Be extremely careful to preserve the exact meaning, tone, and semantics of the original text.

- Do **not** modify, omit, or add any information other than adapting the gender reference to {gender} for the {occupation}.

- Return **only the translation**, without any additional comments, notes, or explanations.

Text:

{text}

Translation:

Below is the prompt used for the gender-adaptation procedure in translations. In this setting, the variable {gender} assumes the opposite value from that assigned in the initial stage of the workflow-that is, if the initial assignment is "male," it is here set to "female," and vice versa. The variable {occupation} corresponds to the occupation label provided in the GAMBIT dataset, while {lang} specifies the language into which the translation is to be rendered. The instructions require the translation model to maintain complete semantic fidelity to the source text, altering only the gendered form of the {occupation} in accordance with the designated {gender}, without introducing, removing, or rephrasing any other content.

Gender Adaptation Prompt

You are an expert professional translator. Translate the following English text into {lang}.

Important instructions:

- Any reference to the word "occupation" must be translated using the {gender} form in {lang}.

- Be extremely careful to preserve the exact meaning, tone, and semantics of the original text.

- Do ***not*** modify, omit, or add any information other than adapting the gender reference to {gender} for the "{occupation}".

- Return ***only the translation***, without any additional comments, notes, or explanations.

Text:

{text}

Translation:

For languages without grammatical gender, namely Turkish and Finnish, no gender adaptation process is applied. In these cases, only the standard translation prompt is employed, as provided below, ensuring that occupational and role references remain neutral in accordance with the structural characteristics of the target language.

Genderless Translation Prompt

You are an expert professional translator. Translate the following English text into lang.

Important instructions: - Pay close attention to the gender of any occupations or role titles. - If the gender is not clear or not mentioned, do not assume or infer it; keep the translation gender-neutral or ambiguous as appropriate in the target language. - Return only the translation, without any additional comments, notes, or explanations.

Text:

{text}

Translation:

For the evaluation phase, the following prompt was employed to compare two texts in the target language. Its primary function was to determine whether any differences between the two texts were solely attributable to the explicit mention of the gender of the specified occupation or whether other differences

were present. Text 1 and Text 2 correspond to the two translations of the same source text, each rendered with a different specified gender for the occupation under study.

Evaluation Prompt

You are a linguistic comparison assistant. Analyze the following two {lang} texts and identify the differences between them.

If the only differences are related to the explicit mention of the gender of the occupation occupation_title (e.g., masculine vs. feminine forms of the occupation {occupation_title}), respond with "yes".

If you find any other type of difference, respond with "no" and list all the differences you found.

Return only the answer, without any additional comments, notes, or explanations, especially when the answer is "yes".

B ISCO Code–Occupation Mapping

Table 7 provides the mapping between the ISCO codes referenced in Table 1 and their corresponding occupational titles as defined in the ISCO-08 classification.

ISCO Code	ISCO Name	Emojis
3151	Ships' Engineers	⚓🔧
3513	Computer Network and Systems Technicians	💻⚙️
7126	Plumbers and Pipe Fitters	💧🔧
7542	Shotfirers and Blasters	💥💣
7231	Motor Vehicle Mechanics and Repairers	🚗🔧
7127	Air Conditioning and Refrigeration Mechanics	❄️⚙️
7421	Electronics Mechanics and Servicers	⚡⚙️
6224	Hunters and Trappers	🎯🐗
7213	Sheet Metal Workers	⚙️🔨
3114	Electronics Engineering Technicians	⚡💻
5241	Fashion and Other Models	👗👔
5311	Child Care Workers	🧒👶
2222	Midwifery Professionals	👶🩺
3222	Midwifery Associate Professionals	👶🩺+
2221	Nursing Professionals	💊🩺
3221	Nursing Associate Professionals	💊🩺+
5151	Cleaning and Housekeeping Supervisors	🏠🧹
4226	Receptionists (general)	☎️🖊️
9111	Domestic Cleaners and Helpers	🧹🏠
4120	Secretaries (general)	📝🖊️

Table 7: Mapping of emojis from Table 5 to their corresponding occupational titles and the respective ISCO codes.

C Gender-Density Correlation Plots

Figure 1 shows the correlation plots of gender density to normalized score difference for each metric. Plots are shown for English as a source language. Other source languages show the same trend.

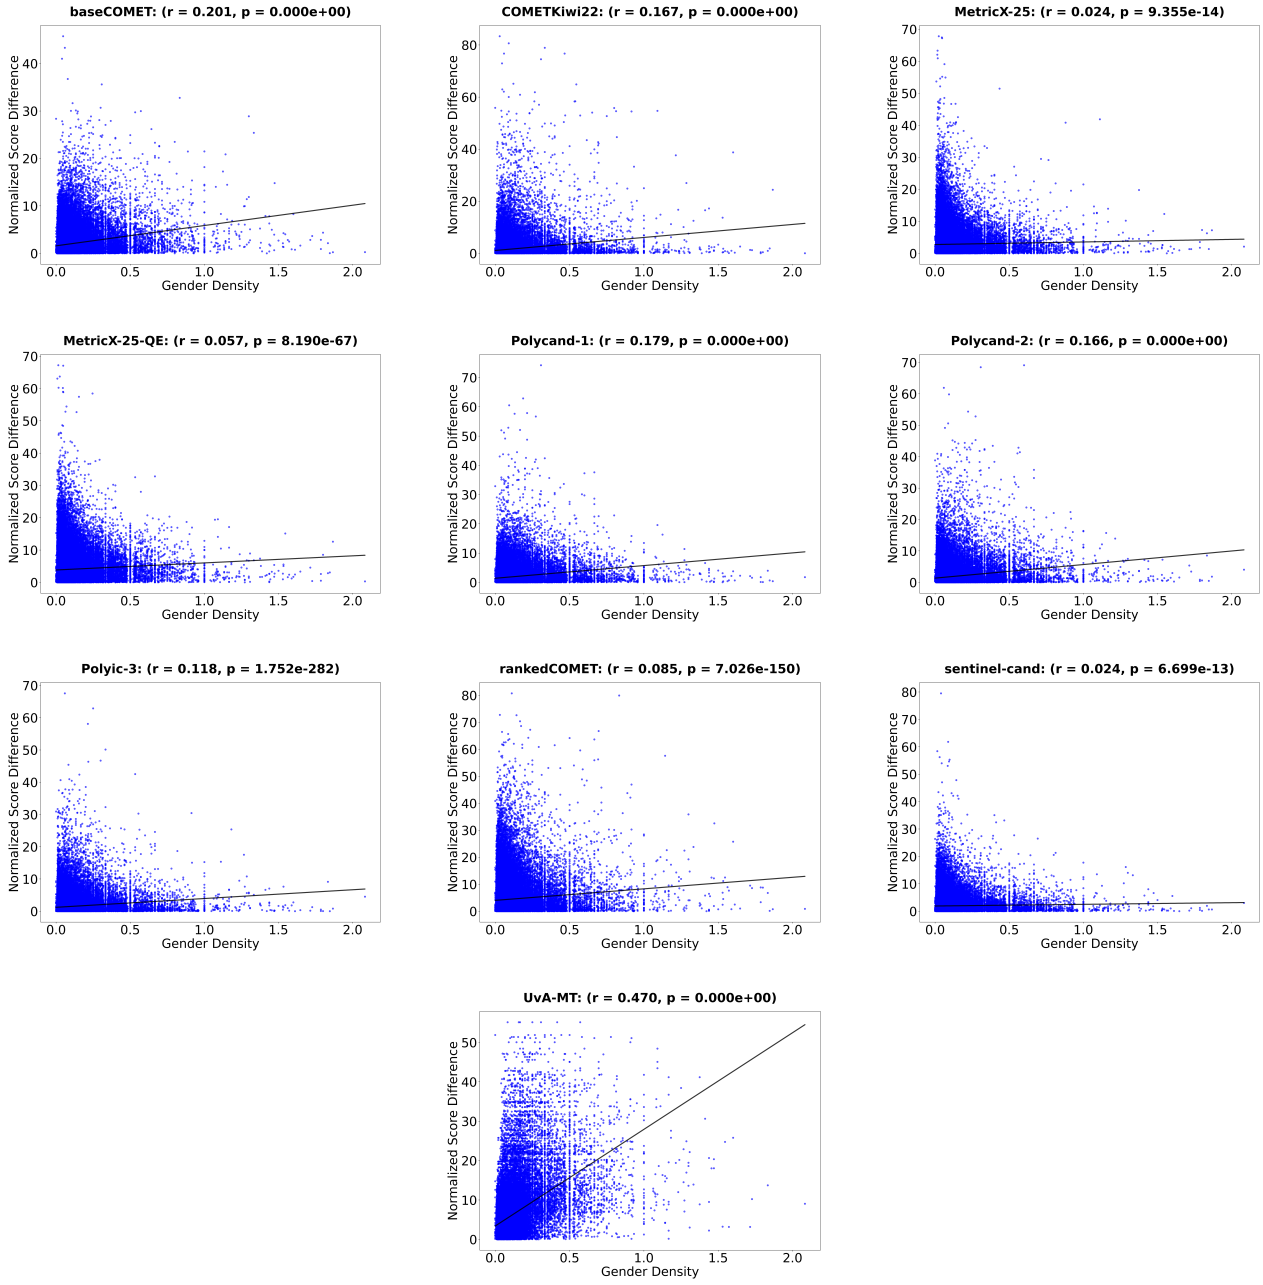

Figure 1: Gender density to normalized score difference correlation for all metrics.

Implementing and Evaluating Multi-source Retrieval-Augmented Translation

Tommi Nieminen and **Jörg Tiedemann** and **Sami Virpioja**
University of Helsinki

Abstract

In recent years, neural machine translation (NMT) systems have been integrated with external databases with the aim of improving machine translation (MT) quality and enforcing domain-specific terminology and other conventions in the MT output. Most of the work in incorporating external knowledge with NMT has concentrated on integrating a single source of information, usually either a terminology database or a translation memory. However, in real-life translation scenarios, all relevant knowledge sources should be used in parallel. In this article, we evaluate different methods of integrating external knowledge from multiple sources in a single NMT system. In addition to training single models trained to utilize multiple kinds of information, we also ensemble models that have been trained to utilize a single type of information. We evaluate our models against state-of-the-art LLMs using an extensive purpose-built English to Finnish test suite.

1 Introduction

Most NMT systems receive as their input a source sentence on its own, without any additional context. This is problematic, as producing a correct translation often requires information that is external to the source sentence. For instance, source sentences that are translated as part of a larger document have to be consistent with other parts of the document. Even if the translation of a sentence is not constrained by document context, the translation often needs to conform to terminological or phraseological conventions of a genre, domain, or a house style. Beyond acting as a contextual constraint, external information may also improve translation quality by providing the NMT system with translation examples. These examples can simplify the task of translation, as the NMT system does not have to generate the translation from scratch, but can adapt the provided external information.

One method of providing relevant external information to an NMT system is to query an external database for data based on the source sentence, and then either include the retrieved information as part of the NMT system input or constrain the decoding process based on the retrieved information. As similar information retrieval approaches used with large language models are called retrieval-augmented generation (RAG) (Lewis et al., 2020), we will refer to this family of methods as retrieval-augmented translation (RAT), following Hoang et al. (2023).

Even though almost all published RAT methods concentrate on a single kind of retrieved information (usually either terminology or translation memory matches), in actual practical translation scenarios all the kinds of retrieved information are used simultaneously. For instance, a human translator working in a computer-assisted translation (CAT) tool will be provided with matches from both terminology database and translation memories, and they will need to make their translations conform with both of these information sources.

In this article, we introduce several NMT systems, which can utilize different kinds of retrieved information when generating translations. We experiment with both single NMT models that are trained to utilize multiple kinds of information, and with systems that combine models that have been trained to utilize a single kind of information using a novel ensembling method called contrastive ensembling. We also compare our models with instruction-tuned LLMs, which have a native capability of utilizing multiple types of retrieved information.

Our models are trained to utilize two kinds of information:

1. **Fuzzy matches**: Parallel sentences retrieved from a translation database (translation memory or TM). The search is based on the edit distance between the source sentence being trans-

Proceedings of the Tenth Conference on Machine Translation, pages 327–339
November 8-9, 2025

lated and the source sentence in the translation database. Usually the matches are restricted to those whose normalized edit distance exceeds a specific threshold (in the translation industry a threshold corresponding to a similarity level of 70 percent is normally used).

2. **Term matches**: Terms retrieved from a terminology database (termbase or TB). The database is searched for all the sub-strings of the source sentence being translated, and all terms where the source term matches the sub-string are returned. As the TB usually contains the terms in their dictionary forms, the sub-strings are lemmatized or stemmed before the search.

The motivation for including these two kinds of information is that they are routinely used in the CAT tools that professional translators use. They represent the types of information that are readily available and have been found useful in real-life translation workflows (Hutchins, 1998). Building the RAT system around widely used types of information also ensures that it can easily be integrated into existing workflows.

As mentioned, RAT can be used in two ways: either as constraining the MT system to utilize the retrieved information in its output (especially in the case of terminology), or as providing contextual information to enable the generation of better translations. In this article, we are mainly concerned with constraining RAT, as it has applications in professional translation. One of the problems in developing constraining RAT systems is that the common MT evaluation methods, such as BLEU and COMET, are not well suited to evaluating them, as they provide no information on how well the retrieved information has been utilized. To help us develop and evaluate our models, we therefore compiled an extensive test suite, which contains test cases consisting of source sentences, terms, fuzzy matches, and tests that can be used to check whether the terms and fuzzy matches are used in translations.

2 Related work

We structure our system around retrieval methods that have been used in professional translation since the 1960s. These methods have been developed gradually and organically within the translation industry, so their origins are often unclear. For background on fuzzy match and term retrieval, see Hutchins (1998).

The first MT method that can be characterized as RAT was example-based machine translation (EBMT) (Nagao, 1984), where translations were generated based on examples retrieved from a translation database. Statistical machine translation (SMT) methods could also be characterized as a form of RAT, as they rely on retrieving partial translations from a database of translation fragments, and retrieval was also more explicitly integrated into SMT systems (Koehn and Senellart, 2010).

In the context of NMT, one of the first methods recognizable as RAT was introduced in Gu et al. (2017), where fuzzy matches were retrieved from a TM and the attention component of the model was modified to cover the matches in addition to the source sentence. Constraining NMT to adhere to retrieved terminology was first introduced in Hokamp and Liu (2017), where the beam search decoder is modified to always produce the specified target terms in the output. Song et al. (2019) was the first to implement RAT using data-based methods, by replacing sub-strings in the source sentences of the training data with equivalent target language sub-strings. Dinu et al. (2019) introduced data-based RAT for terminology and Bulte and Tezcan (2019) for fuzzy matches.

While most work on RAT has concentrated on a single kind of information, there has been some recent work on unified RAT, where NMT systems can utilize multiple kinds of information. Wang et al. (2023) prefix the inputs and outputs of their model with three different kinds of retrieved information: fuzzy matches, translation templates, and terms. Raunak et al. (2024) fine-tune an NMT model with data augmented with many different kinds of instructions, some of which are similar to RAT, such as an instruction to utilize a particular term in the translation. Moslem et al. (2023) experiment with prompting an LLM with both terms and fuzzy matches to generate adapted translations. What differentiates our approach from the previous implementations is that we focus exclusively on the types of information that are routinely used in CAT tools, which enables easy integration with professional workflows. We also use an ensemble of specialized models in addition to a single model trained to utilize multiple types of information.

The concept of generating translations using multiple different inputs originates from the field

of multi-source translation (Och and Ney, 2001), where the different inputs are equivalent source sentences in different languages. Firat et al. (2016) were the first to implement multi-source translation by ensembling different NMT models that are provided with different inputs, which resembles our ensembling method.

For evaluation, we will use a dedicated test suite for the phenomena we want to tackle. Test suites have been used for evaluating MT quality since at least the 1990s (King and Falkedal, 1990), and they have become more popular in recent years (see for example Macketanz et al., 2022), as the dramatically improving MT quality has created A demand for more granular evaluation methods. As far as we know, our test suite is the first suite designed specifically for RAT evaluation.

3 Models

We train a selection of models, including separate term and fuzzy match RAT models, and unified RAT models, which process both types of retrieved information. For term models we train models that can process a single term, and models which can process up to ten terms. For fuzzy models, we train models that can process a single fuzzy match, and models that can process up to three fuzzy matches.

Models are created with continued training using the Tatoeba-Challenge (Tiedemann, 2020) models as the base models. As our test suite is English to Finnish, we only train models in that language direction. For all models but one we use the standard transformer model *opusTCv20210807+bt-2021-09-01* as the base model. To see the effect of model size, we also train one model using a base model with the transformer-big architecture (*opusTCv20210807+news+bt_transformer-big_2023-04-13*). Continued training has many advantages compared to training the models from scratch: as continued training is much faster, it is easier to test different model variations and the carbon footprint of the training is smaller. The base models can also be used as strong baselines for evaluation, as they have been trained on all the available data from the OPUS corpus (Tiedemann, 2009).

Our models use special symbols to separate the retrieved information from normal source text (see the left column in Figure 1 for an example of how the symbols are used). The vocabularies of the base models do not have any spare symbols that can be used as these special symbols, so we need to re-purpose some of the existing symbols. We pick ten of the least common symbols from the vocabulary, and assign them as our special symbols. Not all symbols are used in the experiments, but we reserve extra symbols in case more are needed in future experiments with the same models. As the vocabularies remain otherwise identical, we can easily ensemble the trained models with each other and with the base model.

Training is continued with a high-quality subset of the Tatoeba-Challenge dataset that was originally used to train the base models. Ten million sentences are included in the continued training subset. The subset does not include data from crawled corpora due to quality problems associated with them (Kreutzer et al., 2022). The data is also scored with BiCleaner-AI (Zaragoza-Bernabeu et al., 2022), and sentence pairs scoring less than 0.7 are excluded from the subset. The duration of continued training is one epoch, and the learning rate is set to 0.00001 to prevent catastrophic forgetting (McCloskey and Cohen, 1989).

For both fuzzy and term models, the training set is annotated with the appropriate RAT data for that type (see Figure 1 for examples of the annotations). The models are trained using the Marian NMT framework (Junczys-Dowmunt et al., 2018).

3.1 Term models

The terminology models are trained using the data augmentation method first introduced in Dinu et al. (2019): source terms are identified in the source sentence, and target terms are appended to the source sentence after the corresponding source terms. Following Bergmanis and Pinnis (2021) we append the source sentence with lemma forms of the target terms instead of the surface forms, in order to train the model to inflect the provided target terms on the target side instead of copying them directly. We also follow Bergmanis and Pinnis (2021) in using synthetic terms, which are generated by aligning the parallel data on the token-level using *fast-align* (Dyer et al., 2013) and then selecting aligned noun and verb phrases as the synthetic terms. *Stanza* (Qi et al., 2020) was used for lemmatization and to identify noun and verb phrases.

3.2 Fuzzy match models

The fuzzy match models are trained using the Neural Fuzzy Repair (NFR) method introduced in Bulte and Tezcan (2019). We use the continued training

subset as a translation database from which fuzzies are retrieved. The database is searched for matches using the *fuzzy-match*[1] library, and the target sides of the matches are prefixed to the source sentences to produce the training data.

Preparing training data for fuzzy match models is more complicated than for term models. In the term model training data we can always make sure that the target term appended to the source sentence is actually present on the target side, but the situation is different with fuzzy matches. Fuzzy matches have to be retrieved from naturally occurring data, as producing them synthetically is not feasible. Also, fuzzy matches are not binding in the sense that terminology is: in the case of terms, the target term can almost always be used in a translation, but it is very common to have a fuzzy match that cannot be used in any valid translation for a source sentence. Because of this, the ideal training data for fuzzy match models consists of the following types of sentence pairs:

1. **Positive examples**: Sentence pairs, where the source sentence is appended with a usable fuzzy match (i.e. a fuzzy match that can be used in a valid translation for the source sentence), and parts of that fuzzy match are present in the target sentence.

2. **Negative examples**: Sentence pairs, where the source sentence is appended with an unusable fuzzy match (i.e. a fuzzy match that cannot be used in a valid translation for the source sentence), and that fuzzy match is not used in the target sentence.

If fuzzy matches are retrieved based on source similarity, the mix of training examples is not optimal, as it will contain many examples where a usable fuzzy match is not used on the target side. On the other hand, if fuzzy matches are retrieved based only on target similarity, the training set will only contain positive examples, and the model will learn to always copy from the fuzzy matches, even when inappropriate. Because of this, we retrieve fuzzies using both source and target similarity, as in Nieminen et al. (2025).

3.3 Unified model

In addition to the separate term and fuzzy models we also train a unified model, which is trained on both two types of data. The training data for this model is generated by merging the training data for the term and fuzzy models. Specifically, we combine the training data of those models, that are trained to process multiple terms or fuzzies, as the unified model also has to process multiple terms and fuzzies.

4 Multisource ensembling

In addition to using a unified model capable of processing both terms and fuzzies, we ensemble models trained to utilize a single kind of information to produce a system that can utilize multiple kinds of information. Each model in the ensemble has its own input, which is prefixed (full matches) or interleaved (terms) with appropriate retrieved information. See Figure 1 for a schematic of the inference pipeline. The ensemble decoder is implemented by modifying the generation functionality in the HuggingFace *Transformers* library[2].

We experiment with the following ensembling methods (see Figure 2 for a visual example):

1. **Naive ensembling**: The next token probabilities of each model in the ensemble are averaged during inference, with equal weight given to each model.

2. **Contrastive ensembling**: Naive ensembling dilutes the effect of the individual models in the ensemble. This is undesirable in our use case, as we want certain models to have more effect than other models at certain phases of generation. For instance, when the next token to be generated is part of the translation for a source term, we want to emphasize the effect of the terminology model that has been provided that specific source term as part of its input. To achieve this, we compare the next token probability distribution for each model to the token probabilities of a contrast model which has not been provided any external information. If a symbol's probability of a model differs significantly from its probability with the base model, the weight of the symbol is boosted in the ensemble (see source code[3] for implementation details). We use the base model from which the RAT models have been trained from as the contrast model.

[2] https://github.com/huggingface/transformers

[3] https://github.com/Helsinki-NLP/OpusDistillery/blob/modularization/pipeline/hf/multisource_eval.py

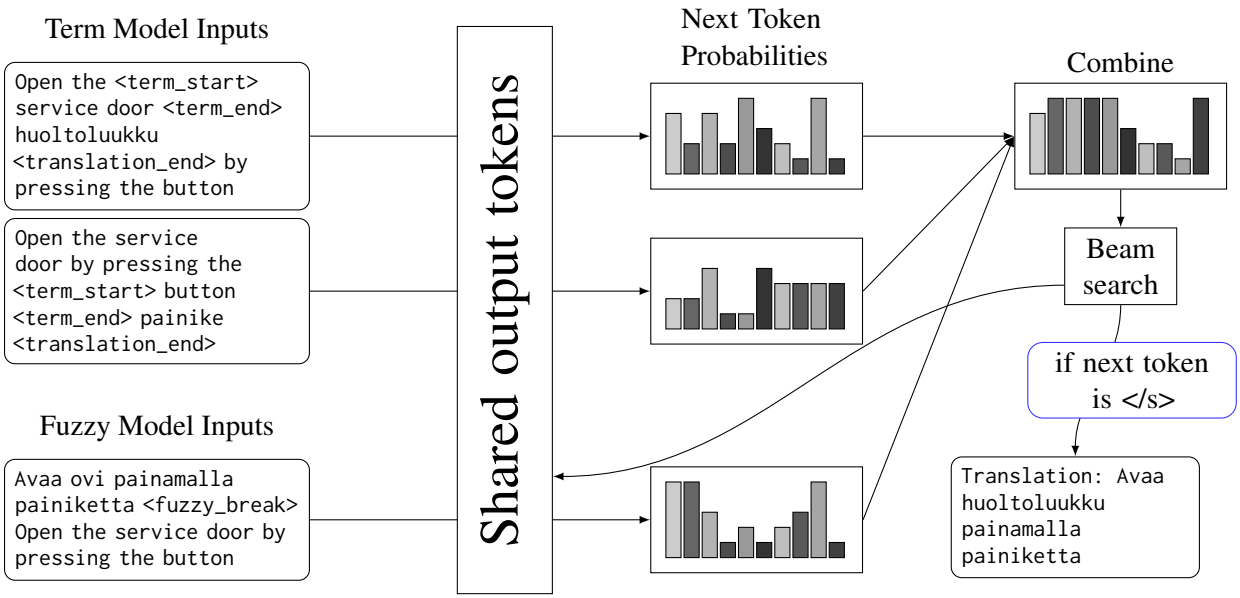

Figure 1: The ensembling inference pipeline with three models and three different inputs. The output tokens are always shared between the models. Note differences in utilization: terms are used completely and inflected, and fuzzy matches are used partially.

Ensembling serves two purposes. First it allows us to utilize multiple kinds of retrieved information during inference, but it also acts as conventional ensembling, the purpose of which is to improve generic output quality. We also hypothesize that ensembling models trained for different RAT methods and provided with different inputs during inference will enhance the quality improving effect of ensembling, as it has been shown (Hoang et al., 2024) that ensembling diverse models produces better results than ensembling similar models, such as different checkpoints of a single training run.

5 Evaluation

RAT systems can be used both for improving generic translation quality and for domain adaptation. When used to improve generic translation quality, it is not relevant whether the translations actually adhere to the terminology and phraseology used in the retrieved examples. For domain adaptation, however, adherence to the retrieved examples is important.

We evaluate model performance from two points of view: correct utilization of the retrieved information in the translations, and general translation quality. For evaluating the correct utilization, we use our test suite, which is covered in detail below. The main purpose of general translation quality evaluation is to see whether continued training with RAT-augmented data degrades generic translation quality. Measuring general translation quality for RAT systems is complicated by the fact that RAT systems are meant to be used with retrieved information: their performance when not provided with any such information is almost irrelevant, as any RAT system can be paired in production with a back-off system that processes source sentences with no retrieved information.

Therefore evaluating RAT systems with standard evaluation sets, which are not paired with retrieved information, does not provide much useful information about the primary use case for RAT systems. Because of these concerns, we use our test suite also as the generic quality test set, so that we can provide retrieved information to the systems. As the test suite does not contain any reference translations, we use the reference-free *wmt23-cometkiwi-da-xl* metric (Rei et al., 2023) for evaluation. This metric has been shown (Freitag et al., 2024) to correlate reasonable well with human judgments and to perform better than many standard reference-based metrics such as BLEU and chrF.

5.1 Test suite

To evaluate the utilization of retrieved information in the generated translations, we created a test suite consisting of source sentences, examples of retrieved information, and tests for checking whether the examples of retrieved information have been utilized in the translations. The test suite was gen-

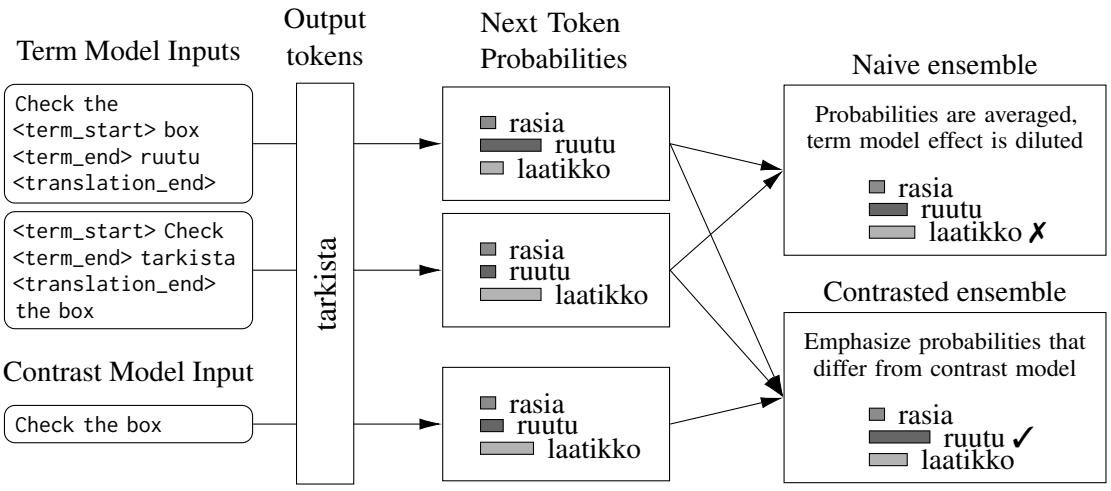

Figure 2: An example of the two ensembling methods. The graph represents a scenario where the source sentence is *Check the box*, and so far the output token *tarkista* has been generated. The word *box* that is being translated in the example is highly polysemous, but the context favours the translation *laatikko*. However, our terminology stipulates that the translation *ruutu* must be used. Naive ensembling produces incorrect output due to treating all models as equal in the context, while contrasted ensembling correctly emphasizes the model that is relevant in the context.

erated semi-automatically: an LLM was used to generate the data, which was then validated and edited by a human reviewer. Initially we tested whether a test suite could be created in a single phase using an LLM (*DeepSeek-V3*), by prompting the LLM to produce complete test cases. While this approach worked for a small test suite (ten or so test cases), when prompted to generate a larger test suite (tens of test cases), the LLM output quality started to degrade noticeably. Because of this degradation, we decided to divide the task into smaller sub-tasks.

As the first step of test suite creation, we prompted the LLM to generate English source sentences. Again, prompting for a large amount of output lead to noticeable output quality degradation, such as repetitive and short sentences. To generate a sufficient amount of high-quality source sentences, we also had to subdivide the sentence generation task to sub-tasks. First we specified seven domains (medical, pharmaceutical, public administration, EU texts, IT administration, IT customer support, and legal), for which sentences could be separately generated for. To add variety, for each of the domains we prompted for the generation of sentences in three different length classes (short, medium, long). In total, we therefore used 21 different prompts, each requesting ten sentences, to generate the source sentences.

The LLM was then prompted to generate a number of fuzzy matches for each of the generated source sentences. For each sentence, three types of fuzzies were generated:

- **Addition fuzzies**: Sentences, which contain additional tokens compared to the source sentence.
- **Deletion fuzzies**: Sentences, which are modifications of the source sentence where some part has been removed.
- **Replacement fuzzies**: Variation of the source sentence where some part has been replaced with a semantically different part.

Note that at this phase only the source side of the fuzzy matches were generated, the target sides were generated later in a separate phase. The edit distance between the generated fuzzies and source sentences was calculated, and all fuzzies below a 70 percent similarity threshold (standard in the translation industry) were automatically discarded.

Once the source sentences and fuzzies had been generated, a human reviewer validated them using a graphical interface (also generated using an LLM) displaying each source sentence and its fuzzy matches on different pages. The reviewer selected 1-5 credible fuzzies for each source sentence. If there were no suitable fuzzies, the reviewer deleted the sentence from the test suite. The reviewer also corrected minor mistakes in some sentences and fuzzy matches.

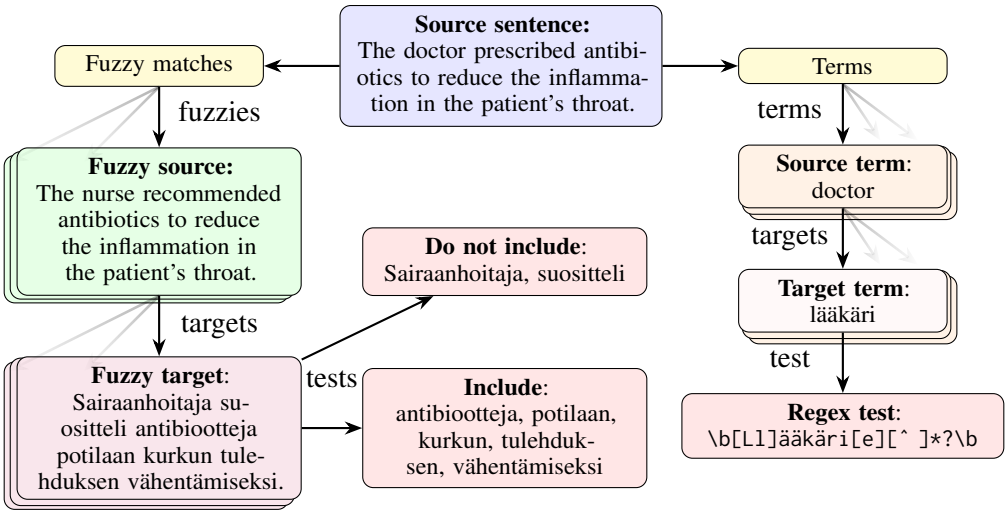

Figure 3: A single test sentence from the test suite. Fading arrows indicate that there can be multiple elements (only one element is shown in the graph to save space).

After the fuzzy validation phase, we prompted the LLM to generate terms and their Finnish translations for each source sentence, as well as regular expression tests for checking whether the term is used in Finnish sentence. The prompt specified that there should be multiple plausible translations for each term. This is important, since if a term has only one plausible translation, it cannot be used to make distinctions between MT systems, as most MT systems are likely to include the correct translation in their output. The terms were also validated manually by a human reviewer using an LLM-generated graphical interface, where the reviewer could select the most plausible terms and their translations, and remove test cases for which no plausible terms had been generated. The reviewer also corrected terms using the interface. The regular expression tests for correct term use that the LLM generated were not usable as such due to them not reflecting Finnish morphology, so the reviewer had to manually correct the tests.

The next phase was to generate translations for the fuzzies. For all other generation phases we used *DeepSeek-V3*, but as the quality of its English to Finnish translations was very uneven, we switched to *GPT4.1* model for generating the translations. The reviewer again reviewed, validated and corrected the translations using an LLM-generated user interface.

The last phase of the test suite generation was generating tests for identifying correct usage of fuzzy matches. Unlike naturally occurring fuzzies, all of the fuzzies in the test suite can be used to construct a valid translation for the source sentence. The test suite is also aimed at scenarios, such as professional translation, where using as much of the fuzzy as possible is desirable, in order to ensure consistency with previous translations. Because of this, we decided to use simple lexical tests to identify whether a fuzzy has been correctly used in a translation. We divided the tokens in each fuzzy into two sets: 1. **Include**: those that correspond semantically to tokens in the source sentence, and should be used in the translation and; 2. **Do not include**: those tokens that have no semantic equivalents in the source sentence and should not be used in the translation.

To create the **Include** and **Do not include** sets, we prompted an LLM with the source sentence, fuzzy source, and the translation of the fuzzy, and instructed the LLM to divide the tokens into the two sets. We also tested traditional word alignment methods, but their accuracy turned out to be too low.

The completed test suite contains 128 source sentences, 434 fuzzy source sentences, 620 fuzzy translations, 403 terms, and 870 term translations. In total, over 200,000 different test cases can be constructed by combining the fuzzy source sentences, fuzzy translations and terms in different combinations. To keep the test suite size manageable for testing (especially with larger models), we create a limited test suite by first organizing the test suite into groups based on how many terms and fuzzy matches each test case contains. Then we randomly pick 50 test cases from each group,

whilst making sure to pick a similar amount of test cases from each domain. We exclude test cases with more than three fuzzy matches to simplify the evaluation task. Our limited test suite contains 1150 test cases.

During evaluation, the test suite produces eight different scores:

1. **Term success (TS)**: the target sentence passes the term test.
2. **Term failure (TF)**: the target sentence fails the term test.
3. **Suitable fuzzy token included (FP)**: the target sentence contains a fuzzy token from the **Include** token list.
4. **Suitable fuzzy token not included (FN)**: the target sentence does not contain a fuzzy token from the **Include** token list.
5. **Invalid fuzzy token not included (IN)**: the target sentence does not contain a token from the **Do not include** token list.
6. **Invalid fuzzy token included (IP)**: the target sentence contains a token from the **Do not include** token list, indicating over-copying.
7. **Suitable fuzzy token bigram included (BP)**: the target sentence contains a bigram of fuzzy tokens from the Include token list.
8. **Suitable fuzzy token bigram not included (BN)**: the target sentence does not contain a bigram of fuzzy tokens from the Include token list.

The bigram scores are included to reward using the same order of tokens in the translation as in the fuzzy. If there are multiple fuzzy matches available to the system, the fuzzy match that has the best overall score is used as the basis of the fuzzy match scores.

We report average term and fuzzy scores for each system, which are calculated with the following formulas:

$$TermScore = \frac{TS}{TS + TF} \quad (1)$$

$$FuzzyScore = \frac{1}{3}\left(\frac{FP}{FP + FN} + \frac{IN}{IN + IP} + \frac{BP}{BP + BN}\right) \quad (2)$$

To facilitate comparison between systems, we also produce a composite score using the following formula:

$$CompositeScore = \frac{5 * TermScore + 3 * FuzzyScore}{8} \quad (3)$$

The composite score intentionally emphasizes term accuracy, as using correct terminology is more important than utilizing fuzzies maximally. Also, in many cases a fuzzy will contain a translation for a term, and if that happens to be different from the specified term, using the correct term lowers the fuzzy scores. Emphasizing term scores compensates for that. The composite score for the whole test suite is calculated as the average of the composite scores for individual test cases, to lessen the effect of test cases with many terms and fuzzies on the overall score.

5.2 Comparison to LLMs

LLMs have been shown to produce better translations than traditional NMT models, at least for high-resource language pairs, such as English to Spanish (Kocmi et al., 2024). LLMs can also be used for RAT by modifying the prompt used to generate the translations (Moslem et al., 2023). While LLM superiority has been shown in the field of generic MT, RAT implemented with NMT (NMT-RAT) has not been thoroughly compared to RAT implemented with LLMs (LLM-RAT). Bouthors et al. (2024) compares NMT-RAT with LLM-RAT using 1-3 fuzzy matches, and finds NMT-RAT much better, but the LLM they compare against does not represent the state of the art.

We compare our models against two recent LLMs, Gemma 3 12B and EuroLLM 9B. We choose these models as they are both competitive and relatively small. We do not compare our models against the largest available models, as our models are aimed at professional translation, where latency and the possibility to deploy models locally is important.

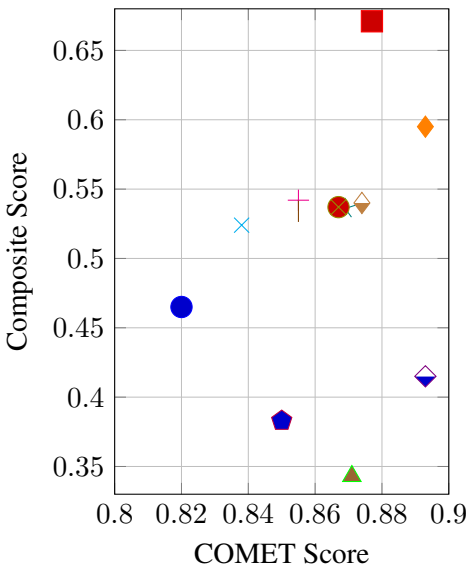
One use case that we foresee for RAT systems is interactive MT, where the MT output is influenced by translator actions. Interactive MT with RAT can for instance take the form of excluding an irrelevant match or modifying a somewhat relevant match manually during translation. This requires very fast generation of translations, as the translator should be able to see the effect of their actions almost immediately. Traditional NMT can gener-

System	Description
Baseline	Standard MT model trained without term or fuzzy annotations.
TermOnly	Model trained with 1-10 term annotations per sentence.
FuzzyOnly	Model trained with 1-3 fuzzy annotations per sentence, using both **source** and **target** similarity fuzzies.
TermAndFuzzy	Model trained with both 1-10 term and 1-3 fuzzy annotations, using both **source** and **target** similarity fuzzies.
TermAndFuzzyBig	Model trained with both 1-10 term and 1-3 fuzzy annotations, using both **source** and **target** similarity fuzzies. Transformer-big model.
ContrastEnsembleTS	Contrastive ensemble of a term and a fuzzy model (trained with both **source** and **target** similarity fuzzies). Each term and fuzzy gets own model in the ensemble.
ContrastEnsembleS	Contrastive ensemble of a term and a fuzzy model (trained with **source** similarity fuzzies). Each term and fuzzy gets own model in the ensemble.
ContrastEnsembleT	Contrastive ensemble of a term and a fuzzy model (trained with **target** similarity fuzzies). Each term and fuzzy gets own model in the ensemble.
BaselineEnsembleTS	Normal ensemble of a term and a fuzzy model (trained with both source and target similarity fuzzies). Each term and fuzzy gets own model in ensemble.
ContrastEnsembleMulti	Contrastive ensemble of a term and a fuzzy model (trained with both source and target similarity fuzzies). Ensemble contains one model for all terms, and one model for all fuzzies.
Gemma3-12B-IT	Instruction-tuned Gemma-3 LLM model with 12B parameters.
EuroLLM-9B-Instruction	Instruction-tuned EuroLLM model with 9B parameters.

Table 1: MT systems evaluated using the test suite.

ate translations fast enough, even running on desktop computers, but it is an open question whether LLMs can achieve the same. While it is not feasible currently to generate translations quickly enough locally with Gemma 3 12B and EuroLLM 9B, we use them as stand-ins for near-future LLMs that can produce translations almost immediately on desktop computers.

5.3 Results



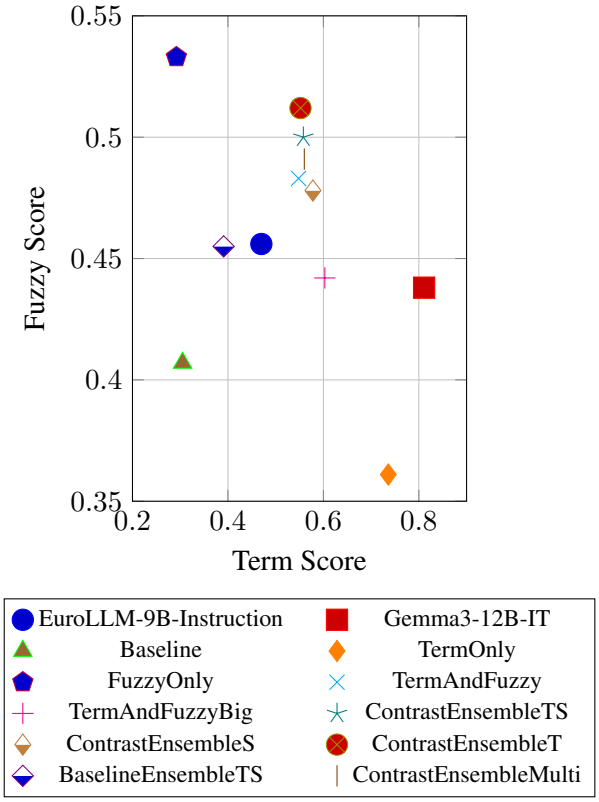


Figure 4: Term score vs Fuzzy score and COMET score vs Composite score.

We evaluated the output of 12 systems with the test suite (see models and their descriptions in Table 1). The main impression of the evaluation is that the

System	COMET ref-free	Comp. score	Term score	Fuzzy score	Fuzzy score (0 terms)
Baseline	0.871	0.343	0.305	0.407	0.520
TermOnly	**0.893**	0.595	0.736	0.361	0.481
FuzzyOnly	0.850	0.383	0.292	**0.533**	0.680
TermAndFuzzy	0.838	0.524	0.548	0.483	0.670
TermAndFuzzyBig	0.855	0.542	0.603	0.442	0.608
ContrastEnsembleTS	0.869	0.536	0.558	0.500	0.**687**
ContrastEnsembleS	0.874	0.540	0.578	0.478	0.642
ContrastEnsembleT	0.867	0.537	0.552	0.512	0.676
BaselineEnsembleTS	**0.893**	0.415	0.391	0.455	0.675
ContrastEnsembleMulti	0.855	0.534	0.560	0.491	0.659
Gemma3-12B-IT	0.877	**0.671**	**0.811**	0.438	0.639
EuroLLM-9B-Instruction	0.820	0.465	0.470	0.456	0.592

Table 2: Test suite scores for each model. The Comet model used is *wmt23-cometkiwi-da-xl*.

test suite is difficult for MT systems, with most systems performing poorly. The strongest performer by far is Gemma-12B-IT, which is also the largest evaluated model. This is a further demonstration of the edge that LLMs have over traditional NMT models, although it should also be noted that the second evaluated LLM (EuroLLM-9B-Instruction) performed worse than the NMT-RAT models. It is also noteworthy that Gemma-12B-IT excels above all in using the correct terminology in its translations. However, it does not score nearly as well in the fuzzy categories. As mentioned, high term accuracy impacts the scores of the fuzzy categories, but Gemma-12B-IT fuzzy score is lower than with the NMT-RAT systems also in cases where there are no terms in the input (see the last column in Table 2).

When comparing the NMT-RAT systems to each other, we can confirm that naive ensembling of models (BaselineEnsembleTS) results in the dilution of the impact of individual models, causing lower term and fuzzy scores. Contrastive ensembling (ContrastEnsemble models) clearly remediates this problem, although term scores remain low compared to the scores produced by the pure term model. The only transformer-big model (TermAndFuzzyBig) in the evaluation has comparable performance to the ContrastEnsemble models, which again demonstrates the effectiveness of contrastive ensembling.

The reference-free COMET scores are fairly similar across systems, with EuroLLM-9B-Instruction being the only outlier. Based on these scores, the RAT methods used do not degrade general output quality.

It is notable that the term scores are low relative to comparable previously published scores, such as those in Alam et al. (2021). This is likely due to the fact that the terms in the test suite have multiple feasible translations by design, which makes the task of applying the correct terminology more difficult.

6 Conclusion

Our experiments demonstrate that combining multiple types of information in a RAT system remains an open problem, even though LLMs show much promise also in this field. The main contributions of this paper are the introduction of contrastive ensembling and the dedicated, extensive test suite for evaluating RAT. Using the test suite we confirm that contrastive ensembling with separate term and fuzzy models provides better results than naive ensembling or single models that can process both terms and fuzzies. While contrastive ensembling does not perform as well as Gemma-12B-IT LLM, its computational requirements are much lower, which makes it suitable to more use cases, such as local low-latency RAT. We have made the training and evaluation pipeline[4] and the test suite[5] available under a permissive license.

7 Limitations

Because we rely entirely on the test suite for evaluation, our experiments are limited to one language

[4]https://github.com/Helsinki-NLP/OpusDistillery/tree/modularization

[5]https://github.com/TommiNieminen/RatTestSuite

direction. However, as our language direction is challenging due to a morphologically complex target language, we can be reasonably confident that the results also apply to less demanding language directions. The test suite has been generated semi-automatically, and while all the test items have been reviewed manually, they may not fully resemble naturally occurring data. The formulas we use to calculate the composite scores of the test suite are motivated by practical considerations, but they may place too much emphasis on certain aspects of the translations, especially correct terminology use. While reference-free MT quality metrics have been shown to work well in recent evaluations (Freitag et al., 2024), they may behave unexpectedly with unusual text types and language pairs.

A Prompt used for generating RAT output with LLMs

Both LLMs tested use the same system prompt, but the user prompt had to be customized for each model to produce clearly delineated translation output.

System prompt for both LLMs: You are a translator translating from English to Finnish.

User prompt for Gemma3-12B-IT: Translate the sentence below to Finnish using the specified terms and fuzzy matches. Use the structure of the fuzzy matches in the translation if appropriate, but do not copy parts of the fuzzy match to the translation if they are not semantically present in the source sentence. Using the specified term is more important than using the fuzzy match, so if a term and the fuzzy match conflict, always prefer the term. Output the answer in the following format, and do not output anything else:
TRANSLATION: TRANSLATION GOES HERE
Terms: *source term 1=target term 1*,*source term 2=target term 1*...
Fuzzy match 1: *target side of fuzzy match 1*
Fuzzy match 2: *target side of fuzzy match 2*...

User prompt for EuroLLM-9B-Instruction: Translate the sentence below to Finnish using the specified terms and fuzzy matches. Use the structure of the fuzzy matches in the translation if appropriate, but do not copy parts of the fuzzy match to the translation if they are not semantically present in the source sentence. Using the specified term is more important than using the fuzzy match, so if a term and the fuzzy match conflict, always prefer the term. Only output the translation.
Terms: *source term 1=target term 1*,*source term 2=target term 1*...
Fuzzy match 1: *target side of fuzzy match 1*
Fuzzy match 2: *target side of fuzzy match 2*...

A Cross-Lingual Perspective on Neural Machine Translation Difficulty

Abstract

Intuitively, machine translation (MT) between closely related languages, such as Swedish and Danish, is easier than MT between more distant pairs, such as Finnish and Danish. Yet, the notions of 'closely related' languages and 'easier' translation have so far remained underspecified. Moreover, in the context of neural MT, this assumption was almost exclusively evaluated in scenarios where English was either the source or target language, leaving a broader cross-lingual view unexplored. In this work, we present a controlled study of language similarity and neural MT difficulty for 56 European translation directions. We test a range of language similarity metrics, some of which are reasonable predictors of MT difficulty. On a text-level, we reassess previously introduced indicators of MT difficulty, and find that they are not well-suited to our domain, or neural MT more generally. Ultimately, we hope that this work inspires further cross-lingual investigations of neural MT difficulty.

1 Introduction

In neural machine translation (NMT), the choice of the language pair(s) under study is often heavily influenced by data availability. But how does the choice of language pair influence the difficulty of the translation task? This question has been studied extensively for statistical MT (e.g., Koehn, 2005; Birch et al., 2008; Paul et al., 2009); these works are still frequently cited to explain linguistic disparity in MT (e.g., Rowe et al., 2025). But to date, similar studies on NMT have been scarce. A notable exception was presented by Bugliarello et al., 2020, who quantified translation difficulty for Transformer models (Vaswani et al., 2017). Yet, whereas the aforementioned studies in statistical MT focused on more than 100 translation directions, the NMT study is limited to English-centric translation scenarios: settings where English is either the source or the target language. As a result, little is known about cross-lingual NMT difficulty in a broader sense. The first goal of this work is to address this knowledge gap, by expanding the scope of analyzed language pairs (e.g., Figure 1).

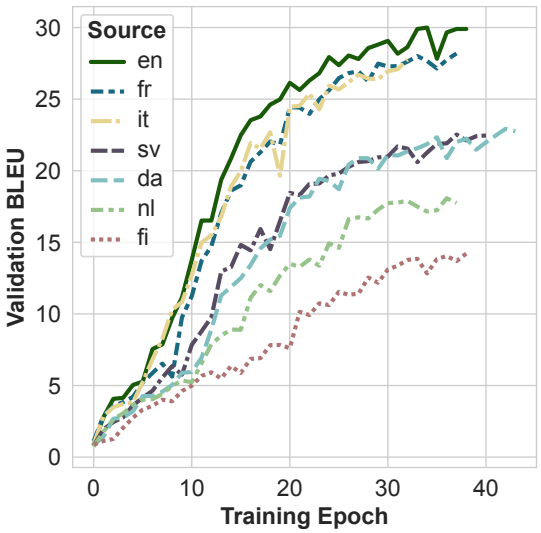

Figure 1: Training curves for MT into Portuguese; Italian (*it*) and French (*fr*) are 'easier' source languages to learn than e.g. Danish (*da*) and Swedish (*sv*).

Beyond advances in MT architectures, new approaches for quantifying language similarity have also emerged. The `lang2vec` (Littell et al., 2017) toolkit is one of the most popular typological similarity tools in natural language processing (NLP), despite major issues of data sparsity and irreproducibility (Khan et al., 2025). Typological research has resulted in newer databases, such as Grambank (Skirgård et al., 2023), which was developed with computational applications in mind (Haynie et al., 2023). This data was shown to be informative for NLP tasks, for example in the case of part-of-speech tagging (Rice et al., 2025), but there has not yet been a study on relating this new source of information to MT difficulty. The second objective of this work is therefore to systematically compare these typological databases in the context of MT.

Proceedings of the Tenth Conference on Machine Translation, pages 340–354
November 8-9, 2025

The third aim of this work is to bridge two perspectives on MT difficulty. Separately from language-level approaches to performance prediction (e.g., Birch et al., 2008; Bugliarello et al., 2020), MT difficulty has long been approached from the perspective of *text-level* difficulty (e.g., Underwood and Jongejan, 2001; Bernth and Gdaniec, 2001; O'Brien, 2004). It is not clear how these two perspectives influence each other. Are typical indicators of translation difficulty, such as sentence length, perhaps less problematic when the source and target language are more similar? In summary, this work aims to address the following three research questions:

- **RQ1:** Are there differences in NMT difficulty, beyond English-centric language pairs?
- **RQ2:** Which measures of language similarity are informative for predicting NMT performance?
- **RQ3:** How language pair-dependent are text-level translatability indicators?

Our study additionally aims to address a methodological issue in similar previous work. The inclusion of translated text in MT evaluation sets can artificially inflate results (Zhang and Toral, 2019; Graham et al., 2020), but this variable was not controlled for in relevant previous studies. To control as much as possible for variations beyond language similarity (data size, domain, topic, genre, proportion of translated text), we construct a new fully multi-parallel dataset. Because of these strict constraints and data availability, we limit our scope to 8 European languages. We train and analyze bilingual NMT models for each of the 56 resulting translation directions.

2 Related work

2.1 Machine Translation Difficulty

Estimating the difficulty of a translation task (*translatability*) from text has long been an important research direction in translation studies (Sun, 2015), for both manual and automatic translation (Bernth and Gdaniec, 2001). For MT, assessing the difficulty of translation tasks has had two prominent applications in the translation industry. The first is to distinguish samples that are suitable for MT from more difficult samples that likely require manual translation (Underwood and Jongejan, 2001). This line of research was especially popular when the performance of MT systems was much poorer than it is now. Still, more recently, Fernicola et al. (2023) showed that NMT suitability can also be predicted from source texts with reasonable accuracy. The second application has been to inform *controlled language* writing (e.g., Miyata et al., 2015). Given indicators of text characteristics that pose issues to MT, writers can choose to avoid these, to make their texts easier for MT systems to translate.

Text-level Approaches Certain text-level characteristics have been associated with MT difficulty. Examples include personal pronouns, post-modifying adjective phrases, ellipsis and very long or short sentences (Bernth and Gdaniec, 2001). Such indicators are also called *translatability indicators* (TIs). Underwood and Jongejan (2001) distinguish *general* TIs from *system-specific* ones. O'Brien (2004) writes that "it has been acknowledged that some TIs are more problematic for certain language pairs and directions than others". In the context of neural MT, however, the relevance of these TIs has not been investigated, and the influence of the language pair is also unclear. We explore a number of general TIs across multiple language pairs in Section 7.

Language-level Approaches The relationship between language similarity and MT difficulty has been a longstanding area of interest in MT research. Early work on statistical MT by Koehn (2005) and Birch et al. (2008) explored translation challenges across language pairs, using BLEU scores (Papineni et al., 2002) as a primary evaluation metric. These studies showed that translation performance tends to correlate with linguistic proximity; historically closely related languages generally yielded higher BLEU scores. Bugliarello et al. (2020) presented the first similar study on neural MT, noting that BLEU scores are only comparable on test sets in the same target language. They separated source- and target-language difficulty explicitly, through measuring cross-mutual information, with evaluations on 40 English-centric language pairs.

2.2 Language Similarity in MT

How to best measure language similarity to inform NLP research is an open question. Blaschke et al. (2025) conducted a large-scale study on distance measures for cross-lingual transfer in three NLP tasks: dependency parsing, part-of-speech tagging and topic classification. They found that the definition of linguistic similarity is an important factor

for cross-lingual transfer success, and the most effective similarity measure is dependent on the downstream task. Since MT was not investigated, it is not clear which kind of similarity measure is most informative for this task. Within MT research, language similarity has mostly been of interest for improving transfer learning performance (e.g., Lin et al., 2019; Oncevay et al., 2020; Fekete et al., 2025). Factors beyond language similarity can play a major role in such investigations, such as data availability and domain similarity (Khiu et al., 2024). By contrast, we are interested specifically in the difficulty of the translation task by itself, all other factors being as equal as possible.

3 Constructing a Multi-Parallel Corpus

Our aim is to investigate the difficulty of translation tasks, while controlling for factors other than language similarity. We first establish three criteria that should be met for comparable cross-lingual MT studies (Section 3.1). We then describe how these were accounted for in the creation of our dataset (Section 3.2), and how these restrictions impact the diversity of our language selection (Section 3.3).

3.1 Criteria

If MT models for different language pairs are trained on different datasets, then differences in results could be attributed to that instead of linguistic divergences. So, to rule out the effects of dataset size and domain differences, the dataset should be fully multi-parallel across all included languages. Secondly, within the multi-parallel corpus, the distribution of 'original text' should be equal across languages. A well-described problem in the evaluation of MT systems is that the presence of translated data in the evaluation set can inflate performance assessments (Zhang and Toral, 2019; Graham et al., 2020).[1] Ideally, test sets should contain text originally written in a language, to not exhibit 'translation artefacts'.[2] However, since such a dataset should also be completely multi-parallel, this is not possible for more than one language. We argue that a dataset should therefore ensure equal *proportions* of translated text in the multi-parallel test set. In addition to consistent proportions across languages, it should be the same across training and testing sets, to avoid training on one text type and evaluating another. Lastly, to provide a cross-lingual perspective beyond English, the dataset should contain translation pairs that do not include English as either source or target language. In summary, we establish three criteria:

1. Full multi-parallelism
2. Equal translated text distribution
3. Beyond English-centric MT

To the best of our knowledge, a ready-to-use dataset that satisfies these three criteria does not yet exist.

3.2 Dataset Creation

Multiple popular multi-parallel datasets with broad language coverage exist (e.g., Parallel Bible Corpus, Mayer and Cysouw, 2014; OpenSubtitles, Lison and Tiedemann, 2016). Yet, these datasets do not contain information on the original languages of the data. The CoStEP corpus (Graën et al., 2014) includes speaker turns from the European Parliament, cleaned and aligned across languages, with original-language annotations. In Figure 2, we illustrate the steps for creating a dataset that satisfies the criteria from Section 3.1. Starting from the CoStEP corpus (1) we first extract all bilingually aligned speaker turns (2). Since speaker turns vary in length (some are very long while others are very short), we split the turns into sentences (3) using the `sentence-splitter` toolkit.[3] Then, we re-align the bilingual parallel sentences (4) using `hunalign` (Varga et al., 2008). Note that we refrain from using embedding-based models like VecAlign (Thompson and Koehn, 2019), to avoid potential cross-lingual biases (English-centric pairs having higher-quality alignments, because English is very well-represented in pre-trained models). Next, given these aligned sentences per original language, we assess for which languages we have enough multi-parallel data for MT training and evaluation (5). We find that there are eight languages that have both high coverage and meta-information available in the typological database Grambank (Skirgård et al., 2023), which we use because of its suitability for computational applications (Haynie et al., 2023): Danish, Dutch, English, Finnish, French, Italian, Swedish and Portuguese. We select all samples for which we have translations in all languages and make a multi-parallel dataset with equal original-language proportions (6). Lastly, we divide the text

[1] In the MT literature, this is commonly described as the 'translationese effect', while this term is not uncontroversial (Jimenez-Crespo, 2023).

[2] We empirically verify this for our dataset in Appendix A.

[3] https://github.com/mediacloud/sentence-splitter

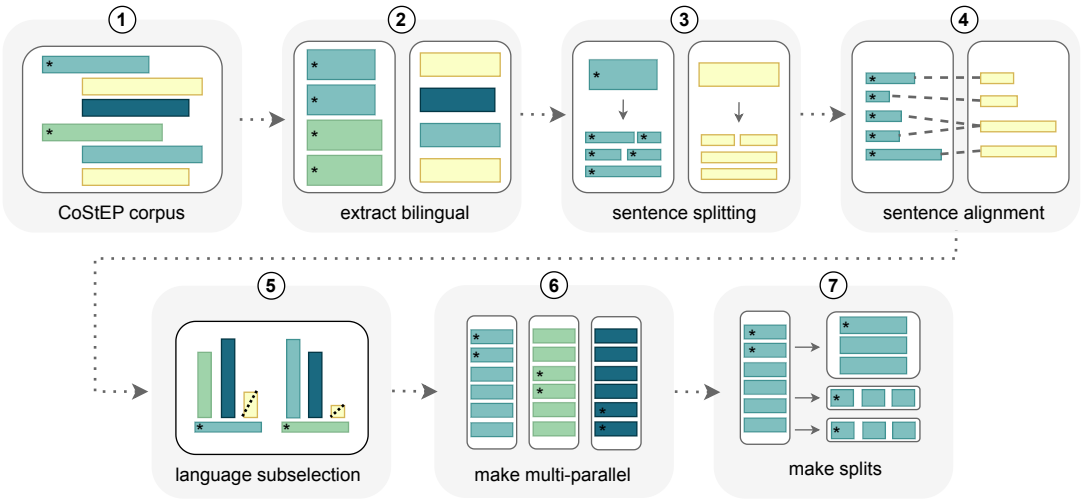

Figure 2: Schematic overview of the dataset creation process, starting from the CoStEP corpus, where we ensure an equal original text distribution (indicated schematically with an asterisk) among the included languages.

into splits for MT training, validation and testing such that the original text proportion remains equal among languages (7). We reserve 800 samples for validation (100 original per language) and 1,600 for testing (200 original per language). We use the remaining lines (77,941 per language) for training.

The number of space-separated tokens per language (as obtained by running the `wc -w` command) is in Table 1. Here, it stands out that Finnish contains a lower number of 'words' than the other languages, as it exhibits more morphologically complexity than the others.

Language	Train	Valid	Test
Danish (da)	1.9M	20.0K	39.3K
Dutch (nl)	2.1M	21.8K	43.0K
English (en)	2.1M	22.0K	42.6K
Finnish (fi)	1.4M	14.8K	28.9K
French (fr)	2.2M	23.0K	44.6K
Italian (it)	2.0M	21.2K	40.9K
Swedish (sv)	1.9M	22.2K	43.0K
Portuguese (pt)	2.1M	19.8K	38.8K

Table 1: Number of 'words' per language in the multi-parallel dataset.

Our strict filtering criteria result in a controlled, but small dataset which is not necessarily representative of state-of-the-art high-resource NMT more generally. These strict controls are necessary for our study, and we retrieve reliable results within our set-up, but we cannot make claims regarding the broad generalizability of these results.

3.3 Typological Diversity

Our language selection contains languages from three genera (Germanic: Danish, Swedish, Dutch, English; Romance: Italian, French, Portuguese; and Finnic: Finnish). To gain a more fine-grained image beyond genealogical similarities, we look into the typological similarity of these languages using the Grambank database (Skirgård et al., 2023).[4] Figure 3 shows a PCA plot of the Grambank feature vectors, showing our language selection is not representative of typological diversity generally. While this limited language diversity, also in terms of writing systems, means we cannot make any claims about what makes NMT difficult *in general*, it is appropriate for the objective of providing cross-lingual (but not universal) insights.

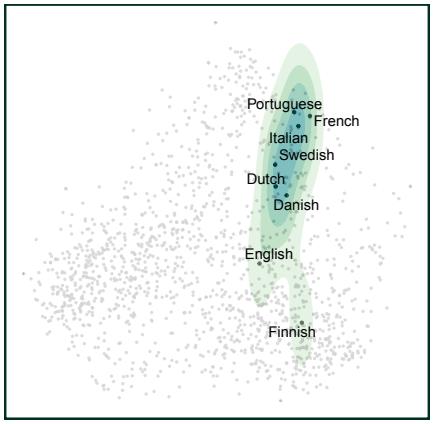

Figure 3: PCA plot from Grambank features, illustrating the (limited) typological diversity in this study.

[4]Typological diversity using *typdiv* (Ploeger et al., 2025, default settings): MPD: 0.51, FVO: 0.79, FVI: 0.77, H: 0.42.

Table 2: chrF2 and BERTScore for each target language (columns), per source language (rows). **Highest** and **lowest** scores per metric are highlighted for each target language.

4 Machine Translation Models

For each language separately, we train a Unigram (Kudo, 2018) subword segmenter on the training corpus, with vocabulary size 8,000, to tokenize the text. We then train a separate bilingual MT model for each of the 56 language pairs in our dataset. We choose to train small models from scratch, rather than leveraging pre-trained NMT models or LLMs, to avoid cross-lingually unfair pre-training distributions. The goal is not to create optimally functioning systems, which would require intensive parameter tuning, but rather to compare systems that learn to translate between different language pairs under otherwise identical circumstances. We use the Fairseq toolkit (Ott et al., 2019) to train MT models with a standard Transformer (Vaswani et al., 2017) architecture, consisting of 6 encoder and 6 decoder layers. We use a learning rate of 0.0001 and a dropout rate of 0.2. We use a cross entropy with a label smoothing of 0.2. and a maximum of 4,000 tokens per training batch. As a best checkpoint metric we use cross-entropy, with patience 5. No model took more than 50 epochs to converge.

5 Cross-lingual Translatability (RQ1)

5.1 Measuring Translation Difficulty

We approach translation difficulty from two perspectives: MT performance estimates, and the computational resources required for training.

Translation Accuracy Inspired by works from human translatability, e.g., Vanroy et al. (2019) and Hale and Campbell (2002), as well as MT approaches (Koehn, 2005; Birch et al., 2008), we deem a translation task difficult if it triggers errors. The intuition is that language pairs that are more difficult to translate lead to lower translation accuracy. As a widely spread measure of translation quality, we report chrF2 (Popović, 2015) scores (Table 2), which were previously shown to be robust against varying degrees of morphological complexity (Popović, 2016). This is a surface-level metric, based on a reference translation. We use SacreBLEU (Post, 2018) to calculate this.[5] One shortcoming of these measures, is that wording differences in the human reference translations can influence the results. This is why we also ran an embedding-based evaluation. We do not use reference-free metrics such as COMET (Rei et al., 2020), since the unequal training data in language embeddings may introduce cross-lingual unfairness in evaluation. Instead, we compare (monolingually) the MT hypothesis against the reference using BERTScore (Zhang et al., 2019), which renders it comparable per target language.

Computational Resources Inspired by works on human translation and post-editing that measured translation difficulty through cognitive and temporal effort (e.g., Campbell, 1999; Beinborn, 2010), we deem a translation direction more difficult if it requires more resources. We examine "machine effort" through a proxy: training dynamics. Beyond the overall performance, we record the loss and BLEU on the validation set per epoch as measures of effort, and compare this across source languages for MT into the same target language.

5.2 Difficulty as Translation Accuracy

Overall Performance We list the chrF2 and BERTScore per target language in Table 2. We exclusively compare the source languages per target language, since direct comparison across different target languages' test sets may be unfair (Bugliarello et al., 2020). Higher scores indicate higher translation accuracy, and thereby suggest lower MT difficulty. While the absolute scores are

[5] signature: `nrefs:1|case:mixed|eff:yes|nc:2|nw:0|space:no|version:2.5.0"`

low compared to the state-of-the-art, we observe that, indeed, there are language-level translatability differences. In other words, it is not the case that the same source language is the easiest for all target languages. For example, the easiest source language for MT into Danish is Swedish, while the easiest for Portuguese is French. Finnish, as the only language outside of the Indo-European language family in this study, also stands out in terms of MT performance. For most target languages (Danish, Dutch, English, French, Portuguese), it is among the most difficult. Moreover, we see that Dutch is a difficult source language for many target languages. These results indicate that, also in scenarios beyond English-centric MT, translation difficulty varies translation per direction. We observe some intuitive patterns, such as Danish↔Swedish being a relatively easy translation direction. In Section 6, we assess the connection with language similarity more systematically.

5.3 Difficulty as Effort

Training Epochs for Validation BLEU Analogous to "the extent to which cognitive resources are consumed by a translation task for a translator to meet objective and subjective performance criteria." (Sun, 2015), we assess how many computational resources ("machine effort") are required for an objective performance criterion. Specifically, we assess how many training epochs are needed to reach 15 BLEU on the validation set. While this threshold is somewhat arbitrary, we note that the full training progressions are shown in Appendix C. While this metric cannot be compared across languages, due to its reliance on word boundaries, it provides an intuitive and easy to interpret measure of difficulty. Here, a lower number (of epochs) indicates that fewer computational resources are required, signaling that the translation direction is easier. Table 3 shows the results. Firstly, we observe that this analysis reveals different nuances than when approaching difficulty as accuracy. Namely, English is an 'easy source language' for more languages here. As such, generalizing English-centric translation results may lead to overestimating NMT performance. This is especially noteworthy, as most previous studies (and MT in general) center research claims around this language. An explanation for this, relative to our dataset, could be that the European Parliament sometimes uses relay translations, i.e. manual translations are produced through English as a pivot language. Unfortunately, it is not possible to control for this variable.

Furthermore, it is interesting to analyze the translation directions which never reach 15 validation BLEU, indicated by the ∅ symbol. Especially Finnish stands out here, as it only reaches the threshold from English. Additionally, none of the Romance target languages reach 15 BLEU when Finnish is the source language. These are patterns that follow intuitive language similarity ideas, which are further explored in Section 6.

Loss Slopes While intuitive, the 15 BLEU threshold has shortcomings. For one, it is only comparable per target language, due to its reliance on word boundaries. Here, we analyze a more cross-lingually comparable metric: the loss slope between two consistent, pre-defined points in the training process (5^{th} epoch vs. 25^{th} epoch). Starting from epoch 5 gives the decoders a chance to learn a very basic language model, ahead of actually learning to translate. In Appendix D, the full slopes are visualized. Higher numbers indicate steeper slopes, which indicates faster learning, and

Figure 5: Visual comparison of language-based (a, b) and data-based (c, d) language similarity, where line thickness illustrates similarity. For example, subword overlap between Danish and Swedish is particularly high (d).

thus suggests lower translation difficulty. In Figure 4, the steepest slopes (darker colors) are mostly found for English. This is in line with our findings from using the validation BLEU threshold, where English also was commonly 'easy'. Additionally, it stands out that Dutch is relatively difficult. One possible explanation for this is found in Figure 5c, where Dutch generally has the most dissimilar word order to the other languages. We verify this relationship in Section 6.

All in all, we conclude that there are indeed language pair-level differences in NMT translation difficulty. This indicates that the vague notion of 'easier translation' can be operationalized more systematically. Results on translation difficulty, both from the angles of accuracy and effort, show intuitive patterns with regard to language similarity patterns, which are further examined in the next section.

6 Language Similarity Analysis (RQ2)

6.1 Measuring Language Similarity

Any effort to reduce languages and their similarities to single floating point numbers risks being simplistic. Yet, to enable systematic comparison, we need to compare the different aspects of similarity on the same scale. We compare two categories of metrics: those derived on a language-level, and dataset-specific measures.

Language-Level Metrics A first approach is to determine language similarity based on expert annotations, such as phylogenies and typological features. The popular `lang2vec` toolkit provides six categories of language distances (geographical, genealogical, syntactic, phonological, featural and inventory-based), based on the URIEL database (Littell et al., 2017). Given these distances, d, the resulting language similarity is then defined as $1 - d$. We compare this with a Grambank-based (Skirgård et al., 2023) measure, as proposed in Ploeger et al. (2025): the Euclidean distance between Grambank's morphosyntactic feature vectors, accounting for missing values. We again subtract this from 1, to compute a similarity score.

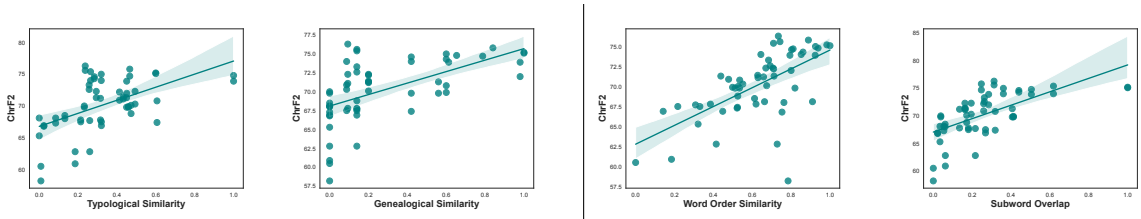
Text-Driven Metrics As a more data-specific measure of *syntactic* similarity, we use the relative amount of word reordering between two languages, calculated over the test set using Eflomal (Östling and Tiedemann, 2016). Since reordering scores are directional, we take the average over both directions to retrieve a single similarity score, in line with the language-level metrics. To go from reordering to word order similarity, we again subtract it from 1. As a *lexical* measure of data-driven similarity, we take the proportion of overlapping subwords from the tokenized texts, relative to the sum of the number of subwords of both languages in the test set. Finally, we apply MinMax scaling.

6.2 Results and Analysis

Table 4 shows the Pearson correlation coefficients for each of the language similarity metrics with

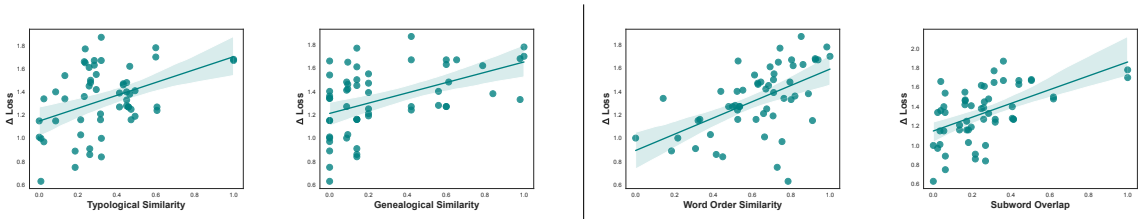
Similarity Measure	chrF2	Δ Loss
12v (geographic)	0.41*	0.26
12v (genetic)	**0.56***	**0.47***
12v (syntactic)	0.46*	0.43*
12v (featural)	-0.08	0.10
12v (inventory)	-0.18	-0.22
12v (phonological)	-0.04	-0.04
Grambank	**0.52***	**0.41***
Word reordering	**0.63***	**0.54***
Subword overlap	**0.63***	0.53*

Table 4: Pearson correlation coefficients between similarity metric and performance. Statistically significant values ($p < 0.005$) are indicated with an asterisk.



(a) Typological similarity (gb) ($r \approx \mathbf{0.52}, p < 0.005$)
(b) Genealogical similarity ($r \approx \mathbf{0.56}, p < 0.005$)
(c) Word order similarity ($r \approx \mathbf{0.63}, p < 0.005$)
(d) Subword overlap ($r \approx \mathbf{0.63}, p < 0.005$)

Figure 6: Correlation between linguistic similarity measures and chrF2 scores.



(a) Typological similarity (gb) ($r \approx \mathbf{0.41}, p < 0.005$)
(b) Genealogical similarity ($r \approx \mathbf{0.47}, p < 0.005$)
(c) Word order similarity ($r \approx \mathbf{0.54}, p < 0.005$)
(d) Subword overlap ($r \approx \mathbf{0.53}, p < 0.005$)

Figure 7: Correlation between linguistic similarity measures and Δ training loss.

chrF2 and Δ loss. From the table, it follows that morphosyntactic distance based on Grambank is a better predictor of MT difficulty than `lang2vec`'s syntactic distance. Still, `lang2vec`'s genetic distance and the data-driven measures yield higher correlations. We now examine these four metrics with the strongest correlations (Table 4, bold font) in more detail. These language similarity metrics are correlated positively with chrF2 and the Δ loss. That is, the more similar the languages in the translation direction, the 'easier' it is to translate between them. All correlations are statistically significant, with $p < 0.005$. Interestingly, the correlation coefficients of the data-driven metrics (c, d) are higher than those of the language-level metrics (a, b). This indicates that tailoring language similarity measures to the dataset under study may be beneficial for retrieving accurate difficulty predictions.

To gain an insight into why these correlations differ, we qualitatively assess the language similarities. Figure 5 illustrates the pairwise distances per metric. Absolute numbers are given in Appendix B. In the Grambank-based measure (a), the link between Italian and Portuguese is especially pronounced, while with the genealogical metric (b), we for example see a strong similarity between Portuguese, Italian and French. In terms of the data-driven measures, what stands out in (c) is that Dutch has relatively low word order similarity scores with all other languages, and that the subword overlap (d) between Danish and Swedish is especially prominent. This influences the correlation coefficients. As visualized in Figure 6 (for difficulty as accuracy; chrF2) and Figure 7 (for difficulty as effort; Δ loss), outliers –Portuguese and Italian, Danish and Swedish– influence the correlation coefficients, notably in Figure 6/7a and 6/7d respectively.

7 Translatability Indicators (RQ3)

As mentioned in Section 2, approaching translation difficulty from text on a data-level has been an important research direction in the past, mostly in statistical MT (Bernth and Gdaniec, 2001). Which textual characteristics make MT difficult? We revisit source-text indicators of translation difficulty that were proposed in previous work (Underwood and Jongejan, 2001), and contribute an investigation of these indicators in the context of neural MT.

7.1 Identifying TIs

We reassess 'general indicators' of machine translatability from Underwood and Jongejan (2001), listed in Table 5. For this case study, we take a closer look at translation with English as a source, since these TIs were formulated for that language specifically. We obtain the TIs through POS tags and dependency relations, retrieved through Trankit (Nguyen et al., 2021), with the default XLM-RoBERTa as the underlying model. We follow the heuristics defined in Underwood and Jongejan

Translatability Indicator	#	da	nl	fi	fr	it	sv	pt
No verb	11	+13.85	+12.71	+14.79	+19.30	+12.67	+13.13	+13.11
No finite verb	13	+12.92	+10.04	+12.38	+14.84	+11.43	+12.31	+13.28
Long (> 25 words)	713	**-0.21**	**-0.14**	**-0.36**	+0.52	+0.43	+0.01	+0.30
Short (< 3 words)	4	+19.7	+24.98	+27.71	+32.75	+0.68	+18.15	+25.45
$\geq$ 1 nominal compound	520	**-0.09**	**-0.13**	+0.06	+0.55	+0.56	+0.30	+0.38
Multiple coordination	759	**-0.18**	**-0.30**	+0.14	**-0.20**	+0.48	+0.43	**-0.35**

Table 5: Delta between the average chrF2 score for the TI lines, and the average non-TI chrF2. Negative values (bold font) imply increased translation difficulty. # Indicates how often the TI appears in our English test set.

(2001) for detecting the translatability indicators. Our implementation is as follows:

Missing Verbs A line does not have a verb if it contains no token with an `AUX` or `VERB` tag. An example from our dataset is: *"All well and good."* A line does not contain a finite verb if there is no verb with `VerbForm=Fin` present. An example: *"But what about all the other protective considerations listed in Article 13 of the Treaty?"*.

Sequence Length Long and short sentences are determined through the number of words: long sentences contain more than 25 words, while short sentences contain less than 3. While long sequences are ubiquitous in our dataset, an example of a (much rarer) short line is: *"No one!"*.

$\geq$1 Nominal Compound A sentence contains a nominal compound if it contains a `NOUN` that has the dependency relation of `compound`, for example: *"But we also need better regulation and principles for future EU legislation when it comes to motor vehicles."*.

Multiple Coordination Lastly, we detect multiple coordination if the sentence contains more than one `SCONJ` and/or `CCONJ`. An example: (e.g. *"That is why, of course, donor cards should be voluntary, and the same applies to the European donor card, which we intend to introduce in our action plan."*).

We first identify which samples in the English test set contain these markers. Then, we calculate the chrF2 score per sample in the test set, and compare the average score of the TIs with the average score of the non-TIs. We expect that if a certain group of sequences (TIs) is more difficult to translate, it yields a lower chrF2 score than the average non-TI chrF2 score per sample. Table 5 shows the difference between the average TI score, minus the average non-TI score. If a table cell contains a negative number (bold), this indicates that the translation of the TI samples obtained a lower chrF2 score than the others, indicating potential translatability issues.

7.2 Results and Analysis

We find no consistent patterns indicating that the defined TIs are more difficult for MT than non-TIs. For some TIs, there is too little evidence to base any robust conclusion on (e.g. only 4 lines contain $<$ 3 words in our dataset) and verb-less lines are rare. This may differ per studied domain. Secondly, it could be that common indicators of translation difficulties do not apply to our systems, because the training data is domain-specific. For example, nominal compounds occur relatively frequently in our dataset, as a result of the domain (e.g. *"member states"*, *"employment plans"*, *"terrorist list"*, *"labour taxes"*). If a model is trained on many of these, this may result in better capabilities to deal with such features. Another possible reason is that the paradigm shift to neural MT has weakened the impact of formerly informative TIs. For example, Transformers' (Vaswani et al., 2017) cross-attention implies that long-range dependencies have become less problematic.

Beyond general challenge sets, future work could be dedicated to defining TIs specifically for neural MT (cf. Bisazza et al., 2021): are there common translatability issues for state-of-the-art architectures, and consistently across datasets? Special care could be taken to make these more cross-lingually comparable: for example, taking the number of words as length indicator (Underwood and Jongejan, 2001) is dependent on the morphological complexity of a language.

8 Conclusions

In this work, we aimed to operationalize language similarity and translation difficulty in the context of neural MT. We control for confounding factors from previous work, and use the resulting dataset to answer three research questions about how language similarity affects translatability. In summary, we find the following. Firstly, there are language pair-level differences in NMT difficulty in our experiments, beyond English-centric scenarios (RQ1). Moreover, NMT difficulty can be predicted from language pair similarity with reasonable success, with syntactic and genetic measures of similarity. Text-driven metrics, tailored to the dataset, are even more informative (RQ2). Lastly, we found that text-level indicators of MT difficulty from previous work were not suitable for our dataset or evaluation set-up (RQ3).

Our models achieve limited performance (approx. 60-70 chrF2). This is because we train models on relatively small datasets. This performance is far below the state-of-the-art of these European language pairs. Still, it provides interesting insights. We show that some language pairs are reliably and consistently more difficult (e.g. much lower chrF2 scores) than others, under the same, controlled circumstances. These results are stable, as demonstrated by the steady train loss decrease in Appendix D. Furthermore, the performance differences between translation directions are substantial and predictable ($p<0.005$, Fig. 6, 7), showing that even in a limited setting, consistent results emerge. Although these strict controls are necessary for our controlled study and we retrieve reliable results in our case study, we cannot make claims regarding the broad generalizability of these results. Generalizability is a challenging topic in MT more generally, as it is unclear whether scaling approaches will always solve previously encountered issues.

These findings open up various possible applications and future research directions. For example, future work could investigate to what extent MT difficulty is influenced by tokenization strategies. In our experiments, we kept the tokenizer and vocabulary size consistent across languages, but variations could yield different results. In downstream scenarios, systematic notions of language similarity could be used to select pivot languages, especially in data-scarce scenarios. On a text-level, we showed that identifying new TIs, relevant to neural MT, may be an interesting research direction.

Limitations

Several limitations of this work should be noted. Firstly, due to the strict constraints (full multi-parallelism, equal distribution of original text), the typological diversity of the languages in our study is limited. Our findings may not generalize to other translation directions. For the same reason, we only trained and evaluated in one domain; this cannot be assumed to generalize directly either. Note that previous studies on translation difficulty (Koehn, 2005; Birch et al., 2008; Bugliarello et al., 2020) were also limited to this domain. Despite these strict constraints, 100 percent clean data is not guaranteed. For one, automatic alignments may still include noise. Also, the European Parliament sometimes includes relay translations, meaning that certain translated texts may have been translated 'through English', which could impact the results. Yet, as this information is not available in CoStEP or elsewhere, we cannot control for this. While the Transformer architecture is representative for neural MT, our study only uses this one neural architecture. For broader insights into neural MT as a whole, more approaches could be investigated. Furthermore, the language similarity measures that we evaluate are not exhaustive; for example, semantic language similarity (for example in the form of colexification) was not taken into account. Lastly, no human evaluation was included. This choice was made to ensure cross-lingually consistent comparisons, but it could still have yielded important novel insights, for example comparing human translatability and NMT features (cf. Lim et al., 2024).

A Translation Performance for Source-original and Target-original Test Lines

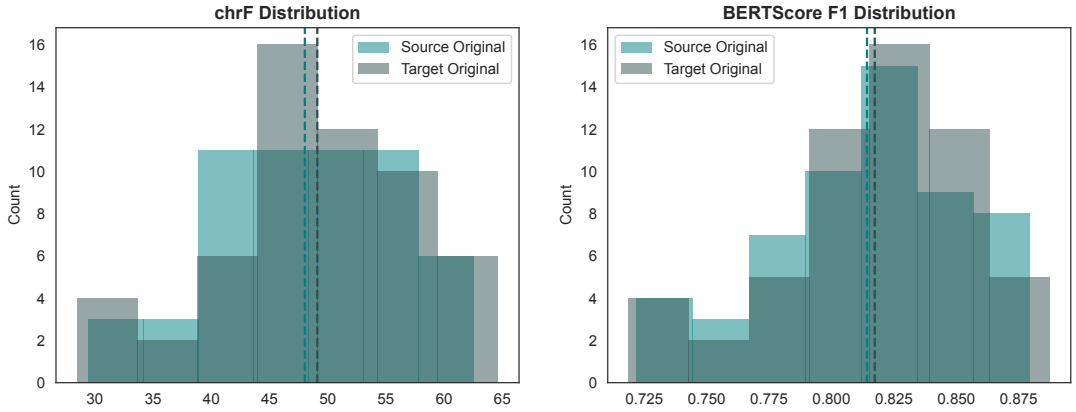

Figure 8: For each of the 56 translation directions in our study, we compute the average chrF2 and BERTScore (F1), for only those test samples that were originally spoken in the source language, with those that were originally spoken in the target language. Comparing these distributions, we observe that, in line with previous work (Zhang and Toral, 2019), scores for the target-original portion are on average higher, implying that "translationese" in the source text can inflate MT performance, albeit slightly. For this reason, we control for the proportion of translated text in our experiments.

Abstract

This paper presents the results of the General Machine Translation Task organized as part of the 2025 Conference on Machine Translation (WMT). Participants were invited to build systems for any of the 30 language pairs. For half of these pairs, we conducted a human evaluation on test sets spanning four to five different domains. We evaluated 60 systems in total: 36 submitted by participants and 24 consisting of translations we collected from large language models (LLMs) and popular online translation providers. This year, we focused on creating challenging test sets by developing a difficulty sampling technique and using more complex source data. We evaluated system outputs with professional annotators using the Error Span Annotation (ESA) protocol, except for two language pairs, for which we used Multidimensional Quality Metrics (MQM) instead. We continued the trend of increasingly shifting towards document-level translation, providing the source texts as whole documents containing multiple paragraphs.

1 Introduction

The Tenth Conference on Machine Translation (WMT25)[1] was held in conjunction with the 2025 Conference on Empirical Methods in Natural Language Processing (EMNLP 2025). This 20th iteration of the conference builds on previous editions (Koehn and Monz, 2006; Callison-Burch et al., 2007, 2008, 2009, 2010, 2011, 2012; Bojar et al., 2013, 2014, 2015, 2016, 2017, 2018; Barrault et al., 2019, 2020; Akhbardeh et al., 2021; Kocmi et al., 2022, 2023, 2024a)[2] and hosted ten shared tasks on various aspects of machine translation (MT). This paper describes one of these tasks: the General Machine Translation shared task.

The goal of the General Machine Translation shared task is to explore the translation capabilities of current systems across a broad range of languages. Determining how best to test general MT performance is a research question in itself. Numerous phenomena could be evaluated, the most important of which include:

- **different domains** (news, medicine, IT, patents, legal, social, gaming, etc.),
- **styles of text** (formal or spoken language, fiction, technical reports, etc.),
- **non-standard user-generated content** (errors, code-switching, abbreviations, etc.),
- **source modalities** (text, speech, image).

[1] www2.statmt.org/wmt25/

[2] WMT was organized as a workshop for ten years (2006-2015) before becoming a conference, making this the 20th event overall.

Proceedings of the Tenth Conference on Machine Translation, pages 355–413
November 8-9, 2025

Since individually evaluating all of these phenomena is infeasible, we focus on a selection of domains: news, social/user-generated content, speech, literary, and educational texts. These domains were chosen to cover diverse styles while remaining broadly accessible; thus allowing for evaluation by human annotators without in-domain expertise. However, due to limited access to monolingual data, the set of evaluated domains is not identical across all language pairs.

Our evaluation includes the following 16 language pairs, with those new to this year's task marked by ***(new)***:

Czech→Ukrainian,
Czech→German,
Japanese→Simplified Chinese,
English→Egyptian Arabic ***(new)***,
English→Bhojpuri ***(new)***,
English→Simplified Chinese,
English→Czech,
English→Estonian ***(new)***,
English→Icelandic,
English→Italian ***(new)***,
English→Japanese,
English→Korean ***(new)***,
English→Maasai, Kenya ***(new)***,
English→Russian,
English→Serbian, Cyrillic script ***(new)***,
English→Ukrainian.

A new multilingual subtrack, subject only to automatic evaluation, also introduced 15 additional language pairs:

English→Bengali,
English→German,
English→Greek,
English→Hindi,
English→Indonesian,
English→Kannada,
English→Lithuanian,
English→Marathi,
English→Persian,
English→Romanian,
English→Serbian, Latin script,
English→Swedish,
English→Thai,
English→Turkish,
English→Vietnamese.

Furthermore, this year's task is also distinguished by several key choices:

- **Non-textual modalities:** In addition to textual data, we also incorporated audio and image sources. For the speech domain, participants received audio files with their automatic speech recognition (ASR) transcriptions. For the social domain, screenshots of posts were provided. Participants had the option to use the original audio directly, rather than relying on the provided ASR text.
- **Difficulty sampling:** We used the difficulty sampling method to select more challenging documents, hence increasing the overall difficulty of the test set.
- **Evaluation:** For most languages, we use the Error Span Annotation protocol (ESA; Kocmi et al., 2024b) which combines aspects of DA (Graham et al., 2013) and MQM (Lommel et al., 2014a). For English→Korean and Japanese→Chinese, we use the MQM annotation schema instead.
- **Document-level test set:** Each source text is an entire document (e.g., a news article or social media thread),[3] which is then segmented while preserving paragraph boundaries. This allows us to evaluate translations within their full document context, while giving participants the flexibility to choose their translation strategy: processing the entire document at once, or splitting it by segments or paragraphs.[4]
- **Training corpora:** We prepared a list of recommended training corpora, adding document-level information and CometKiwi22 (Rei et al., 2022) scores for most data sets.

Finally, as in previous years, this year's shared task included several test suites that focused on a range of **translation challenges**, described in Section 8.

All submissions to the General MT Task, along with sources, references, and human judgments, are available in the dedicated GitHub repository.[5]

This paper is organized as follows. We first describe the data used in the shared task, detailing the collection and preparation of our test sets (**Section 2**) and outlining the permitted training data for the constrained track (**Section 3**). Next, we introduce the participating systems, including the large language model baselines added by the organizers (**Section 4**). We then explain our evaluation methodology, covering both automatic metrics (**Section 5**) and human evaluation protocols (**Section 6**). Finally, we present the official results

[3] In some cases, an initial section of a document was used rather than the full text.

[4] No sentence-level segmentation is provided.

[5] github.com/wmt-conference/wmt25-general-mt

(**Section 7**), describe the test suites (**Section 8**), and offer concluding remarks (**Section 9**).

Findings of the General MT Task. We make the following observations:

★ **The number of participants continues to grow:** Participation increased again this year, with a total of **36 submissions**. The majority of these participants used LLMs in their systems, most commonly by fine-tuning (Section 4).

★ **Automatic scores are biased:** Although Shy-hunyuan-MT placed first for all but one language pair in the automatic rankings, human evaluation revealed its performance was considerably lower than that of the top-rated systems (Section 7.2).

★ **Human translations are not always in the winning cluster:** Human references are in the winning cluster for only six out of 15 language pairs (Section 7.2).

★ **Constrained models challenge the performance of LLMs:** The top-performing constrained system was Shy-hunyuan-MT, which placed in the winning cluster for 11 language pairs within its category followed by Algharb placed in winning cluster for 6 language pairs. The best system overall, was Gemini 2.5 Pro, which was in top cluster in 14 language pairs (Section 7.2).

★ **Speech domain was the most challenging:** The speech domain texts were most challenging to translate (likely due to ASR errors) while literary texts were the easiest (Section 7.2).

★ **SOTA systems still struggle with robustness:** Analysis from six specialized test suites reveals that state-of-the-art (SOTA) systems still struggle with robustness to non-standard input, linguistic complexity, domain-specific terminology and gender choice/agreement in particular language pairs. This is despite notable improvements from advanced LLMs in areas like inclusivity and performance in certain specialized domains (Section 8).

2 Test Data

In this section, we describe the test data collection process (Section 2.1) and the creation of human reference translations (Section 2.2). This year, we introduced a new difficulty-based sub-sampling of source texts procedure (Sections 2.1.1 and 6). Motivated by the ever-increasing capabilities of modern MT systems, this step is designed to make our test sets more challenging by selecting source documents that are estimated to be more difficult to translate.

2.1 Collecting test data

Collecting source data. As in previous years, the test sets consist of unseen translations created specifically for the shared task and released publicly as translation benchmarks. We collected public domain or open-licensed source data from a range of domains, focusing on the most recent data available to minimize potential overlap with the pretraining and fine-tuning data of the systems under evaluation. Importantly, for all language pairs, the source texts were originally written in the source language and subsequently translated into the target languages by human translators. This approach is crucial to avoid "translationese" in the source texts, which can negatively affect evaluation accuracy (Toral et al., 2018; Freitag et al., 2019; Läubli et al., 2020; Graham et al., 2020).

Domain and language coverage. We collected data from six domains (news, literary, speech, social, educational, and dialogue) and three source languages (Czech, English, and Japanese). However, not all domains cover all three source languages. Detailed statistics on our test sets, including the language coverage for each domain, are provided in Table 1.

2.1.1 Difficulty sampling

To identify documents that are particularly challenging for modern MT systems, we adopted the translation difficulty estimation introduced in Proietti et al. (2025). Specifically, we estimated the difficulty of the collected source documents using their best-performing estimator, `sentinel-src-25`.[6] This model is an improved version of `sentinel-src`, a regression model, based on XLM-Roberta Large (Conneau et al., 2020), which was trained to predict translation quality using only the source text (Perrella et al., 2024).

For each document, we estimated the difficulty of each paragraph and then averaged the results to derive a document-level difficulty score. We then retained the most difficult documents for inclusion in our test sets. To ensure this process did not introduce ill-formed or garbled sources, we also

Czech→*	0.52	-	0.42	0.44	0.51	0.23

Table 1: Per-domain statistics of our test sets, calculated on the source side. To compute word counts, we used simple whitespace tokenization for Czech and English and the MeCab morphological analyzer for Japanese. Sentence segmentation was carried out using the language-specific Spacy models for English and Japanese, and the multilingual Spacy model for Czech (Honnibal and Montani, 2017), given that a language-specific one is not available.

manually validated the selected texts and discarded any problematic ones.

We applied this difficulty-based sub-sampling only to the news, speech, and social domains, as the amount of source data available for the other domains was insufficient for the procedure.

2.1.2 Test sets statistics

Source text segmentation. To balance the evaluation across domains and source languages, we aimed for a consistent size for each test set, that is, approximately 9,000 words distributed across 60 to 100 segments (see Table 1).[7] We also aimed to keep the average segment length around 100 words, whenever possible. This design enables micro-averaging of results without any single category disproportionately influencing the final scores.

These choices were motivated by the aim to keep approximately the same number of segments per domain, which is important for balancing the domains for manual evaluation. The number of segments per domain is therefore more balanced than in last year's test sets, as can be shown in Table 1. The composition of the texts included remains domain-specific due to the differing natures of the texts. For example, in the literary domain texts are longer and therefore only 2 documents were used for each source language. These were split into a large number of segments (42.5 per document on average for English→*). In contrast, the speech domain, where 59-86 documents were used depending on the source language, with each document forming its own segment. The longest segments are in the speech domain, while the shortest are in the news domain (respectively 145.27 and 94.86 words per segment on average for English→*).

Language-specific adjustments. For practical reasons, we were not always able to meet the objective of having a minimum of 100 words per segment. Most notably, the average segment length was longer in the speech domain for English (145.27 words) and Japanese (180.59 tokens), and in the dialogue domain for English (178.8 words)

[7] A segment contains one or more paragraphs, where each paragraph is defined by a line break in the source document. We then separate the segments from each other using double line breaks.

and Czech (147.3 words).

Finally, for Japanese, based on the 1-to-2 ratio derived from our observations of previous WMT Japanese-English test sets, we targeted approximately 18,000 characters per domain. We adopted a character-based metric, because the lack of spaces in Japanese complicates word segmentation. This approach also aligns with industry standards for translation pricing.

In the following paragraphs, we provide other information regarding the data collection process, but specific to each domain.

News domain. For this domain, the data was prepared similarly to previous years (Kocmi et al., 2024a). We collected news articles published in February 2025 on online news sites and extracted the text while preserving the paragraph boundaries. This year we specifically aimed to extract articles that were more challenging to translate. For English, we limited the news crawl to opinion pieces on the basis that they tend to use a more complex, literary style than the straightforward event reporting. For Czech and Japanese, we extracted a larger pool of news covering the entire month to follow up with down-sampling.

Social domain. The social domain data was sourced using the Mastodon Social API.[8] Mastodon is a federated social network that is compatible with the W3C standard ActivityPub (Webber et al., 2018). Users publish short-form content known as "toots", with the possibility of replying to other toots to form threads. We decided to use the original server, `mastodon.social` because of its large community and publicly available toots.

We collected data in March and April of 2025, using the reported language ID label to target the source languages of interest.

Given the document-level nature of the task, our aim was to collect threads comprising multiple toots. Our sourcing therefore involved regularly scraping random toots from the previous hour but also identifying and scraping any missing toots that made up threads only partially sourced (identified using the 'in_reply_to_id' attribute of already sourced toots). To avoid spam and uninformative toots, we removed empty toots, texts that appeared several times (probable spam), texts from accounts that produced a large number of toots overall (we set this to 100) and from accounts we heuristically identified as being news outlets or bots (containing the keywords 'bot', 'news', 'weather', 'sports', 'feeds' or 'press' in their handle, as well as a few known media accounts). We created threads from the individual toots and manually selected threads of interest from threads of minimum 2 and maximum 100 toots. Our selection was based on having a diverse range of topics and targeting those characteristic of non-standard user-generated content.

The selected documents contain either a whole toot or a line of text within a toot (depending on whether the toot contained newlines, i.e. there is no distinction between newlines indicating a boundary between two toots and a newline within a toot). Each segment can therefore contain one or several sentences, depending on the original composition of the toots.

A new aspect of the task this year was the inclusion of screenshots capturing entire conversations. This decision was influenced by requests from human translators, researcher efforts to expand last year's test set (Deutsch et al., 2025), the evolving nature of social media, and an overall interest in exploring the impact of multimodal translation. To accomplish this, we focused on Mastodon conversations that included an image. While the image is not needed for translation, our objective was to provide visual context for translators if needed. Furthermore, even without an image, non-standard domains like social media often convey meaning through layout features such as whitespace, text positioning, and other non-textual elements that may be lost without visual reference. After filtering, we had 481 conversations containing an image for final selection. See an example of the screenshots in Figure 1.

Due to insufficient data for Japanese in the social domain, we adjusted the size of the news test set to compensate, targeting approximately 24,000 characters.

Similarly, we were unable to obtain a sufficient amount of Czech Mastodon data. We therefore decided to use personal communication (usually between a Czech and Ukrainian speaker) from Charles Translator[9] for the Czech Social domain. This data is similar to the domain called "Personal" last year. The texts were collected with users' opt-in consent, filtered and pseudonymized in the same way as in the last three years (Kocmi et al., 2022). Each document is one conversation with one user.

[8] mastodon.social/api/v1/timelines/public

[9] translator.cuni.cz (Popel et al., 2024)

The lines reflect the formatting provided by the users. Segment boundaries (empty lines) were added based on the content (trying not to split a paragraph or sentences that are closely related), so as a result the average number of words per segments is close to 100.

Literary Domain. For the English source texts, we selected an amateur-written story from the Archive of Our Own[10] based on several criteria: its recency (published April 2025), its narrative quality, and the absence of explicit sexual or harmful content. The first two chapters, comprising approximately 9.9k words, were treated as two documents. The documents were then segmented so that each segment contained at least 100 words and all paragraph boundaries were maintained.

For the Japanese source texts, we selected two short stories[11] from Aozora Bunko, a public-domain digital archive of Japanese literature.[12] Selection was guided by three criteria: recent publication on the platform, the use of modern orthography (*shinjitai*), and a prose style accessible to contemporary readers. In line with the methodology for the English texts, both stories were segmented into passages of similar length ensuring that all paragraph-level boundaries were preserved. For the test set, we used all six chapters of the first story (*Bishōjo Ichiban-nori*) and the first four chapters of the second story (*Omokage*).

Speech domain. The speech corpus was compiled from Creative Commons–licensed YouTube videos. For each language, we collected approximately 2,700 videos retrieved with 200 distinct queries spanning documentaries, instructional content, lectures, interviews, news, lifestyle vlogs, sports, and performing arts.

From each video, a segment was randomly sampled, with a minimum duration of 30 seconds and a maximum of 50 seconds, containing at least 30% speech. This constraint was introduced to balance the amount of context required for ASR and translation with the number of available documents.

Transcription of the segments was carried out using the *Whisper-large-v3* model (Radford et al., 2023). For English and Czech, punctuation was expected to be provided directly by Whisper. In cases where the model hallucinated or returned text without punctuation, *Whisper-large-v2* was used instead. For Japanese, Whisper almost never returned punctuation. Therefore, an additional punctuation restoration model was applied.[13]

After the sampling procedure, 90% of the documents were discarded, and subsequent manual filtering retained approximately one third of the remaining examples.

While the shared task participants had access only to the original videos and automatic transcripts, the reference translations from Czech to Ukrainian and German where prepared with an initial manual correction of the ASR errors using the videos as a first step. As a result, the Ukrainian and German translations are expected to be more accurate in cases where the original transcript was ambiguous.

Education domain. The Educational domain includes selected exercises from an online portal *Škola s nadhledem*[14] for elementary-school students from various subjects (chemistry, geography, Czech language, etc.). Some segments are not full sentences but short phrases. The reference translations into Ukrainian and German for this domain were created by professional translators within the EdUKate project. Last year, each page of an exercise was treated as a separate document, while this year, each exercise (with all its pages) was compiled into a single document. To meet the target of 9k words per document and 100 words per segment, we excluded documents with less than 90 words. Longer documents were split into multiple segments along page boundaries to ensure that no segment is longer than 200 words.

Dialogue domain. The Dialogue domain texts originates in the MultiWOZ2.4 dataset (Ye et al., 2022)[15] simulated dialogues between a user and a mock dialogue system (Wizard-of-Oz setup) responding to the user's requests in multiple domains. Each document contains two parts: a description of what should be achieved in a dialogue with the agent (e.g. find a restaurant in Cambridge or finding and booking accommodation), and the dialogue of the user and the agent itself. As such, the sentences in this dataset are rather simple for translation, but the point lies in cross-sentence co-

herence and primarily in gender and politeness preservation (or biases), which was promoted in the dataset through our translation process: We selected a subset of the MultiWOZ2.4 test set and professionally translated it from the original English to Czech. English typically keeps the gender of the parties unexpressed and conveys little or no markers of politeness. The first official translation to Czech was thus heavily biased towards the masculine gender and formal politeness level, both of which are explicit in Czech. We requested the translators to add more variance in this regard, i.e. pretend that one or both of the parties are female, and vary the politeness level (formal vs. informal). This varied Czech should not be treated as a canonical reference, but we used it as an interesting *source* for Czech→German translation because German is similarly explicit in gender and politeness as Czech. The participating systems in Czech→German translation thus have to demonstrate their ability to preserve these features (rather than losing them, for example, in implicit or explicit pivoting through English).

2.2 Human References

The test sets were translated by professional translation agencies according to the brief in Appendix B. Since each language pair was sponsored by a different partner, multiple translation agencies contributed, which may account for some variability of the final translations across languages.

Automatic quality assessment of human translations. The quality of human references is critical for reference-based metrics (Freitag et al., 2023). However, obtaining high-quality translations is challenging even with professional translators. This challenge was particularly salient this year, as our difficulty sampling approach (Section 2.1.1) intentionally selected hard-to-translate source texts. Therefore, following WMT24, we report scores from automatic evaluation methods to assess the quality of the collected human references. For this evaluation, we employ the GEMBA-ESA (Kocmi and Federmann, 2023a) as an LLM-as-a-Judge method, using two independent judges: GPT-4.1[16] and Command A (Team, 2025). Our full automatic evaluation approach is detailed in Section 5.

[16] openai.com/index/gpt-4-1/

Discussion on the quality of human references. Table 2 shows the average GEMBA-ESA scores for the human reference translations, broken down by language pair and domain. The two language pairs with the lowest average GEMBA-ESA scores are English→Russian and English→Icelandic. For Russian, this aligns with its human evaluation results, i.e., human translations end up in the third cluster. For Icelandic, however, the pattern diverges: its human reference is the only item in the first cluster, outperforming the best MT system (Gemini 2.5 Pro) by a margin of 20 points (ESA). Given this discrepancy, and the fact that GPT-4.1 largely disagrees with Command A's lower score for the Icelandic reference, it is possible that Command A is systematically underrating this particular translation.[17] This hypothesis is further supported by Command A's training data as out of all target languages included in the evaluation, Command A was not optimized to support Icelandic, Estonian, and Serbian (Team, 2025). Consistent with this, both Estonian and Serbian show notable negative difference values (Command A $<$ GPT-4.1): -12.36 and -7.83, respectively. The main counterexample to this trend is English→Japanese; although Japanese is supported by Command A, it also shows a notable negative difference (-8.91) and, like Icelandic, its human reference also ranks alone in the first cluster. Across the remaining language pairs, Command A and GPT-4.1 yield similar absolute scores, with a mean difference of -4.90 points.

Finally, the English→Bhojpuri and English→Maasai pairs were excluded from this QE evaluation, as metric reliability has not been established for these low-resource languages (Section 5; Falcão et al., 2024; Singh et al., 2024; Wang et al., 2024; Sindhujan et al., 2025).

2.3 Test Suites

In addition to the test sets of the regular domains, the test sets given to the system participants were augmented with several *test suites*, which are custom-made test sets focusing on particular aspects of MT translation. The test suites were contributed and evaluated by test suite providers as part of a decentralized sub-task, detailed in Section 8. Across all language pairs of the shared task, test suites contributed 72,449 source test segments

[17] Command A scored the Icelandic human reference translation 15.04 points lower than GPT-4.1.

	Lit.	News	Social	Speech	Dial.	Edu	Avg.	Hum.

Table 2: GEMBA-ESA scores for human references. Each domain cell is the arithmetic mean of Command A and GPT-4.1; the Avg. column reports the macro-average across available domains. The last column is the human cluster assigned using the ESA protocol.

(detailed numbers can be found in Table 14).

3 Training Data

Similar to the previous years, we provide a selection of parallel and monolingual corpora for model training. The provenance and statistics of the selected parallel datasets are provided in the appendix in Table 18 and Table 19. Specifically, our parallel data selection include large multilingual corpora such as Europarl-v10 (Koehn, 2005), Paracrawl-v9 (Bañón et al., 2020), CommonCrawl, NewsCommentary-v18.1, WikiTitles-v3, WikiMatrix (Schwenk et al., 2021), TildeCorpus (Rozis and Skadiņš, 2017), OPUS (Tiedemann, 2012), CCAligned (El-Kishky et al., 2020), UN Parallel Corpus (Ziemski et al., 2016), and language-specific corpora such as YandexCorpus,[18] ELRC EU Acts, JParaCrawl (Morishita et al., 2020), Japanese-English Subtitle Corpus (Pryzant et al., 2018), KFTT(Neubig, 2011), TED (Cettolo et al., 2012), and back-translated news.

Links for downloading these datasets were provided on the task web page. We have automated the data preparation pipeline using MTDATA (Gowda et al., 2021).[19] This year's monolingual data include the following: News Crawl, News Discussions, News Commentary, CommonCrawl, Europarl-v10 (Koehn, 2005), Extended CommonCrawl (Conneau et al., 2020), Leipzig Corpora (Goldhahn et al., 2012), UberText and Legal Ukrainian.

[18] github.com/mashashma/WMT2022-data
[19] statmt.org/wmt25/mtdata

Our automated dataset preparation pipeline made a best-effort attempt to preserve document identifiers whenever available in the source. In addition, we have precomputed and shared a quality estimation (QE) metric scores on training data to facilitate data filtering. Specifically, we shared COMETKIWI22 (Rei et al., 2022) annotations for all parallel segments in the training corpora. These were computed using the fast and efficient PYMARIAN framework (Gowda et al., 2024), which enabled QE scoring at scale.

4 System Submissions

This year, we received 96 submissions from 36 participating teams. While the number of submissions is slightly lower than last year's 105, the number of participating teams increased by roughly a third.

In line with previous years, we included translations from three public MT services, anonymized as ONLINE-{B,G,W}. We also added contrastive translations from 20 LLMs—including commercial products like GPT-4.1 and open weights models like Llama3.1—and one encoder-decoder system (NLLB). This brought the total to 60 participants.

All participating systems are listed in Table 3. A more detailed description of each submitted system is included in Appendix C, as provided by the authors at the submission time. Section 4.1 discusses the general trends in chosen architectures and training strategies. Section 4.2 presents details on LLM benchmark usage in the task. Section 4.3 outlines two tracks, constrained or unconstrained, to which participants could submit outputs. Section 4.4 describes the submission system platform.

4.1 Architectures and Strategies

Each participating team was asked to submit a form detailing their approach along with an optional description paper. This section discusses the submissions with a summary of strategic details, such as the approach or base model, is provided in Table 3.

Architectures. This year generative language models (denoted as LLM in the table) were the predominant approach, used by all but one external submission. Still, six external team and one organizer submission mentioned using the encoder-decoder architecture, and several others used hybrid approaches.

Base models. The most popular pretrained language models were Qwen (7 submissions), Eu-

Table 3: Submissions to the General MT shared task, including the externally contributed submissions as well as the systems added by the organizers. Row coloring shows unconstrained-track (dark gray) and constrained-track (white) submissions. Entries are ordered lexicographically, with first the submissions that modified the foundation models somehow (training, tuning, etc), then submissions that created adapters without modifying the models and finally the submissions that used models as is. The last column shows the best rank achieved by the submission, as defined in the official results (see Section 7.4) and the translation direction where the rank was achieved.
Abbreviations: **LLM** (decoder-only language model), **enc-dec** (encoder-decoder), **B** (basic data preproc), **E** (elaborate data preproc), **S** (synthetic data), **CPT** (continued pre-training), **SFT** (supervised fine-tuning), **CO** (contrastive optimization/preference tuning), **Ada** (adapters), **MBR** (Minimum Bayes Risk decoding), **QE** (quality estimation), **rules** (rule-based post-processing/regular expressions), **reason** (reasoning in LRMs), **prompt** (prompting), **APE** (automatic post-editing), and **TRR** (translation re-ranking).

roLLM (6 submissions), and Gemma (4 submissions). Twenty-three submissions modified their base model via continued pre-training, supervised fine-tuning, preference optimizations (CPO/DPO), or reinforcement learning (RL). Three submissions trained adapters without changing the model, and eight used prompting without any model training.

Data preparation. For data preparation, 17 submissions reported using basic filtering (e.g., OPUS cleaner or empirical steps), while 15 reported more elaborate techniques (e.g., filtering with quality estimation by utilizing LLM-as-a-judge or CometKiwi). Synthetic data generation, such as back-translation, was reported by 16 teams.

Post-editing. Finally, for post-editing, 16 submissions reported using LLMs (prompt engineering) for automatic post-editing and/or reasoning. Eleven teams reported using Minimum Bayes Risk (MBR) decoding, and nine mentioned using quality estimation separately.

4.2 LLM Benchmark

LLMs have become popular tools for machine translation (Ataman et al., 2025; Chatterji et al., 2025). Following last year, we provide a systematic and unbiased evaluation of the most popular language models on our blind test sets.

Evaluated models. When deciding which LLMs to evaluate, we selected the best performing constrained and best performing unconstrained model from each popular LLM family. In addition, we collected three popular translation provider services as in previous years. The final list of systems is presented in Table 5.

Prompting LLMs for translation. We designed a unified script to collect translations from all LLMs in an identical setup. We used a zero-shot, instruction-following approach, translating full documents at once. To ensure deterministic outputs, we set the temperature to zero. If a model failed to translate a full document while preserving paragraph breaks, we segmented it into paragraphs and translated each one separately.[20] This generic setup may disadvantage systems tuned for specific MT instructions, such as TowerLLM or EuroLLM; these are marked with [M].

[20]The code for collecting translations is available at: github.com/wmt-conference/wmt-collect-translations

Language model	Doc-lvl	Tokens (in/out)	Cost ($)
Gemini-2.5-Pro†	95.1%	2.1 / 16.4 M	250.8
Claude-4	67.5%	2.6 / 3.5 M	60.4
CommandA	70.6%	2.3 / 3.0 M	35.3
GPT-4.1	97.1%	2.0 / 3.5 M	31.7
DeepSeek-V3	57.2%	2.5 / 2.8 M	6.6
AyaExpanse-32B	54.9%	2.5 / 3.0 M	5.7
AyaExpanse-8B	43.2%	2.6 / 2.8 M	5.5
Mistral-Medium‡	54.1%	2.2 / 2.0 M	5.0
Qwen3-235B	65.6%	2.5 / 3.4 M	2.5
Llama-4-Maverick	70.4%	2.3 / 2.2 M	2.5
Qwen2.5-7B	35.7%	3.2 / 3.5 M	2.0
Mistral-7B	35.1%	1.8 / 3.0 M	1.2
Llama-3.1-8B	27.1%	3.3 / 3.1 M	1.2
CommandR7B	49.3%	2.7 / 3.9 M	0.7

Table 4: Ratio of document-level translated data. Token counts are in millions. †Gemini-2.5-Pro used reasoning, increasing cost. ‡Mistral-Medium did not translate four language pairs. Pricing for open-weight models is estimated via together.ai.

Supported languages. We collected translations for all language directions and tried to collect information about which languages are supported and which are not by looking into the original technical reports to see which languages are mentioned.

As shown in Table 4 in column *Doc-lvl*, one of the key limitations of current LLMs is failure to translate a document at once. This is caused by their window size or a failure to keep paragraph breaks.

API inference and cost. We collect all translations via the respective service APIs during the submission period. Table 4 shows the number of input and output tokens as determined by each model's tokenizers. The estimated costs shown are for the main test set and do not include the test suites. While we disabled the "reasoning" mode for Qwen3-235B to prevent collection errors, we did not disable it for Gemini 2.5 Pro, which significantly increased its translation cost.

4.3 Constrained and Unconstrained Tracks

To promote fair comparison and encourage replicability, the WMT25 General MT Task distinguished between two tracks: *Constrained* and *Unconstrained*. These tracks differ in terms of model size, licensing, and reproducibility requirements.

Constrained Track: Systems in this track must adhere to the following criteria:

- Use only models and training data that are publicly available under open-source licenses per-

mitting unrestricted non-commercial use (e.g., Apache, MIT).
- The final model must not exceed 20 billion parameters. Larger models may be used during intermediate stages (e.g., for distillation), but the submitted outputs must be produced by a final model that complies with the size limit.
- Model weights must be released under an open-source license before the camera-ready deadline to ensure replicability.

This track is designed to foster transparency and reproducibility, allowing other research groups to replicate and build upon submitted systems.

Unconstrained Track: This track imposes no restrictions on model size, training data, or licensing. It includes systems built with proprietary tools, closed-source models, or undisclosed training pipelines, such as commercial LLMs (e.g., GPT-based systems). While participation in this track is open, systems are expected to provide as much detail as possible about their setup to support interpretability.

Although this year, we did not restrict training data for either track, we curated a set of corpora that covers the majority of publicly available resources to support participants in building competitive systems.[21]

To assist participants in the constrained track, we provided a non-exhaustive list of suggested models under the 20B parameter limit, including: textual models: Aya Expanse 8B, Aya 101 (13B), Cohere R 7B, LLaMA 7B and 13B, Qwen 2.5 7B, Mistral 7B and 8B, EuroLLM, NLLB; and multimodal models: Whisper, Seamless M4T. The complete list of systems is presented in Table 5.

Systems were evaluated within their respective tracks: constrained systems were compared only against other constrained systems, while unconstrained systems were evaluated in a broader context that includes all submissions.

4.4 System Submission Platform

We used the open-source OCELoT platform[22] to collect system submissions again this year. Given that not all submissions could be included in the human evaluation due to resource constraints, we did not require pre-verification of participating teams. This allowed broader participation and flexibility in the submission process.

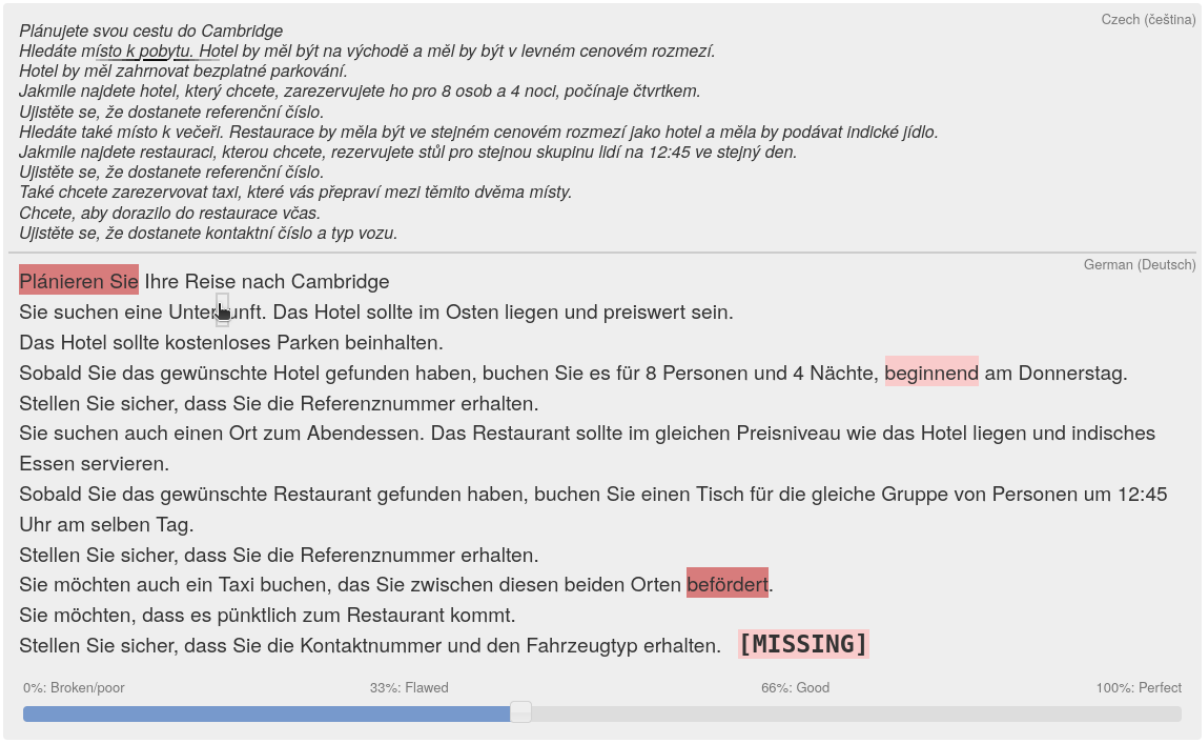
Table 5: List of constrained and unconstrained systems with parameter count. Open-weight models were marked with a cmark (✓).

Participants were asked to submit their systems in a single JSONL file, covering all language pairs, and to use a provided verification script to ensure that the submission adheres to strict formatting and completeness requirements. The verification process included the following checks:

- **Completeness of translations:** while participants could submit outputs for only a subset of languages, each submitted language had to be fully translated.
- **Format verification:** ensured that all documents from the testset were translated with correct paragraph boundaries preserved.
- **Inclusion of testsuite translations:** verified that testsuite segments were not omitted because of their length or other reasons.

To avoid premature publication of rankings based on automatic metrics, all submissions were displayed anonymously on the leaderboards during the submission period.

Teams had one week after the submission deadline to select a single primary submission, specify the track for that submission, and submit an abstract for their system description paper. These steps were mandatory for a system to be included in the human evaluation campaign.



(a) Screenshot of Czech→German annotations in the dialogue domain. Mouseover on the target side shows coarse alignment on the source side.

5 Automatic Evaluation

As in the last year, a high number of submissions[23] made full comprehensive manual evaluation infeasible. We therefore employed automatic metrics to select systems for human evaluation via a procedure we call AUTORANK. This year's procedure improves upon WMT24 by incorporating a broader set of metrics and a revised aggregation method.

Metrics. For most language pairs (see "low-resource exception" below) the AUTORANK is a combination of three distinct families of evaluation methods:

- **LLM-as-a-Judge (reference-less).** We use GEMBA-ESA (Kocmi and Federmann, 2023b) with two independent judges: GPT-4.1[24] and Command A (Team, 2025), both in a reference-less setting.
- **Trained Reference-based Metrics.** Two supervised metrics trained to approximate human quality judgments with references: MetricX-24-Hybrid-XL[25] (Juraska et al., 2024) and XCOMET-XL[26] (Guerreiro et al., 2024).
- **Trained Quality Estimation (QE).** The reference-less QE metric CometKiwi-XL[27] (Rei et al., 2023), which is also trained to mimic human judgments.

This combination of reference-based and reference-less (or QE) methods is designed to balance their complementary failure modes. Reference-based metrics typically achieve a higher correlation with human judgments when high-quality references are available, while reference-less methods reduce susceptibility to reference bias when references are suboptimal (Freitag et al., 2023). We also account for known issues with specific metrics. To mitigate a common QE pitfall, i.e., being fooled by fluent output in the wrong language, the GEMBA-ESA prompt explicitly specifies the target language. However, while GEMBA-ESA is intended to reduce bias toward systems that use re-ranking, we note that some participants incorporated it directly as a reward model.

System-level scores. The system-level score for each language pair is the average of its paragraph-level (segment-level) scores from each metric across the testset. In particular, paragraphs constitute the input units for all the metrics. We make one exception for language pairs without human

[23] We received submissions from 36 unique teams. A total of 43 teams initially registered, but 7 later withdrew or were disqualified.

[24] openai.com/index/gpt-4-1/

[25] huggingface.co/google/metricx-24-hybrid-xl-v2p6

[26] huggingface.co/Unbabel/XCOMET-XL

[27] huggingface.co/Unbabel/wmt23-cometkiwi-da-xl

references by excluding CometKiwi-XL from the AUTORANK computation. This avoids redundancy, as the other hybrid metrics (MetricX-24-Hybrid-XL and XCOMET-XL) can also run in a reference-less (QE) mode to provide the necessary QE signal.

Low-resource exception. For the two lowest-resource languages in the testset, i.e., Bhojpuri and Maasai, we rely solely on `chrF++` (Popović, 2017), computed with `sacrebleu`[28] (Post, 2018). This approach was chosen because the reliability of our main metrics is unestablished for these languages (Falcão et al., 2024; Singh et al., 2024; Wang et al., 2024; Sindhujan et al., 2025), whereas human references required for `chrF++`[29] were available. Moreover, our cross-metric correlation study—based on Pearson correlations of paragraph-level scores across all systems within each language pair—shows that Bhojpuri, Maasai, and Marathi have the weakest inter-metric agreement (Kocmi et al., 2025b). This observation further supports our use of `chrF++` for Bhojpuri and Maasai. For Marathi, reference translations are not available, so its evaluation necessarily relies on QE metrics.

From system-level scores to AUTORANK. To combine the metrics into a single score, we first normalize them using median-interpercentile scaling to address differences in scale and reduce the influence of low-performing outliers. We then compute the average using equal weights. Finally, we linearly rescale the results to the range from 1 to N systems. A detailed description is provided below:

Let S be the set of submitted systems for a given language pair, $|S| = N$, and let M be the set of automatic metrics used for that language pair (for Bhojpuri and Maasai, $|M| = 1$). For each metric $m \in M$ and system $s \in S$, we compute a system-level score $x_s^{(m)}$ as the average of that metric over all available test segments. To combine scores across metrics, we first map them to a common scale; however, classical min–max normalization is highly sensitive to outliers. In fact, anchoring the scale at the single worst and best system allows an extremely low-scoring outlier to set the lower bound and compress the remaining scores into a narrow band near the top, obscuring meaningful differences among competitive systems. To down-weight extremes without discarding any system, we apply a median-interpercentile scaling to each metric m:

$$\tilde{x}^{(m)} = \text{median}\left\{x_s^{(m)} \mid s \in S\right\}, \quad (1a)$$

$$D^{(m)} = \max\left(\varepsilon,\, Q_{100}^{(m)} - Q_{25}^{(m)}\right), \quad (1b)$$

$$z_s^{(m)} = \frac{x_s^{(m)} - \tilde{x}^{(m)}}{D^{(m)}}. \quad (1c)$$

Where $\varepsilon > 0$ and $Q_p^{(m)}$ denotes the p-th percentile of $\{x_s^{(m)} : s \in S\}$. Importantly, Eq. (1) is continuous and monotonic: it keeps all systems and preserves their order within each metric. Then, for each system, we average the robust-scaled values across metrics:

$$\bar{z}_s = \frac{1}{|M|} \sum_{m \in M} z_s^{(m)}. \quad (2)$$

Averaging after robust scaling yields a single comparable score that preserves the magnitude of performance differences between systems (in standardized units) while preventing any single metric's outliers from dominating. Finally, for readability and to follow the WMT convention from last year (lower is better in AUTORANK, i.e., 1 is best and N worst), we apply a final linear mapping to the set $\{\bar{z}_s\}_{s \in S}$. Specifically, within $\{\bar{z}_s\}_{s \in S}$ the system with the highest average score is assigned 1, the system with the lowest average score is assigned N, and all remaining systems are placed linearly between these two endpoints. This remapping is applied only once—after the cross-metric aggregation—so it preserves the ordering and relative spacing between systems while retaining the outlier mitigation provided by the robust scaling. We refer to the resulting value as AUTORANK in the various tables.

Selecting systems for human evaluation. Following the procedure established in the preliminary report (Kocmi et al., 2025b), we use AUTORANK to select the subset of systems that undergo manual assessment. The target size is 18 systems per language pair, although this number can be higher in certain cases. Selection proceeds in two steps:

1. **Prioritizing constrained systems.** We first select the top-8 performing constrained systems according to AUTORANK.
2. **Filling to target.** We then add the best remaining systems—constrained or unconstrained in

[28] github.com/mjpost/sacrebleu

[29] SacreBLEU signature: `nrefs:1|case:mixed|eff:yes|nc:6|nw:2|space:no|version:2.5.1`.

order of AUTORANK—until the language pair reaches the target number of systems.

Systems not selected for human evaluation keep their AUTORANK ranking as the official result for that language pair (Kocmi et al., 2025b).

5.1 Identification of Error Cases and Impact on Automatic Metrics

Generating text in wrong language. A problem that is particularly common with LLMs used for MT is generating text in the wrong language, either because of copying the source or getting the wrong target language (Bawden and Yvon, 2023; Zhang et al., 2023). To diagnose this issue, we ran language identification on the outputs of the systems using `fasttext` (Joulin et al., 2017b,a), considering a system-language pair problematic if the target language is incorrectly detected in more than 10% of examples.

The most problematic target languages detected by `fasttext` were Serbian, both in Latin script (13 systems) and Cyrillic script (9 systems), Kannada (6 systems), and Marathi (6 systems). Many of these outputs were incorrectly detected as closely related languages: Croatian, Serbo-Croatian and Bosnian for Serbian (particularly when in Latin script), and Hindi for Marathi. In the case of Serbian, these misclassifications appear to be mainly a consequence of the language identification tool's bias: when the same outputs are transcribed into Cyrillic, Serbian is correctly detected. For Marathi, which shares a script with Hindi, the issue is more substantive, with outputs containing mixed or predominantly Hindi content. Kannada outputs, written in a different script, are visually telling: many contain Devanagari script (used for Hindi) or a mix of Devanagari and Kannada characters.

Copying the source text. Another commonly observed issue is generating output in the source language, particularly directly copying the source text. In our case, this mostly corresponds to English source texts, which is unsurprising, given that English was by far the most common source language. Aside from clear failure cases (e.g. NLLB and Gemma-3-12B outputs indicating "FAILED"), many of output language errors, particularly from CommandR7B and EuroLLM-9B (other models to a lesser extent), come from copying large portions of the source text. In some cases, this copied content is mixed with text in the correct target language.

Impact of incorrect language and source copying on automatic evaluation. Copying source text instead of translating it can pose challenges for automatic evaluation tools, particularly those that reward semantic similarity without taking into account the intended target language. In AUTORANK, this applies to the CometKiwi-XL metric, which calculates scores solely based on the source text and does not account for the correctness of the target language. To estimate the impact of source copying on this QE metric, we run a controlled experiment comparing predicted scores for (i) reference texts, (ii) source texts and (iii) different degrees of mixing between source and reference texts to simulate different levels of copying.[30] The results in Table 7 show that, in this setup, source copying does not artificially inflate scores as might be expected. Scores for source-only outputs are well below those for the reference, and the greater the proportion of copied source text in the reference, the lower the score. Interestingly, partial copying leads to approximately the same score degradation as only partial translation, i.e., when the same copied portion is empty.

The metrics generally show positive correlation with each other. However, for a significant number of paragraphs, metrics diverge in their estimation of translation quality. To better understand whether specific patterns exist related to source copying or incorrect language generation, we sought to find instances where metric scores diverged for individual paragraphs. For each paragraph (specific to a language direction), we ranked the system scores and assigned each to a decile (1–10) based on their relative performance. Repeating this process for each metric, we defined the spread for a given paragraph as the difference between the highest and lowest decile across metrics. We observed a large number of divergent instances, even with wide spreads (see Table 8), indicating that metrics behave very differently in certain scenarios. While some metrics are clearly more similar to each other (e.g., LLM-based metrics and the two COMET-based metrics), the dissimilarities in rankings are present between all metrics.

Refer to Figure 2 for how often each metric appears as the score in the lowest or highest decile

[30] For each paragraph we took the first 25%, 50% or 75% of whitespace separated tokens from the source text and concatenated them with the last 75%, 50% or 25% of the reference text. We also tested using only the initial parts of the source text without concatenating the reference texts.

Hypothesis	Score
Source	0.23

Ref. (⊢75%)	0.45
Ref. (⊣25%)	0.33
Ref. (⊣50%)	0.41
Ref. (⊣75%)	0.46

Table 7: CometKiwi-XL scores for different hypothesis (compared against the source). · indicates concatenation, and percentages indicate a percentage of the total text tokens taken either consecutively from the start of the text (⊢) or the end (⊣).

relative to others when spreads are greater than 5. No consistent pattern emerges: some metrics appear to reward source copying in certain examples, but not in others, and the overall correlation with the amount of copying and the metric scores is often small. For example, CometKiwi-XL is negatively correlated with the amount of copying (as measured by the 4-gram precision count calculated by `sBLEU`) and XCOMET-XL shows the strongest positive correlation at 0.061 (Pearson coefficient). Similarly, correlations between scores and correct target language decision are also low.

Some further investigation is necessary in following years to better understand the impact of errors on the different metrics, particularly if they are to be used for automatic ranking. Notably, preliminary experiments indicate that the different metrics used are not necessarily well aligned in terms of scores of individual paragraphs, and a more in-depth study could help to understand discrepancies.

	0	2	4	6	8
#paragraphs	370k	320k	206k	89k	22k
%paragraphs	100	86.35	55.73	23.97	5.83

6 Human Evaluation

The human evaluation is done primarily using Error Span Annotation (ESA; Kocmi et al., 2024b). For English→Korean and Japanese→Chinese we rely on the Multidimensional Quality Metrics (MQM; Lommel et al., 2014a).

The ESA Protocol. The annotators (professional translators but not experts in MQM/ESA-style annotations) were asked to mark each error as well as its severity, "Minor" or "Major". In addition, the annotators were also asked to assign a score from 0 to 100, similar to Direct Assessment (DA), to the whole annotation segments (usually a paragraph). However, the ESA score should be more robust than DA alone because the annotators are primed by the highlighted errors at the time of the scoring.

The ESA interface. The interface is shown in Figure 1 with annotator instructions in Appendix A. At the start of annotation, each annotator was exposed to an interactive tutorial where they were asked to interact with the system. The source for the speech domain is a video which is shown in a native HTML video player. The output of the ESA annotation is a list of errors and their severity (minor or major) and the final score from 0 to 100 for each segment.

Task setup. The whole annotation was split into "tasks" where each task had a balanced number of words to make it approximately 1 hour long. Each task is done by a single annotator and contains segments from a single domain but contains output from multiple systems. In contrast to previous years, we do not include a quality control check due

to their annotation costs and low reliability (Zouhar et al., 2025a). Instead, we include "control tasks" for each language, which is the same task that each participating annotator has to fill out exactly once. Because these control tasks are fixed, this allows us to model annotator bias and reliability. Finally, each segment is annotated exactly twice, which can be used to estimate inter-annotator agreement and is especially useful for the metrics shared task (Lavie et al., 2025). See list of changes in contrast to previous version in Appendix A.

Diversity sampling. From the whole testset which all systems translated, we select a subset to human-evaluate. Specifically, we select a 50% of the original data which contains sources that lead to the most diverse translations (as measured by average pairwise ChrF). This ensures that we do not spend the evaluation budget on segments that have very similar translations, which contribute less to the final system ranking (Zouhar et al., 2025b).

The MQM protocol. MQM (Multidimensional Quality Metrics; Lommel et al. (2014b); Freitag et al. (2021)) is the translation evaluation framework that ESA is based on. Professional translators annotate error spans, assigning to each a severity (Major or Minor) and a category from a two-level error hierarchy (e.g. Accuracy/Mistranslation or Fluency/Grammar). Instead of then asking annotators to assign a numeric score to each segment's translation, scores are automatically calculated by applying a severity- and category-dependent weighting scheme to each error and summing the results.

MQM interface. MQM ratings were collected using the open-source Anthea[31] framework. Similarly to the ESA annotations, for the speech domain the video was used as the source side of the evaluation.

Task setup. Due to concerns with rater fatigue, steps were taken to limit the expected time for any individual MQM rating task. To this end, documents were truncated at paragraph boundaries to include no more than 12 source sentences; if the first paragraph contained more than 12 sentences, the document was skipped. For the literary domain in particular, to avoid truncating the vast majority of segments in the very-long documents, the text was instead split into chunks of one or more paragraphs up to the 12-sentence limit, and each chunk was treated as a separate document for the purposes of conducting the evaluation.

[31] github.com/google-research/google-research/tree/master/anthea

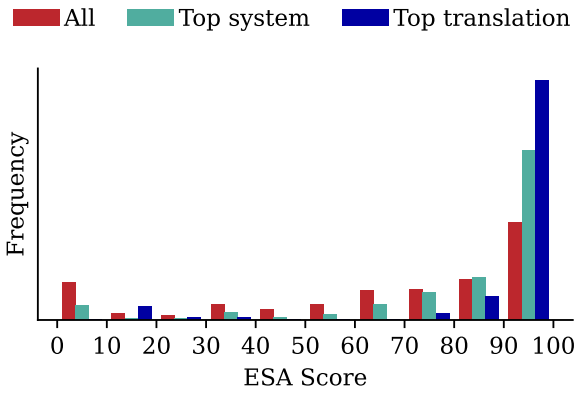

Figure 3: Distribution of final human segment-level scores (ESA) of all systems, top-system in each language, and top translation for each segment. The buckets have a width of 10 (corresponding to xticks). Results include all languages.

6.1 Human Evaluation Analysis

Score distribution. We analyze the score distribution from three perspectives: (1) scores across all systems, (2) scores of the top system in each language pair, and (3) score of top translation for each source segment. While Figure 3 shows that a near-perfect translation (a score of 90-100) is achievable for most source segments by at least one system, the performance of any single system is more modest. Even the top-performing system often fails to achieve a score above 90, a trend that is naturally more pronounced for lower-ranked systems.

Cost and reliability. We also analyze the annotation process itself, focusing on the trade-off between cost and reliability (Kocmi et al., 2024b; Zouhar et al., 2025a). Table 9 provides an overview of annotation volume, time (as a proxy for cost), and inter-annotator agreement (pairwise Pearson). Our analysis finds that while annotation speed and the number of annotated errors vary considerably, neither is predictive of inter-annotator agreement.

Domain and language difficulty. In Table 10, we present the score of the top-performing system for each language and domain. Focusing on the top-performing system mitigates the effect of low-performing outliers. While absolute scores are not directly comparable across languages (due to dif-

Table 10: Human evaluation scores for the top-performing system per language, by domain.

ferent sets of systems, annotators, and sources), we again observe a consistent pattern (Kocmi et al., 2024a): the speech domain receives the lowest scores, suggesting it is the most challenging, likely due to its reliance on ASR-generated text. The social and news domains follow in difficulty. Surprisingly, the literary domain achieved the highest scores.[32]

Most language pairs show similar difficulty patterns, with English→Maasai as a notable outlier. Overall, English→Arabic (Egyptian) and English→Italian proved to be the most challenging.

[32]This could be due to two factors: first, its source texts were not subject to difficulty sampling due to limited number of stories. Second, an evaluation that asks annotators to mark errors may award high scores to translations that are technically error-free, even if they do not fully capture stylistic qualities such as the author's voice or the reader's enjoyment (Carpuat et al., 2025).

7 Official Ranking Results

We now describe how we compute the final ranking and then discuss the final results and potential issues. The ranking is presented in tabular form in Section 7.4.

7.1 Human Ranking Computation

We calculate three different scores: the human ESA or MQM score, rank, and the cluster. The human ESA or MQM scores are the micro-average of the segment-level scores. This disregards any domain balancing, though we show per-domain results in Appendix D. For the statistical analysis and clustering, we use the Wilcoxon signed-rank test, a paired non-parametric test (Wilcoxon, 1945), with $p < 0.05$. The rank ranges differ from last year's implementation. Systems are sorted by their average human score and for a system in row i we define its rank range $\langle i_\downarrow, i_\uparrow \rangle$ as follows: $i_\downarrow := \max\{j | j < i, \text{significant(i, j)}\} + 1$ and $i_\uparrow := \min\{j | j > i, \text{significant(j, i)}\} - 1$. In words, the ranks expand from i until a system that is statistically distinguishable is encountered. Lastly, the clusters are the maximal partition of systems such that ranks of systems from one cluster do not overlap with ranks of systems in another cluster.

7.2 Human Evaluation Discussion

In this section, we discuss the results of the human evaluation presented in Section 7.3 (constrained systems only) and in Section 7.4 (all systems).

7.3 Ranking of Constrained Systems

English→Chinese

Rank	System	Human
1-1	Algharb	88.4

Human evaluation shifts overall ranking. Overall, the best-performing model in the human evaluation is Gemini 2.5 Pro (see Figure 5).[33] It places in the top cluster for 14 of the 16 evaluated language pairs and is on par with or surpasses human translation in 10 of those pairs.[34]

This result differs notably from the AUTORANK results (Kocmi et al., 2025b), where Shy-hunyan-MT ranked first for all but one language pair (English→Bhojpuri). The discrepancy may be due to Shy-hunyan-MT's use of GRPO with XCOMET-XXL and GEMBA with DeepSeek V3 as its training signals.[35] However, despite its lower ranking in the human evaluation, Shy-hunyan-MT remains the best-performing *constrained system*, winning in this category for 11 language pairs. The second best constrained system is Algharb, which ranks first in six language pairs.

Finally, human translations, often treated as a "gold standard," place in the top cluster for only six of the 15 language pairs where they were available. This finding highlights the inherent difficulty of translation, though it could also reflect the stylistic or lexical preferences of the annotators.

7.4 Official Ranking Results Tables

Results tables legend

The human score is the micro-average of human judgments across all domains and double annotations (single annotations for MQM language pairs). AutoRank is calculated from automatic metrics as per (Kocmi et al., 2025b). Significance testing is done using a Wilcoxon signed rank test with a p-value threshold of 5%. The rank range for the ith model begins as $\langle i, i \rangle$ and is expanded in both directions until a significant difference is found. Clusters are formed such that their constituent rank ranges do not overlap.

Systems are either constrained (white), or unconstrained (gray). Systems that do not officially support the language pair are marked with 🚫 and those where language support cannot be verified are marked with ❓. The [M] suffix marks systems (submitted by the WMT organizers) that were trained/-tuned with specific MT instructions, but prompted without these specific instructions (using a generic setup, same for all LLMs, see Section 4.2), which could disadvantage these systems. See Appendix D for a per-domain breakdown of system performances.

[33] The translations with Gemini 2.5 Pro were collected with the "thinking" mode enabled, and it is unclear how much this contributed to its overall performance.

[34] Note that while human translations for WMT are prepared by professional translators, they are not necessarily free of errors or undergo the same level of post-editing as human translations used in high-stake scenarios (e.g., sworn translation) or published translations (e.g., literary translation).

[35] Similar shifts, i.e., a higher automatic rank and lower placement after human evaluation, are visible for other systems, some of which also use metrics as a signal in training or reranking (see Figure 4).

While best system scores high many stay in the middle. Although the best system almost always achieves a score of 90 or higher, no system (including human references) achieves a perfect score of 100 (see Table 10 and Appendix D). The spread of scores is also quite large: mid-tier models often score 60 or below, and the worst-performing systems can score as low as 0, depending on the language pair and domain (see Figures 6 and 7).

Translation into low-resource languages remains a challenge. The translation quality for Maasai, a low-resource language, is largely unusable. We observe that for this language, systems often produce large portions of their output in Swahili, and the few acceptable spans in Maasai are frequently overlooked by annotators.[36] Additional errors arise from translations that fail to capture the meaning and context of the source text. While human translations into Maasai also score low (9.6 ESA scores), we were able to independently confirm that these are generally understandable by native speakers and often sound natural. However, they may exhibit extensive code-mixing of English and Swahili (Figures 6 and 7). We speculate that our Maasai annotators, when evaluating a large portion of poor-quality system outputs, failed to notice the one translation that was mostly reasonable.

A similar issue occurs with Egyptian Arabic, where systems tend to output Modern Standard Arabic (MSA). This type of error would likely be overlooked by quality estimation metrics, which typically do not incorporate target language labels into their pipeline (though they could potentially be trained to do so).

[36]While many Maasai people speak Swahili, Maasai (or Maa) is a distinct language from a different language family.

7.5 Additional Analysis of English→Serbian translations

In addition to the official human evaluation, an analysis of English→Serbian translations was carried out by an MT researcher with experience in human translation. One part of the analysis deals with the two scripts (Latin and Cyrillic), and another one with translation quality taking into account both errors as well as exceptionally good idiomatically translated parts named "rewards".

Scripts. Due to historical and cultural reasons, the Serbian language is bi-alphabetical, using both Latin and Cyrillic scripts. Serbian Cyrillic alphabet is a highly phonetic alphabet with a one-to-one correspondence between letters and sounds. Serbian Latin alphabet is almost perfectly compatible with Cyrillic with a one-to-one correspondence, except for the three digraphs each representing one sound (Љ ↔ /lj/, Њ ↔ /nj/, Џ ↔ /dž/). Serbian speakers switch easily between the two scripts without much thinking. The choice of the script is partly random but also influenced by the context, medium, or even ideological preferences. However, the scripts should not be mixed within a single text with a few exceptions: URLs or foreign brand names which should be in Latin even in Cyrillic texts. The automatic conversion of Serbian Cyrillic into Latin script is easier than the other way round. The primary reason is the one-to-one character mapping from Cyrillic to Latin, while converting from Latin to Cyrillic introduces ambiguity due to the three previously mentioned digraphs.

Training data for generative NLP including MT are available in both scripts, and it might be challenging to ensure that the outputs are written in the desired script. Therefore, the WMT translations were checked in this aspect, by measuring the percentage of words written in another script.

The results are presented in Table 11. In Cyrillic translations there is always a small percent of words written in Latin, because of URLs, named entities or similar. Overall, there is more mixing in Cyrillic translations: found in more systems and also to the larger extent. The probable reason is that there is more available data in Latin script. Another observation is that some systems use only one script (e.g. ONLINE-B and ONLINE-G only Cyrillic,

(b) % Unexpected Latin script detected in a Cyrillic-script translation

Table 11: Comparison of script intrusions across Latin and Cyrillic translations.

CUNI-SFT and Llama-3.1-8B only in Latin, UvA-MT almost all in Latin).

We further explored qualitative differences between the outputs in different scripts. The first step was automatic: Cyrillic outputs were converted into Latin and then compared by word bi-gram overlap (F-score). For some systems, there was almost no difference, but for the majority there were notable differences (for example, around 75% overlap score for Gemini and GPT, around 60% for Shy, see the full table can be seen in Appendix Table 20). However, qualitative manual inspection did not identify any major or systematic differences regarding translation quality or types of errors.

Errors and rewards. We next looked into the annotated error spans similarly to Popovic (2021). However, due to discrepancies in error span annotations it was difficult to determine the nature of the annotated spans. For example, a number of non-existing or obviously incorrect words were not marked at all, and overall scores were not lowered at all or only slightly, while there were completely correct passages which are marked as errors. Furthermore, a number of segments seemed to be heavily penalized only for using the Latin script: all words there were marked as errors without looking at actual errors, and the scores were lowered but inconsistently, ranging from 90 to 10. The affected systems were CUNI-SFT, UvA-MT, LLama-3.1-8B and EuroLLM-9B. After qualitative inspection, it seemed that the translation quality of LLama-3.1-8B and EuroLLM-9B was indeed low, while CuNI-SFT and UvA-MT might be underestimated.

For these reasons, a full additional ESA annotation has been carried out on a small selected set: last ten documents from each of the domains, so 40 documents in total. The following nine translations were included: the best ranked systems in the official evaluation (Gemini, GPT, Shy, ONLINE-B, Claude) and the human translation, the two low-ranked systems which were potentially over-penalised for the script (UvA and CUNI), as well as one system from the middle cluster (GemTrans).

For each translated documents, first all errors were marked, and then overall scores were assigned (the same process as in the official evaluation, although no distinction between major and minor errors was made). During the evaluation, the annotator observed that, apart from error spans, there were passages translated exceptionally well, namely idiomatically: diverging from the source, but fully keeping the meaning while sounding completely natural in the target language. These spans were then marked as "rewards".

The results from the additional span annotation are aggregated as word-level error rates and reward rates, namely number of words in the marked spans divided by total number of words (length). Also, a total score is presented, where error spans are subtracted from the length and reward spans are added. In addition, the official scores and error rates are extracted for the 40 selected documents and presented for comparison.

The results can be seen in Table 12. The largest percentage of idiomatic translations can be found in the middle-ranked GemTrans translation (5.67%), followed by human translation (4.17%). Gemini

Table 13: Rankings of the selected translations for English→Serbian according to different scores.

and Shy have around 3.5% idiomatically translated words, while all other systems have around 1% or less.

Table 13 presents rankings of the systems according to different scores: official overall score and error rate, additional overall score and error rate, as well as reward rate and total span-based score. It can be noted that Gemini, Shy, GPT and Human are almost always on the top, while CUNI is always the last. Furthermore, Gemini clearly surpasses human translation in terms of both scores and error rates in both evaluations.

Claude and ONLINE-B might be over-estimated in the official evaluation, since in the additional one they obtained notably lower scores, higher error rates, and almost no rewards, being comparable to possibly under-estimated UvA-MT. Also, human translation might be under-estimated in the official evaluation, but it is clearly worse than Gemini and comparable with Shy and GPT.

Furthermore, the middle-ranked GemTrans system turned out to be very interesting, since it generated a notable amount of idiomatic translations (5.67%), even more than humans (4.19%), but also exhibits relatively high number of errors (9.6%), many of them being morphological/agreement issues which were typical for statistical systems.

According to idiomatic translations, GemTrans and human are ranked the best, followed by the two overall top-ranked Gemini and Shy. And according to the total rate, taking into account both errors and rewards, the best three translations are Gemini, Shy and Human, followed by GemTrans and GPT.

It might be worth noting that there were 15 translations (originating from 10 source segments) without any errors: 7 were translated by Gemini, 5 by Shy, and 3 by human translators. Three of them are from the literary domain, one from speech and 11 from the social domain. Of those, 11 also have idiomatic translations: 7 by Gemini, 2 by Shy, and 2 by human translators.

As for different domains, there are no notable differences regarding idiomatic translations, although there are slightly more in news and literature (3.2% and 2.2%) than in speech and social (2.0% and 1.5%).

8 Test Suites Sub-task: "Help us break LLMs vol. 2"

For a second year in a row, we have invited the community to submit test suites in the sub-task under the call "help us break LLM". The aim is again to demonstrate evaluation methods that can expose weaknesses in LLMs which cannot be detected using standard evaluation methods. With more LLMs participating this year, and the technology advancing quickly, this call remains particularly relevant.

8.1 Setup of the Sub-task

Each test suite is a customised extension of the standard test sets that focuses on specific aspects of the machine translation (MT) output. Evaluation of the MT output takes place in a decentralised manner. Test suite providers were invited to submit their customised test sets following the setup introduced at the Third Conference on Machine Translation (Bojar et al., 2018). For this purpose, each test suite provider submitted a source-side test set, which the organisers of the General MT Shared Task then appended to their standard test sets. After generating the corresponding system outputs, the organizers returned them to the respec-

tive providers, who then conducted the evaluation according to their own methodological approach. Detailed results and analyses for each test suite are presented in separate description papers, while a consolidated summary is provided below.

8.2 Submissions

Six test suites are participating this year, covering a wide range of translation phenomena, domains, and language pairs. An overview of the test suites can be seen in Table 14. Descriptions of each submission, along with their main findings, can be found below.

DFKI (Manakhimova et al., 2025). This test suite offers a fine-grained linguistically motivated analysis of the shared task MT outputs for English–Russian, based on 465 manually devised test items, which cover 55 phenomena in 13 categories. Extending their previous test suite submissions (e.g. Avramidis et al., 2020; Macketanz et al., 2021, 2022; Manakhimova et al., 2023, 2024), the submission of this year analyzes how English–Russian machine translation (MT) systems submitted to WMT25 perform on linguistically challenging translation tasks, similar to problems used in university translator training.

The findings show that in 2025, even top-performing MT systems still struggle with translation problems that require deep understanding and rephrasing, much like human novices do. The best systems exhibit marked improvements in handling such 'extra-credit' challenges, often producing more natural translations rather than producing word-for-word renditions. However, persistent structural and lexical problems remain: literal word order carry-overs, misused verb forms, and rigid phrase translations were common, mirroring errors typically seen in beginner translator assignments.

EAA-Terminology (Hauksdottir and Steingrimsson, 2025). The EEA terminology test suite is a novel evaluation set designed to assess the capabilities of machine translation (MT) systems in handling terminology found in the EEA Agreement. It is designed for English-to-Icelandic translations, but can be easily adapted for other languages. The test suite evaluates four subdomains of the terminology in EEA regulations: science, technology, finance, and society. The test suite consists of 300 text examples in the form of sentences in English, stored in a single text file, which is to be translated by the MT systems. The suite also contains a gold standard translation meant for comparison, where each example has been translated as expected into Icelandic.

GENDER1PERSON (Popović and Lapshinova-Koltunski, 2025). The GENDER1PERSON test suite is designed for measuring gender bias in translating first-person singular forms from English into two Slavic languages, Russian and Serbian. The test suite consists of 1 000 Amazon product reviews, uniformly distributed over 10 different product categories. The bias is measured through a gender score ranging from -100 (all reviews are feminine) to 100 (all reviews are masculine).

The test suite shows that the majority of the systems participating in the WMT-2025 task for these two target languages prefer the masculine writer's gender. There is no single system which is biased towards the feminine variant. Furthermore, for each language pair, there are seven systems which are considered balanced, having the gender scores between -10 and 10.

Finally, the analysis of different products showed that the choice of the writer's gender depends to a large extent on the product. Moreover, it is demonstrated that even the systems with overall balanced scores are actually biased, but in different ways for different product categories.

IITP-legal (Singh et al., 2025a). The study critically examines various Machine Translation systems, particularly focusing on Large Language Models, using the WMT25 Legal Domain Test Suite for translating English into Hindi. It utilizes a dataset of 5, sentences designed to capture the complexity of legal texts, based on word frequency ranges from 5 to 54. Each frequency range contains 100 sentences, collectively forming a corpus that spans from simple legal terms to intricate legal provisions. Six metrics were used to evaluate the performance of the system: BLEU, METEOR, TER, CHRF++, BERTScore and COMET. The findings reveal diverse capabilities and limitations of LLM architectures in handling complex legal texts. Notably, Gemini-2.5-Pro, Claude-4 and Llama-4-Maverick topped the performance charts, showcasing the potential of LLMs for nuanced translation. Despite these advances, the study identified areas for further research, especially in improving robustness, reliability, and explainability for use in critical legal contexts. The study also supports the WMT25 subtask focused on evaluat-

ing weaknesses of large language models (LLMs). The dataset and related resources are publicly available.[37]

RoCS-MT v2 (Bawden and Sagot, 2025). Robust Challenge Set for Machine Translation,[38] is designed to test MT systems' ability to translate user-generated content with non-standard characteristics, such as spelling errors, devowelling, acronymisation, etc. The original English Reddit texts are associated with manual normalisations and translations in five languages (French, German, Czech, Ukrainian and Russian). This second version of the test suite presents several improvements over the previously published version (Bawden and Sagot, 2023)., including (i) minor corrections of normalisation, (ii) corrections to reference translations and addition of alternative references to accommodate for different possible genders (e.g. of speakers) and (iii) a redesign and re-annotation of normalisation spans for further analysis of different non-standard UGC phenomena.

In previous editions of the shared task, we saw that non-standard UGC phenomena still posed problems for many models, although some of the larger, closer-sourced models handle them better. The behaviour of the systems varies greatly, with different handling of the translation of the phenomena, some systems producing more standardised outputs than others. In this edition, we saw that there was still a wide range in behaviour of systems, not all of which is accurately characterised by the automatic metric used in evaluation (COMET-Kiwi). We show some preliminary analysis showing that for elongation as a mark of expressivity (e.g. *mooooorreeee* instead of *more*), some systems are rewarded for copying the source text rather than translating the word, either in its standard or expressive form. This especially reveals issues in the current evaluation protocol for the test suite, and will require clarifying in future work.

SportsEval (Sigurdsson et al., 2025). Sports are a consistently popular domain in most news media. Although many sports attract extensive media attention and feature a rich, polysemous language, often shaped by active neologism and community-driven translations, the sports domain has received relatively little focus in MT research.

The SportsEval test suite was developed to examine the robustness of MT systems in translating sports-related texts from English into Icelandic. It covers five sports that are popular in Iceland: football (100 segments), basketball (100), chess (50), gymnastics (25), and golf (25), with a total of 300 segments. Each of these sports has a long-established domain-specific vocabulary in Icelandic, and mistranslations can easily render a text unintelligible. The segments range from single to multi-sentence passages, and most include multiple terms. While the majority are drawn from authentic usage examples, some have been adapted for brevity, and a small number are synthetic, created to illustrate specific terminological challenges.

In total, the test suite contains 971 term instances. Since some terms recur across segments, the design also enables an evaluation of translation consistency. The findings of our study indicate that current MT systems face considerable challenges in this domain.

8.3 Aggregated Results

In order to have a more general overview of the comparative system performance with regard to the test suites, we present the ranks produced by

Table 16: Aggregated system ranking for English→ Russian according to human evaluation and test suites.

test suites of the same language direction side by side, including the human ranks of the official WMT25 General MT test set (first column). In Tables 15, 16, 17 we present results for the language directions where we have more than one test suite. For visualisation purposes, the table rows are ordered primarily by the human ranks of the WMT25 General MT test set and then by the average of the rest of the test suites. It must be noted that this visualisation has to be taken with a grain of salt, as test suites employ different evaluation methods over different test sets off different sizes. Also, due to the different methods, the confidence intervals between the ranks have not been always taken into consideration.

One can see that there is quite some variety between the ranks of the WMT25 General MT test set and the test suites, with most obvious the ones of RoCS-MT-v2, indicating the non-standard nature of the data means that some systems which otherwise perform good, are unusually poor. The gender1person testsuite also indicates that systems with high overall performance indicate a strong male bias towards the selection of the male gender. The linguistically motivated test suite by *dfki* also has quite some variability for the systems that are evaluated. Meanwhile, the two terminology test suites are a bit closer to the WMT25 General MT testset, albeit with a few exceptions.

8.4 Summary

The evaluation of multiple test suites across diverse language pairs and domains reveals persistent challenges for current MT systems. Fine-grained linguistic analysis for English–Russian indicates high

Table 17: Aggregated system ranking for English→ Serbian according to human evaluation and test suites.

error rates in semantic roles, domain-specific terminology, and proper names, although an increase in gender-inclusive renderings was observed compared to previous years. Domain-specific evaluations for English–Icelandic, including EEA terminology and sports-related texts, demonstrate substantial difficulties in maintaining terminological accuracy and consistency. Gender bias assessment for Russian and Serbian shows a systematic preference for masculine forms, with product-specific variation even among systems classified as balanced. Legal-domain evaluation for English–Hindi confirms the superior performance of advanced LLMs such as Gemini-2.5-Pro and Claude-4, while highlighting the need for improved robustness and explainability in critical applications. Finally, robustness testing on user-generated content underscores ongoing weaknesses in handling non-standard linguistic phenomena, despite incremental progress in larger models.

9 Conclusions

The WMT 2025 General Machine Translation Task covered 30 language pairs, with human evaluation conducted on half of them across four to five domains. We prepared more challenging test set by utilizing novel difficulty sampling.

We evaluated 60 systems in total: 36 participant submissions and 24 systems collected from LLMs and popular online providers. Participation continued to grow compared to last year, and most teams utilize LLMs, often via fine-tuning.

We adopt ESA and MQM as the human evaluation protocols, which show the weak-points of models, especially in Egyptian Arabic dialect or in extremely low-resource language Maasai.

Automatic rankings did not always match human judgments: systems that topped automated metrics such as Shy-hunyuan-MT, did not consistently win under human evaluation, pointing to persistent metric bias in MBR and reinforcing that human evaluation should remain the final arbiter of translation quality.

Domain analyses showed speech as the most challenging (likely due to ASR noise), while literary was the easiest among those tested. Targeted test suites revealed remaining weaknesses in robustness to non-standard input, linguistic complexity, domain terminology, and gender choice/agreement, even as advanced LLMs improved inclusivity and performance in some specialized areas.

All source data, system outputs, and human judgments are released to support transparency, reproducibility, and further research on machine translation.

10 Limitations

We tested the general capabilities of MT systems. However, we have simplified this approach and only used three to five domains. Out of various possible modalities, we used audio and text.

Some models used pretrained metrics such as xComet or MetricX during their training, for example, using Minimum Bayes Risk or as a reward model. This significantly affected the automatic evaluation of such models giving them artificially higher scores. Furthermore, automatic metrics are limited, brittle, and biased (Karpinska et al., 2022;

Moghe et al., 2025), especially in novel domains (Zouhar et al., 2024a,b), which motivates them being superseded by human evaluation. Another potential problem may have been that test sets we use are paragraph-level; automatic metrics have usually been tested in a sentence-level scenario. Therefore, we strongly advise careful interpretation of automatic scores.

Although we use human judgments as the gold standard, giving us more reliable signal than automatic metrics, we should mention that human annotations are noisy (Wei and Jia, 2021) and their performance is affected by the quality of other evaluated systems (Mathur et al., 2020). Lastly, different annotators use different ranking strategies, which may have an effect on the system ranking.

11 Ethical Considerations

Inappropriate, controversial, and explicit content was filtered out prior to translation, keeping in mind the translators and not exposing them to such content or obliging them to translate it.

Human evaluation using Appraise for the collection of human judgements was fully anonymous. Automatically generated accounts associated with annotation tasks with single-sign-on URLs were distributed among pools of annotators and we do not store any personal information. We do store the mapping between which annotator (pseudoanonymized) annotated which segments. Annotators received standard professional translator's or evaluator's wage with respect to their countries.

A Error Span Annotation Miscellaneous

The following instructions were shown in the annotation interface and could be accessed at any time.
Higlighting errors: *Select the part of translation where you have identified a translation error (drag or click start & end). Click on the highlight to change error severity (minor/major) or remove the highlight.*
Choose error severity:
- *Minor errors: Style, grammar, word choice could be better or more natural.*
- *Major errors:: The meaning is changed significantly and/or the part is really hard to understand.*

Tips:
- *Missing content: If something is missing, highlight the word [MISSING] to mark the error.*
- *Tip: Highlight the word or general area of the error (it doesn't need to be exact). Use multiple highlights for different errors.*
- *Tip: Pay particular attention to translation consistency between texts across the whole document.*
- *Tip: If the translation is in the wrong language, mark it fully and assign it 0*
- *Tip: If the translation contains additional text (e.g. "Here is the translation") or alternative secondary translation, mark it as a major error.*
- *Using external tools for annotations (chatbots, LLMs) is not allowed.*

Score the translation: *After marking errors, please use the slider and set an overall score based on meaning preservation and general quality:*
- *0: Broken/poor translation.*
- *33%: Flawed: significant issues*
- *66%: Good: insignificant issues with grammar, fluency, or consistency*
- *100%: Perfect: meaning and style aligned completely with the source*

Changes to ESA interface. We introduced the following changes to the ESA interface since the previous use in WMT 2024 (Kocmi et al., 2024a):
- Dropped the requirement for a task being strictly 100 segments.
- We added a crude character-based alignment (Figure 1, top).
- We include images on the source text (Figure 1, bottom right).
- We use a translated version of the tutorial for each language pair.
- Updated the annotation instructions and the annotation scale.
- Updated the interface style slightly (Figure 1).

B Translator Brief

The following instructions were given to human translators:
In this project we wish to translate data from several domains for use in the evaluation of Machine Translation (MT). The translations produced by you will be compared against the translations produced by a variety of different MT systems. They will be released to the research community to provide a benchmark, or "gold-standard" measure for translation quality. The translation therefore needs to be a high-quality rendering of the source text into the target language, as if it was originally written directly in the target language. However, there are some constraints imposed by the intended usage:

- *All translations must be "from scratch," without post-editing from machine translation or usage of CAT tools. Post-editing machine translation would bias the evaluation, so we need to avoid it. We can detect post-editing and will reject translations that are post-edited.*
- *Translators must preserve paragraph boundaries, which are marked by empty lines in the source text, but they are free to adjust the number of sentences within each paragraph.*
- *Translators should avoid inserting parenthetical explanations into the translated text and obviously avoid losing any pieces of information from the source text. We will check the translations for quality and will reject translations that contain errors.*
- *If the original data contains errors, typos, or other problems, do not change the source sentences, instead try to prepare a correct translation as if the error wouldn't be in the source.*

- *The data contain four domains (news, speech, social, literary), each folder containing one domain source and each domain needing a specific handling*

The source files will be delivered as text files (sometimes known as "notepad" files), with paragraphs separated by an empty line. We need the translations to be returned in the same format. The translation file needs to have the same name as the original file.

Speech Domain. Your task is to translate the speech from provided video. We also provide you with automated transcription, which is not human edited and contains errors, thus should be used only as a guideline for translation from the video. Each file represents one segment of video. Videos correspond to different domains: they differ in formality, style, topics and number of speakers. The idea is to translate using the most similar language in the target language, matching as best as possible the characteristics of the source video.

Social Domain. The texts are from the social network Mastodon (similar to Twitter). Each file represents a thread or part of a thread from one or several users. Different posts within a thread are separated with empty line. Individual posts can also span several lines. The sentences have been selected so that they do not contain offensive or sensitive content (hate speech, taking-drugs, suicide, politically sensitive topics, etc.). However, profanities were kept as they were taken to be illustrative of the sociolect of online language. If however, you do not feel comfortable with translating something, please let us know.

The texts are particular in that they may contain spelling errors, slang, acronyms, marks of expressivity, etc. The idea is to translate using the most natural language in the target language, matching as best as possible the style and familiarity of the source text.

- *Spelling mistakes should not be preserved in their translations, i.e. the translation should be spelt correctly. Introduce proper capitalization in translations.*
- *Marks of expressivity (e.g. asterisks *wow*, capitals letters WOW) should be conserved as best as possible. However, do not attempt to reproduce repeated characters (e.g. woooow) in translation, as the choice as to which character to repeat is often arbitrary.*
- *There will be abbreviations and acronyms (e.g. btw -> by the way, fwiw -> for what it's worth). These do not need to be translated using abbreviation or acronyms unless an abbreviation/acronym is the best translation choice in the target language.*
- *Users (@user123) and URLs should be left as they are, i.e. not translated.*
- *Platform-specific elements such as hashtags should be translated as hashtags, but the content should be translated appropriately into the target language.*
- *Punctuation can be added if it necessary to avoid comprehension difficulties. Otherwise, we recommend following the punctuation of the source text.*

Please always refer to the screenshots included alongside the source texts. These screenshots show the original context of the entire thread contained in the source text file and should be consulted during translation. Screenshot files have the same name as the corresponding source text files but with a .png image extension instead of .txt. The screenshots may also contain images attached in the thread that can provide further context for the translation.

Literary domain. The texts in this domain are stories written by aspiring writers. Each story should be translated as one coherent text, preserving characters' speech patterns and personalities consistently. Aim to maintain the original tone and register, retaining the emotional depth of the story. Dialogues should sound natural and follow the conventions of the target language.

C System Submission Summaries

This section lists all the submissions to the translation task and provides the authors' descriptions of their submission.

C.1 Algharb (Wang et al., 2025)

In this paper, we introduce a large language model system for translation, developed through a comprehensive training pipeline. Our submissions include translations from English to Chinese, Arabic, Czech, Japanese, Korean, Russian, Ukrainian, Serbian, Bhojpuri, and Estonian, as well as from Czech to German/Ukrainian and Japanese to Chinese. Our approach integrates Machine Translation-based Supervised Fine-Tuning with post-training reinforcement via Group Relative Policy Optimization (GRPO). For decoding, we employ a Minimum Bayes Risk (MBR) algorithm enhanced with a finetuned reranker. This combined strategy ensures the generation of robust and consistent high-quality translations across a diverse set of languages.

The model is available on Hugging Face: huggingface.co/AIDC-AI/Marco-MT-Algharb.

C.2 AMI (Jasonarson and Steingrimsson, 2025)

We present the submission of the Árni Magnússon Institute's team for the WMT25 General translation task. We focus on the English→Icelandic translation direction. We pre-train Llama 3.2 3B on 10B tokens of English and Icelandic texts and fine-tune on parallel corpora. Multiple translation hypotheses are produced first by the fine-tuned model, and then more hypotheses are added by that same model further tuned using contrastive preference optimization. The hypotheses are then post-processed using a grammar correction model and post-processing rules before the final translation is selected using minimum Bayes risk decoding. We found that while it is possible to generate translations of decent quality based on a lightweight model with simple approaches such as the ones we apply, our models are quite far behind the best participating systems and it would probably take somewhat larger models to reach competitive levels.

The model is available on Hugging Face: huggingface.co/arnastofnun/Llama-3.2-3B-wmt25-AMI-en-is.

C.3 CGFOKUS (Grozea and Verbitsky, 2025)

We report here the outcome of evaluating Qwen3 for the English to Ukrainian language pair of the general MT task of WMT 2025. In addition to the quantitative evaluation, a qualitative evaluation was performed, leveraging the cooperation with a native Ukrainian speaker - therefore we present an example-heavy analysis of the typical failures the LLMs still do when translating natural language, particularly into Ukrainian. We report also on the practicalities of using LLMs, such as on the difficulties of making them follow instruction, on ways to exploit the increased "smartness" of the reasoning models while simultaneously avoiding the reasoning part interfering wrongly with the chain of which the LLM is just one element.

C.4 COILD-BHO (Singh et al., 2025b)

This paper presents an English to Bhojpuri machine translation (MT) system developed for the WMT25 General MT Shared Task. Given the low-resource nature of Bhojpuri, we adopt a two-stage training pipeline: unsupervised pretraining followed by supervised fine-tuning. During pretraining, we use a 300,000-sentence corpus comprising 70% Bhojpuri monolingual data and 30% English data to establish language grounding. The fine-tuning stage utilizes 29,749 bilingual English to Bhojpuri sentence pairs (including training, validation, and test sets). To adapt the system to instruction-following scenarios, we apply a novel optimization strategy: Contrastive Preference Optimization (CPO). This technique enables the model to capture fine-grained translation preferences and maintain semantic fidelity in instruction-tuned settings. We evaluate our system across multiple metrics, demonstrating moderate performance in low-resource MT tasks, particularly in diverse domains such as literary, news, social, and speech.

The model is available at: drive.google.com/drive/folders/1ZzJ9ZlfqaT-fEo5umovNN4HWkZhOlqqC.

C.5 CommandA-WMT (Kocmi et al., 2025a)

We built our system on top of Command-A using a direct preference optimization with data preparation pipeline that emphasizes robust data quality control, primarily incorporating standard quality filtering along with a novel difficulty filtering component, which serves as the key innovation of our approach. The final translation is built through step-by-step reasoning, and we employ limited Minimum Bayes Risk decoding with a limited candidate pool size of 20, using MetricX-XL as the primary utility metric. For unsupported languages, we use a second model prepared identically but with an additional initial supervised fine-tuning step for the unsupported languages that Command-A model has not been trained on.

The model is available on Hugging Face: huggingface.co/CohereLabs/command-a-translate-08-2025

C.6 CUNI-EdUKate-v1 (Jon et al., 2025)

CUNI-EdUKate-v1 is an unconstrained system trained on educational domain data using LoRA, SFT, and Contrastive Preference Optimization. It is also fine-tuned from the EuroLLM-9B-Instruct model. It only supports the cs2uk language direction and, unlike CUNI-MH-v2, both training and inference were done at the sentence level.

C.7 CUNI-MH-v2 (Jon et al., 2025)

CUNI-MH-v2 is a constrained system trained on partially synthetic data sampled from the CzEng 2.0 dataset using LoRA and Contrastive Preference Optimization. We plan on releasing both the model and the filtered training data. It is fine-tuned from the EuroLLM-9B-Instruct model. We currently only support two language directions, en2cs and cs2de, and offer separate LoRA adapters for each. The translations were done on the paragraph level.

The models are available on Hugging Face: huggingface.co/hrabalm/CUNI-MH-v2-encs and huggingface.co/hrabalm/CUNI-MH-v2-csde.

C.8 CUNI-SFT (Jon et al., 2025)

This paper describes the joint effort of Phrase a.s. and CUNI/UFAL on the WMT25 Automated Translation Quality Evaluation Systems Shared Task. Both teams participated both in a collaborative and competitive manner, i.e. they each submitted a system of their own as well as a contrastive joint system ensemble. In Task 1, we show that such an ensembling—if chosen in a clever way—can lead to a performance boost. We present the analysis of various kinds of systems comprising both "traditional" NN-based approach, as well as different flavours of LLMs—off-the-shelf commercial models, their fine-tuned versions, but also in-house, custom-trained alternative models. In Tasks 2 and 3 we show Phrase's approach to tackling the tasks via various GPT models: Error Span Annotation via the complete MQM solution using non-reasoning models (including fine-tuned versions) in Task 2, and using reasoning models in Task 3.

The model is available on Hugging Face: huggingface.co/ufal/wmt25-cuni-sft.

C.9 CUNI-Transformer and CUNI-DocTransformer (Popel et al., 2022, 2019)

CUNI-Transformer and CUNI-DocTransformer rely on standard NMT training with Block backtranslation and optionally document-level training.

The models are available at lindat.mff.cuni.cz/repository/items/b1cfdecf-fda3-4198-a537-e58a20ddea60 and lindat.mff.cuni.cz/repository/items/4b5d758f-ca9e-4ca6-8129-2331928ba950.

C.10 DLUT_GTCOM (Zong et al., 2025)

This paper presents the submission from Dalian University of Technology (DLUT) and Global Tone Communication Technology Co., Ltd. (GTCOM) to the WMT25 General Machine Translation Task. Amidst the paradigm shift from specialized encoder-decoder models to general-purpose Large Language Models (LLMs), this work conducts a systematic comparison of both approaches across five language pairs. For traditional Neural Machine Translation (NMT), we build strong baselines using deep Transformer architectures enhanced with data augmentation. For the LLM paradigm, we explore zero-shot performance

and two distinct supervised fine-tuning (SFT) strategies: direct translation and translation refinement. Our key findings reveal a significant discrepancy between lexical and semantic evaluation metrics: while strong NMT systems remain competitive in BLEU scores, fine-tuned LLMs demonstrate marked superiority in semantic fidelity as measured by COMET. Furthermore, we find that fine-tuning LLMs for direct translation is more effective than for refinement, suggesting that teaching the core task directly is preferable to correcting baseline outputs.

C.11 Erlendur (Ingólfsdóttir et al., 2025)

We present Miðeind's system contribution for English-to-Icelandic translation. We participate in the Terminology Shared Task with the same system. Erlendur is a multilingual LLM-based translation system which employs a multi-stage pipeline approach, with enhancements especially for translations from English to Icelandic. We address translation quality and grammatical accuracy challenges in current LLMs through a hybrid prompt-based approach that can benefit lower-resource language pairs. In a preparatory step, the LLM analyzes the source text and extracts key terms for lookup in an English-Icelandic dictionary. Main results of the analysis and the retrieved dictionary results are then incorporated into the translation prompt. When provided with a custom glossary, the system identifies relevant terms from the glossary and incorporates them into the translation as well, to ensure consistency in terminology. For longer inputs, the system maintains translation consistency by providing contextual information from preceding text chunks. Lastly, Icelandic target texts are passed through our custom-developed seq2seq language correction model (Ingólfsdóttir et al., 2023), where grammatical errors are corrected. Using this hybrid method, Erlendur delivers high-quality translations, without fine-tuning.

C.12 HYT (Li, 2025)

This paper illustrates the submission system of the HYT team for the WMT25 General Machine Translation shared task. We submitted translations for all translation directions in the general machine translation task and test suites subtask. The ID of our submission in OCELoT system is 43, which can be categorized as being in the unconstrained track. The base model we use is Hunyuan-TurboS. Overall, we first performed continued pretraining(CPT) using open-source data to enhance the model's multilingual capabilities. Then, we used DeepSeek-V3-03241 to synthesize a large amount of parallel data and performed Reinforcement learning on the CPT model. Finally, we used ensemble learning to further improve translation quality.

C.13 GemTrans (Finkelstein et al., 2025)

Large Language Models have shown impressive multilingual capabilities, where translation is one among many tasks. Google Translate's submission to the 2025 WMT evaluation tries to research how these models behave when pushing their translation performance to the limit. Starting with the strong Gemma 3 model, we carry out supervised fine-tuning on high quality, synthetically generated parallel data. Afterwards we perform an additional Reinforcement Learning step, with reward models based on translation metrics to push the translation capabilities even further. Controlling the combination of reward models, including reference-based and quality estimation metrics, we found that the behaviour of the model could be tailored towards a more literal or more creative translation style. Our two submissions correspond to those two models. We chose the more creative system as our primary submission, targeting a human preference for better sounding, more naturally flowing text, although at the risk of losing on the accuracy of the translation. It is an open question to find the sweet spot between these two dimensions, which certainly will depend on the specific domain to handle and user preferences.

C.14 In2x (Pang et al., 2025)

This paper presents the open-system submission by the In2x research team for the WMT25 General Machine Translation Shared Task. Our submission focuses on Japanese-related translation tasks, aiming to explore a generalizable paradigm for extending large language models (LLMs) to other languages. This paradigm encompasses aspects such as data construction methods and reward model design. The ultimate goal is to enable large language model systems to achieve exceptional performance in low-resource or less commonly spoken languages.

C.15 IR-MultiagentMT (Kim, 2025a)

We introduce our model, referred to as Multi-agentMT, for participation in the WMT 25 General Machine Translation Shared Task. This model operationalizes the notion of an AI Agent by employing a multi-agent workflow known as Prompt Chaining (Briva-Iglesias, 2025) alongside the automatic MQM (Multidimensional Quality Metrics) error annotation framework designated as RUBRIC-MQM (Kim, 2025b). Our primary submission is developed through the Translate-Postedit-Proofread paradigm, whereby the positions of the errors are clearly marked and enhanced throughout the process. Our study suggests that a semi-autonomous agent scheme in Machine Translation is viable with an older and smaller model in some language pairs, resulting in comparable results with 2.3x faster speed and only 2% of the budget.

C.16 IRB-MT (Grubišić and Korencic, 2025)

Large Language Models (LLMs) have been demonstrated to achieve state-of-art results on machine translation. LLM-based translation systems usually rely on model adaptation and fine-tuning, requiring datasets and compute. The goal of our team's participation in the "General Machine Translation" and "Multilingual" tasks of WMT25 was to evaluate the translation effectiveness of a resource-efficient solution consisting of a smaller off-the-shelf LLM coupled with a self-refine agentic workflow. Our approach requires a high-quality multilingual LLM capable of instruction following. We select Gemma3-12B among several candidates using the pretrained translation metric MetricX-24-XL and a small development dataset. WMT25 automatic evaluations place our solution in the mid tier of all WMT25 systems, and also demonstrate that it can perform competitively for approximately 16% of language pairs.

C.17 Kaze-MT (Tan, 2025)

This paper describes the Kaze-MT submission to the WMT25 General Machine Translation task for the Japanese-Chinese track. The system relies on a minimalist Test-Time Scaling (TTS) pipeline composed of three stages: Sampling, Scoring, and Selection. In the sampling stage, we utilize zero-shot Qwen 2.5 models (72B and 14B) to generate 512 candidate translations under a fixed temperature schedule, encouraging diversity without compromising fluency. In the scoring stage, each candidate is evaluated using multiple quality estimation (QE) models, namely KIWI22, MetricX-24, and ReMedy-24. Finally, we select the final candidate based on rank aggregation across QE scores. Our approach requires no fine-tuning, in-context examples, or specialized decoding heuristics, and we participate in both constrained and unconstrained tracks. Preliminary results show competitive performance on automatic metrics, with final human evaluation results to be reported in the camera-ready version.

C.18 KIKIS (Iwakawa et al., 2025)

We participated in the constrained English–Japanese track of the WMT 2025 General Machine Translation Task. Our system collected the outputs produced by multiple subsystems, each of which consisted of LLM-based translation and reranking models configured differently (e.g., prompting strategies and context sizes), and reranked those outputs. Each subsystem generated multiple segment-level candidates and iteratively selected the most probable one to construct the document translation. We then reranked the document-level outputs from all subsystems to obtain the final translation. For reranking, we adopted a text-based LLM reranking approach with a reasoning model to take long contexts into account. Additionally, we built a bilingual dictionary on the fly from the parallel corpus to make the system more robust to rare words.

C.19 KYUoM (Xiong and Zhao, 2025)

This paper describes the KYUoM team's submission system for the WMT 2025 general translation task. We focused on exploring the capabilities of inductive generalization from a multimodal domain to a text-based domain of machine translation. Our submission system consists of a two-stage adaptation process with multimodal domain learning in the first stage and textual domain adaptation in the second stage for the English to Ukrainian task in the unconstrained track. The main advance is using a GAT adapter to achieve two-stage continuous learning for cross-modal generalization.

C.20 Laniqo (Guttmann et al., 2025)

This work describes Laniqo's submission to the constrained track of the WMT25 General MT Task. We participated in 11 translation directions. Our approach combines several techniques: fine-tuning the EuroLLM-9B-Instruct model using Contrastive Preference Optimization on a synthetic dataset, applying Retrieval-Augmented Translation with human-translated data, implementing Quality-Aware Decoding, and performing postprocessing of translations with a rule-based algorithm. We analyze the contribution of each method and report improvements at every stage of our pipeline.

The model is available on Hugging Face: huggingface.co/laniqo/WMT25-EuroLLM-9B-CPO.

C.21 NTTSU (Yin et al., 2025)

This paper presents the submission of NTTSU for the constrained track of the English–Japanese and Japanese–Chinese language directions at the WMT2025 general translation task. For each translation direction, we build translation models from a large language model by combining continual pretraining, supervised fine-tuning, and preference optimization based on the translation quality and adequacy. We finally generate translations via context-aware MBR decoding to maximize translation quality and document-level consistency.

The models are available on Hugging Face: huggingface.co/UtsuroLab/WMT25_En-Ja and huggingface.co/UtsuroLab/WMT25_Ja-Zh.

C.22 RuZH-Eole (no paper submission)

Eole NLP Submission uses Tower+ 9B model with an extra layer for quality estimation. It generates multiple hypotheses and rank them according to an internal score.

C.23 SalamandraTA (Gilabert et al., 2025)

In this paper, we present the SALAMANDRA**TA** family of models, an improved iteration of SALAMANDRA LLMs (Gonzalez-Agirre et al., 2025) specifically trained to achieve strong performance in translation-related tasks for 38 European languages. SALAMANDRA**TA** comes in two scales: 2B and 7B parameters. For both versions, we applied the same training recipe with a first step of continual pre-training on parallel data, and a second step of supervised fine-tuning on high-quality instructions. The BSC submission to the WMT25 General Machine Translation shared task is based on the 7B variant of SALAMANDRA**TA**. We first adapted the model vocabulary to support the additional non-European languages included in the task. This was followed by a second phase of continual pre-training and supervised fine-tuning, carefully designed to optimize performance across all translation directions for this year's shared task. For decoding, we employed two quality-aware strategies: Minimum Bayes Risk Decoding and Tuned Re-ranking using COMET and COMET-KIWI respectively.

We publicly release both the 2B and 7B versions of SALAMANDRA**TA**, along with the newer SALAMANDRA**TA**-V2 model, on Hugging Face: huggingface.co/LangTech-MT/salamandraTA-7b-instruct-WMT25.

C.24 SH (Shiroma, 2025)

We participated in the unconstrained track of the English-to-Japanese translation task at the WMT 2025 General Machine Translation Task. Our submission leverages several large language models, all of which are trained with supervised fine-tuning, and some further optimized via preference learning. To enhance translation quality, we introduce an automatic post-editing model and perform automatic post-editing. In addition, we select the best translation from multiple candidates using Minimum Bayes Risk (MBR) decoding with the use of COMET-22 and LaBSE-based cosine similarity as evaluation metrics.

C.25 Shy-hunyuan-MT (Zheng et al., 2025)

This paper presents our submission to the WMT25 shared task on machine translation, for which we propose **S**ynergy-en**h**anced polic**y** optimization, named Shy, a novel two-phase training framework that synergistically combines ensemble knowledge distillation with reinforcement learning optimization. In the first phase, we introduce a multi-stage training framework that harnesses the complementary strengths of multiple state-of-the-art large language models to generate diverse, high-quality translation

candidates. These candidates serve as pseudo-references to guide the supervised fine-tuning of our model, Hunyuan-7B, effectively distilling the collective knowledge of multiple expert systems into a single efficient model. In the second phase, we further refine the distilled model through Group Relative Policy Optimization, a reinforcement learning technique that employs a composite reward function. By calculating reward from multiple perspectives, our model ensures better alignment with human preferences and evaluation metrics. Extensive experiments across multiple language pairs demonstrate that our model **Shy-hunyuan-MT** yields substantial improvements in translation quality compared to baseline approaches. Notably, our framework achieves competitive performance with state-of-the-art systems while maintaining computational efficiency through knowledge distillation and strategic ensemble.

The model is available on Hugging Face: huggingface.co/collections/tencent/hunyuan-mt-68b42f76d473f82798882597.

C.26 SRPOL (Dobrowolski et al., 2025)

This work presents an innovative decoding approach utilizing the A* (A-star) algorithm, which generates a diverse and precise set of translation hypotheses. Subsequent reranking through the Noisy Channel Model Reranking and Quality Estimation selects the best among these diverse hypotheses, leading to a significant improvement in translation quality. This approach achieves up to a 0.5-point reduction in the MetricX-24 score and a 1.5-point increase in the COMET score. The A* algorithm can be applied to decoding in any LLMs or classic transformers. The experiment shows that by using freely available, open-source MT models, it is possible to achieve translation quality comparable to the best online translators and LLMs using only a PC under your desk.

C.27 Systran (Zhang et al., 2025)

We present an English-to-Japanese translation system built upon the EuroLLM-9B (Martins et al., 2025) model. The training process involves two main stages: continue pretraining (CPT) and supervised fine-tuning (SFT). After both stages, we further tuned the model using a development set to optimize performance. For training data, we employed both basic filtering techniques and high-quality filtering strategies to ensure data cleanness. Additionally, we classify both the training data and development data into four different domains and we train and fine-tune with domain specific prompts during system training. Finally, we applied Minimum Bayes Risk (MBR) decoding and paragraph-level reranking for post-processing to enhance translation quality.

The models are available on Hugging Face: huggingface.co/collections/Systran/wmt25-en-ja-6867eed78ea21e28a282aaed.

C.28 TranssionMT (no paper submission)

The team employs the Transformer architecture and finetuning the translation of a specific language within the multilingual pretrained model to enhance its translation performance. They adopts various strategies, such as finetuning language model instructions, joint training of similar languages, integrated model decision-making, and non-English data mining, all aimed at improving the translation outcomes.

C.29 TranssionTranslate (no paper submission)

This paper presents our machine translation system developed for the WMT25 shared task. Our approach leverages state-of-the-art neural architectures, including transformer-based models with advanced pre-training and fine-tuning techniques. We focus on multilingual and domain-adaptive strategies to enhance translation quality across diverse language pairs. Key features include: (1) large-scale pretraining on parallel and monolingual corpora, (2) dynamic data filtering and domain adaptation, (3) ensemble and reranking methods to improve fluency and accuracy. We explore both supervised and zero-shot settings, particularly for low-resource languages. Our system demonstrates competitive performance on WMT25 evaluation benchmarks, achieving improvements in BLEU, TER, and human evaluation metrics. We analyze challenges such as rare word translation, syntactic divergence, and robustness to noisy inputs. The results highlight the effectiveness of our approach in balancing generalization and language-specific optimization. This work contributes insights into scalable and adaptive MT systems, with potential

applications in multilingual NLP tasks. Future directions include better handling of linguistic diversity and real-time adaptation.

C.30 UvA-MT (Wu et al., 2025)

The UvA-MT's submission is competing in the unconstrained track across all 16 translation directions. Unusually, this year we use only the source side of the test set to generate synthetic data for LLM training, and translations are produced using pure beam search for submission. Overall, our approach can be seen as a special variant of data distillation, motivated by two key considerations: (1) perfect domain alignment, where the training and test domains are distributionally identical; and (2) the strong teacher model, GPT-4o-mini, offers high-quality outputs as both a reliable reference and a fallback in case of mere memorization. Interestingly, the outputs of the resulting model, trained on Gemma3-12B using Best-of-N (BoN) outputs from GPT-4o-mini, outperform the original BoN outputs in some high-resource languages across various metrics, including CometKiwi-XXL which is the very metric used for BoN selection. We attribute this to a successful model ensemble, where the student model (Gemma3-12B) retains the strengths of the teacher (GPT-4o-mini) while implicitly avoiding their flaws. Our experiments on other datasets, such as WMT24++, also confirm this observation.

C.31 Wenyiil (no paper submission)

This paper introduces Wenyiil, an advanced translation system based on a large language model (LLM). This multilingual model supports 13 language directions, and its superior performance is derived from a comprehensive training process that includes multi-stage supervised fine-tuning (SFT) for translation tasks and a two-stage post-training scheme. Furthermore, we propose a novel hybrid decoding strategy to overcome the limitations of standard decoding. This method integrates word alignment with an advanced Minimum Bayes Risk (MBR) re-ranking algorithm. This approach not only enhances translation stability but also ensures excellent accuracy across diverse linguistic contexts.

C.32 Yandex (Karpachev et al., 2025)

This paper describes Yandex's submission to the WMT25 General Machine Translation task. We participate in the English-to-Russian translation direction and propose a purely LLM-based translation model. Our training procedure comprises a training pipeline of several stages built upon YandexGPT, an in-house general-purpose LLM. In particular, firstly, we employ continual pretraining (post-pretrain) for MT task for initial adaptation to multilinguality and translation. Subsequently, we use SFT on parallel document-level corpus in the form of P-Tuning. Following SFT, we propose a novel alignment scheme of two stages, the first one being a curriculum learning with difficulty schedule and a second one - training the model for tag preservation and error correction with human post-edits as training samples. Our model achieves results comparable to human reference translations on multiple domains.

C.33 Yolu (no paper submission)

This paper details Yolu's submission for the WMT'25 General Machine Translation Task. Our work, situated within the constrained track, investigates the efficacy of Reinforcement Learning (RL) in enhancing machine translation. Our system is built upon the open-source Qwen3 model. We introduce a robust methodology for continuous performance improvement, which combines meticulous data cleaning with advanced data distillation techniques. This is complemented by a multi-stage optimization strategy, sequentially employing Continued Pre-Training (CPT), Supervised Fine-Tuning (SFT), Contrastive Preference Optimization (CPO), and a novel policy optimization algorithm, Decoupled Clip and Dynamic sAmpling Policy Optimization (DAPO). Furthermore, we integrate a Quality Estimation (QE) model to facilitate online QE distillation, thereby refining the model's output during the decoding phase.

D Official Ranking Results (extends Section 7.4)

Results tables legend

The human score is the micro-average of human judgments across all domains and double annotations (single annotations for MQM language pairs). AutoRank is calculated from automatic metrics as per (Kocmi et al., 2025b). Significance testing is done using a Wilcoxon signed rank test with a p-value threshold of 5%. The rank range for the ith model begins as $\langle i, i \rangle$ and is expanded in both directions until a significant difference is found. Clusters are formed such that their constituent rank ranges do not overlap.

Systems are either constrained (white), or unconstrained (gray). Systems that do not officially support the language pair are marked with 🚫 and those where language support cannot be verified are marked with ❓. The [M] suffix marks systems (submitted by the WMT organizers) that were trained/tuned with specific MT instructions, but prompted without these specific instructions (using a generic setup, same for all LLMs, see Section 4.2), which could disadvantage these systems.

English→Arabic (Egyptian)

Rank	System	Human	AutoRank	literary	news	social	speech
1-1	**Human**	78.5		83.8	74.7	79.1	77.3

E Analysis of Human Evaluation Scores

Figure 4 shows the correlation between ranks obtained from human evaluation ranks and automatic evaluation (AUTORANK) for each system. Figure 5 shows the distribution of human evaluation ranks across all systems. Finally, Figure 6 and Figure 7 break down the distribution of average human evaluation scores by language pair and by domain, respectively.

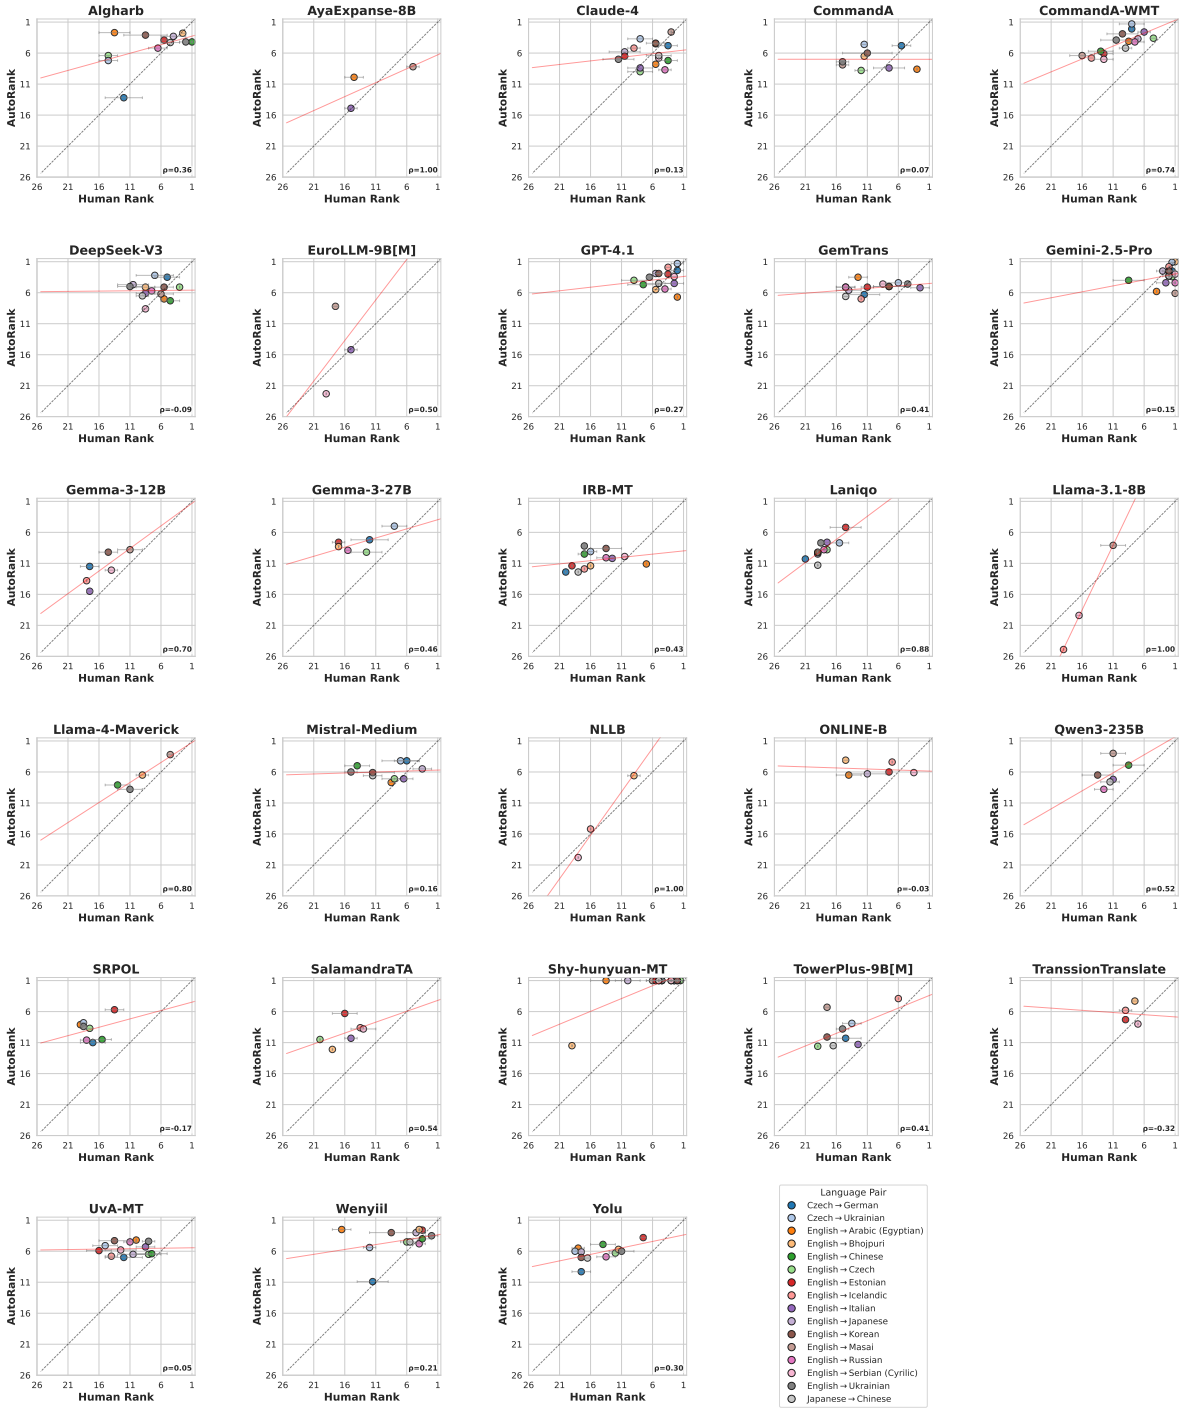

Figure 4: Correlation between automatic (AUTORANK) and human evaluation ranks by model (lower=better). Whiskers indicate the range of human ranks. The gray diagonal represents perfect correlation; points above this line mean AUTORANK ranked a model higher than humans, and vice versa. Colors denote language pairs, and the red line shows the Spearman correlation (ρ).

Figure 5: Distribution of ranks from human evaluation for each system, with whiskers indicating the assigned ranges. Systems are sorted by the number of "wins" (which refers to the situation when a system is being ranked first or has a rank range that includes the first position) and then by average rank.

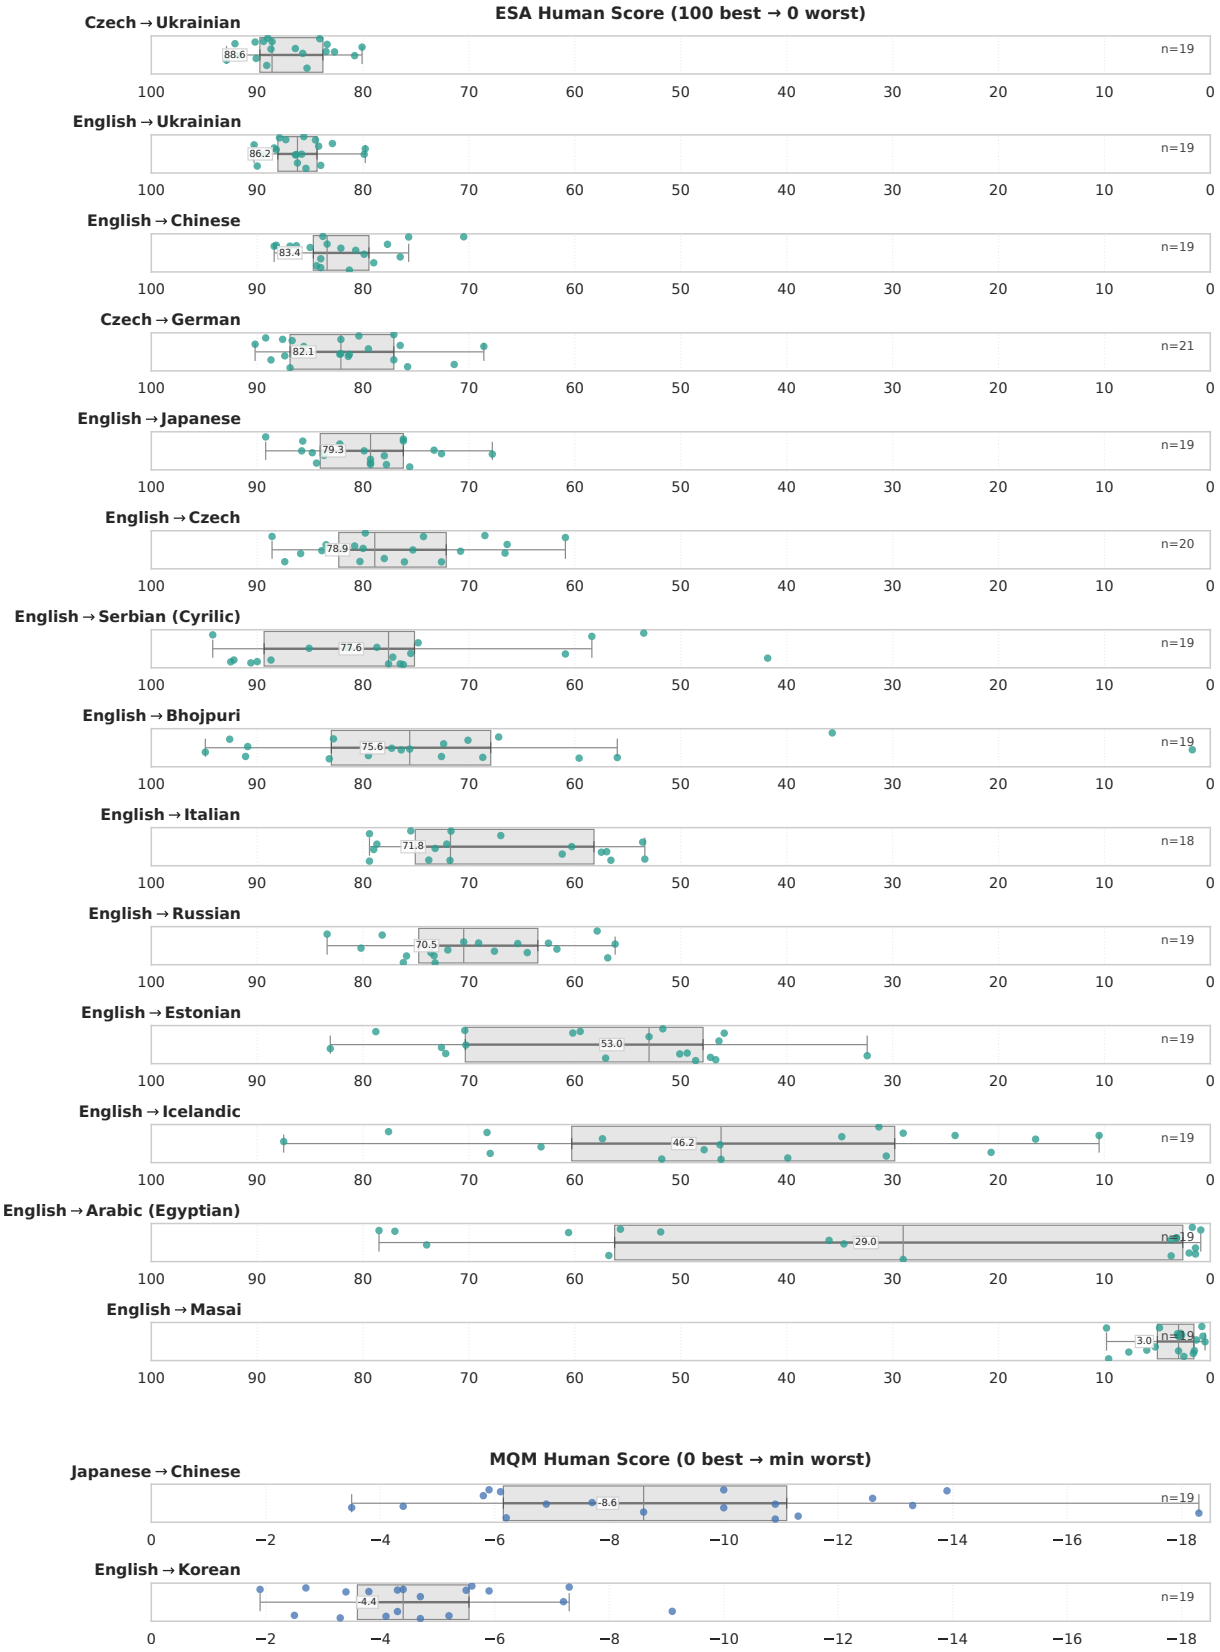

Figure 6: The distribution of human evaluation scores for each language pair. Pairs are grouped by their evaluation protocol, with ESA at the top and MQM at the bottom.

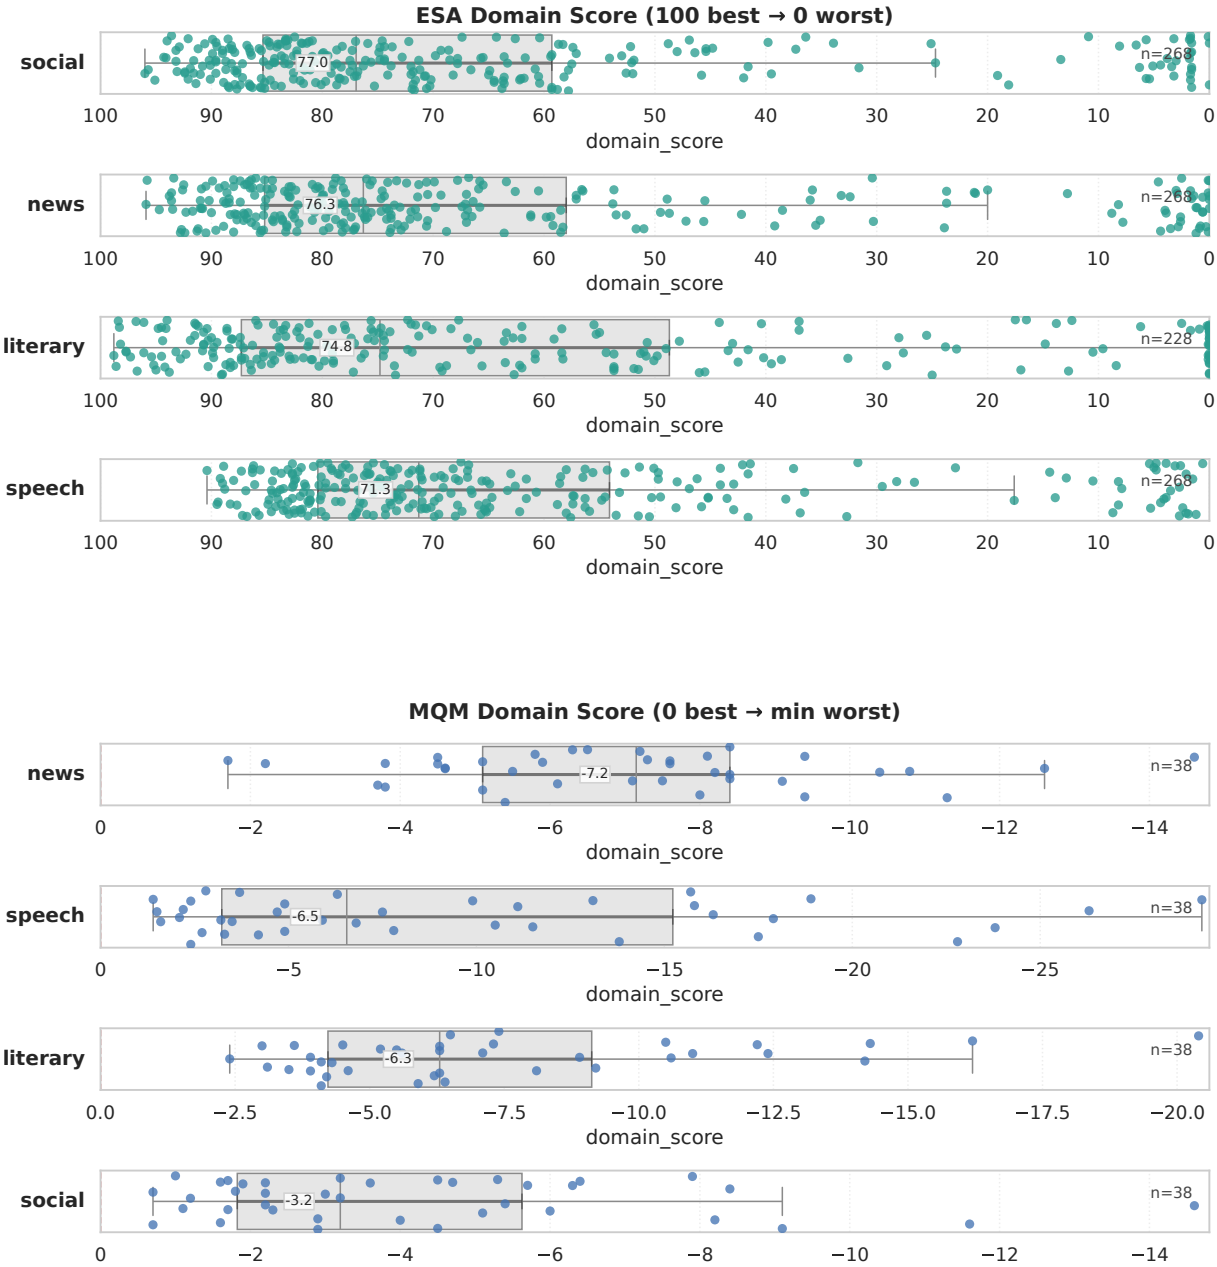

Figure 7: Distribution of scores by domain for four main domains. ESA scores are presented at the top, while MQM scores are presented at the bottom.

F Dataset Statistics

Statistics for the parallel training data provided for the shared task are shown in Tables 18 and 19.

Abstract

The WMT25 Multilingual Instruction Shared Task (MIST) introduces a benchmark to evaluate large language models (LLMs) across 30 languages. The benchmark covers five types of problems: machine translation, linguistic reasoning, open-ended generation, cross-lingual summarization, and LLM-as-a-judge. We provide automatic evaluation and collect human annotations, which highlight the limitations of automatic evaluation and allow further research into metric meta-evaluation. We run on our benchmark a diverse set of open- and closed-weight LLMs, providing a broad assessment of the multilingual capabilities of current LLMs. Results highlight substantial variation across sub-tasks and languages, revealing persistent challenges in reasoning, cross-lingual generation, and evaluation reliability. This work establishes a standardized framework for measuring future progress in multilingual LLM development.

1 Introduction

We are witnessing rapid development of multilingual large language models (LLMs). However, as pointed out by recent works (Kreutzer et al., 2025; Wu et al., 2025; Cruz Blandón et al., 2025), multilingual benchmarks lack comprehensiveness, scientific rigor, and consistent adoption across research labs, undermining their value in guiding multilingual LLM development. Among common problems are benchmark contamination (Ahuja et al., 2024), label noise (Chalamalasetti et al., 2025), reliance on non-native (machine-)translated instances (Chen et al., 2024b), and inconsistent evaluation pipelines. For instance, some leading LLM descriptions report multilinguality solely through translated MMLU. There is a mist surrounding multilingual evaluation that we aim to see through with this year's MIST shared task.

We introduce a novel multilingual evaluation benchmark that systematically assesses several key capabilities of LLMs across 30 diverse languages using the following sub-tasks:

- **Machine Translation (MT)**: A standardized, well-defined cross-lingual task.
- **Linguistic Reasoning (LR)**: Structured linguistic problem solving in multiple languages.
- **Open-Ended Generation (OEG)**: Using localized open-ended questions to assess language proficiency instead of specific capabilities.
- **Cross-lingual Summarization (XLSum)**: Synthesizing multilingual content from multiple documents written in different languages.
- **LLM-as-a-Judge**: Testing the effectiveness of LLMs in evaluating the quality of outputs in other sub-tasks that do not have definitive answers (MT, OEG, and XLSum).

We benchmark several of the most commonly used open- and closed-weight systems on our tests. These tests provide a multi-faceted evaluation framework that highlights the strengths and limi-

Proceedings of the Tenth Conference on Machine Translation, pages 414–435
November 8-9, 2025

Linguistic Reasoning	Here are some word combinations in Hadza and their English translations: 1. chutisa zzokwanako: the giraffe's neck 2. athuitcha slimibii: the men's axe (for collecting honey) [. . .] Translate into Hadza: the male impalas' horns
Open-Ended Generation	As a news reporter, write an article about the opening of a new shopping complex, including who will enjoy it and what activities are available.
Cross-lingual Summarization	Fass bitte diese 6 Bewertungen eines Produkts auf Amazon auf Deutsch zusammen. Fleetwood Mack är som de är. Sköna att lyssna på. I am super pleased with my purchase and would order from this seller again. [...]
Machine Translation	You are a professional Czech-to-Ukrainian translator, tasked with providing translations for use in Ukraine. [...]
LLM-as-a-judge	Score the response generated by a system to a user's request in Lithuanian on a Likert scale from 1 to 7. The quality levels associated with numerical scores are provided below: [...]

Table 1: Example prompts for each sub-task.

tations of current LLMs across diverse linguistic phenomena while drawing on the rigorous principles established within the MT evaluation research.

In addition to automatic metrics, we conduct human evaluation for all sub-tasks without definitive answers, which is then used to assess LLM-as-a-judge systems. Test sets, system outputs, and human judgments are released with a permissive license.[1]

2 Data and Methodology

In this section, we describe the datasets and preparation steps used for each of the sub-tasks in our benchmark. For every sub-task, we curated or adapted data across up to 30 languages. The high-level statistics are in Table 2. The following sections detail the sources of the data, the translation or localization processes applied, and any additional filtering or validation steps specific to each sub-task.

2.1 Linguistic Reasoning

The data for the linguistic reasoning sub-task were sourced from the 2024 International Linguistics Olympiad (IOL). In this olympiad, high school students compete in solving linguistic puzzles. Problems and solutions are released online and manually translated into the participants' languages. Previous benchmarks built from previous linguistics olympiads in English, such as Linguini (Sánchez et al., 2024) and LINGOLY (Bean et al., 2024), have shown that this type of puzzle is challenging even for the best LLMs. To evaluate multilinguality, we propose a multilingual version of this problem. This enables us to not only benchmark LLMs on challenging, unseen problems but also measure language disparities. The key to these puzzles is not retrieving acquired knowledge, but rather applying reasoning.

	Langs	Samples per lang
Machine Translation	30	384
Linguistic Reasoning	15	90
Open Ended Generation	20	100
Cross-lingual Summarization	14	350
LLM-as-a-judge MT	16	1520
LLM-as-a-judge OEG	10	2256
LLM-as-a-judge XLSum	14	3200

Table 2: Number of languages and the number of samples (prompts) for each language or language pair in case of MT.

From problem PDFs to evaluation prompts IOL problems and solutions are published as PDFs under the CC-BY-SA 4.0 license.[2] They are typeset in the same LaTeX, format for all languages, which motivates our approach of tuning an automatic extraction for English, and then transferring it to the other languages. First, we manually extract questions and solutions from the PDFs for the five tasks of IOL (languages are Koryak, Hadza, Komnzo, Dâw, and Yanyuwa), which includes breaking tasks into sub-tasks (e.g. turning a matching task with four phrases to match across languages into four individual tasks), capturing metadata such as task authors, unifying task formulations and formats across task types. Then, we prompt an LLM to repeat this process for the other languages.[3] Last, with the help of human annotators that are proficient in the respective languages, we fix any errors, post-edit for cross-task consistency and translate task-level instructions.[4] This yields a total of

[1] github.com/wmt-conference/wmt-mist

[2] ioling.org

[3] A detailed description of this process is in Appendix A.

[4] Early attempts to translate tasks automatically rather than relying on parsing the language-specific solutions, quickly showed that automatic translation is not well-equipped for this task (at least not out-of-the-box) because the task involves disambiguating many single-word terms without much context (e.g. the word " roast" could be translated as noun or verb and in a literal or abstract sense), and special handling of

Grounding	localized	46
	generic	54
Type	brainstorming	23
	creative	35
	informational	25

Available Locale	ar_EG, bn_BD, cs_CZ, de_DE, el_GR, en_US, fa_IR, hi_IN, is_IS, id_ID, it_IT, ja_JP, kn_IN, ko_KR, ro_RO, ru_RU, sr_RS (both Latin and Cyrillic), uk_UA, zh_CN.	

Table 3: A breakdown of the 100 test questions in the open-ended generation sub-task.

90 prompts per language, covering five task types (classification (4), editing (1), fill-in-blanks (20), mapping (24) and translation (41)) for 15 languages (Chinese, Czech, Dutch, English, Estonian, French, German, Japanese, Korean, Persian, Portuguese, Russian, Spanish, Swedish, Ukrainian). Languages were chosen based on overlap with the 30 languages from the General MT task. For the final evaluation prompts, we add a simple instruction for context and answer format to each puzzle (e.g. English: "Solve the following linguistic puzzle with the help of the given context. The last line of your response should only contain the solution within square brackets [], nothing else."). We chose not to explicitly prompt the models for reasoning in order to avoid introducing any reasoning instruction bias and favoring models that are explicitly trained for reasoning. As a result, we can analyze how much each model tends to reason about each of these, but without having any expectations on the correctness, form, or volume of reasoning traces.

2.2 Open-Ended Generation

In this sub-task, we test multilingual language proficiency, e.g. generating native-sounding, useful, and coherent responses. Below a language's surface form are culture, values, and knowledge, so we also want to test LLMs' true ability grounded in the use of each language. The core motivation behind this is that LLMs sound native in English, but their responses in other languages are non-natural, contain English phenomena, or sound robotic (Guo et al., 2025). While some open-ended generation test sets exist, e.g. mArenaHard (Cohere Labs et al., 2024), they are often translated from English (Chen et al., 2024b) and skewed towards narrow domains like coding and math, which are not typical multilingual LLM use cases. Therefore, we focus on building a test set that asks native open-ended questions in many different domains, rather than specific tasks, e.g. writing a news article about a topic.

We prepared 100 questions manually with the help of LLMs, localized them into different languages, and asked native speakers to post-edit them to make them more natural and native. As a result, this multilingual test set contains comparable questions localized into each locale (language and country/region). The details of the process for question creation and localization are as follows.

English question creation First, we obtained a set of 100 English questions via two complementary workflows:

1. Three authors of this paper wrote a small pool of diverse questions.
2. We iteratively fed five randomly selected human-authored questions to two LLMs (GPT-4.1-mini and Command A), asking for a new question.
3. Then we manually inspected and post-edited these questions while mixing them with the original human-written questions.

To ensure each question's applicability to multiple locales, all locale-specific mentions stay as placeholders, e.g., using "`{language}`" instead of "English" in prompts like "Please suggest an idiom in `{language}`".

Localization and quality control We localized the English questions into 19 more unique language-writing script combinations, each of which is designated a country too, to better ground questions in locales. A full list of locales is available in Table 3, and the five-step process is detailed below:

1. Localization: We used four LLMs[5] to localize the questions and replace placeholders with locale-specific content, yielding four candidate variants per question.
2. Baseline: We also generated a reference translation for each question using Google Translate.
3. Sanity Check: To prevent LLMs from answering the question rather than faithfully localizing it, using the Google Translate version as a reference, we discarded any model variant that has a chrF score below 30 or exceeds the baseline

grammatical annotations such as for singular and plural.

[5]DeepSeek V3, Gemini 2.5 Pro, Command A, GPT 4.1

length by more than 50% per NLLB-200 tokenization.

4. Selection: From the remaining variants, we discarded the lowest-scoring chrF candidate, then randomly selected a variant translation for inclusion. If no variant passed filtering, we defaulted to the Google Translate baseline.
5. Human Inspection: we conducted a review and applied post edits if necessary for all languages to minimize non-nativeness and translationese.

Nature of the questions In Table 3, we present a breakdown of the types of test questions and expected responses. By counting placeholders in the seed English questions, we find that 46 questions explicitly mention a language/country-specific entity (i.e., locale-grounded), and 54 questions are more generic. Using Gemini 2.5 Pro followed by human inspection, we classified the nature of the expected responses into one of "brainstorming", "creative", "informational", or "professional". It is worth noting that while we assigned only one label to each question, the labels are not strictly mutually exclusive.

2.3 Cross-lingual Summarization

Our cross-lingual summarization dataset combines multilingual review data from two complementary sources: Amazon product reviews and Google Maps restaurant reviews. The dataset construction process involved systematic sampling, language balancing, and content filtering to ensure high-quality cross-lingual evaluation data.

Data collection We integrated data from two distinct domains to maximize linguistic diversity: Amazon product reviews for consumer products, and Google Maps restaurant reviews for restaurants This resulted in an initial scraped dataset of 12,040 reviews spanning 853 products and restaurants. Each data item was paired with a product or restaurant-specific summarization prompt in 14 target languages: Arabic (Egyptian), Czech, Chinese (Simplified), French, German, Hindi, Indonesian, Italian, Japanese, Korean, Russian, Spanish, Swedish, and Turkish. The summarization prompt instructions were created by translating the original English summarization prompt into all target languages, with all translations checked by proficient speakers of each respective language to ensure linguistic accuracy and cultural appropriateness.

Content filtering and quality control We applied comprehensive filtering criteria to ensure high-quality multilingual content suitable for cross-lingual evaluation:

- Language-based filtering: Using language identification[6], we omitted reviews in languages not covered by the sub-task and retained only products/venues with reviews in more than one languages.
- Content length filtering: Reviews shorter than 50 characters (Amazon) or 20 characters (Google Maps) were removed as non-informative. We applied IQR-based outlier removal per language to eliminate excessively long individual reviews, while enforcing a 1,500-character limit on the final merged multi-document input for manageable human evaluation.
- Language pair balancing: We removed over-represented language combinations to maintain dataset balance and promote multilingual scenarios. We implemented a mixed-content counting algorithm that handles both alphabetic and logographic writing systems appropriately.

Balanced sampling To ensure equal representation of each target language while maximizing data diversity, we implemented a two-stage sampling approach, which first maximizes coverage across unique data items, then achieves exactly 350 examples per target language (4,900 total examples). We prioritized examples without English input to promote true cross-lingual scenarios for less-explored languages.

Data characteristics The final dataset contains 1.1M words across all examples, with an average of 230 words per example. it exhibits strong cross-lingual properties: 86.3% of examples require summarization in a target language different from any of the input languages, and 46.8% contain no English in the source reviews. The dataset comprises 66.0% Google Maps restaurant reviews (3,232 examples) and 34.0% Amazon product reviews (1,668 examples).

2.4 Machine Translation

The MT sub-task adopts the WMT25 General MT test set; full details on data sourcing, difficulty sampling, and human references collection are documented in Kocmi et al. (2025a).

[6] github.com/saffsd/langid.py

Sources and domains Source documents were collected across six domains (news, social, speech, literary, educational, dialogue) and three source languages (Czech, English, Japanese). Speech includes source audio with ASR transcripts, and social includes thread screenshots, with the objective of looking at some of the impacts of multimodal translation. The focus is on the most recent data possible to minimize potential overlap with the pretraining and fine-tuning data of the models under evaluation. All source texts were originally authored in the source language. This approach is crucial to avoid "translationese" in the source texts, which can negatively affect evaluation accuracy (Toral et al., 2018; Freitag et al., 2019; Läubli et al., 2020; Graham et al., 2020). To balance domains and source languages, for each domain and source language combination, we targeted ∼9k words and 60–100 segments, with an average segment length of ∼100 words. This design enables the micro-averaging of results across languages and domains without any single category disproportionately influencing the final scores. However, there are some exceptions, as keeping these variables fixed was impractical. For example, the average segment length for the English and Japanese Speech data is 145.27 and 180.59 words, respectively, which is higher than the 100-word objective. Similarly, the dialogue domain's segments have an average length of 178.8 and 147.3 words, respectively. Comprehensive domain-specific collection procedures and final test set statistics are detailed in Kocmi et al. (2025a).

Translation instructions There is no standardized prompt instructions for WMT machine translation evaluation, various are used, from simple 'Translate into {target_lang}:' to more complex instructions adding additional instructions such as 'Your goal is to accurately convey the meaning and nuances of the original {source_lang} text while adhering to {target_lang} grammar, vocabulary, and cultural sensitivities.' (Deutsch et al., 2025).

For our use case, we extend the instruction to cover more details that human translators are asked for. Furthermore, we modify the instructions for each domain. Detailed prompt instructions are in Table 18.

2.5 LLM-as-a-judge for OEG and XLSum

LLM-as-a-judge has recently emerged as an automated solution to open-ended generation evaluation (Zheng et al., 2023b; Verga et al., 2024). It achieves high correlation with human judgment, but its efficacy for languages other than English remains little known (Son et al., 2024). To evaluate the capabilities of models to perform quality assessment of other LLM outputs, we set up the sub-tasks of LLM-as-a-judge for open-ended generation, cross-lingual summarization, and machine translation, where participating systems run evaluation on system outputs from those sub-tasks.

The LLM judges are given the same instructions provided to human annotators, and are assessed by computing their judgments' correlation to human judgment. To evaluate LLM-as-a-judge for the OEG and XLSum sub-tasks, we take all samples that are evaluated with human annotators and use a prompt instruction to judge the system output on a Likert scale of 1–7. For each system output, we run LLM-as-a-judge separately on different evaluation criteria, guided by a rubric each. Specifically:

- OEG: instruction following, naturalness, and coherence
- XLSum: faithfulness, coverage, naturalness, and coherence

The exact prompt instructions are provided in Appendix B. As human evaluation was available for only a subset of languages and systems, LLM-as-a-judge was tested on the same set of data.

2.6 LLM-as-a-judge for MT

Automatic machine translation evaluation is the catalyst of progress in translation technologies, offering a quick, low-cost signal of quality. Early metrics were string-matching against a reference, such as BLEU or ChrF (Papineni et al., 2002; Popović, 2015), which were replaced by trained metrics, such as COMET or MetricX (Rei et al., 2020; Juraska et al., 2023), and finally LLM-as-a-judge (Kocmi and Federmann, 2023). Even though each replacement increased the correlation with human judgment of translation quality, new concerns have emerged regarding language bias, robustness (Moghe et al., 2025; Zouhar et al., 2024a,b), and self-bias for evaluation (Wataoka et al., 2024; Zheng et al., 2023a; Stureborg et al., 2024). This meta-evaluation of automated metrics is usually handled by the WMT Metrics Shared Task (Lavie et al., 2025; Freitag et al., 2024).

In order to test the capabilities of models to perform as LLM-as-a-judge to judge machine translation, we adjust the GEMBA-DA (Kocmi and Fe-

Table 5: Aggregate results across four sub-tasks, converted into percentile ranking (100%=first).

dermann, 2023) prompt with the latest WMT25 human evaluation instruction. The exact prompt instruction is in the Appendix B.

3 Benchmarked Models

For this shared task, we defined two categories for model participation: constrained with several restrictions on model size and licensing; and unconstrained without any limitations. The same way as the General Machine Translation task (Kocmi et al., 2025a). Specifically, the constrained category is restricted to models with fewer than 20B parameters and requires that models be shared as open weights.

Unfortunately, our shared task did not obtain any (valid) participating systems. However, we collected and benchmarked outputs of popular models. The selection process was to identify the strongest-performing system per category for each of the popular model families. This approach ensured that both constrained and unconstrained models were consistently represented; the resulting model list thus reflects a broad yet balanced selection of models, enabling multilingual assessment of the current LLM landscape across languages and problems.

The list of all systems is in Table 4. During the output collection, we ran into budget and API throttling restrictions and thus could not collect some of the systems' outputs for all sub-tasks. When collecting outputs, we set the temperature to 0 and used a unified script.[7]

4 Results

In this section, we present the results and key insights for each sub-task and benchmarked model. Although automatic evaluation was applied to all prompts and outputs, human evaluation was not conducted for all tasks, systems, or languages, due to budget constraints and annotator availability. Nonetheless, human evaluation often proved more reliable than automatic metrics, so we release all annotations for future work on meta-evaluation.

4.1 Linguistic Reasoning

In order to evaluate linguistic reasoning, we choose to break them as much as possible into tasks so that we can grade LLM answers as precisely as possible (which distinguishes this work from previous linguistic reasoning benchmarks). Depending on the task type, we choose either exact match (classification, mapping, fill-in-blanks, editing) or ChrF (translation) as a metric. The scores have to be taken with a grain of salt because ChrF is likely not perfectly expressing the degradations between useless and perfect translation. We assume it rather overestimates translation quality compared to IOL judges. Each task comes with a number of points ([0.5, 1.0, 1.5, 2.0, 2.5]), summing to 20

Table 6: Results (number of points) for the linguistic reasoning sub-task (LR) across languages.

points per task and 100 points in total. Points express difficulty, which is not the same across tasks, e.g. translation tasks typically give more points than mapping tasks. The final metric is the sum of prompt-level scores ([0–1]) multiplied by their points, such that the maximum attainable score for each language is 100. The final model ranking is determined by the average number of points across languages. The number of obtained points (out of 100) for each model and language is shown in Table 6. Below are our three key observations.

First, we note that the maximum score in a single language is 40.9 and the maximum average score is 36.3, **indicating headroom** for this kind of task overall. All models failed the majority of tasks. Due to the niche-ness of linguistic reasoning (as opposed to mathematical reasoning), it is unlikely that any of the models has seen very similar tasks during training, which lets this task measure generalization more than memorization. In the 2024 IOL, the winning participant scored 79[8] with human and not automatic scoring, but presented with the same tasks in their mother tongue. The top-scoring model here would have barely made it to a Bronze medal.

Second, the **model ranking is fairly consistent across languages in the top ranks**, with the leading model being Gemini 2.5 Pro across all languages, Claude 4 following in second place, and DeepSeek V3, GPT4.1, and Llama 4 Maverick alternating in place 3. As expected, model size also plays a major role in the ranking: closed-source (presumably large) LLMs are leading in the subtask, followed by CommandA and Qwen3 235B. Notably, Gemma 3 shows good multilingual reasoning performance, with its 27B and 12B versions outperforming TowerPlus at 72B and Aya Expanse at 32B. In the 7–9B range, Llama 3.1 8B is the best. Still, at this model size, we see a steep decline when moving from higher to lower-resource (or unsupported) languages, which is partially due to a lack of instruction following and failing to respond in the required answer format.

Third, most surprisingly, we find that **English is not the language that most models perform strongest in**, although it typically dominates reasoning tasks like math (Chen et al., 2024a). In fact, the "best" solution to the tasks was found by Gemini 2.5 Pro with Korean as the instruction language. In particular, the stronger models show surprising performance drops in English: For Claude, the top performance is 33.8 in German or Spanish, while English lags behind with 24.6 points, scoring the lowest across all languages. Overall, only Gemma 3 12B, Qwen2.5 7B, Aya Expanse 8B, CommandR7B, and EuroLLM 9B performed better in English than all other languages, and in these cases only with a small, perhaps negligible margin.

Table 8: Per-rubric results for the cross-lingual summarization sub-task. The points are on a Likert-7 scale where 7 is the maximum. See a per-language breakdown in Appendix E Table 20.

Explanations for this could be that prompting in other languages brings up the context that is more favorable for solving linguistic reasoning tasks, or that it is just the lack of English dominance in task-relevant data that usually gives it an advantage for other tasks like math or knowledge retrieval. Another explanation could be that model uncertainty might generally be quite high, so that resampling within the same language could cause similar variance as the one we see across languages. We invite future work to dive further into these questions.

4.2 Open-Ended Generation

The open-ended generation sub-task is human-evaluated. We designed a rubric to assess three aspects: instruction following, naturalness, and coherence. This rubric is given to both human evaluators and LLM judges. We only human-evaluated a subset of OEG outputs: 16 systems, 10 languages, and the same 46 questions for all system-language combinations. This is because some questions led to an overly long response, and TowerPlus and EuroLLM models had very high failure rates.

Results are shown in Table 7, with models ranked by their average scores on naturalness, instruction following, and coherence, across all languages. Three points stand out. First, proprietary models generally perform better, except for DeepSeek V3, which is a large open-source mix-of-expert model. Second, performance differences among the leading systems are narrow. Third, naturalness scores show a wider spread than instruction following or coherence, implying a larger gap between the strongest and weakest systems, and highlighting the limitations of systems to produce native sounding text that can be directly used.

4.3 Cross-lingual summarization

We performed a rubric-based human evaluation similar to the setup in OEG. We specifically test for naturalness, faithfulness, coherence, and coverage. We evaluated all 14 target languages in the sub-task. Annotators were proficient in the target language and English but were not expected to speak any other language; therefore, we translated source reviews in all other languages to English using Gemini 2.5 Flash. The user interface allowed them to view the original phrasing of the reviews, if desired.

Three models were excluded from human evaluation for the following reasons: the two EuroLLM models frequently copied input summaries in source languages rather than summarizing them, and CommandR7B had an issue with outputting Polish rather than Czech. Given the novelty and current lack of this type of problem in the field, we conducted the human evaluation for all 17 remaining systems that did not exhibit these evident issues.

Due to budget constraints, we restricted the number of evaluated outputs to 18, resulting in 306 examples rated for each language. The samples were selected based on output diversity using BLEU as the metric. We anticipate that a diverse set of outputs with human ratings will help future efforts in validating automatic metrics for this problem.

We present our preliminary analysis based on 12 target languages in Table 8. When averaged across all target languages, closed-source models have an advantage, with Gemini 2.5 Pro being the best-performing system in the unconstrained track. However, open-weight models are not far behind, led by Gemma3-27B. Model size seems to matter with all of the constrained systems, except for Gemma 3 12B, which punches above its weight, consistently showing lower scores across all languages.

Most models performed well (average rating of 5 and higher) on German, French, Chinese, Italian, Russian, and Spanish. Japanese was the most challenging language. Egyptian Arabic was the most divisive language with 4 clusters, showing a clear advantage of Gemini 2.5 Pro, GPT 4.1, and Claude, with all other models having an average score below 5. Naturalness was the weakest aspect of the generated summaries, often suffering from the models not adhering to the specifically requested language or dialect, or containing untranslated quotes from the source documents.

4.4 Machine Translation

Automatic evaluation We evaluate the MT subtask across 31 language pairs and report AUTORANK, a rank induced by automatic MT metrics where lower is better (1 is best). The AUTORANK is a combination of five different metrics Kocmi et al. (2025a) from three distinct metric families:

- **LLM-as-a-Judge (reference-less).** We use GEMBA-ESA (Kocmi and Federmann, 2023) with two independent judges: GPT 4.1 [9] and CommandA (Cohere et al., 2025), both in a reference-less setting.
- **Trained Reference-based Metrics.** Two supervised metrics trained to approximate human quality judgments with references: MetricX-24-Hybrid-XL[10] (Juraska et al., 2024) and XCOMET-XL[11] (Guerreiro et al., 2024).
- **Trained Quality Estimation (QE).** The reference-less QE metric CometKiwi-XL[12] (Rei et al., 2023), which is also trained to mimic human judgments.

This combination of reference-based and reference-less (or QE) methods is designed to balance their complementary failure modes. Reference-based metrics typically achieve a higher correlation with human judgments when high-quality references are available, while reference-less methods reduce susceptibility to reference bias when references are suboptimal (Freitag et al., 2023). We also account for known issues with specific metrics. To mitigate a common QE pitfall, i.e., being fooled by fluent output in the wrong language, the GEMBA-ESA prompt explicitly specifies the target language.

However, for the two lowest-resource languages in the test set (Bhojpuri and Maasai), we do not apply QE and instead rely solely on `chrF++` (Popović, 2017), computed with `sacrebleu` (Post, 2018). This approach was chosen because the reliability of our main metrics is unestablished for these languages (Falcão et al., 2024; Singh et al., 2024; Wang et al., 2024; Sindhujan et al., 2025), whereas human references required for `chrF++`[13] were available.

The system-level score for each language pair is the average of its paragraph-level (segment-level) scores from each metric across the test set.

Human evaluation The human evaluation is done by Kocmi et al. (2025a) using Error Span Annotation (ESA; Kocmi et al., 2024) and for English to Korean and Japanese to Chinese it relies on Multidimensional Quality Metrics (MQM; Lommel et al., 2014).

The ESA annotators are asked to mark each translation error as well as its severity, "Minor" or "Major". In addition, the annotators are also asked to assign a score from 0 to 100 to the entire annotation segment (usually a paragraph).

In the MQM, annotators are asked to assign categories and subcategories to all error spans. Then, instead of a 0 to 100 slider, the final score is calculated as a sum of error severities, where minor error equals -1 and major error equals -5.

Table 9: Average MT AUTORANK results across language pairs (lower is better). For fairness, all model averages are computed over the same 27 of 31 language pairs, matching Mistral Medium, which lacks outputs for four pairs (see Table 21).

Overall ranking Table 9 reports the average AUTORANK results across the various language pairs. **Gemini 2.5 Pro** leads with an average AUTORANK of **1.02**, followed by **GPT 4.1** (1.51), **DeepSeek V3** (2.62), and **Claude 4** (2.86). This top cluster is clearly separated from a mid-tier (4–6 average ranks; e.g., Qwen3 235B, Llama 4 Maverick, CommandA, Gemma 3 27B) and from compact open-weight models which concentrate above 7–8 on average. **Mistral Medium** remains competitive (3.10), but translating for fewer language pairs than all the other models (27 vs. 31). At the other end, small open-weight baselines (e.g., Qwen2.5-7B, Mistral-7B) cluster around ranks 15–18.

Human evaluation results are in Table 22; due to budget restrictions, not all systems have been evaluated. The overall picture highlights the AUTORANK results. However, we can already see some significant differences showing the limitation of automatic metrics: there is a significant drop in the English to Egyptian Arabic as LLMs mostly output the modern standard Arabic, and DeepSeek significantly underperforms in Serbian, which was not visible on AUTORANK.

Language-pair effects Table 21 in Appendix F reports the fine-grained AUTORANK results across the 31 language pairs. The fine-grained table reveals two consistent trends: (i) High-resource or typologically close directions (e.g., English→German, English→Italian, Japanese→Chinese) yield tight spreads among the strongest systems, often near ranks 1–3. (ii) Low-resource and/or orthography-sensitive directions are much harder. In particular, English→Maasai and English→Bhojpuri show large rank dispersion. Some leaders stay robust (e.g., Gemini 2.5 Pro), while others drop sharply on these pairs (e.g., GPT 4.1 on English→Maasai).

Open vs. closed trends Closed-weight models dominate the top cluster, but **DeepSeek V3** stands out as an open-source mix-of-expert model that competes closely with them. Among mid-sized open models, quality is uneven across language pairs and degrades most on low-resource or script-variant directions.

Relation to other tasks The qualitative picture resembles the pattern in Section 4.1: a tight group of leaders at the top, followed by a broader middle where performance varies more by condition. In MT, the key conditions are the choice of language pairs (especially low-resource and script variants), which ultimately drive the gaps we observe in AUTORANK.

4.5 LLM-as-a-judge for OEG and XLSum

Meta-evaluation of LLM-as-a-judge against humans is a research question in itself. Various correlation techniques are used, e.g., Cohen's Kappa, Kendall Tau, Pearson's, or Spearman's correlations (Liu et al., 2023; Verga et al., 2024). Meta-evaluation in machine translation highlighted many problems of common correlation metrics, such as how handling of ties affects the correlation (Deutsch et al., 2023), how critical grouping of items under Kendall Tau is (Perrella et al., 2024), or why Pearson's correlation may be misleading (Mathur et al., 2020). Thus, we build on top of the MT meta-evaluation research, following the best practices (Freitag et al., 2024).

We anticipate almost no ties in system ranking when all scores are aggregated at the system level, but a large number of ties at the instance level due to our use of rubric scores. Our preliminary data inspection also supports this. We compute two types of correlations at the system and instance levels:

- **Pairwise Accuracy**: pairwise accuracy between

	Pairwise Accuracy	group-by-item acc_{eq} Average	Naturalness	Instruction Following	Coherence
Claude 4	0.95	0.56	0.55	0.57	0.56
GPT 4.1	0.95	0.57	0.54	0.59	0.59
CommandA	0.93	0.57	0.53	0.59	0.59
Qwen3 235B	0.91	0.57	0.53	0.59	0.59
Mistral Medium	0.88	0.55	0.54	0.55	0.56
DeepSeek V3	0.85	0.54	0.50	0.58	0.53
Llama 4 Maverick	0.83	0.53	0.51	0.52	0.56
AyaExpanse 32B	0.73	0.50	0.47	0.53	0.51
Qwen2.5 7B	0.70	0.48	0.46	0.49	0.48
Llama 3.1 8B	0.63	0.44	0.40	0.44	0.47
CommandR7B	0.62	0.49	0.44	0.52	0.51
AyaExpanse 8B	0.58	0.48	0.44	0.51	0.48
Mistral 7B	0.55	0.45	0.40	0.50	0.45

Table 10: System-level (Pairwise Accuracy) and Segment-level (group-by-item acc_{eq} by evaluation criterion) correlation between LLM-as-a-judge and human judgment for OEG.

system ranking and human ranking, neglecting ties.

- **acc_{eq}**: group-by-item pairwise accuracy with ties, then averaged across all items, as introduced by Deutsch et al. (2023). Without losing generality across all sub-tasks, an "item" refers to an input prompt requiring an output in a specific language. We report the results for each evaluation criterion separately, as well as an overall average.

Results for OEG LLM-as-a-judge Table 10 shows both system-level and instance-level accuracy measures between LLM judgment and human judgment. Regarding system ranking pairwise accuracy, the models are roughly split into two groups: LLMs with more than 100B parameters, including both closed-source and open-source ones, achieve high accuracy; small open-source models perform worse, with the lowest performance close to a random toss of a coin of 50%.

Instance-level acc_{eq} scores display a similar overall trend, but top-performing LLM judges are closer to each other. We see that the then top Claude 4 becomes lower than GPT 4.1, CommandA, or Qwen3 235B. The best LLM judge for each criterion also varies: Claude 4 is the best at judging naturalness, but three LLMs, GPT 4.1, CommandA, and Qwen3 235B, achieve the best individual accuracy for judging instruction following and coherence.

	Pairwise Accuracy	group-by-item acc_{eq} Average	Naturalness	Faithfulness	Coverage	Coherence
GPT 4.1	0.93	0.51	0.53	0.50	0.47	0.54
CommandA	0.91	0.50	0.53	0.44	0.50	0.52
Mistral Medium	0.91	0.49	0.51	0.44	0.50	0.52
Llama 4 Maverick	0.89	0.45	0.50	0.41	0.42	0.47
Qwen3 235B	0.89	0.49	0.50	0.47	0.47	0.51
DeepSeek V3	0.87	0.47	0.49	0.46	0.46	0.47
CommandR7B	0.78	0.38	0.35	0.38	0.39	0.40
Qwen2.5 7B	0.78	0.39	0.37	0.36	0.40	0.42
AyaExpanse 32B	0.73	0.40	0.38	0.39	0.42	0.42
Llama 3.1 8B	0.71	0.38	0.38	0.35	0.38	0.42
AyaExpanse 8B	0.69	0.38	0.35	0.38	0.37	0.41
Mistral 7B	0.67	0.36	0.33	0.35	0.39	0.39

Table 11: System-level (Pairwise Accuracy) and Segment-level (group-by-item acc_{eq} by evaluation criterion) correlation between LLM-as-a-judge and human judgment for XLSum.

Results for XLSum LLM-as-a-judge Table 11 shows both system-level and instance-level accuracy measures between LLM judgment and human judgment. At the system level, pairwise accuracy follows a pattern similar to OEG: larger models (CommandA, GPT 4.1, and the 100B+ parameter models) achieve high accuracy between 0.87 and 0.91, while smaller open-source models below 10B parameters perform substantially worse, with accuracies between 0.71 and 0.80.

However, instance-level acc_{eq} scores reveal more concerning patterns. Overall correlations are lower than in OEG, with the best average scores around 0.50. GPT 4.1 demonstrates particularly severe overscoring tendencies, systematically assigning perfect scores to almost all outputs of 4–9 models across all criteria. The best-performing judge also varies considerably by criterion: CommandA achieves the highest accuracy for naturalness and coverage, while GPT 4.1 performs best on faithfulness and coherence despite its overscoring behavior. These patterns suggest that the system-level correlations may reflect spurious text properties rather than the intended evaluation criteria, raising questions about the validity of LLM-as-a-judge for this task.

4.6 LLM-as-a-judge for MT

The meta-evaluation of LLM-as-a-judge was collected in the same way as this year's metric shared task Lavie et al. (2025). Correlations are computed

Model	Avg. SPA	Avg. acc_{eq}
GPT 4.1	0.83	0.49
Claude 4	0.82	0.36
CommandA	0.80	0.39
DeepSeek V3	0.79	0.37
Qwen3 235B	0.78	0.38
AyaExpanse 32B	0.73	0.28
Llama 4 Maverick	0.72	0.19
Qwen2.5 7B	0.67	0.36
Llama 3.1 8B	0.66	0.28
CommandR7B	0.58	0.26
AyaExpanse 8B	0.58	0.22
Mistral 7B	0.54	0.29

Table 12: System-level (Pairwise Accuracy) and Segment-level (acc_{eq}) correlation between LLM-as-a-judge and human judgment for machine translation. Correlations have been averaged across translation directions. Full results are reported in Tables 23 and 24.

at the system level using Pairwise Accuracy (PA, Kocmi et al., 2021) and at the segment level using Pairwise Accuracy with Tie Calibration (acc_{eq}, Deutsch et al., 2023).

We report the average correlations between LLM judges and human annotators in Table 12. At the system level, results resemble those reported in OEG LLM-as-a-judge (Section 4.5): the models are split into two groups, with closed-source and very large models (100+ billion parameters) achieving higher SPA scores ($\geq$ 0.78), while smaller ones range from 0.54 to 0.73. The only outlier is Llama 4 Maverick, which performs poorly compared to similar-sized models, placing in the group of smaller LLMs.

At the segment level, results align with the system-level ones, with models again splitting into the same two performance-based groups. However, two models stand out relative to their peers: GPT 4.1 achieves an acc_{eq} score of 0.49, outperforming all others by a clear margin. Similarly, Qwen2.5 7B reaches 0.36 in terms of acc_{eq}, placing it closer to larger models than to others of comparable size.

Finally, we highlight CommandA, as a dense model with 111B parameters, surpasses several larger MOE competitors such as DeepSeek V3 and Qwen3 235B in Pariwise Ranking and ranks second in acc_{eq}.

5 Conclusion

We introduced the WMT25 Multilingual Instruction Shared Task, where the main contribution is a unified benchmark spanning five evaluation tasks: machine translation, linguistic reasoning, open-ended generation, cross-lingual summarization, and LLM-as-a-judge. The benchmark covers up to 30 languages evaluated both automatically and by humans, and emphasizes robust evaluation of multilingual LLM capabilities. We release all prompts, outputs, and human annotations to facilitate reproducibility and research.

- **Substantial headroom in linguistic reasoning.** Across languages, the best systems achieve well below half of the attainable LR points, indicating that current models struggle with structured, language-agnostic reasoning rather than knowledge recall.
- **English is not always the easiest instruction language.** Several leading models reach their top LR scores in non-English (e.g., Korean, German, Spanish), with noticeable drops in English, suggesting prompting language effects that merit further study.
- **Naturalness is the bottleneck for generation.** In OEG human evaluation, score spread is widest for *naturalness* compared to *instruction following* and *coherence*, echoing user reports that non-English outputs often sound robotic or translationese.
- **Closed-weight models lead, but strong open models follow closely.** Aggregate results and MT AUTORANK ranks show a top cluster of proprietary models, with large open models competitive on several tasks and language pairs.
- **MT quality varies sharply by pair and script.** High-resource or typologically close pairs exhibit tight spreads among top systems, while low-resource and script-variant directions show large gaps and instability.
- **LLM-as-a-judge correlates well at the system level, unevenly at the instance level.** Larger models achieve higher system-level accuracy in OEG/XLSum/MT, while smaller models are not suited for the task.
- **Evaluation reliability still hinges on humans.** Automatic scores enable broad coverage, but human annotations exposed language/script biases, instruction-following failures, and cases where metrics or judges disagree, underscoring the value of our released human-rated subsets.

6 Limitations

Budget-driven coverage limits and occasional model unavailability led to uneven per-task participation. Furthermore, human evaluation was

performed on a subset of the samples.

While we usually report aggregate results across all languages (or language pairs), not all models are trained for all languages. This analysis inevitably penalizes them if some languages are unsupported. Practitioners can refer to the raw data for performance in individual languages of interest.

7 Acknowledgements

We thank many people for their help with annotations, reviewing the linguistic reasoning subtask, and providing or reviewing translations of instructions. They are: Özge Agca, Sweta Agrawal, Ondřej Bojar, Rawan Essam Bondok, Philipp Burlakov, Daryna Dementieva, TG Gowda, Alexandra Grieva, HyoJung Han, Katsuki Isobe, Gunny Kim, Ivan Korovin, Nalin Kumar, Mateusz Lango, Ariston Lim, Jiaming Liu, Andrei Manea, Sourabrata Mukherjee, Youssef Nafea, Ricardo Rei, Steinþór Steingrímsson, Hanka Štěříková, Dušan Variš, Gianluca Vico, and Razan Dyas Wibowo.

We thank Apify and Julian McAuley for their support in obtaining the cross-lingual summarization data.

A LLM-in-the-loop PDF Parsing

As described in Section §2.1, the data for 14 of the 15 linguistic exams was extracted using an LLM-in-the-loop pipeline. This approach leveraged the manually parsed English data as a reference to efficiently scale the extraction process, which was followed by human verification and editing. Concretely, we prompted Gemini 2.5 Pro to structure each translated PDF's content into a JSON object by mimicking the provided English example. The LLM was given the unparsed English and translated PDFs, along with the reference JSON object from the English version as a string input.

Prompt Development and Iterations The exact prompt used is shown in Figure 13. As seen, the JSON extraction proved to be highly demanding, requiring the LLM to simultaneously parse content from PDF documents, process long-context inputs, and generate a structured output that must be syntactically valid and programmatically parsable. To improve reliability of the LLM automation process, we iterated on our approach by:

- **Adding step-by-step** instructions to the prompt.
- **Breaking the task down** to parse one problem at a time, which drastically reduced JSON validation failures. This means that for each exam we need at least 5 calls to an LLM (one for each language problem).
- **Implementing a resampling strategy** that only accepted outputs confirmed to be parsable JSON. Figure 14 shows the number of samples drawn for each task/problem language to arrive at a valid JSON. For most problems, a single API call was sufficient. However, the Dâw and Yanyuwa tasks, which employed more complex JSON structures, consistently required more attempts, with some outlier cases, such as for Persian, requiring as many as 50 calls to successfully generate a valid JSON object.

After parsing the PDFs to JSON, we imported the resulting data into spreadsheets so that native speakers could verify its correctness.

```
You are given:
*   An English Linguistic Exam (PDF) with its
    solutions (PDF).
*   The JSON representation of the English
    exam (referred to as "English JSON").
*   The {language} version of the exam (PDF) and its
     solutions
    (PDF).

Objective: Generate a JSON object for the {
    no_problem}
problem ("{problem_language}") of the {language}
    exam.
This JSON should follow
the structural format of the English JSON.

Steps:
1.  Target the "{problem_language}" Problem:
    Isolate the "{problem_language}" problem data.
2.  Structural Template: Use the "{problem_language
    }"
    problem section from the English JSON as the
    structural basis for your new {language} JSON.
3.  Field Handling:
    *  Copy Directly from English JSON: For the
      "{problem_language}" problem, copy the values
          of these
      fields from the English JSON: `Identifier`, `
          Points`,
      `Work Language`, `Task Type`, `Eval Type`, and
          `Task
       Meta`.
    *  Extract from {language} PDFs: For all
       remaining fields,
       populate them with the corresponding content
          extracted
       from the "{problem_language}" section of the
          {language}
       PDFs.
    *  Content Adaptation: The English JSON models
       how PDF
       content should appear in the JSON. If its
          content isn't
       a direct PDF copy (e.g., it's formatted/
          structured),
       then similarly adapt the {language} PDF
          content to match
       this presentation style and any processing
       evident in the English JSON.

Attached are the PDFs, here is the English JSON:
```
{json_object}
```
Make sure all values in the JSON have the same
    length and
that the JSON itself is parsable with json.loads()
    in Python.
Output only the JSON object and nothing else.
```

Table 13: Prompt used to extract a JSON object from a translated PDF by mimicking the structure of a manually parsed example ("json_object") from the original English PDF.

Language	Koryak	Hadza	Komnzo	Dâw	Yanyuwa
Ukrainian	1	1	1	2	4
Russian	1	1	1	4	18
Portuguese	1	1	3	11	11
Czech	1	1	1	1	11
Spanish	1	1	1	2	1
Swedish	1	1	1	1	1
Chinese	1	1	1	1	2
Korean	1	1	1	1	5
Persian	1	1	1	1	52
French	1	1	1	1	2
German	1	1	1	16	14
Japanese	1	1	1	1	4
Estonian	1	1	1	1	1
Dutch	1	1	3	3	9

Table 14: Number of API calls required to extract a parsable JSON object varied by task and language.

B LLM-as-a-judge Instructions

LLM-as-a-judge prompts for OEG, MT, and XLSum are in Tables 15 to 17 respectively.

```
Score the response generated by a system to a user's request in {language} on a likert scale from 1 to 7. The quality levels associated with numerical scores are provided below:
7: The response fully adheres to all instructions that the user provided.
5: The chatbot mostly followed the instructions, conforming to the main points of the request but missing some details.
3: The chatbot followed only a small portion of the instructions or missed important points.
1: The chatbot entirely disregarded the instructions; the response appears to have no relation to the user's request or is not in {language}.
Return only the score and nothing else.
Prompt: {input}
Response: {response}
Score (1-7):
```

```
Score the response generated by a system to a user's request in {language} on a likert scale from 1 to 7. The quality levels associated with numerical scores are provided below:
7: The response represents fluent {language} text that might have been written by a native human speaker.
5: The response has some disfluencies that are noticeable but don't significantly hinder understanding the response.
3: The response is highly disfluent. There are several grammatical errors. Most of the meaning can be determined, but only with conscious effort.
1: The response is incomprehensible or is not in {language}.
Return only the score and nothing else.
Prompt: {input}
Response: {response}
Score (1-7):
```

```
Score the response generated by a system to a user's request in {language} on a likert scale from 1 to 7. The quality levels associated with numerical scores are provided below:
7: The response is logically sound and appropriately structured with a clear sequence of nicely connected ideas and topics with no leaps in reasoning.
5: The response is generally well-structured and has a generally clear overall progression of ideas, but introduces a few logical gaps, or suddenly switches topics without an appropriate transition.
3: The response lacks an overall flow, and/or has multiple noticeable jumps between topics. It is possible to discern some relevant ideas, but the overall purpose of the response is incoherent.
1: The response has no overall structure, is in no way logically sound, and/or can be divided into many mostly-unrelated sections. It is difficult to identify any points the text is trying to make.
Return only the score and nothing else.
Prompt: {input}
Response: {response}
Score (1-7):
```

Table 15: Prompt instructions used in the LLM-as-a-judge for OEG sub-task.

```
Score the following translation from {source_lang} to {target_lang} on a scale from 0 to 100, where a score of 0 means a broken or poor translation; 33 indicates a flawed translation with significant issues; 66 indicates a good translation with only minor issues in grammar, fluency, or consistency; and 100 represents a perfect translation in both meaning and grammar. Answer with only a whole number representing the score, and nothing else.
{source_lang} source text:
{source_seg}
{target_lang} translation:
{target_seg}
```

Table 16: Prompt instructions used in the LLM-as-a-judge for MT sub-task.

```
Score the summary generated by a system based on a set of reviews in {language} on a likert scale from 1 to 7. Evaluate whether all information in the summary can be traced back to the reviews. Treat the reviews as the source of truth and do not consider any external information. The quality levels associated with numerical scores are provided below:
7: All of the information in the summary is fully supported by the reviews and no meaning was changed.
5: Most information is supported, but a small part of the summary contains information that either contradicts or cannot be verified by the reviews.
3: More than half of the information in the summary either contradicts or cannot be verified by the reviews.
1: The summary is fully made up of information that either contradicts or cannot be verified by the reviews.
Return only the score and nothing else.
Reviews: {input}
Summary: {response}
Score (1-7):
```

```
Score the summary generated by a system based on a set of reviews in {language} on a likert scale from 1 to 7. Read the reviews and identify the most important points, then evaluate whether these key points are covered by the summary. The quality levels associated with numerical scores are provided below:
7: The summary covers all key points.
5: The summary covers about two thirds of the key points.
3: The summary covers about a third of the key points.
1: The summary does not cover any of the key points mentioned in the reviews.
Return only the score and nothing else.
Reviews: {input}
Summary: {response}
Score (1-7):
```

```
Score the summary generated by a system based on a set of reviews in {language} on a likert scale from 1 to 7. Evaluate the degree to which the summary appears to be fluent, natural text in {language}, that is appropriate in terms of tone and formality. The quality levels associated with numerical scores are provided below:
7: The summary represents fluent {language} text that might have been written by a native human speaker.
5: The summary has some disfluencies that are noticeable but don't significantly hinder understanding the summary.
3: The summary is highly disfluent. There are several grammatical errors. Most of the meaning can be determined, but only with conscious effort. Alternatively, there are some words in a foreign language.
1: The summary is incomprehensible, or is not in {language}.
Return only the score and nothing else.
Reviews: {input}
Summary: {response}
Score (1-7):
```

```
Score the summary generated by a system based on a set of reviews in {language} on a likert scale from 1 to 7. Evaluate the degree to which the summary appears to be logically sound and internally consistent. The quality levels associated with numerical scores are provided below:
7: The summary is logically sound and appropriately structured with a clear sequence of nicely connected ideas and topics with no leaps in reasoning.
5: The summary is generally well-structured and has a generally clear overall progression of ideas, but introduces a few logical gaps, or suddenly switches topics without an appropriate transition.
3: The summary lacks an overall flow, and/or has multiple noticeable jumps between topics. It is possible to discern some relevant ideas, but the overall purpose of the summary is incoherent.
1: The summary has no overall structure, is in no way logically sound, and/or can be divided into many mostly-unrelated sections. It is difficult to identify any points the text is trying to make.
Return only the score and nothing else.
Reviews: {input}
Summary: {response}
Score (1-7):
```

Table 17: Prompt instructions used in the LLM-as-a-judge for XLSum sub-task.

C MT Prompt instructions

```
You are a professional {source_language}-to-{
    target_language} translator, tasked with
    providing translations suitable for use in {
    target_region} ({tgt_language_code}). Your goal
     is to accurately convey the meaning and
    nuances of the original {source_language} text
    while adhering to {target_language} grammar,
    vocabulary, and cultural sensitivities. The
    original {source_language} text {
    domain_description}. {domain_instruction}
    Produce only the {target_language} translation,
     without any additional explanations or
    commentary. Retain the paragraph breaks (double
     new lines) from the input text. Please
    translate the following {source_language} text
    into {target_language} ({tgt_language_code}):\n
    \n{input_text}
```

```
news: Ensure the translation is formal, objective,
    and clear. Maintain a neutral and informative
    tone consistent with journalistic standards.
social: Ensure you do not reproduce spelling
    mistakes, abbreviations or marks of
    expressivity. Platform-specific elements such
    as hashtags or userids should be translated as-
    is.
literary: Aim to maintain the original tone and
    register, retaining the emotional depth of the
    story. Dialogues should sound natural and
    follow the conventions of the target language.
speech: Pay attention to errors that mimic speech
    transcription errors and fix as necessary.
    Maintain the flow and colloquial style of the
    speaker in the translation.
edu: Preserve the line breaks. Use precise
    terminology and a tone appropriate for academic
     or instructional materials.
dialogue: Maintain dialog turn structure and speaker
     indicators (X, Y). Ensure natural flow,
    consistent tone (feminine/masculine, polite/
    familiar), and preserve any HTML tags (e.g.,
    italics).
```

Abstract

The WMT25 Shared Task on Automated Translation Evaluation Systems evaluates metrics and quality estimation systems that assess the quality of language translation systems. This task unifies and consolidates the separate WMT shared tasks on Machine Translation Evaluation Metrics and Quality Estimation from previous years. Our primary goal is to encourage the development and assessment of new state-of-the-art translation quality evaluation systems. The shared task this year consisted of three subtasks: (1) segment-level quality score prediction, (2) span-level translation error annotation, and (3) quality-informed segment-level error correction. The evaluation data for the shared task were provided by the General MT shared task and were complemented by "challenge sets" from both the organizers and participants. Task 1 results indicate the strong performance of large LLMs at the system level, while reference-based baseline metrics outperform LLMs at the segment level. Task 2 results indicate that accurate error detection and balancing precision and recall are persistent challenges. Task 3 results show that minimal editing is challenging even when informed by quality indicators. Robustness across the broad diversity of languages remains a major challenge across all three subtasks.

1 Introduction

The WMT25 Shared Task on Automated Translation Quality Evaluation Systems[1] evaluates automated systems for assessing and improving translation quality, including automated quality metrics, quality estimation systems, and quality-informed translation error correction. This task builds on previous years' shared tasks (Freitag et al., 2024; Zerva et al., 2024) and unifies previously separate WMT shared tasks on Machine Translation Evaluation Metrics and Quality Estimation. Automated translation quality evaluation systems play a critical role in the research, development and deployment of machine translation systems, and more recently, of multilingual LLMs. They are also critical components in automated translation workflows for large-scale commercial translation use-cases.

Task 2: error span prediction	→ I don't speak Spanish!
Task 3: post-editing	→ We don't speak Italian.

Table 1: Illustration of the three primary subtasks: segment-level quality score prediction, span-level error detection, and quality-informed post-editing. (The challenge sets subtask is not shown.)

The shared task consists of three primary subtasks shown in Table 1: (1) segment-level quality score prediction, (2) span-level translation error detection, and (3) quality-informed segment-level error correction. Curated evaluation data sets were provided for all three subtasks. These include test material obtained from the WMT25 General Machine Translation task as well as a collection of "challenge sets" that were developed by the organizers and members of the research community. A fourth subtask solicited the submission of these challenge sets.

The primary focus of this year's updated task

[1] www2.statmt.org/wmt25/mteval-subtask.html

Proceedings of the Tenth Conference on Machine Translation, pages 436–483
November 8-9, 2025

is on robust translation quality evaluation systems that can effectively detect translation errors generated by increasingly accurate LLM-based translators as well as handle previously unseen problems related to using LLMs for translation, such as output verbosity and incorrect output language. Newly, the evaluation data, originating from the General MT task, were intentionally chosen to be challenging for MT: they feature longer length, sourcing from some originally non-textual modalities, and translation into a wider variety of languages than in previous years.

Task 1 this year was designed to evaluate both MT metrics and QE systems. Reference-based automatic metrics score MT output by comparing the translation with a reference translation generated by human translators, who are instructed to translate "from scratch" without post-editing from MT. Reference-free quality estimation (QE) systems score translations solely based on their adherence to the source language. We collectively refer to all of these systems as "auto-raters" throughout the rest of the paper. All auto-raters were evaluated based on their agreement with human ratings when scoring MT systems and human translations at the system and segment level. In Task 2, systems are evaluated on their ability to detect and accurately annotate the spans of translation errors by contrasting them with the human error annotations. For Task 3, systems that correct a given translation are evaluated based on the quality of their post-edits, rewarding effective improvements with minimal changes.

Below are some of the key details and changes implemented for this year's shared task:

- **Subtasks**: As illustrated in Table 1, we solicited participation in segment-level quality score prediction, span-level error detection, and quality-informed post-editing.

- **Language Pairs**: Based on the General MT shared task, this year covers 16 language pairs, many of which are novel: English→{Czech, Estonian, Icelandic, Egyptian Arabic, Bhojpuri, Maasai, Russian, Serbian Cyrillic, Ukrainian, Japanese, Chinese, Italian, Korean}, Czech→{German, Ukrainian}, and Japanese→Chinese. The domains are Literary (short story), News, Social, Speech (video transcripts), and Social.

- **Human Evaluation**: Human evaluation was done as part of the General MT task, and these same annotations were then reused for our shared task. For 14 of the language pairs, annotations were conducted with the ESA protocol (Kocmi et al., 2024); the remaining two language pairs were annotated using the MQM protocol (Freitag et al., 2021). ESA annotations included two sets of human annotations per translation.

Task	Level	Meta-metric
1	system	SPA
1	segment	acc^*_{eq}
2	char	F1
3	segment	Δ-COMET

Table 2: Each language was given equal weight in the overall average.

- **Meta-Evaluation**: Each of the three subtasks employs its own individual meta-evaluation methods, described in more detail in the respective sections later in the paper. Task 1 follows the same approach as last year's Metrics task and uses two primary measures: soft pairwise accuracy (SPA) at the system level (Thompson et al., 2024), and "group-by-item" segment-level accuracy with tie calibration (acc^*_{eq}) at the segment level (Deutsch et al., 2023). Task 2 follows a similar approach to last year's QE task, and calculates the character-level F1 score between the predicted errors and the gold error spans, weighted to allow for half points for correctly identified spans with incorrect error severity. Task 3 evaluates the quality of the correction of the original MT using ΔCOMET as the primary measure and Gain-to-Edit Ratio (GER) to quantify editing efficiency.

- **MTME**: Similar to last year, all the data for Tasks 1 and 2 has been uploaded to the `mt-metrics-eval` codebase (MTME),[2] and all results in this paper are calculated with this analysis tool. We encourage developers of auto-rater systems to use MTME for greater reproducibility.

Our main findings are:

- The prediction of quality scores, with or without references, remains a challenge. Strong LLM-based auto-raters now top the rankings at the system level, where the task is to accurately identify the better MT system. At

[2] github.com/google-research/mt-metrics-eval

the segment level, LLM-based auto-raters still underperform; this year, unlike in recent years, reference-based baseline metrics (YiSi-1, chrF, and BERTScore) fill out the top three rank clusters, outranking recently strong trained metrics. We provide some analysis of this surprising result, but further analysis is needed to develop a better understanding of this outcome (Section 4).

- Auto-raters continue to struggle with precise error detection, span annotation, and severity classification, with significant gaps with human performance and large variations across language pairs (Section 5). This underscores the complexity of the task and highlights the critical need for advances in automated error analysis that better align with human judgments.

- While automatic translation correction systems can improve translation quality, this improvement is often at the cost of diverging from human-generated reference translations, indicating a gap between automated systems and human lexical choices, and that improvement does not necessarily mean alignment with human preferences (Section 6).

- By using carefully-crafted challenge sets, it is shown that current automatic MT evaluation systems still exhibit major weaknesses, including susceptibility to fluent but semantically irrelevant content, systematic gender bias, instability on low-quality or corner-case outputs, and poor correlation with human judgments for low-resource languages (Section 7).

The rest of the paper is organized as follows. Section 2 introduces our subtasks. Section 3 presents the evaluation set and the MT systems whose output was judged. Following that, the baselines, participants, meta-evaluation procedure, and main results of each subtask are discussed in Section 4 for segment-level quality score prediction, in Section 5 for span-level error annotation, and in Section 6 for quality-informed post-editing. Section 7 presents the submitted challenge sets, and Section 8 concludes.

2 Tasks

The shared task this year consisted of three primary subtasks that address translation quality assessment from three perspectives: (1) segment-level quality score prediction, (2) span-level translation error detection, and (3) quality-informed segment-level error correction. An additional fourth subtask solicited the submission of challenge sets that identify where automated metrics and auto-rater systems fail. All subtasks are introduced below:

2.1 Segment-Level Quality Score Prediction

The goal of the segment-level quality prediction subtask is to predict a quality score for each source–target segment pair in the evaluation set, with a reference translation optionally being provided. Depending on the language pair, the participants were asked to predict either the Error Span Annotation (ESA) score (Kocmi et al., 2024) or the Multi-dimensional Quality Metrics (MQM) score (Freitag et al., 2021). Submissions are evaluated and ranked based on their prediction correlations with these human-annotated scores at both the segment and system levels.

2.2 Span-Level Error Detection

In this subtask, the goal is to predict the precise span of each translation error along with its severity. For this subtask we use the error spans obtained from the MQM and ESA human annotations generated for the General MT primary task as the target "gold standard". Participants were asked to predict both the error spans (start and end indices) as well as the error severities (major or minor) within each segment. Submissions are evaluated and ranked based on their ability to correctly identify the presence of errors, correctly mark the spans of any identified errors, and correctly identify the severity of each of these errors.

2.3 Quality-Informed Segment-level Error Correction

The overarching goal of this subtask is to correct the output of machine translation. Recent work shows that joint optimization for QE and APE helps improve the performance of both tasks (Deoghare et al., 2023, 2024). Furthermore, fine-grained QE signals can also be leveraged to apply limited corrections and help mitigate over-correction, known as a common problem in APE systems (Deoghare et al., 2025). We invited participants to submit systems capable of automatically generating corrections for machine-translated text, given the source, the MT-generated target, and a QE-generated quality annotation of the MT. The objective is to ex-

plore how quality information, including both error span annotations and Direct Assessment (DA) scores, can inform automated error correction. For instance, sentence-level quality scores may help identify which segments require correction, while span-level annotations can be used for fine-grained, pinpointed corrections. Participants were provided with the quality information. Submissions were evaluated and ranked based on the quality of the corrections they generate, with as few changes as possible.

2.4 Challenge Sets

For the fourth year, our shared task included a subtask involving challenge sets. This subtask is inspired by the *Build it or break it: The Language Edition* shared task (Ettinger et al., 2017), which aimed at testing the generalizability of NLP systems beyond the distributions of their training data. Whereas the standard evaluation of the shared task is conducted on test sets containing generic text from real-world content, the challenge set evaluation is based on test sets designed with the aim of revealing the abilities or the weaknesses of the metrics or evaluating particular translation phenomena. In order to shed light on different perspectives on evaluation, the subtask takes place in a decentralized manner: contrary to the main metric tasks, the test sets are not provided by the organizers but by different research teams, who are also responsible for analyzing and presenting the results (Section 7).

3 Evaluation Data

3.1 Data Sourcing and Translation

Similar to previous years' editions, the source sides, MT outputs, and reference texts for our shared task are mainly derived from the WMT25 General MT Shared Task (Kocmi et al., 2025a).

Newly this year, the source segments were automatically selected to be more challenging for translation systems, using a source-only difficulty estimator (Proietti et al., 2025). The test data domains cover news, literary (short stories), speech, and social. For the General MT shared task, some of this test material was multimodal: the speech data was provided as audio files with uncorrected automatic transcripts, and the social-media content was provided with screenshot images. However, for our shared task, we released only a text version of our evaluation set.

The selection of MT outputs was made based on an evaluation with automatic metrics (Kocmi et al., 2025b), giving slight prioritization to constrained (small, open-weight) systems. In keeping with our goal of exposing participants to a wide range of translation qualities and phenomena, we included output from around 20 different MT systems for each language pair. An exception is Task 3, which subsampled the original set for computational feasibility.

Reference translations were provided in 14 of our 16 language pairs, produced by professional translators from scratch. We ran English→Italian and English→Maasai as reference-free scenarios: the former because the General MT shared task intentionally did not produce any references, and the latter because the references produced by General MT were not yet available at the beginning of our evaluation period.

For more details regarding sourcing and translation of the test set, we refer the reader to the WMT25 General MT Shared Task (Kocmi et al., 2025a). All data has been released publicly.[3]

3.2 ESA and MQM Human Evaluation

This year, translations in most language pairs (English→{Czech, Estonian, Icelandic, Egyptian Arabic, Bhojpuri, Maasai, Russian, Serbian Cyrillic, Ukrainian, Japanese, Chinese, Italian} and Czech→{German, Ukrainian}) were evaluated with the ESA protocol (Kocmi et al., 2024). Japanese→Chinese and English→Korean were annotated with the MQM protocol (Freitag et al., 2021). The ESA protocol differs from MQM by not requiring the error categorization (fluency, punctuation, etc.) for each span and by providing a free-form 0% to 100% slider for assessing the final translation quality. Annotators were given guidance defining a score of 0% as "broken," 33% as "flawed," 66% as "good," and 100% as "perfect." In MQM, the translation score is instead derived mathematically from the count of error spans and their annotated severities. Generally, each minor error contributes –1 point while each major error counts as –5.

Our ESA annotations contain two judgments of each translation ("human1" and "human2"). This allows us to calculate intercoder agreement as a measure for task difficulty in each language and also provides a human "oracle" against which automated metrics can be compared (e.g. by treating

[3] github.com/wmt-conference/wmt25-general-mt

one human annotation as a "metric" and comparing it against actual auto-rater results). Additionally, the human annotations also contain control tasks (a fixed set of translations that all annotators annotated) designed to establish annotator reliability; this has been shown to work better than ad-hoc attention checks (Zouhar et al., 2025a).

In order to maximize differences between systems, human evaluation was limited to the top 50% of the most diversely translated inputs, computed with pairwise chrF between systems. Therefore, all source segments have either received two annotations for all selected systems, or none. This has the effect of avoiding spending human effort on annotating identical or similar translations, as well as translations that have little impact on the rankings of auto-rater systems (Zouhar et al., 2025b).

4 Task 1: Segment-Level Quality Score Prediction

This section presents the segment-level quality score prediction subtask in detail. We describe the auto-rater systems participating in the subtask in Section 4.1, our meta-evaluation procedure in Section 4.2, and our main results in Section 4.3. Section 4.4 reports some further analysis of the results beyond correlation and accuracy.

4.1 Participating Systems

We processed three distinct types of auto-rater systems participating in the segment-level quality score prediction subtask: baselines, official submissions, and "LLM as a judge" models. Each type is described in more detail below. A synthesized overview of all 48 systems is also given in Table 3, based on information provided by each participant at the time of submission. Full authoritative details are available in each team's separately prepared system description paper.

4.1.1 Baselines

We computed scores for several baseline systems in order to compare submissions against previous well-studied metrics.

SacreBLEU baselines We used the following metrics from SacreBLEU (Post, 2018):

- **BLEU (Papineni et al., 2002)** is based on the precision of n-grams between the MT output and its reference, weighted by a brevity penalty. We used the SacreBLEU command line with default arguments [4] for system-level BLEU, and we used the `-sl` argument to obtain segment-level BLEU.
- **spBLEU (NLLB-Team et al., 2022)** is the BLEU score computed with subword tokenization by the standardized FLORES-200 SentencePiece models. We used the SacreBLEU command line to compute system-level spBLEU,[5] and we used the `-sl` argument to obtain segment-level spBLEU.
- **chrF (Popović, 2015)** uses character n-grams instead of word n-grams to compare the MT output with the reference. We used the SacreBLEU command line with default arguments[6] for system-level chrF and used the `-sl` argument to obtain segment-level chrF.

BERTScore (Zhang et al., 2020) leverages contextual embeddings from pre-trained transformers to create soft alignments between words in hypothesis and reference segments using cosine similarity. Based on the alignment matrix, BERTScore returns a precision, recall, and F1 score. We used F1 without TF-IDF weighting.

COMET-22 (Rei et al., 2022a) is a learned metric fine-tuned using direct assessments from previous WMT translation shared tasks. This metric relies on sentence embeddings from the source, translation, and reference to produce a final score. We used the default model `wmt22-comet-da` provided in version 2.0.2 of the Unbabel/COMET framework. This model employs XLM-RoBERTa large as its backbone model and is trained on data from the 2017 to 2019 WMT shared tasks, in combination with the MLQE-PE corpus (Fomicheva et al., 2022).

COMETKIWI (Rei et al., 2022b) is a reference-free learned metric that functions similarly to BLEURT, but instead of encoding the translation along with its reference, it uses the source. We used the `wmt22-cometkiwi-da` model, which was a top-performing reference-free metric from the WMT 2022 shared task. This metric is fine-tuned on the same data as `wmt22-comet-da` using version 2.0.2 of the Unbabel/COMET framework.

[4] nrefs:1|case:mixed|eff:no|tok:13a|smooth:exp|v:2.3.1. For into-Chinese, into-Japanese, and into-Korean language pairs, we used tok:zh, tok:ja-mecab, and tok:ko-mecab as the tokenizer, respectively.

Table 3: Summary of Task 1 participants. We distinguish four different purposes of participation: as a baseline, as an official primary submission, as an official secondary submission, or as an "LLM as a judge." Basic self-submitted properties of each entrant are summarized above, sorted by auto-rater name.

Sentinel baselines We also included two metrics from the Sentinel family. Unlike the other baselines, Sentinel metrics are intentionally formulated to lack important information when assigning their scores. They are instead meant as a probing mechanism to highlight evaluation scenarios that may be "too easy" or that are prone to spurious correlations, if the Sentinel metrics place competitively among other evaluators that have access to more complete information.

- **SENTINEL-SRC-25 (Proietti et al., 2025)** predicts the quality of a translation solely based on its source string, without considering the reference or even the translation itself. It is an updated version of the original SENTINEL-SRC: a regression model based on XLM-RoBERTa, trained with data from previous WMT editions up through and including the WMT 2024 test set.

- **SENTINEL-CAND (Perrella et al., 2024)** assesses the quality of a translation based on the output string alone, without taking the source or reference into account. It is also based on XLM-RoBERTa, trained with WMT data up

through 2022.

YISI-1 (Lo, 2019) is an MT evaluation metric that measures the semantic similarity between a machine translation and human references by aggregating the IDF-weighted lexical semantic similarities based on the contextual embeddings extracted from pre-trained language models (BERT-base-chinese for evaluating Chinese and XLM-RoBERTa for evaluating other target languages in this shared task).

4.1.2 Official Submissions

Each team participating in Task 1 was allowed to submit one primary and up to two secondary systems for meta-evaluation. The primary systems are described below. Secondary systems are included in the general tabular overview (Table 3).

ENSEMBLESLICK (Hrabal et al., 2025) For Task 1, this system uses a combination of Phrase proprietary fine-tuned GTE and similar models and fine-tuned GPT-4o-mini.

GEMBA-V2 (Junczys-Dowmunt, 2025) GEMBA-V2 is an updated version of GEMBA (Kocmi and Federmann, 2023).

HW-TSC (Luo et al., 2025) This system's approach integrates sentence segmentation tools and dynamic programming to construct sentence-level alignments between source and translated texts, then adapts sentence-level evaluation models to document-level assessment via sliding-window aggregation.

METRICX-25 (Juraska et al., 2025) METRICX-25 is an encoder-only regression model initialized from Gemma 3 12B and fine-tuned on publicly available DA and MQM scores from WMT 2015–23 in a two-stage fashion. Similar to METRICX-24, the first stage uses z-normalized DA scores, and the second stage uses a mixture of raw DA scores (rescaled to the MQM range of 0–25) and MQM scores. Due to the dual nature of meta-evaluation this year (ESA/DA vs. MQM), a score type indication is included in the input, indicating for each training example whether it corresponds to a DA or MQM score.

MR7.2.1 (Hrabal et al., 2025) This submission experimented with the Gemma 3 27B IT model prompted using the DSPy framework and using its MIPROv2 optimizer. The system first generates seven 0–10 integer scores for various aspects of the translation (e.g. "accuracy and completeness" or "fluency and coherence"). Afterwards, it generates the overall 0–100 score.

POLYCAND-2 (Züfle et al., 2025) The supervised reference-less metric $\text{COMET}_{\text{poly-}*}$ has similar architecture and training to standard COMET but incorporates additional information beyond one single translation. $\text{COMET}_{\text{poly-cand2}}$ incorporates two alternative translations of the same source segment (provided by other translation systems) to better contextualize and assess the quality of the translation being scored. The metric was trained on a limited combination of DA, ESA, and MQM data on a unified scale.

RANKEDCOMET (Maharjan and Shrestha, 2025) This system is based on the pre-trained Unbabel/wmt22-comet-da model, deployed in a zero-shot inference setting. Raw segment-level quality scores are generated and then post-processed with per-language-pair rank normalization. This method transforms raw scores into a calibrated distribution that significantly improved correlation with the preliminary evaluation metrics.

ROBERTA-LS (Haq and Osuji, 2025) ROBERTA-LS (Roberta Long-Span) is a reference-based evaluation metric built using the COMET framework. Designed to provide multi-sentence quality scores, it is trained on augmented long-context data that captures translation quality beyond isolated sentences. To construct the long-span MT evaluation dataset, adjacent short segments are concatenated, and a multi-segment quality score is computed as a length-weighted average of their original scores. Unbabel/wmt22-comet-da and XLM-RoBERTa-base are fine-tuned on the augmented data.

SEGALE-QE (Yan et al., 2025) This system extends METRICX to long texts by adding a pipeline before running the metric. It first segments the data down to individual sentences with Ersatz, then runs Vecalign to align system translations to the source. Vecalign's deletion penalty is adaptively adjusted to obtain good alignments that exclude over/under-translation to the maximum extent possible. When over/under-translated sentences are identified, they are assigned a score of 25. Individual sentence scores are then averaged to form the score for the long-form translation pair.

TASER-NO-REF (Maheswaran et al., 2025) TASER (Translation Assessment via Systematic Evaluation and Reasoning) is a Large Reasoning Model–based metric for translation quality assessment. This metric uses OpenAI's o3 to estimate the quality of a translation in reference-free scenarios. It posits that LRMs are capable of better assessing the quality of translations than vanilla LLMs with advanced prompting strategies.

UVA-MT (Wu and Monz, 2025) This system calibrates quality estimation and likelihood on the google/gemma3-12b-it model, then directly uses the token average likelihood as a metric for quality estimation. No human annotation data is used; the only reliance is on a translation's likelihood as the metric. The same resulting model was also submitted to the WMT 2025 General Translation Task, meaning that it grades its own output as part of the segment-level quality prediction task.

4.1.3 LLMs as Judges

As a third category of system, the shared task organizers obtained quality scores on our test set from 12 different publicly available large language models, using their standard APIs and a templated prompt. These submissions test the ability of general-purpose LLMs as judges of translation quality without fine-tuning or few-shot examples.

LLMs for which we obtained quality scores are: AyaExpanse 8B, AyaExpanse 32B, Claude 4, Command A, Command R7B, DeepSeek V3, GPT 4.1, Llama 3.1 8B, Llama 4 Maverick, Mistral 7B, Qwen 2.5 7B, and Qwen 3 235B. The templated ESA-like prompt is given in Appendix A.

4.2 Meta-Evaluation

The goal of auto-rater meta-evaluation is to quantify how well automatic systems agree with human ratings of translation quality. There are a multitude of ways to approach this problem, as evidenced by the variety of solutions proposed by previous years' editions of the shared task.[7] Ranking-based approaches (traditionally Spearman's ρ, Kendall's τ, or pairwise accuracy) assume the least about the relative shapes of the score distributions: only the directionality matters, and the magnitude of difference is ignored. Linear correlation (traditionally Pearson's r) captures magnitude but thereby assumes a constant slope to the scores and can be unduly influenced by outliers (Mathur et al., 2020).

We follow the same approach as last year to this year's meta-evaluation of Task 1, focusing on improved ranking-based methods.

At the system level, we use soft pairwise accuracy, or SPA (Thompson et al., 2024). SPA uses p-values as a proxy for certainty about the difference between two systems, calculated over both the auto-rater and human scores. This rewards auto-raters that result in the same statistical conclusion as the human scores. However, computation of the p-values requires repeated resampling of segments in order to determine the statistical range of system-level scores. For efficiency of meta-evaluation, SPA *averages* the segment-level scores in each resample as a proxy for the system-level score. Such averaging is a technically incorrect aggregation method for BLEU, CHRF, and a number of other submissions that self-reported that they employ some more complicated methodology.

At the segment level, we again follow last year's process and meta-evaluate metrics using "group-by-item" segment-level accuracy with tie calibration (Deutsch et al., 2023), denoted acc^*_{eq}. Group-by-item processing, recommended by Perrella et al. (2024) avoids pairwise comparisons between translations originating from different source segments.

Because SPA and acc^*_{eq}meta-metrics are based on ranking, we do not perform any normalization on the raw scores output by the auto-raters or annotated by the humans.

We assign ranks to auto-raters based on their significance clusters in the same way that we did last year. We compare all pairs of auto-raters and determine whether the difference in their correlation scores is significant according to the PERM-BOTH hypothesis test of Deutsch et al. (2021). We use 1000 re-sampling runs and set $p = 0.05$. As advocated by Wei et al. (2022), we divide the sample into blocks of 100, compute significance after each block (cumulative over all blocks sampled so far), and stop early if the p-value is < 0.02 or > 0.50. To calculate p-values for SPA, we use a paired permutation test (Noreen, 1989) with 1000 resamples.

Given the significance results (p-values) for all pairs of auto-raters, ranks are assigned starting with the highest-scoring auto-rater. We move down the list of auto-raters in descending order by score, assigning rank 1 to all auto-raters until we encounter the first one that is significantly different from any that have been visited so far. That auto-rater is

[7] See Section 5 of Thompson et al. (2024) and Table 1 of Deutsch et al. (2023) for nice summaries of the approaches taken in prior WMT shared tasks to meta-evaluation at, respectively, the system and segment level.

assigned rank 2, and the process is repeated. This continues until all auto-raters have been assigned a rank. Note that this is a greedy algorithm, and hence it can place two auto-raters that are statistically indistinguishable in different clusters.

The code for running the meta-evaluation is available in the `mt-metrics-eval` library.[8]

While the segments in language pairs evaluated with ESA received two independent human judgments (as per Section 3.2), most of the results and analyses presented in Section 4.3 and Section 4.4 are based on the first complete annotation that we received, which we refer to as "human1." The second set of human judgements ("human2") did not arrive in time to permit a complete analysis with the `mt-metrics-eval` package.

4.3 Main Results

Summarized results for the quality score prediction subtask are shown in Table 4 and Table 5. Table 4 reports average performance across the 14 language pairs for which references were provided, while Table 5 covers the remaining two reference-less language pairs. (Since we do not have complete information about which auto-raters make use of the reference or may do so optionally, we list in Table 5 all the entrants that submitted scores for reference-free language pairs.) Note that three participating systems (ROBERTA-LS, LONG-CONTEXT, and ROBERTA-MULTI) returned output for only three language pairs and are thus not included in either summary table for lack of a fair comparison. Full detailed results broken down by individual language pair are given in Table 19 (part 1) and Table 20 (part 2) in Appendix B; all participating systems appear there.[9]

A striking pattern in this year's results is the strong performance of many baseline systems — especially those based on lexical overlap or embedding similarity. YISI-1, CHRF, and BERTSCORE fill out the top three rank clusters when judged at the segment level in the presence of references. General-purpose LLMs do quite poorly in terms of correlation with human judgments at the segment level, but their system-level performance is better, led by GPT 4.1 and Claude 4. GPT 4.1 and TASER-REF, a reasoning-based model, achieve top-tier performance on system-level correlation when a reference is present; reference-free models are led by GEMBA-V2.[10] Sentinel models, as desired, rank lowly throughout.

Table 5: Task 1 results summary against the "human1" annotations for all language pairs without references (i.e. English–Italian and English–Maasai).

Divergence in these results compared to recent years may be due to a variety of causes. In particular, we note that the source texts were intentionally chosen to be difficult, that they consist of longer paragraph-like segments, and that there are therefore fewer segments available for scoring in each language pair than in the past. Further, we ran the quality score prediction task in a wider variety of language pairs, with a correspondingly wider variety in the quality of the MT output being judged.

We will further explore a few interesting facets of the results in the following section.

4.4 Analysis

In this section, we discuss the performance of MT auto-rater systems from several additional perspectives, in order to interpret our results, to provide further insights on strength and weakness of various classes of auto-raters, and to shed light on upcoming challenges in automated translation quality evaluation research.

4.4.1 SPA vs. Pairwise Accuracy

Because the results in Section 4.3 differ from those obtained in other recent years — notably on the relative strength of string-based metrics — we ran a contrastive evaluation where the system-level meta-metric was changed from SPA to "hard" pairwise accuracy instead. System-level pairwise accuracy (Kocmi et al., 2021) was used as a meta-evaluation metric in the WMT metrics task from 2021 through 2023. This method, similarly to SPA, compares MT system pair ranking decisions between humans and auto-raters, but it ignores the magnitude of the human and auto-rater score differences. Pairwise accuracy also does not require any resampling or averaging of segment-level scores to create proxies for system-level scores.

Table 6 shows the correlation results obtained by using each system-level meta-metric, for language pairs that were provided with references, against the "human1" annotations as the gold standard. The "SPA" columns of the table are equivalent to the system-level data shown in Table 4, repeated here for easy side-by-side comparison. The "Pair Acc" columns show the analogous results using pairwise accuracy. (Note that the use of pairwise accuracy leads to a smaller number of statistically significant auto-rater clusters, so the rank ordinals are not comparable between the "SPA" and "Pair Acc" columns.) The right-most "Diff" column shows the differences in correlation between the two settings.

SPA and pairwise accuracy produced very similar correlation scores and overall rankings of auto-raters. Our contrastive experiments therefore did not shed light on why string-based metrics are performing better than expected. The main difference we observe is that SPA produced substantially more statistically significant comparisons, resulting in twice as many (20 vs. 10) significance clusters. This finding is consistent with Thompson et al. (2024).

Table 7: Average system-level correlations using either all available MT output (equal to Table 4) or only output from selected MT systems unlikely to have hill-climbed on metrics. Correlations are computed against "human1" annotations.

4.4.2 MT Systems That Hill-Climb Metrics

Some systems in the WMT General MT task (Kocmi et al., 2025a), whose output we rely on to create this task's test set, are tuned against automatic metrics (for example, as part of the reward model). This presents a challenge when the same automatic metric is now asked to judge the qual-

ity of the MT: a bias towards the translations that have been specially optimized towards it could negatively affect the metric's correlation with independent human judgments.

To investigate this effect, we conducted a follow-up analysis in which we calculated auto-rater performance only when judging output from a population of MT systems that are highly unlikely to be metric-tuned. These selected MT systems primarily consist of general-purpose LLMs and publicly available MT services. We repeated the system-level meta-evaluation from Section 4.2, using SPA, on this reduced portion of our test set.

Table 7 shows a comparison of the results in the two cases. The "All MT" column represents the rank and average system-level correlation of each participant for the 14 language pairs in the original test set that provide reference translations. (This section of the table is equivalent to the system-level columns of Table 4.) In the "Select MT" column, we display the analogous results on the smaller test set. (Note that the smaller test set leads to a smaller number of statistically significant metric clusters, so the rank ordinals are not comparable between the two columns.) The right-most "Diff" column shows the differences in average correlation between the two settings.

As expected, metrics that are the most likely targets of MT hill-climbing see their correlations with human judgments improve once we remove the affected MT systems. This is true most visibly for the numerous variations of COMET — including all three POLYCAND* auto-raters, all of which rank in the top 10 "most improved." Conversely, the smallest changes in average correlation tend to come from classic string- or embedding-based metrics, which are unlikely to serve as modern-day MT optimization targets, as well as TASER variants and high-performing general-purpose LLMs.

With these results in mind, we caution MT practitioners against evaluating system variants according to the same metrics that played any role in the systems' training process.

4.4.3 Detecting Catastrophic Translations

The distribution of translation quality varies greatly across languages. For example, high-resource languages in our test set tend to come with the most translations that are near perfect, while even state-of-the-art MT systems struggle with lower-resource languages or languages and domains not previously in WMT. We show this distribution of human-annotated ESA scores in Figure 1. This is a problem for trained auto-rater systems, which underperform in unseen domains and tend to follow the language distribution; they are thus likely to score translations into a low-resource language as lower in quality and they have greater variance (Zouhar et al., 2024a,b).

This year's language pairs created a new issue for MT systems: incorrect output language. Specifically, for some language pairs, some MT systems outputted the wrong language, dialect, or script.

Table 8: Ability of auto-raters to detect catastrophic translations (best threshold for F_1). Rows are ordered by average performance; auto-raters perform worse than human for languages with bimodal distributions (Figure 1).

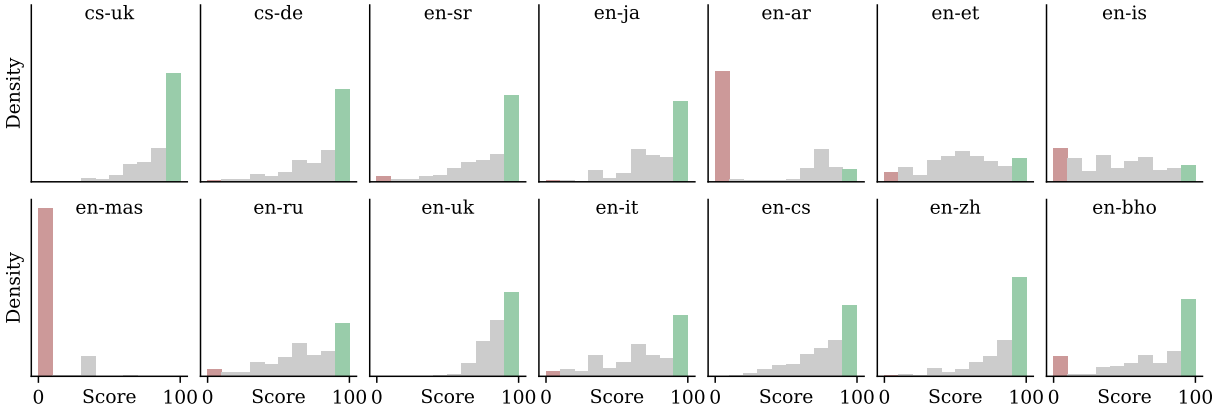

Figure 1: Human score distribution across languages evaluated with the ESA protocol. The pink bar corresponds to translation with less than 10 ESA points, and the green bar shows translations with above 90 ESA points.

Examples include English→Egyptian Arabic (oftentimes incorrectly translated as modern standard Arabic), English→Bhojpuri (incorrectly translated as a mixture of languages), or English→Serbian (incorrectly translated into a Latin script). These systems still made it into the human evaluation because the automatic evaluation filter used did not flag any major issues. In this section, we discuss the failure of auto-rater systems to detect catastrophic translation failure, in use-cases similar to those used by the General MT shared task.

We investigate select languages that do have a notable proportion of catastrophic translations, defined as those receiving an ESA score lower than 10. For those, we collect the set of catastrophic translations and select the threshold for each auto-rater to classify a catastrophic translation that maximizes the F_1 score (true positive = ESA score < 10). This threshold would, in theory, be possible to be used for identifying catastrophic translations without any human input. The results are shown in Table 8. For languages where the mismatch in languages, dialects, and scripts was a critical issue (Arabic, Bhojpuri, Serbian), the second human annotator was able to detect the catastrophic translations much better than automatic systems. This leaves headroom for improvements for auto-rater systems, which have to be able to score translations from state-of-the-art LLMs that might not always follow the instructions.

4.4.4 Utility of the Reference

Having investigated auto-rater systems capabilities in the face of especially poor MT output, we now turn to the complementary question: a study of our submissions' abilities to cope with poor *reference* translations.

Table 9: Auto-raters recording the largest drops (left) and gains (right) in average system-level correlation between language pairs with high- and low-quality references.

We would expect to see a divergence in performance between auto-raters that adhere closely to the reference and those that are reference-free. When the provided reference is itself of poor quality, auto-raters in the first group may be misled into misjudging the MT output. When the reference is quite accurate, on the other hand, auto-raters in the second group may suffer from not being able to consult it. Below we examine each of these cases individually.

For this analysis, we divide the language pairs in our test set into groups based on the *references'* performance in the human evaluation. In the WMT General Translation task (Kocmi et al., 2025a), the reference translation was judged to fall alone into the top-ranked cluster of "systems" in five language pairs: English→Arabic, English→Estonian, English→Icelandic, English→Japanese, and Japanese→English. Conversely, the reference placed relatively lowly in English→Russian (rank

9–11 of 19), English→Chinese (11–13 of 19), and Czech→German (9–12 of 21).

We extract system-level correlations for each participating auto-rater out of Table 19 and Table 20 in Appendix B in order to compute the average correlation separately per each group of language pairs. Since a strong auto-rater is more likely to outperform a weak auto-rater in *any* language pair, we compare instead the difference in correlation for the *same* auto-rater from one group to another, as a measure of its specific degradation in the face of low-quality references.

Table 9 shows the results. Indeed, our five string- and embedding-based baselines are much more sensitive to poor reference quality than any other auto-rater, by a significant margin. Likewise, on the other hand, the auto-raters that improve their performance the most on languages with poor references comprise of six of the "LLM as a Judge" models and four official submissions to the shared task: (MR7.2.1 and MR6 are based on Gemma 3 models; Q_MQM and Q_RELATIVE-MQM are based on Qwen 3.) All are reference-free systems, as expected.

4.4.5 Metric Score Difference Interpretation

Following the WMT Metrics Shared Task in the last two years, we continue to conduct analyses to find the threshold of metrics' score differences that corresponds to statistical significance of MT system rankings demonstrated by human annotators and the metrics themselves.[11] These analyses provide an interpretation of the metrics' score differences, support building an intuitive sense of metric score meanings, and encourage broader adoption of new automatic MT evaluation metrics. This year, since we expanded the number of language pairs (LPs) from 3 to 16, instead of analyzing metrics score differences by individual LP we are pooling the 14 LPs with references together in the following analyses for clear presentation and ease of understanding.

As a reminder, the results in this section should *not* be used as arguments to forego significance tests or appropriate human evaluation.

Correspondence to human scores significance: We first study the relationship between statistically significant differences in human scores and the magnitude of metric differences as in (Lo et al., 2023a). We run a one-sided paired t-test with an equal variance assumption for each system pair on segment-level human scores. After that, we fit the corresponding metric score differences and the p-values of the t-test on the human scores to an isotonic regression (Robertson et al., 1988), which predicts whether the human score difference will be significant given the metric's score difference. This year, we also consider the sign of the metric's difference. If the metric's decision disagrees with the human's but the human score difference is insignificant, we also consider that as a correct prediction. Isotonic regression produces a non-decreasing function where the classifier output can be interpreted as a confidence level.[12] We set $p_h < 0.05$ as the significance level of human scores. Thus, the output of the isotonic regression function can be viewed as $Pr(p_h < 0.05 \mid \Delta m)$ where p_h is the p-value of the t-test on the human scores for each system pair and Δm is the metric score difference.

Figure 2 shows the (log) p-value of one-sided paired t-test on the human scores against the corresponding BLEU, YISI-1, and TASER-REF score difference for each system pair. Additional figures (Figures 9-11 in Appendix C) show the same analyses for all metrics. For each metric, we can choose a particular level of confidence (i.e., a point along the y-axis on the right) to get the metric score difference cutoffs (i.e. a point along the x-axis) that this metric difference reflects significant human score differences. Drawing a horizontal line from the confidence level, say 80%, to the red line enables us to find the minimum metric difference cutoff required at the corresponding x-value down from the red line, i.e. 3.0 for BLEU in Figure 2. Using this lookup method, Table 10 show the cutoffs of Δm when $Pr(p_h < 0.05 \mid \Delta m) = 0.8$ for each metric. We run 10-fold cross-validation, and Table 10 shows that the range of precision in the cross-validation is consistently high across metrics. This means the metric cufoffs we find using the regression model are reliable.

Table 10 serves as a reference for understanding the score differences between MT systems provided by modern metrics. For example, we see that a BLEU difference of 3.0 corresponds to 80% confidence that two MT systems ranked by BLEU will match the decision made by human annotators with a significant difference. Meanwhile, a

[11] This section uses the term "metric," but the analysis is extended to auto-raters of all types as defined earlier in this paper.

[12] scikit-learn.org/stable/modules/isotonic.html

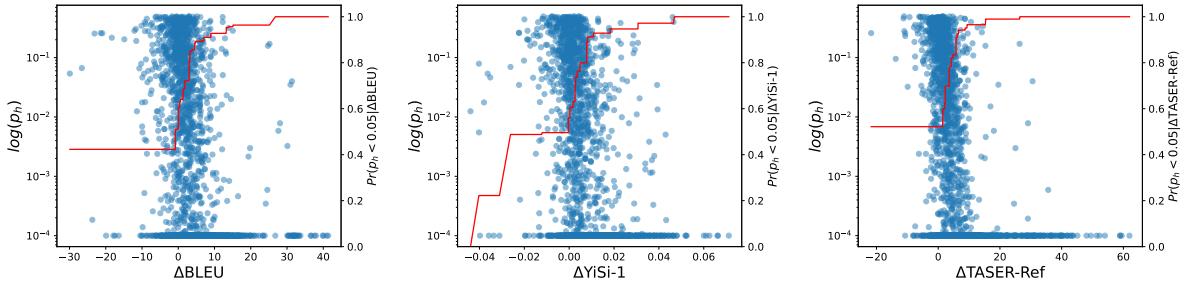

Figure 2: Log p-value of one-sided paired t-test on human scores (p_h) against each metric (left: BLEU, center: YISI-1, right: TASER-REF) score difference for each system pair. The red line is the isotonic regression fit to all data points, representing $Pr(p_h < 0.05 \,|\, \Delta m)$. Note: for readability, values of p_h are rounded up to 0.0001 when they are less than 0.0001.

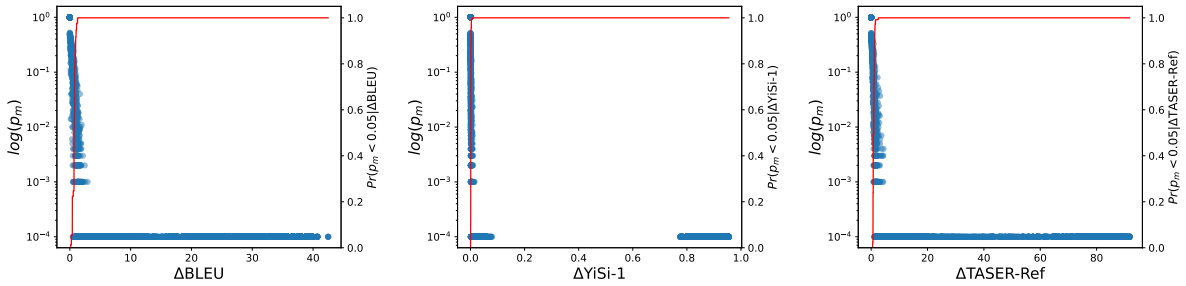

Figure 3: Log p-value of significance test with bootstrap resampling (p_m) on system-level metric scores against each metric (left: BLEU, center: YISI-1, right: TASER-REF) score difference for each system pair. The red line is the isotonic regression fit to all data points, representing $Pr(p_m < 0.05 \,|\, \Delta m)$. Note: for readability, values of p_m are rounded up to 0.0001 when they are less than 0.0001.

TASER-REF score difference of 4.2 would have the same 80% chance of human-judged significant difference.

Correspondence to metric scores significance: We run a study similar to that above, but on the relations between statistically significant differences in metric scores and the magnitude of metric differences as inspired by Marie (2022). Instead of the one-sided t-test on human scores, the p-values are now obtained by running statistical significance tests with bootstrap resampling on the metric scores for each system pair. We fit the corresponding metric score differences and the p-values of the significance test to an isotonic regression for predicting whether the translation quality improvement as indicated by the metric will be significant given the metric score difference. We set $p_m < 0.05$, and thus the output of the isotonic regression function is now $Pr(p_m < 0.05 \,|\, \Delta m)$, where p_m is the p-value of the significance test on the metric scores for each system pair and Δm is the metric score difference.

Figure 3 shows the (log) p-value of the significance test with bootstrap resampling on the metric scores for BLEU, YISI-1 and TASER-REF score difference of each system pair. Additional figures (Figures 12-14 in Appendix C) show the same analyses for all metrics. Using the same lookup method described in the previous study, Table 11 shows the cut-offs of Δm when $Pr(p_m < 0.05 \,|\, \Delta m) = 0.8$ for each metric. We run 10-fold cross-validation, and Table 11 shows that the range of precision in the cross-validation is consistently high across metrics. This means that the metric cutoffs we find using the regression model are reliable.

Table 11 serves as a reference of metric differences that correspond to statistical significance with high confidence. For example, we see that a BLEU difference of 0.87 corresponds to 80% confidence that the difference is statistically significant. Meanwhile, a TASER-REF score difference of 1.1 would have the same 80% chance of being statistically significant. Our results, agreeing with Marie (2022), show that to claim significant differences ($p_m < 0.05$) on BLEU with high confidence (80%), the differences should be higher than the shared understanding (0.5 BLEU) in the research community.

We have to emphasize again that this result

should *not* be interpreted as evidence to forego significance test or appropriate human evaluation. Instead, we are only providing assistance to build an intuition on the meaning of the scores provided by the new metrics to encourage the transition away from lexical metrics towards more recent and stronger metrics.

5 Task 2: Span-Level Error Detection

This section presents the span-level error detection task in more detail. We discuss in more depth the error annotations per language pair (Section 5.1), and describe the baselines (Section 5.2) and the participant submissions (Section 5.3). Our meta-evaluation is described in Section 5.4. We then present the results, mostly focusing on the primary submissions, in Section 5.5.

5.1 Error Annotations

We use the ESA and MQM annotations sourced from the General MT task for this task as well, considering only the subset of documents and systems that were human-evaluated. We note that the error span patterns vary significantly per language as shown in Figure 4, which is a complementary view of Figure 1. For the translation pairs referring to lower-resource languages (e.g. English-Maasai), we frequently have the phenomenon where the whole segment is annotated as an error (frequently corresponding to hallucinated text). In contrast, annotations for higher-resource language pairs (e.g. Czech-German, English-Italian) correspond mostly to smaller, isolated error spans.

5.2 Baselines

XCOMET (Guerreiro et al., 2024) XL (3.5B) and XXL (10.7B) are neural models that are trained to identify MQM error spans in sentences along with a final quality score, thus leading to an explainable neural auto-rater. It adopts a unified input and output approach, allowing the prediction of translation quality assessment in multiple input modes (SRC-ONLY, SRC+REF and REF-ONLY), as well as generates sentence-level and word-level quality assessments. We use the SRC+REF mode with word-level predictions as the official shared task baselines.

Human2 For a subset of languages (except JA-ZH_CN and EN-KO_KR), the General MT shared task also collected a second round of human annotations. While not strictly a baseline, comparing submissions against a HUMAN2 set of evaluations provides additional insights into how automated metrics perform relative to human judgment. We report some statistics on HUMAN2 against HUMAN1 annotations in Table 12.

	# Errors	# Major Errors
Human1	33.56%	18.54%
Human2	32.48%	16.95%

Table 12: Translation error distribution on human annotations.

5.3 Submissions

We note that, this year, all task participants employed an LLM-based auto-rater to produce the fine-grained annotations. Specifically, the following systems were submitted to the task:

AIP (Yeom et al., 2025) The participants propose a tagged span annotation (TSA) approach, i.e., using reasoning LLMs to introduce inline numbered tags (e.g. $< v_0 > error\_span < \backslash v_0 >$) that explicitly mark error spans, and can easily map to diverse annotations (error severity, type, etc.) within the translated text. They enhance the tag schema to allow for annotation of omissions using zero-length tags. To be able to insert such tags on the hypothesis segments, they employed the OpenAI o3 and o4-mini reasoning models, leveraging the structured-output response mode to detect translation errors at the span level, formatted as JSON strings with the TSA approach mentioned above. They use few-shot examples and optimize for precision and minimality, explicitly prompting the models to (i) only label spans that it is confident are erroneous, and (ii) restrict the annotation to the minimal substring responsible for the error.

AutoLQA (Hrabal et al., 2025) The participants leveraged their Automatic Linguistic Quality Assessment (AutoLQA) systems, i.e., LLM-based evaluators designed to produce complete MQM-style annotations, including error spans, categories, and severities. The team fine-tuned GPT-4.1 and GPT-4o-mini model variants using internal data (≈100,000 segments), and using the WMT-QE-22 and Google-MQM datasets (dev + test) to determine performance improvements. They experiment with different prompts, controlling for the annotation structure, i.e., relaxing the MQM annotations to remove the category and approximate the ESA style. Their primary submission corresponds to the fine-tuned GPT-4o-mini and the secondary to the GPT-4.1-mini version, respectively.

GemSpanEval (Juraska et al., 2025) The participants fine-tuned a Gemma 3 27B model on past WMT MQM annotations formatted as JSON. Train-

ing data covered the period WMT20–24 (Specia et al., 2020, 2021; Zerva et al., 2024), and optimization was performed with the Adafactor (Shazeer and Stern, 2018). A central focus of their approach was the resolution of error span ambiguity, ensuring that predicted spans are uniquely identifiable within the hypothesis segment. The model was trained to extend spans with additional context whenever a substring was not unique. The context expansion covers both preceding and following context and proceeds incrementally — word by word for alphabetic languages and character by character for logographic or syllabic languages such as Chinese and Japanese — until a unique substring is obtained. The model was designed to operate in both reference-based and reference-free (QE) modes, and the team submitted both variants as their primary and secondary systems, respectively.

5.4 Meta-Evaluation

For Task 2, we use the micro-F1 score between the predicted and the gold error spans calculated at the character level as the primary metric. The score is weighted to allow for half points for correctly identified spans with misclassified severity. Compared to the previous year, instead of computing the best matching annotation for each character (Zerva et al., 2024), we compute F1 over multiple error annotations per character, allowing for separate comparisons for each overlapping error span.

More specifically, for each hypothesis, we compute the counts for the number of "major" and "minor" errors at each character index separately for both gold annotations and predictions. This results in four statistics per hypothesis: gold major counts, gold minor counts, predicted major counts, and predicted minor counts, each of length equal to the length of the hypothesis. We then calculate a true positive (TP) score by iterating through each character position and assigning full credit based to the number of overlaps between gold and predicted counts of the same severity type (major with major, minor with minor) at each character. In the case of overlapping annotations with different severity, we assign a partial credit to the *unmatched* gold counts and predicted counts at the same character position, regardless of the original severity. This allows a predicted major error to get partial credit if it aligns with a character that was part of a gold minor error, and vice-versa. These TP scores are summed across all characters and all hypotheses. Finally, precision (P), recall (R), and F1 score are calculated based on the aggregated TP, total gold counts, and total predicted counts. The complete logic can be seen in Algorithm 1.

5.5 Main Results

Table 13 presents the complete results for all evaluated systems. Below are our primary observations and findings from these performance results.

Current auto-raters fail to localize errors. Across all language pairs where HUMAN2 scores are available, there is a very large gap between the auto-raters' performance scores and the human rater scores. HUMAN2 scores range from around 12% to over 93%, while the best auto-raters rarely exceed 35%, indicating the task is very challenging for current automated methods.

There is large variation across language pairs. No single auto-rater consistently outperforms others across all language pairs. The range of scores across different language pairs suggests varying levels of difficulty for the auto-raters. For example, most systems struggle significantly with EN-UK_UA, yielding very low F1 scores. In contrast, EN-MAS_KE allows the GemSpanEval system to achieve its peak scores. On average, GemSpanEval achieves the highest micro-F1 score (13.47%). AIP follows next with decent average performance (11.63% Primary). AutoLQA systems have the lowest average scores.

Auto-raters exhibit different precision-recall tradeoffs The AIP submissions, unlike all others, seem to be obtaining higher micro-recall, at the cost of lower micro-precision, despite including precision-focused instructions in the prompt.[13] This outcome contrasts sharply with XCOMET, AutoLQA/ESA, and GemSpanEval, which tend to be more conservative, often achieving higher precision than recall, especially on difficult languages. Human2, on the other hand, shows that high performance requires excelling in both measures, a balance that the auto-rater systems currently fail to achieve.

Auto-raters show different strengths in generalization and consistency. Table 14 reports macro-F1 score for all primary and secondary submissions. Similar to the primary evaluation (macro-F1), HUMAN2 achieves the best scores across the board. Interestingly, AIP stands out as the best submission in terms of macro-F1, averaging 30.33%. This is significantly higher than AutoLQA (15.93%) and GemSpanEval (13.53%). This largely suggests that AIP can achieve good F1 scores on average across language pairs, but its overall performance on the sheer volume of errors might be hampered by poor performance on certain heavily-weighted error segments or language pairs. For example, EN-AR_EG has many segments with full spans marked as errors due to hypotheses being in the wrong dialect (see Figure 4), and the gap in micro- and macro-F1 is large (14.23%). On the other hand, GemSpanEval's micro-F1 (13.47) is very close to its macro-F1 (13.53), which suggests a more consistent performance across language pairs in terms of the number of errors.

Overall, the results suggest that precisely locating error spans remain a challenging problem for auto-rater systems.

6 Task 3: Quality-Informed Segment-Level Error Correction

The subtask received a total of 6 submissions, from 3 participants. The results depict a clear outcome in terms of the winning system.

6.1 Data and Baselines

We reduced the number of language pairs to 6, and overall data size to a total of 6,000 instances

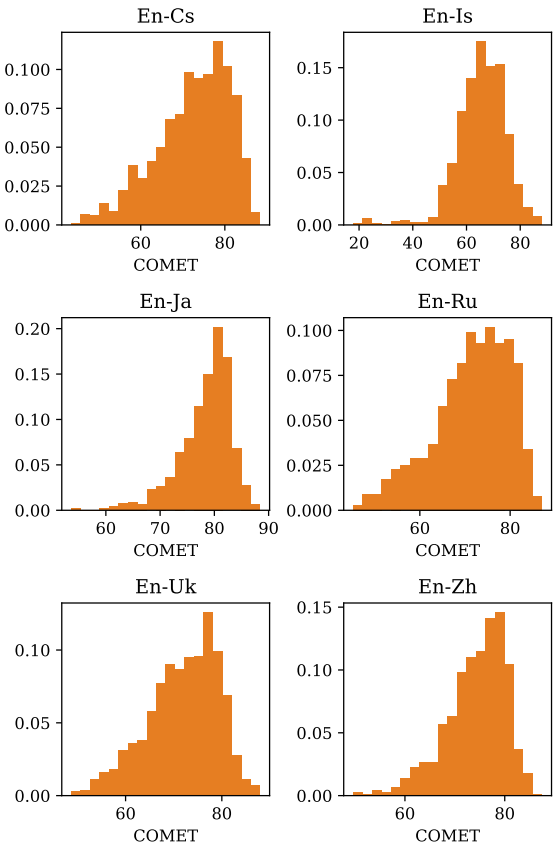

Figure 5: Task 3 - Language-pair-specific COMET score distribution of translations in the evaluation set

with an equal number of samples *per* pair. The preparation of the test set ensured representation of samples across all quartiles of the COMET score distribution. Due to Codabench limitations and memory-intensive COMET models used for evaluation, we displayed leaderboard results using a fixed 100 random samples from each submission during the competition phase. Figure 5 shows the COMET score distribution of the evaluation set of each language pair. We observe that for all language pairs, we have similar distributions skewed towards high-quality scores.

We include the following baselines along with the participants' submissions:

- **BASELINE-S1** This baseline translates the source segment from scratch using Gemma3-it-27B LLM (Gemma Team et al., 2025). It ignores the MT system output, and retranslates the input source segment. We provide the prompt used in Appendix Table 25.
- **BASELINE-S2** The final baseline uses QE information from post-edit original translation based on quality estimation from XCOMET-

[13] Table 23 shows that AIP achieves higher precision than recall on macro-F1 scores, which is aligned with their focus on being precision-focused at the instance level.

XL (Guerreiro et al., 2024), and then uses Gemma3-it-27B for APE. We provide the prompt used in Appendix Table 26.

6.2 Submissions

PHRASE (Hrabal et al., 2025) Participants leverage GPT models, specifically, o3 and o3-mini, to produce corrections over MT output given the source segment, without using the provided QE information. They use a proprietary common prompt for all systems submitted, and add variations to the prompt to change the correction strategy. The three proposed training-free approaches focus on either "only correcting errors (-S3)", "improving fluency (-S2)", and "improving fluency with steps to reason for corrections (-S1)".

SURREYPAI (Padmanabhan, 2025) Participant proposed two training-free approaches to Quality-informed error correction. The first approach (-S1) leverages the provided DA score, uses it as a selector, and routes to a specific open-weight LLM for re-translation using input QE information. This approach leverages one of six selected open-weight LLMs, wherein some LLMs were selected for their robust performance on other NLP tasks in the target language. The second approach (-S2) uses fine-grained error span information to replace an erroneous token with "__BLANK__" and then uses an LLM to replace this token contextually and "fills in the blank".

PACIFICO (Sharma, 2025) Participant proposed using natural language explanations as an intermediate step to the "detector-corrector" approach, which proposes error identification and then error correction. They use xTower to generate intermediate natural language explanations based on input QE information. The approach then feeds the explanation along with the source segment and MT output to the Gemini-1.5-Pro model to obtain final corrections.

6.3 Evaluation Metrics

We evaluate the quality of the corrections over MT, using ΔCOMET as the primary metric, and Gain-to-Edit Ratio (GER) to quantify efficiency.

ΔCOMET: Measures how much the in-post-edits improve over the original MT output (hyp) based on COMET score (Rei et al., 2022b). COMET[14] is a neural evaluation metric trained on human quality assessments, designed to capture meaning preservation and fluency by comparing translations against the source:

$$\Delta\text{COMET} = \text{COMET}(\text{src}, \text{pe}) - \text{COMET}(\text{src}, \text{hyp})$$

Positive values signal that post-editing yields a translation judged closer to human quality, while negative values imply a degradation relative to the initial MT output.

Gain-to-Edit Ratio: This metric evaluates the efficiency of edits by relating quality gains to the editing effort. According to our formulation, it is defined as the ratio between ΔCOMET and the Translation Edit Rate (TER)[15] (Snover et al., 2006) between the post-edited output (pe) and the original MT output (hyp):

$$\text{Gain-to-Edit Ratio} = \frac{\Delta\text{COMET}}{\text{TER}(\text{pe}, \text{hyp})}$$

Higher values indicate that larger quality improvements are achieved with fewer edits, while lower or negative values suggest limited or detrimental improvements relative to the editing cost.

6.4 Main Results

The main results for Task 3 are summarized in Table 15, and other metrics used for analysis are reported in Table 16. Submissions are ranked primarily by the average ΔCOMET across languages (Table 15). SURREYPAI-S1 attains the best system-wide performance, leading on both ΔCOMET for every language pair; PHRASE-S1 stands at the next best, and these two are the only submissions that surpass the BASELINE-S2 results over the primary metrics. However, in terms of efficiency of edits (GER), PHRASE-S1 obtains a higher score for En-Is, and BASELINE-S2 seems to perform the best for En-Uk.

Figure 6 illustrates the mean change in ΔCOMET for eight different systems, including two baselines, across six target languages. A clear finding is the superior performance of the SURREYPAI-S1 system, which consistently achieves a positive ΔCOMET across all language pairs, indicating an improvement in translation quality. This system shows particularly strong gains for Icelandic (`is_IS`) and Russian (`ru_RU`).

[14] Unbabel/wmt22-cometkiwi-da

[15] Computed using TERCOM-0.7.25 with default flags except the case sensitivity. Character-level tokenization is used for Chinese and Japanese, and *sacrebleu* (Post, 2018) '13a' for the rest.

Table 15: Task 3 - Performance of systems across languages with ΔCOMET and Gain to Edit Ratio (GER) metrics. Systems are ranked in order of average ΔCOMET.

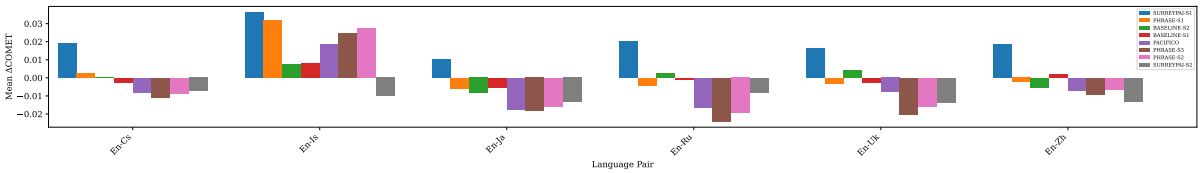

Figure 6: Task 3 - Mean ΔCOMET scores *per* **language pair** across submissions.

In contrast, most other systems exhibit mixed or negative results, with PHRASE-S2 systems frequently showing a degradation in quality, especially for Russian and Ukrainian (uk_UA). Interestingly, the English–Icelandic language pair exhibits the most notable overall improvements, with several systems achieving consistent gains. In contrast, performance on English–Japanese remains relatively limited across all systems. Correlating these outcomes with the corresponding evaluation sets suggests that LLM-based approaches follow trends observed in earlier transformer encoder–decoder APE systems (Akhbardeh et al., 2021; Bhattacharyya et al., 2023; Zerva et al., 2024). Specifically, when baseline translations are weaker—evidenced by TER distributions skewed toward higher values, APE systems tend to yield larger improvements, and vice versa. A similar pattern is observed with COMET: When the score distribution is skewed toward the upper end (Figure 5), the marginal improvements achievable by LLM-based automatic post-editing systems tend to diminish.

Figure 7 indicates that while SURREYPAI-S1 improves translations across all four domains, PHRASE-S1 shows mildly positive or negligible improvements on all. Interestingly, PACIFICO shows decent gains on *literary* and *social* domain data, but degradation in performance on the *news* and *speech* data, leads to its lower rank on the overall results. It also indicates that improvements in the *speech* domain are tough to obtain and no other system, except SURREYPAI-S1, shows improvements in terms of translation quality. We note that the speech domain data is derived from ASR transcriptions, indicating that text data derived from multimodal input may need further investigation or a different approach to correction.

Edit-Operations Figure 8 illustrates the distribution of post-editing operations like insertion (green), deletion (blue), substitution (orange), and shift (red) across various systems for six different language pairs. A clear and consistent trend is observable across all conditions: *substitution* is the most frequent edit operation, typically accounting for more than 50% of all changes. This suggests that the primary challenge for the translation systems lies in lexical choice rather than fluency. Deletion is generally the second most common error, followed by insertion. Shift operations, which correct word order, are consistently the least frequent type of edit, indicating that the models generally produce syntactically plausible translations. While this distribution pattern holds for all systems and language pairs, there are subtle variations; for instance, translations into typologically distant languages like Japanese and Chinese appear to necessitate a mildly higher proportion of insertions and deletions compared to the other language pairs.

6.5 Meta-Evaluation Metrics

While the main evaluation relies on reference-less evaluation through ΔCOMET and GER, we complement them using reference-based metrics for further analysis. In particular, we adopt ΔBLEURT (Sellam et al., 2020), a neural metric that captures semantic similarity, and

Figure 7: Task 3 - Mean ΔCOMET scores *per* **domain** across submissions.

System Name	En-Cs		En-Is		En-Ja		En-Ru		En-Uk		En-Zh		Average

Table 16: Task 3 - Performance of participant systems across languages with ΔchrF for En-Ja, En-Zh, ΔchrF++ for the rest, and ΔBLEURT for all language pairs.

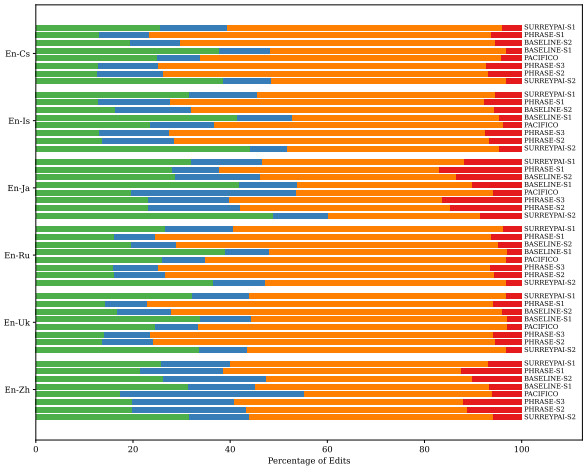

Figure 8: Task 3 - Language pair-wise **distributions of edit operations** performed on the original translation. Green indicates insertion, Blue indicates deletion, Orange indicates substitution, and Red indicates shift operations.

ΔchrF++[16] (Popović, 2017), a character n-gram overlap metric that emphasises lexical similarity. Unlike the primary reference-less metrics, which measure how much system outputs diverge from the raw translations in the desired direction, these allow us to have *an indication of how much closer system outputs have moved toward the reference or gold-standard translations* in terms of semantics and lexical distance.

Δ BLEURT: BLEURT is a learned, reference-based evaluation metric that leverages pretrained language models fine-tuned on human-rated data to capture semantic adequacy and fluency beyond surface overlap (Sellam et al., 2020). According to our formulation, ΔBLEURT measures the change in BLEURT when moving from the original MT output (hyp) to the post-edited output (pe) against the same reference (ref):

$$\Delta\text{BLEURT} = \text{BLEURT}(\text{pe, ref}) - \text{BLEURT}(\text{hyp, ref})$$

A positive ΔBLEURT indicates that resultant corrections improve semantic similarity to the reference, while a negative value suggests a reduction in quality.

ΔchrF++: chrF++ computes an F-score over word-level n-gram precision and recall between the hypothesis translation and a reference (Popović, 2017). The ΔchrF++ captures word n-gram quality gains, providing an additional cross-check beyond semantic metrics such as COMET.

$$\Delta\text{chrF++} = \quad \text{chrF++}\,(\text{pe, ref}) - \text{chrF++}\,(\text{hyp, ref})$$

A positive ΔchrF++ indicates that corrections improve similarity to the reference, while a negative value suggests a reduction in quality. We report ΔchrF for Chinese and Japanese and ΔchrF++ for the rest.

6.6 Meta-Evaluation Results

From Table 16, we observe that gains are mixed across participant systems and languages. Overall, ΔBLEURT improvements are only visible for SURREYPAI-S1 and BASELINE-S1, indicating that corrections did not substantially improve semantic adequacy across most systems. Multiple systems perform strongly on the English–Icelandic pair, particularly in ΔchrF++,

[16]Computed using sacrebleu (Post, 2018) with default flags

while English–Chinese exhibits degradation for nearly all submissions, and English–Czech results remain mixed. On English–Ukrainian, PHRASE-S1 and BASELINE-S1 clearly outperform SURREYPAI-S1 by a wide margin.

BASELINE-S1 achieves the highest system average for ΔchrF++, with PHRASE-S3 and PHRASE-S1 also showing moderate positive gains. In contrast, no other systems achieve consistent improvements in overall translation quality. Among baselines, BASELINE-S1 is comparatively closer to references, delivering competitive results across multiple languages, whereas BASELINE-S2 remains close to neutral.

Several systems (PACIFICO, PHRASE-S2, SURREYPAI-S2) show negative deltas on the secondary metrics for some languages, suggesting that their edits often diverge from reference translations despite attempted corrections. Notably, PACIFICO displays extreme variance—achieving large gains on English–Icelandic and English–Chinese, but severe degradation on English–Russian (–42.936 ΔchrF++), indicating the instability of certain LLM-based approaches across language pairs.

A closer comparison of both SurreyPAI submissions shows contrasting behaviour: SURREYPAI-S1 achieves the best system average in ΔBLEURT (+0.010), suggesting modest improvements in semantic adequacy, but its chrF average remains negative. In contrast, SURREYPAI-S2 underperforms on both metrics, with the steepest degradation in chrF (–4.851), particularly on the English–Ukrainian pair (–22.708), highlighting the sensitivity of system design choices to specific language pairs. Given the approach to SURREYPAI-S1, the system is able to retranslate and improve on translation quality, but Table 16 shows that such an approach does not bring the output closer to a known reference. At a language level, English-Icelandic seems to show the most consistent improvements, while English-Russian shows the most severe degradations. English-Chinese and English-Japanese also prove challenging, with limited gains, which may suggest that languages with morphological richness (Ukrainian and Icelandic) may offer opportunities for effective corrections, whereas typologically distant languages (Chinese and Japanese) are still harder to handle.

We also conducted batchwise significance testing with ΔCOMET scores to compare system performance. The dataset with $6,000$ instances was divided into 60 fixed batches with unique samples and 100 additional randomly sampled batches, yielding a total of 160 batchwise averages per system. For each batch, the system with the highest ΔCOMET score was identified, and the frequency of these "wins" across all batches served as an indicator of each system's consistency and robustness. Table 17 shows SURREYPAI-S1 dominates the evaluation with 157 out of 160 wins, while all other systems achieved at most two wins (PHRASE-S2 with 2 and PHRASE-S1 with 1), and the remaining systems failed to win a single batch. Testing reveals SURREYPAI-S1 to be the best system consistently across both static and random batch settings.

System	Win Count
SURREYPAI-S1	157
PHRASE-S2	2
BASELINE-S2	0
BASELINE-S1	0
PHRASE-S1	1
PACIFICO	0
PHRASE-S3	0

Table 17: Task 3 - Batch-wise meta-evaluation: winning counts per system.

6.7 Task Overview

This sub-task marks the first instance where translations were majorly generated by LLMs rather than by traditional NMT systems. We observe that LLM-based APE systems struggle to further improve these translations. This trend is analogous to earlier iterations: while neural APE systems could successfully enhance SMT outputs, they initially faced difficulties in improving NMT-generated translations. Then last year, LLM-based APE systems demonstrated the ability to improve NMT translations even for underrepresented languages. In contrast, when confronted with LLM-generated translations, even in high-resource languages, they now appear to encounter similar challenges. It requires innovative and sophisticated strategies that can effectively address the unique challenges inherent in the high-quality translations produced by LLMs.

7 Challenge Sets

For the third year, our shared task included a subtask involving challenge sets. This subtask is inspired by the *Build it or break it: The Language Edition* shared task (Ettinger et al., 2017), which aimed at testing the generalizability of NLP systems beyond the distributions of their training data.

Challenge Set	LPs	Phenomena	Items
CoDrift (Tan et al., 2025)	3	continuation drift	3,326
GAMBIT+ (Filandrianos et al., 2025)	33	gender bias	289,443
MSLC25 (Knowles et al., 2025)	2	low quality MT	369
SSA-MTE (Li et al., 2025a)	11	African languages	12,769

Table 18: Overview of the participation at the metrics challenge sets subtask.

Whereas the standard evaluation of the shared task is conducted on test sets containing generic text from real-world content, the challenge set evaluation is based on test sets designed with the aim of revealing the abilities or the weaknesses of the metrics or evaluating particular translation phenomena. In order to shed light on different perspectives on evaluation, the subtask takes place in a decentralized manner: contrary to the main metric task, the test sets are not provided by the organizers but by different research teams, who are also responsible for analyzing and presenting the results.

7.1 Subtask Structure

This subtask is made of three consecutive phases; (1) the *Breaking Round*, (2) the *Scoring Round*, and (3) the *Analysis Round*:

1. In the *Breaking Round*, every challenge set participant (*Breaker*) submits their challenge set S composed of examples for different phenomena, where every example $(s, t, r) \in S$ contains one source sentence s, one translation hypothesis t, and one reference r.

2. In the *Scoring Round*, the metrics participants from the main task (the *Builders*) are asked to score with their metrics the translations in the given test set. Also, in this phase, the metrics task organizers score all data with the baseline metrics.

3. Finally, after having gathered all metric scores, the organizers return the respective scored translations to the *Breakers* for the *Analysis Round*, where they employ their own evaluation for the performance of the metrics with regard to the phenomena they intended to test.

7.2 Challenge Set Descriptions

This year there were 4 submissions, covering a wide range of phenomena and 23 different language pairs, which supersede the official language pairs of the Metrics Shared Task. An overview of the submitted challenge sets can be seen in Table 18. A short description of every submission follows:

CoDrift (Tan et al., 2025) Quality Estimation (QE) models such as COMET-KIWI, MetricX, and ReMedy exhibit a recurring failure mode: they often assign high scores to translations that start faithfully but subsequently drift into fluent yet irrelevant content. To systematically investigate this issue, Tan et al. (2025) present CoDrift, a WMT25 challenge set designed to stress-test QE robustness against continuation drift. The dataset is constructed entirely from controlled large language model (LLM) experiments: for each source sentence, we generate multiple "drift" candidates whose continuation length and topical proximity are systematically manipulated. This design enables precise control over the degree of semantic divergence, while maintaining surface fluency, thereby creating challenging cases that can mislead current QE systems. CoDrift aims to provide the community with a targeted benchmark for diagnosing and improving QE models in the presence of subtle off-target content.

Gambit+ (Filandrianos et al., 2025) In this submission, the authors introduce GAMBIT+[17], a large-scale challenge set designed to probe gender bias in QE systems. The dataset extends the GAMBIT corpus of English gender-ambiguous occupational terms to three source languages (English, Turkish, Finnish), where occupational gender is not specified, and 11 target languages with grammatical gender: Arabic, Czech, Greek, Spanish, French, Icelandic, Italian, Portuguese, Russian, Serbian, and Ukrainian. Importantly, all occupations are linked to the ISCO-08 classification, an internationally recognized standard for categorizing jobs, which enables fine-grained per-occupation analysis and ensures coverage of the full occupational spectrum. For each source text, two parallel target translations were produced, one masculine and one feminine, differing only in the gender of the occupation and all dependent grammatical elements (e.g., pronouns, adjectives) to ensure consistency. An unbiased auto-rater should assign near-identical scores to both versions. Each source-target language pair contains over 8,500 source texts, with two parallel target translations (masculine and feminine),

[17] huggingface.co/datasets/ailsntua/gambit-plus

resulting in more than 17,000 source-translation pairs per language pair and over 550,000 pairs in total across the 33 language combinations. With its scale, full ISCO coverage, and strictly parallel design, GAMBIT+ provides a comprehensive and controlled resource for investigating gender fairness in QE metrics.

The authors benchmarked three baseline metrics and eight shared task submissions on GAMBIT+, though one baseline was excluded from the analysis since it evaluated only source texts rather than target translations. Across the remaining auto-rater systems, all showed statistically significant differences between masculine and feminine outputs, but the scale of these differences varied widely. For instance, UvA-MT and rankedCOMET displayed average normalized score gaps of over 100% and 70% respectively, while Polycand variants and Polyic metrics registered less than 4%. Bias magnitude was influenced by both the source and target languages, with English sources and target languages such as Arabic, Russian, and Icelandic exhibiting stronger disparities. At the occupational level, most auto-raters favored masculine translations overall, yet stereotypically female-associated roles (e.g., nursing, midwifery, cleaning professions) often saw the opposite pattern, reflecting known tendencies in MT systems. These results show that QE systems are sensitive to gender even in cases where they shouldn't be, amplifying occupational stereotypes rather than remaining neutral, underscoring the need for systematic auditing and fairness-aware design.

MSLC25 Challenge Set (Knowles et al., 2025) Based on the past two iterations of the Metric Score Landscape Challenge (MSLC; Lo et al., 2023b; Knowles et al., 2024), MSLC25 is a smaller-scale study of auto-rater performance on a broad range of MT quality along with several specific corner cases and phenomena. MSLC25 includes a collection of low- to medium-quality MT systems' output on Japanese–Chinese news data from the WMT25 General MT Shared Task test set. As in previous editions, the challenge set explores auto-rater scores assigned to empty strings in the source or target, showing unexpected results for some auto-rater systems. In small-scale proof-of-concept experiments (using Japanese, Chinese, English, and Czech data) the challenge set also examines auto-rater scores assigned to mixed- and wrong-language text and English language spelling variants. The results of MSLC25 continue to highlight the need for auto-rater builders to test their systems on corner cases and wide ranges of MT quality before releasing them to the broader research community.

SSA-MTE Challenge Set (Li et al., 2025b,a) The SSA-MTE challenge set is a large-scale benchmark for machine translation evaluation in Sub-Saharan African languages. It comprises 12,768 human-annotated adequacy scores across 11 language pairs involving English, French, and Portuguese, evaluated on outputs from six commercial and open-source machine translation systems. Results indicate that correlations with human judgments remain generally low, with most systems achieving Spearman correlations below the 0.4 threshold for medium-level agreement. Performance varies substantially across language pairs, and in extremely low-resource cases such as Portuguese–Emakhuwa, correlations drop to around 0.1, underscoring the challenge of evaluating MT for very low-resource African languages. Notably, the long-standing baseline metric chrF (Popović, 2015) achieves performance comparable to the strongest neural supervised submission, MetricX-25 (Juraska et al., 2025), an encoder-only regression model initialized from *Gemma3* (12B) (Gemma Team et al., 2025) and fine-tuned on WMT15–23 DA and MQM scores. However, these findings still highlight the urgent need for more robust and generalizable machine translation evaluation methods tailored to under-resourced African languages.

7.3 Challenge Set Results Overview

The studies collectively reveal critical weaknesses in current automatic MT evaluation systems. CoDrift shows that popular QE models like COMET-KIWI and MetricX often fail when translations drift into fluent but semantically irrelevant continuations, highlighting the need for robustness against subtle off-target content. GAMBIT+ uncovers systematic gender bias in QE systems across 33 language combinations, with some auto-raters showing over 100% score gaps between masculine and feminine translations, amplifying occupational stereotypes. MSLC25 emphasizes that auto-raters can behave unpredictably on low- to mid-quality outputs and corner cases such as empty strings or mixed-language outputs, stressing the importance of thorough auto-rater testing for real-world

robustness. Finally, SSA-MTE demonstrates that auto-rater correlations with human judgments remain very low for Sub-Saharan African languages, especially in extremely low-resource pairs, underscoring the urgent need for inclusive, generalizable evaluation methods.

8 Conclusion

This paper documented the results of the WMT25 shared task on automated machine translation evaluation systems, which unified the Metrics and QE Shared Tasks from previous years. The shared task this year consisted of three subtasks: (1) segment-level quality score prediction, (2) span-level translation error annotation, and (3) quality-informed segment-level error correction. Task 1 results indicate the strong performance of large LLM-as-a-judge auto-rater systems at the system level, while reference-based baseline metrics outperform LLMs at the segment level. Task 2 results indicate that accurate error detection and balancing precision and recall are persistent challenges. Task 3 results show that minimal editing is challenging even when informed by quality indicators. Robustness across the broad diversity of languages remains a major challenge across all three subtasks. As described throughout the paper, this year marked significant changes to multiple dimensions of the evaluation. Evaluation data, originating from the General-MT task, was more challenging for MT systems, and covered a diverse set of new language-pairs. The move to long segments and the adoption of ESA human annotation for most of the languages were also new. We strongly believe that these changes were all warranted by the changing landscape in the field of MT and that they better align our evaluation with the current landscape. However, these changes are also likely responsible for some of the unexpected results observed this year, particularly for Task-1. We encourage further analysis of these results by the MT research community at large.

9 Ethical Considerations

The data for this shared task was generated, screened and human-annotated by the General Machine Translation Shared Task. We acknowledge inheriting any ethical limitations and concerns raised by their shared task. We do not foresee any additional ethical concerns.

10 Acknowledgments

Results for this shared task would not be possible without the tight collaboration with the organizers of the WMT25 General MT Shared Task. We thank them for their hard work and collaboration.

A LLM Prompt for Task 1

Segment-level quality scores from the "LLM as a judge" submissions to Task 1 (Section 4.1.3) were prompted using the template below. Placeholders in curly braces indicate the name of the source language, name of the target language, source segment text, and target segment text.

```
Score the following translation from {source_lang} to
{target_lang} on a scale from 0 to 100, where a score of 0 means a
broken or poor translation; 33 indicates a flawed translation
with significant issues; 66 indicates a good translation with
only minor issues in grammar, fluency, or consistency; and 100
represents a perfect translation in both meaning and grammar.
Answer with only a whole number representing the score, and
nothing else.

{source_lang} source text:
{source_seg}
{target_lang} translation:
{target_seg}
```

B Complete Task 1 Results per Language Pair

Table 19 (part 1) and Table 20 (part 2) show the full detailed results of the segment-level quality score prediction task broken down by individual language pair. Correlations are computed using SPA at the system level and acc^*_{eq} at the segment level, against the "human1" gold-standard annotations, matching the approach taken in the summary results of Section 4.3.

Table 21 and Table 22 show a similar detailed per-language-pair breakdown of the results as above, except now using "human2" as the gold standard. Only language pairs annotated with ESA have this second human score; Japanese→Chinese and English→Korean are thus excluded from these tables.

Table 22: System- and segment-level correlations per language pair for Task 1, with rankings shown in parentheses, computed against "human2" as the gold standard. Metrics are ordered by category. Part 2 of 2.

C Task 1 Score Difference Interpretation Additional Figures

Figures 9-11 show the (log) p-value of one-sided paired t-test on the human scores against the score difference of each auto-rater for each system pair. Figures 12-13 show the (log) p-value of significance test with bootstrap resampling on the auto-rater scores against the score difference of that auto-rater for each system pair in each language pair.

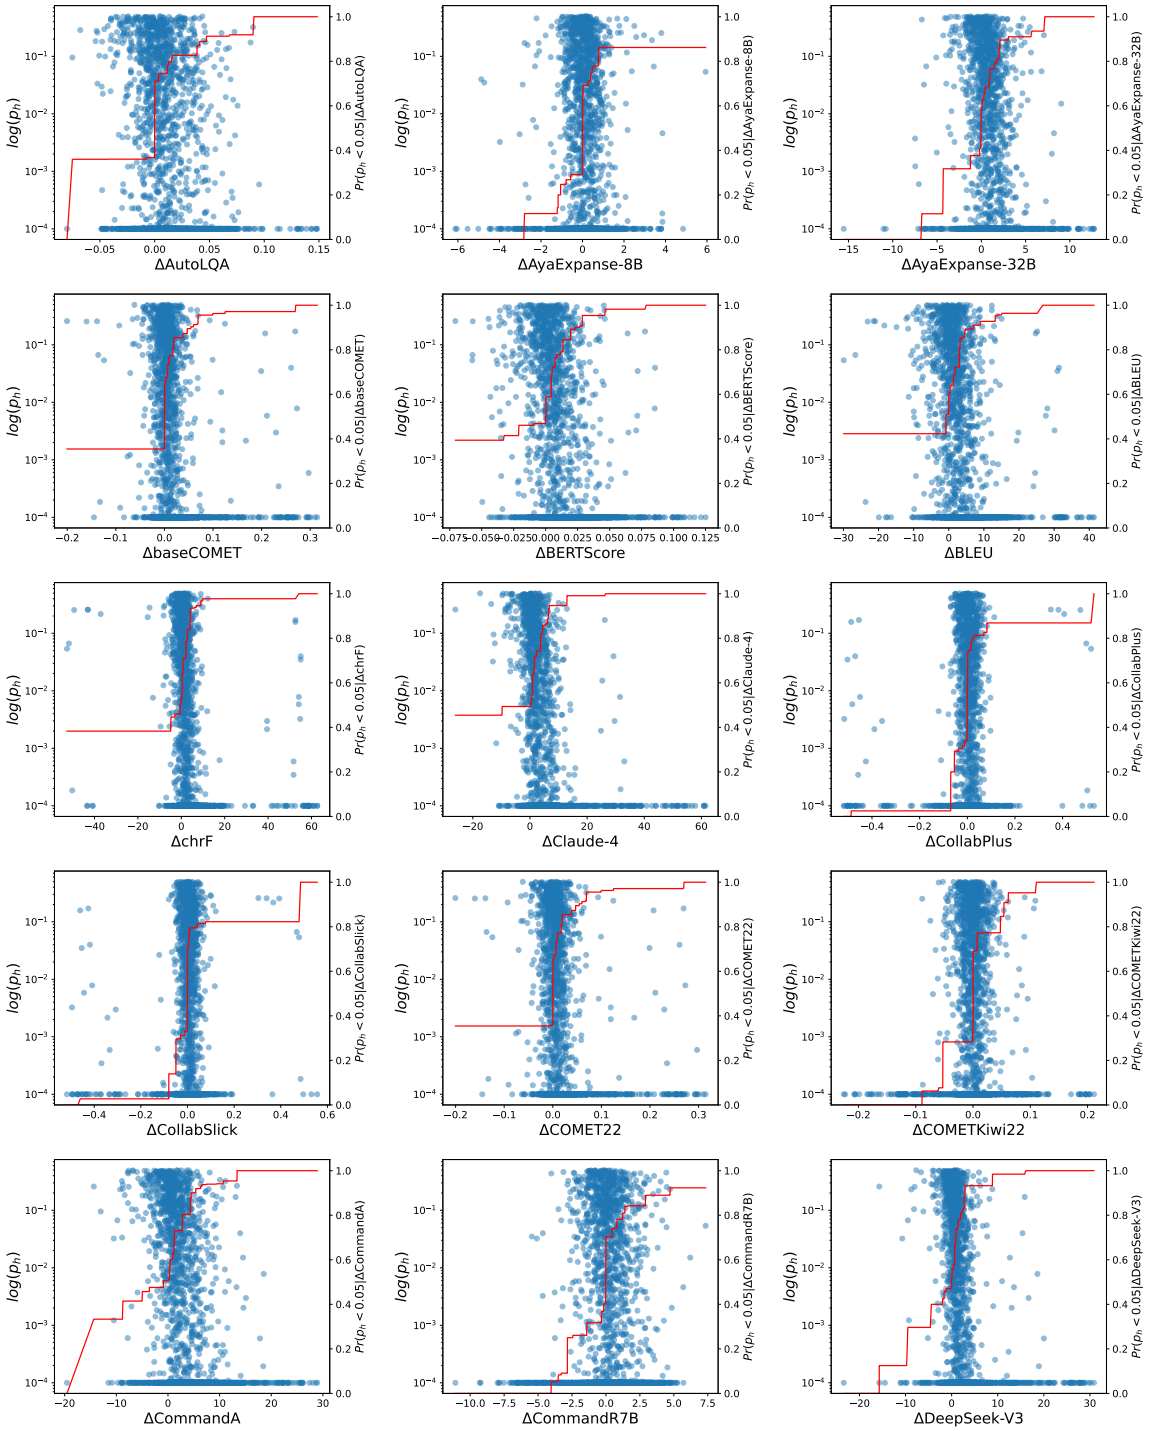

Figure 9: Log p-value of one-sided paired t-test on MQM scores (p_h) against the score difference of each auto-rater for each system pair. The red line is the isotonic regression fit to all data points, representing $Pr(p_h < 0.05 \mid \Delta m)$. Note: for readability, values of p_h are rounded up to 0.0001 when they are less than 0.0001. (Part 1/3)

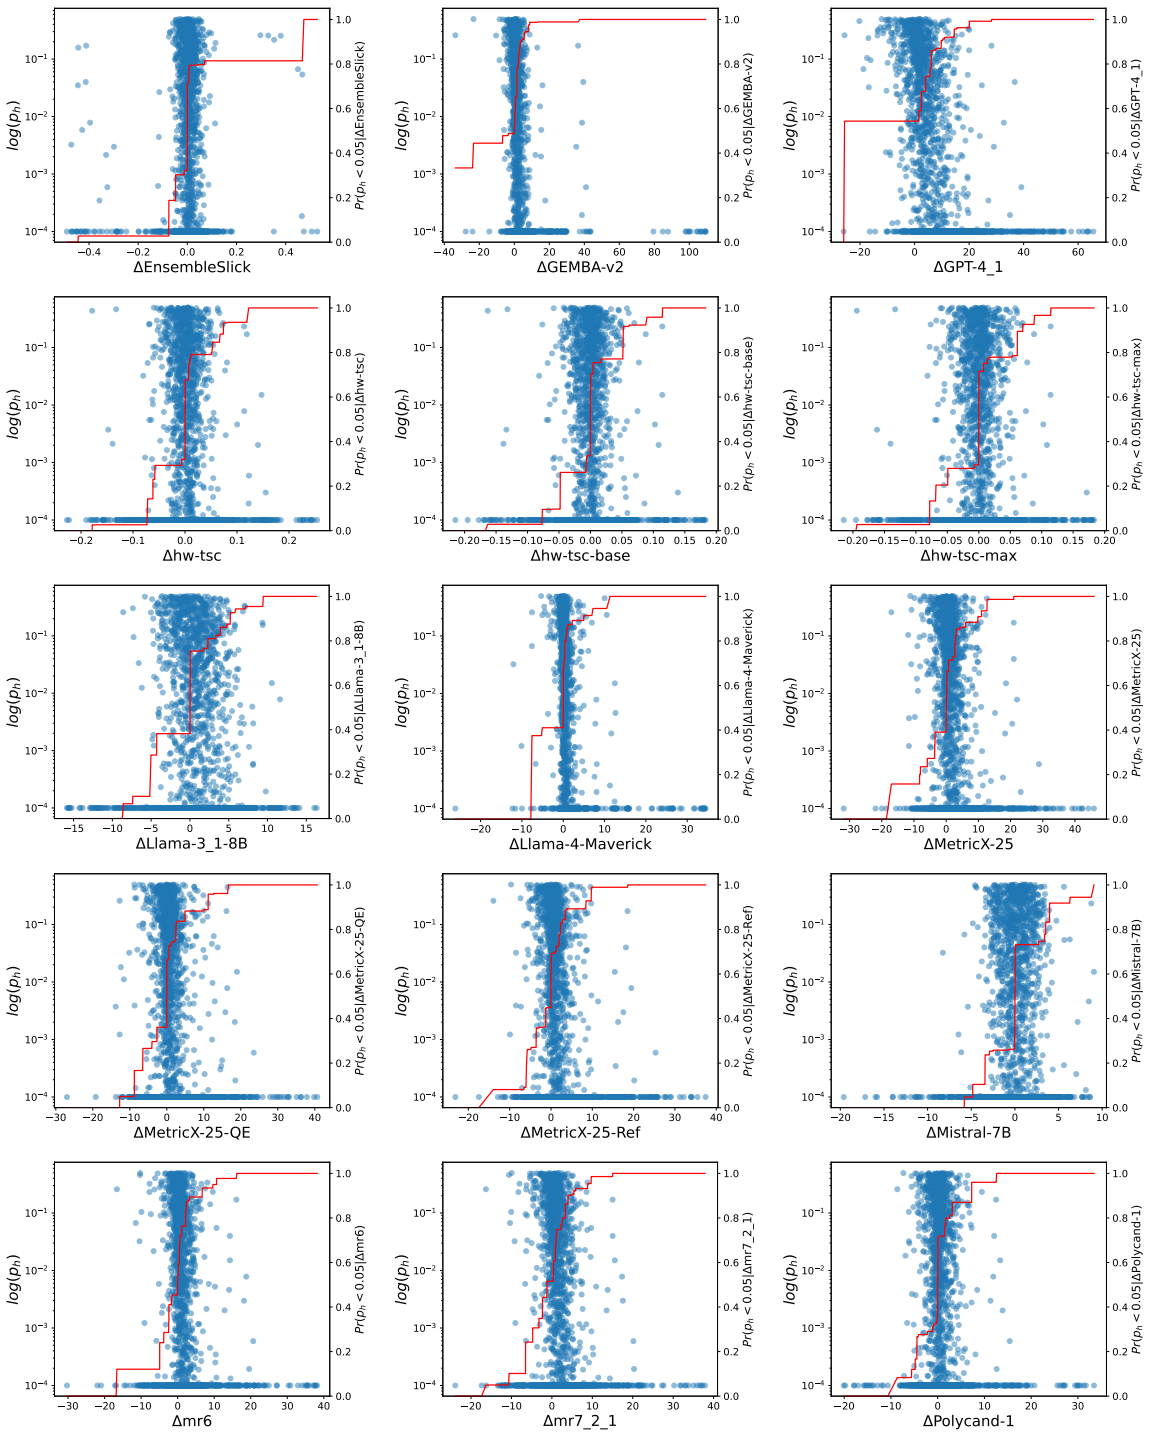

Figure 10: Log p-value of one-sided paired t-test on MQM scores (p_h) against the score difference of each auto-rater for each system pair. The red line is the isotonic regression fit to all data points, representing $Pr(p_h < 0.05 \mid \Delta m)$. Note: for readability, values of p_h are rounded up to 0.0001 when they are less than 0.0001.(Part 2/3)

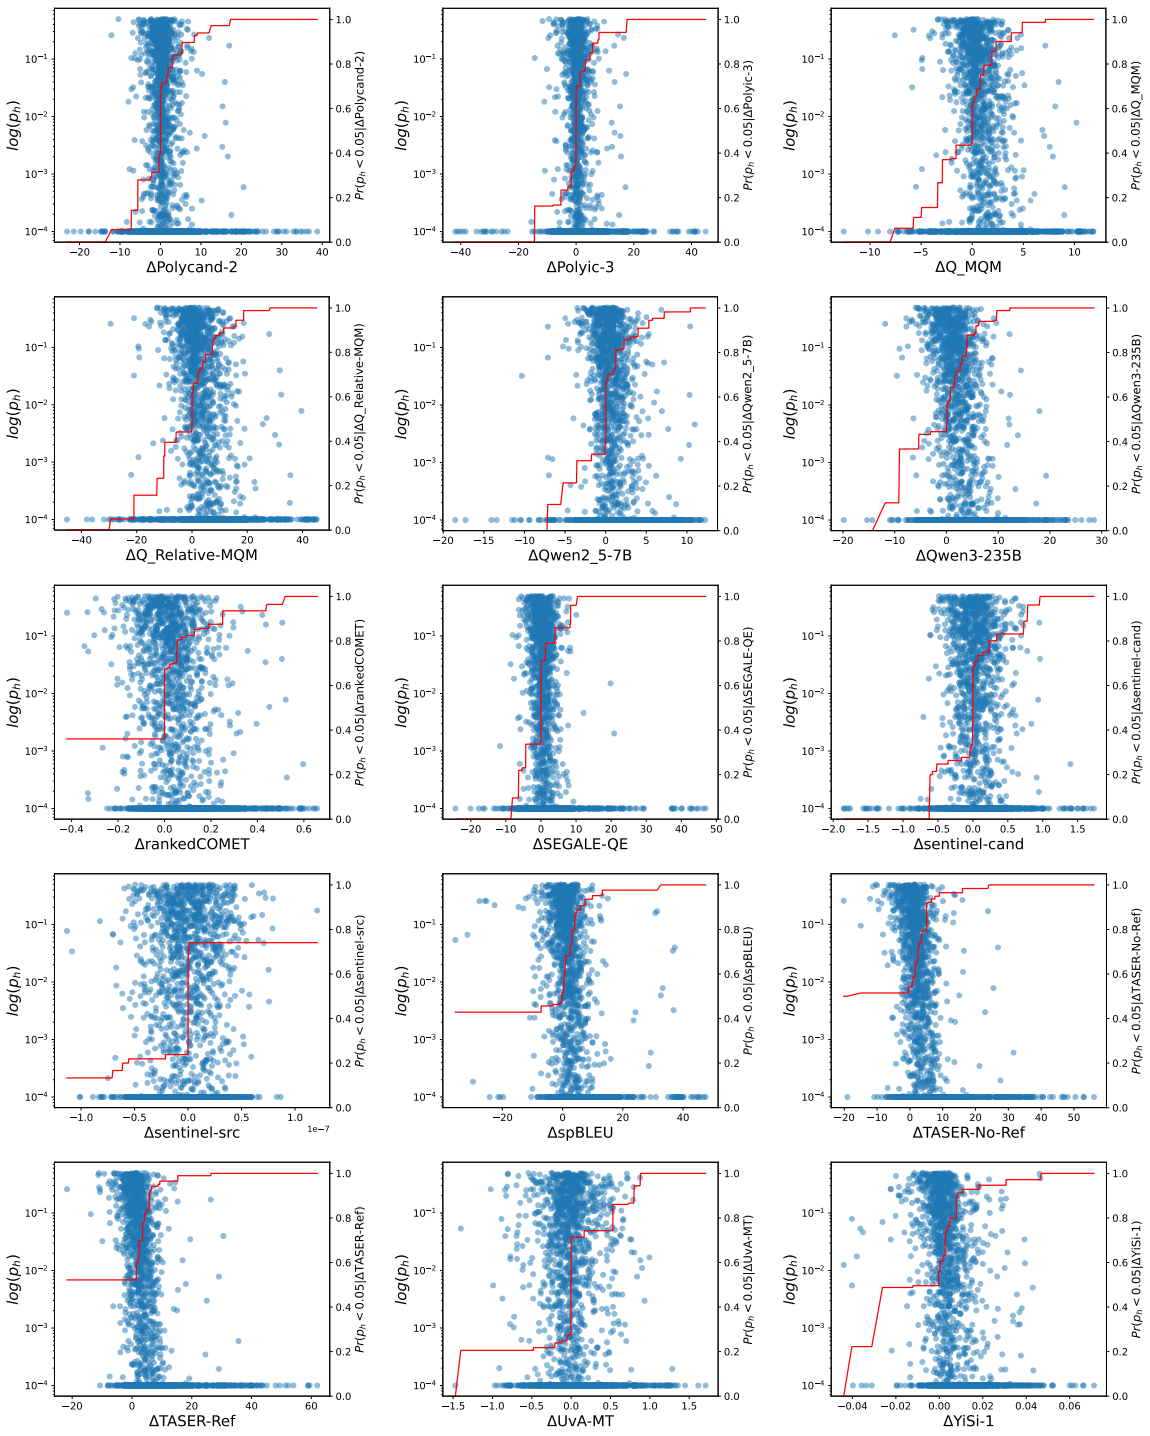

Figure 11: Log p-value of one-sided paired t-test on MQM scores (p_h) against the score difference of each auto-rater for each system pair. The red line is the isotonic regression fit to all data points, representing $Pr(p_h < 0.05 \mid \Delta m)$. Note: for readability, values of p_h are rounded up to 0.0001 when they are less than 0.0001.(Part 3/3)

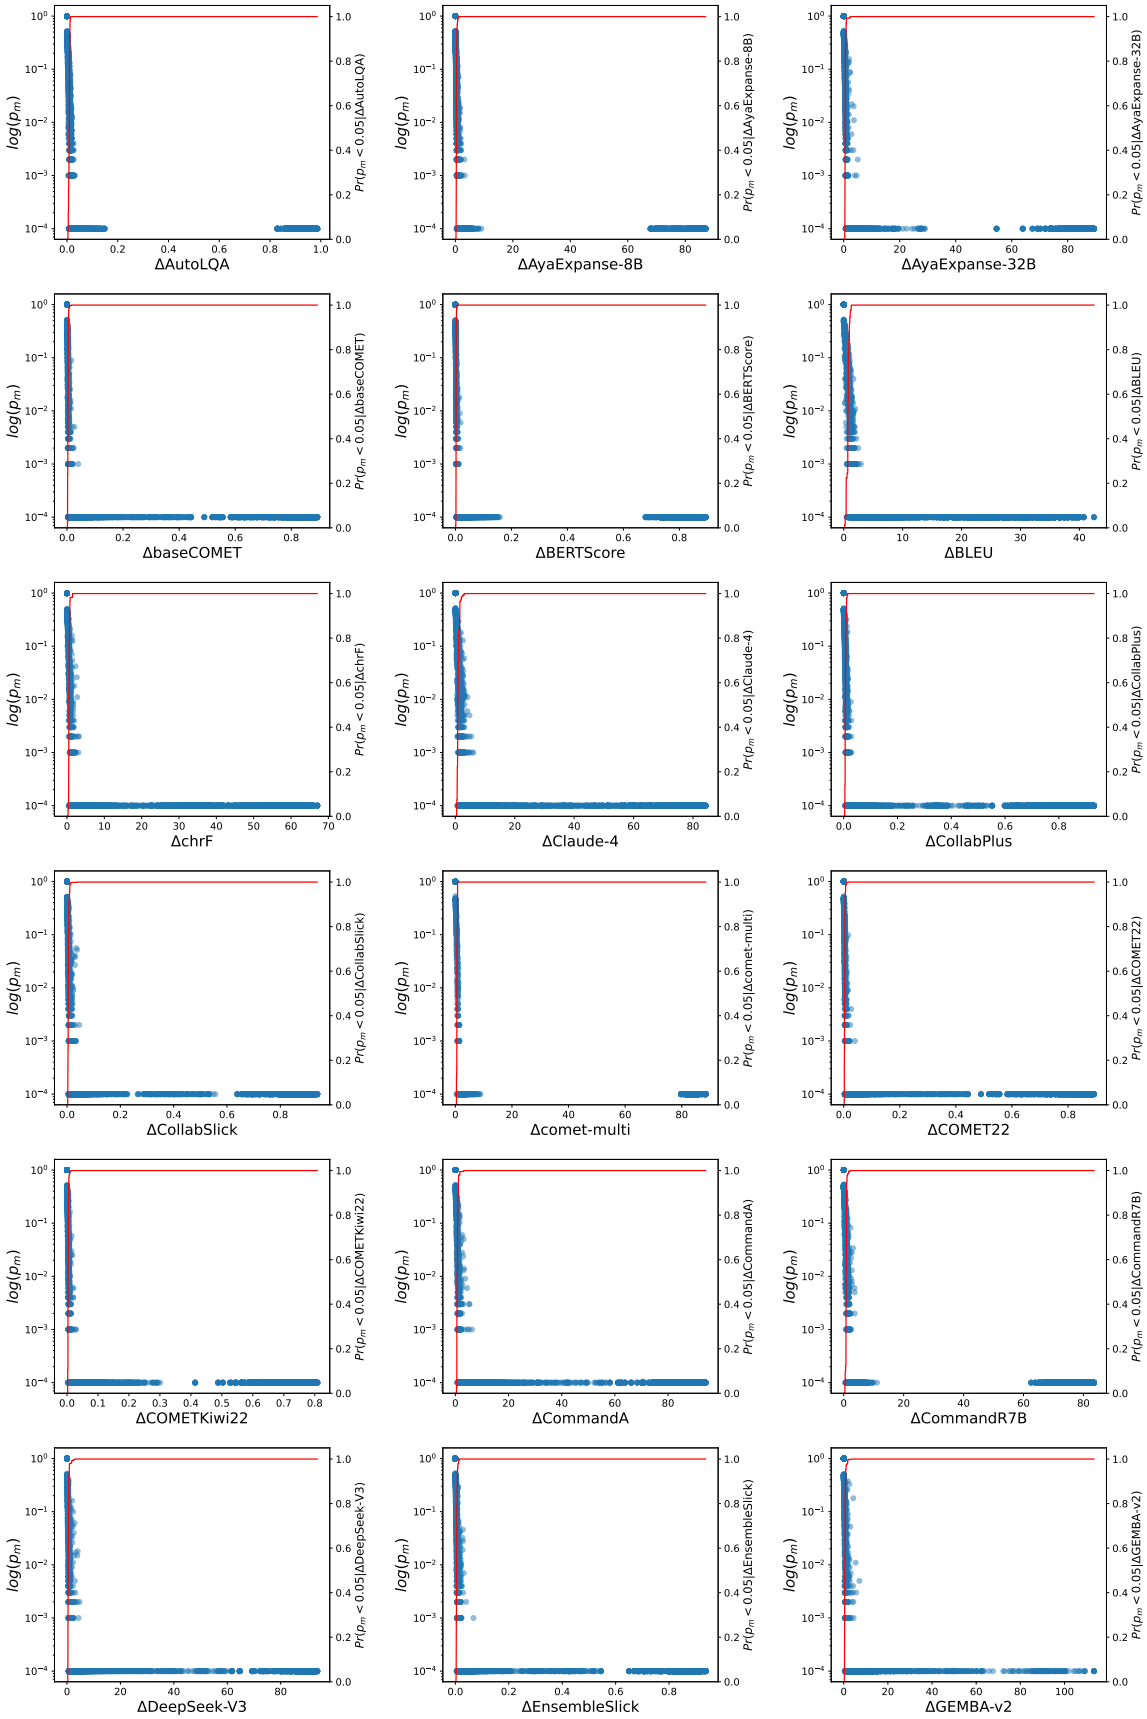

Figure 12: Log p-value of significance test with bootstrap resampling (p_m) on system-level against the score difference of each auto-rater for each system pair. The red line is the isotonic regression fit to all data points, representing $Pr(p_m < 0.05 \mid \Delta m)$. Note: for readability, values of p_m are rounded up to 0.0001 when they are less than 0.0001. (Part 1/3)

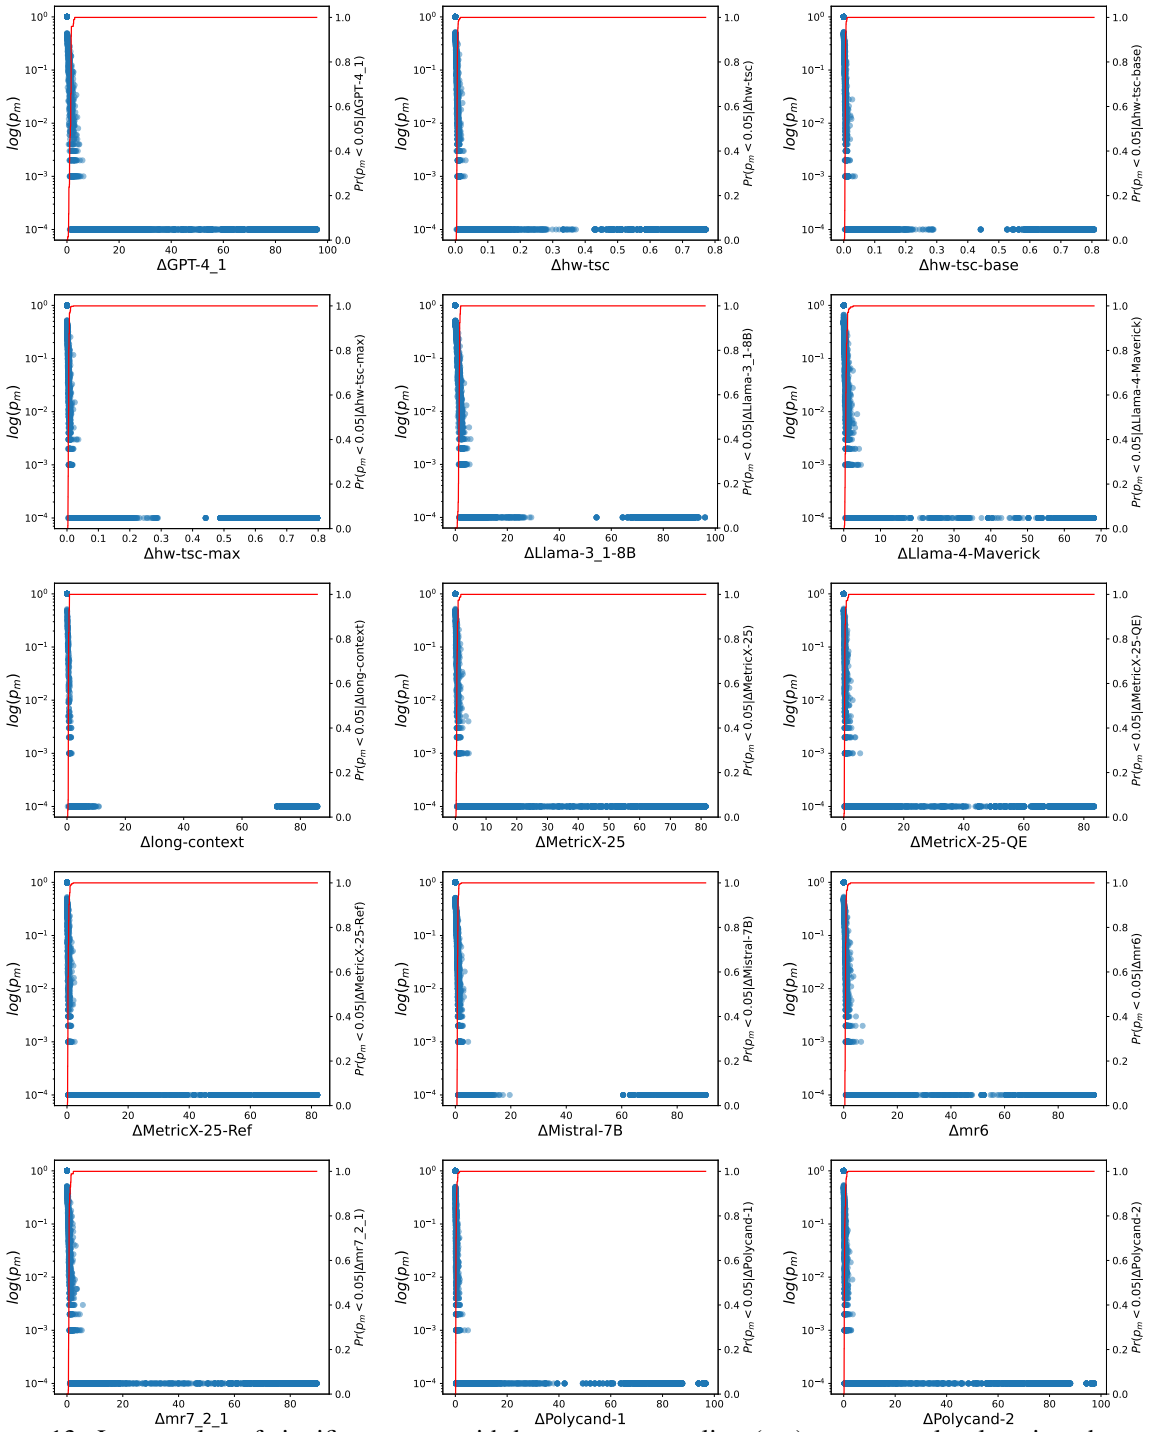

Figure 13: Log p-value of significance test with bootstrap resampling (p_m) on system-level against the score difference of each auto-rater for each system pair. The red line is the isotonic regression fit to all data points, representing $Pr(p_m < 0.05 \mid \Delta m)$. Note: for readability, values of p_m are rounded up to 0.0001 when they are less than 0.0001. (Part 2/3)

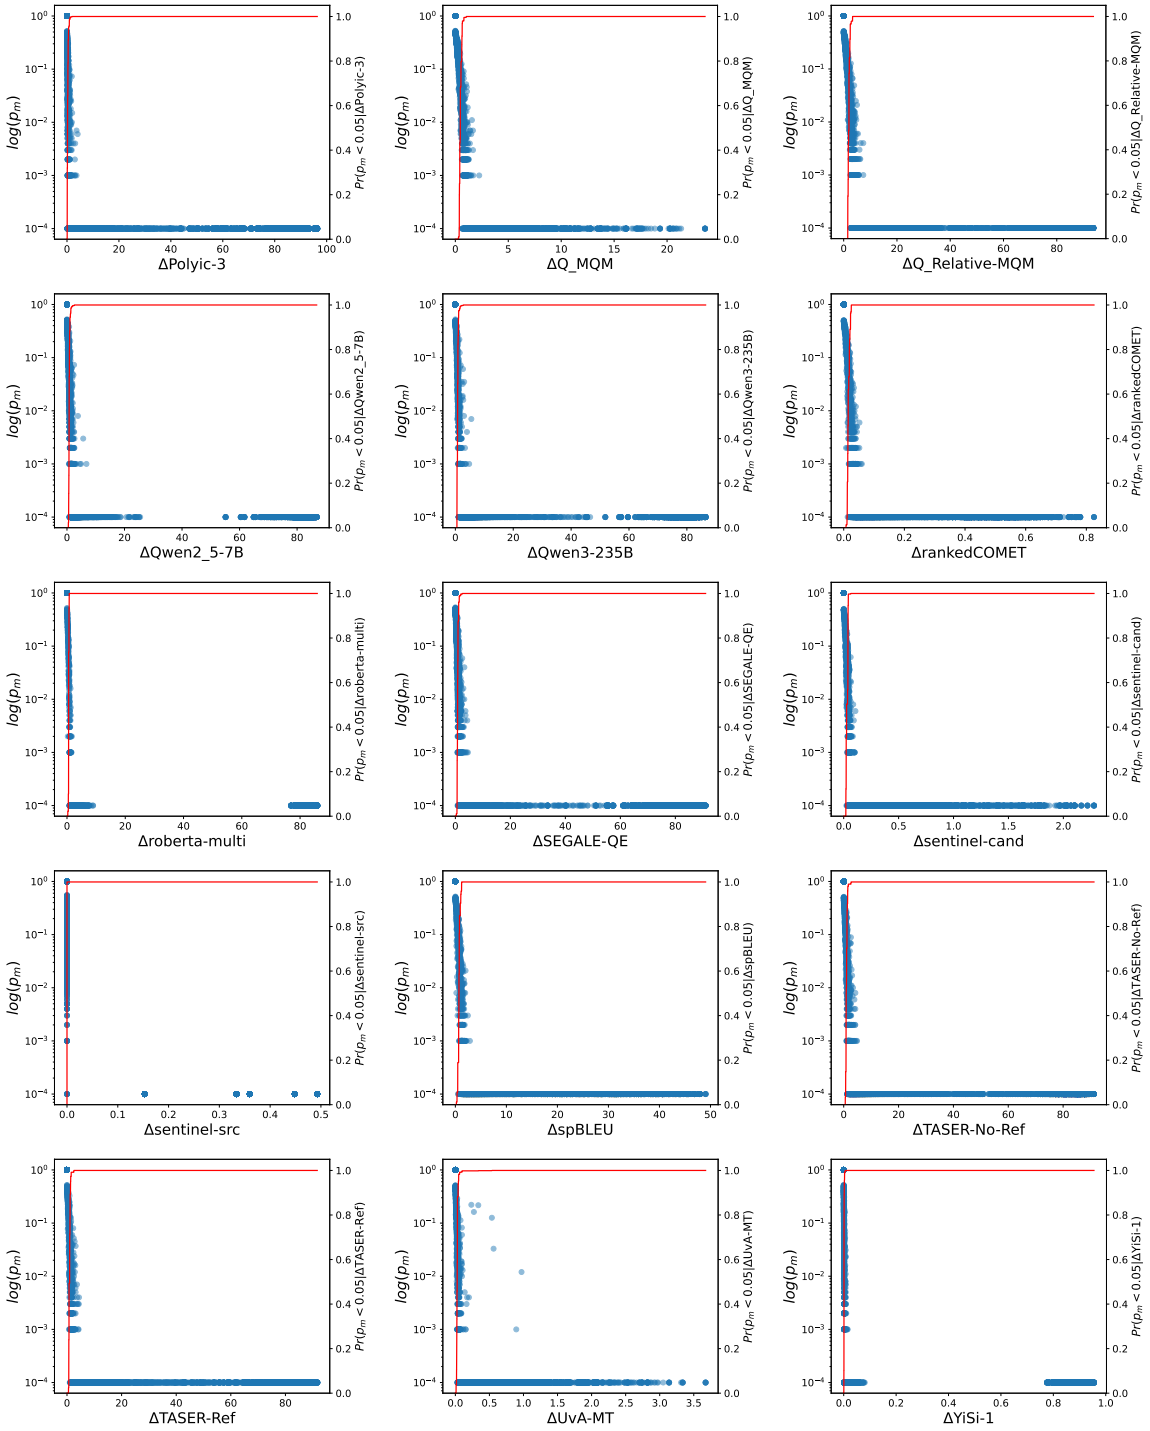

Figure 14: Log p-value of significance test with bootstrap resampling (p_m) on system-level against the score difference of each auto-rater for each system pair. The red line is the isotonic regression fit to all data points, representing $Pr(p_m < 0.05 \mid \Delta m)$. Note: for readability, values of p_m are rounded up to 0.0001 when they are less than 0.0001. (Part 3/3)

D Task 2 Additional Details

Algorithm 1 Character-Level Error Span F1 Score

function GET_CHAR_F1($L_{hyp}, E_{\text{gold}}, E_{\text{pred}}, \rho$)
▷ L_{hyp}: List of hypothesis lengths
▷ E_{gold}: List of lists of gold error dicts
▷ E_{pred}: List of lists of predicted error dicts
▷ ρ: Partial credit factor (e.g., 0.5)
    $tp \leftarrow 0$
    $\text{total\_gold} \leftarrow 0$
    $\text{total\_pred} \leftarrow 0$
    for $i \in 0 \ldots \text{LENGTH}(L_{hyp}) - 1$ **do**
        $H_{\text{len}} \leftarrow L_{hyp}[i]$
        $G_{\text{maj}}, G_{\text{min}} \leftarrow \text{GET\_COUNTS}(E_{\text{gold}}[i], H_{\text{len}})$
        $P_{\text{maj}}, P_{\text{min}} \leftarrow \text{GET\_COUNTS}(E_{\text{pred}}[i], H_{\text{len}})$
        $\text{total\_gold} \leftarrow \text{total\_gold} + \sum G_{\text{maj}} + \sum G_{\text{min}}$
        $\text{total\_pred} \leftarrow \text{total\_pred} + \sum P_{\text{maj}} + \sum P_{\text{min}}$
        for $j \leftarrow 0$ To $H_{\text{len}} - 1$ **do**
            $c_{\text{g\_maj}} \leftarrow G_{\text{maj}}[j]$
            $c_{\text{p\_maj}} \leftarrow P_{\text{maj}}[j]$
            $c_{\text{g\_min}} \leftarrow G_{\text{min}}[j]$
            $c_{\text{p\_min}} \leftarrow P_{\text{min}}[j]$
▷ Full credit for same severity match at index j
            $tp \leftarrow tp + \min(c_{\text{g\_maj}}, c_{\text{p\_maj}})$
            $tp \leftarrow tp + \min(c_{\text{g\_min}}, c_{\text{p\_min}})$
▷ Partial credit for cross-severity match at index j
            $g_{\text{unmatched}} \leftarrow \max(0, c_{\text{g\_maj}} - c_{\text{p\_maj}}) + \max(0, c_{\text{g\_min}} - c_{\text{p\_min}})$
            $p_{\text{unmatched}} \leftarrow \max(0, c_{\text{p\_maj}} - c_{\text{g\_maj}}) + \max(0, c_{\text{p\_min}} - c_{\text{g\_min}})$
            $tp \leftarrow tp + \min(g_{\text{unmatched}}, p_{\text{unmatched}}) \times \rho$
        end for
    end for
    $P, R, F1 \leftarrow \text{PREC\_REC\_F1}(tp, \text{total\_gold}, \text{total\_pred})$
    return $P, R, F1$
end function

Figure 15: F1 Score by Error Category.

E Full Results for Task 2

We report complete results for all submissions (primary and secondary) in Tables 23 (micro-F1) and 24 (macro-F1) respectively. We also show macro-F1 scores broken down by error category and error ratio in Figure 15 and Figure 16 respectively.

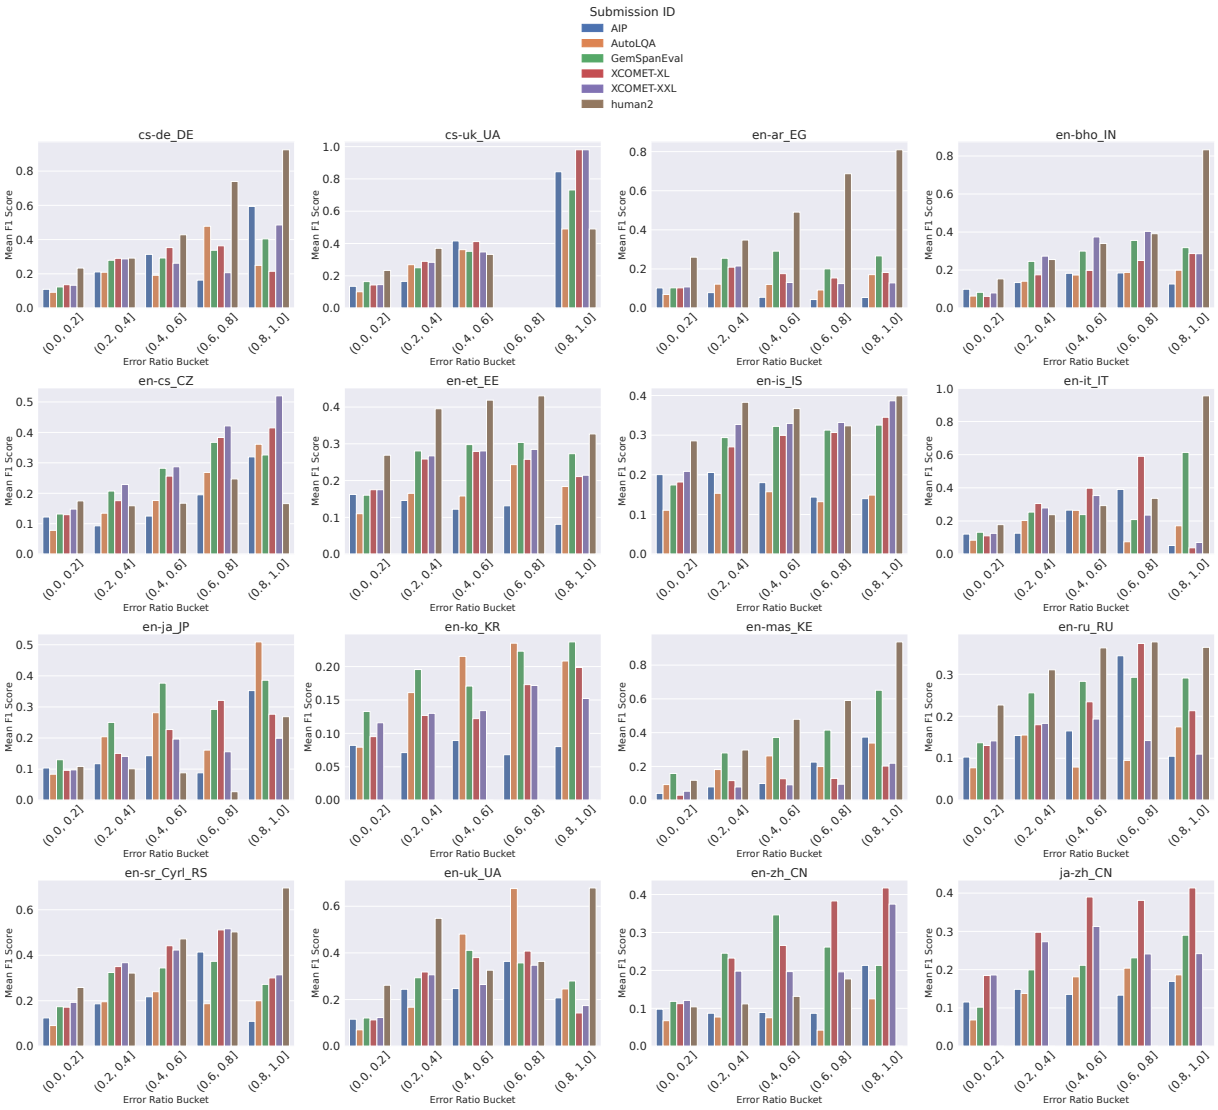

Figure 16: F1 Score by Error Ratio.

Abstract

We present the results of the first edition of the Model Compression shared task, organized as part of the 10th Conference on Machine Translation (WMT25). The task challenged participants to compress Large Language Models (LLMs) toward enabling practical deployment in resource-constrained scenarios, while minimizing loss in translation performance. In this edition, participants could choose to compete in either a constrained track, which required compressing a specific model (Aya Expanse 8B) evaluated on a limited set of language pairs (Czech→German, Japanese→Chinese, and English→Arabic), or an unconstrained track, which placed no restrictions on the model and allowed submissions for any of the 15 language directions covered by the General MT task. We received 12 submissions from 3 teams, all in the constrained track. They proposed different compression solutions and covered various language combinations. Evaluation was conducted separately for each language, measuring translation quality using COMET and MetricX, model size, and inference speed on an Nvidia A100 GPU.

1 Introduction

Large Language Models (LLMs) have demonstrated exceptional performance across a wide range of tasks. However, efforts to enhance their capabilities, by expanding language coverage, integrating multimodal data, and improving task generalization, have led to a dramatic increase in both model size and computational demands (Zhu et al., 2024). This rapid growth poses significant challenges for real-world deployment, particularly in resource-constrained environments such as mobile devices, embedded systems, and edge computing platforms, where low-latency, on-device processing is often required. Compressing foundation models is therefore more than a technical pursuit: it is a strategic priority with implications for global accessibility[1] and the sustainability of computational and environmental costs. Striking the right balance between performance, compactness, and efficiency is thus essential to make LLMs truly ubiquitous and beneficial for everyone, regardless of location or access to high-end infrastructure.

It is with this long-term goal in mind that, following the analogous task for speech translation in the IWSLT 2025 campaign (Abdulmumin et al., 2025), the new Model Compression shared task was introduced at WMT 2025.[2] This initiative follows three editions of the shared task at the Workshop on Machine Translation and Generation (Birch et al., 2018; Hayashi et al., 2019; Heafield et al., 2020) and two editions of the shared task on Efficient Translation (Heafield et al., 2021, 2022). It revives earlier focus on the efficiency of machine translation, while updating it to reflect the current AI landscape with the rise of general-purpose LLMs.

In this context, our aim is to provide a timely evaluation of compression techniques for general-purpose LLMs within the specific task of machine translation. This setting offers a valuable opportunity to explore key research questions, such as:

- *To what extent can the over-parameterization of LLMs—originally pursued to enable generalization, robustness, task flexibility, and broad language coverage—be reduced in favor of compactness and efficiency, while preserving MT quality?*
- *How do different compression techniques, with varying degrees of aggressiveness, impact translation quality in such settings?*

[1] In the U.S. around 15% of adults rely exclusively on mobile devices to access the internet (https://www.pewresearch.org/internet/fact-sheet/mobile/), and it is even more pronounced in developing regions (https://www.eib.org/en/essays/african-digital-infrastructure).

2 Task Description

The goal of the Model Compression task is to reduce the size of a general-purpose LLM while preserving a strong balance between compactness and MT performance. This section provides a brief overview of how the first round of the task was structured, focusing on the proposed tracks, data conditions, and evaluation methodology.

2.1 Tracks

Participants could choose between two tracks: constrained and unconstrained.

The **constrained** track was designed to ensure a level playing field by establishing uniform conditions across all participants, allowing for directly comparable results. It focused on the compression of a specific model in a fixed language setting. The model selected for this purpose was Aya Expanse 8B,[3] chosen for its permissive license (CC-BY-NC 4.0) and its favorable trade-off between the size (8 billion parameters; approximately 16 GB in FP16 precision) and performance.

In the constrained settings, we measured performance across three language pairs: Czech→German, Japanese→Chinese, English→Arabic. These pairs were selected to provide a sufficiently diverse coverage of language families and scripts. Submissions were allowed for any of these directions. Any model compression technique e.g., pruning (Frankle and Carbin, 2019; Frankle et al., 2020), quantization (Devlin, 2017), or distillation (Kim and Rush, 2016), was permitted, provided that the final compressed model remained closely derived from Aya Expanse 8B. For instance, in the case of distillation, student models had to be obtained through compression of Aya Expanse 8B (e.g., by pruning or quantizing it) to qualify for the constrained track. Otherwise, we would consider such systems as unconstrained.

The **unconstrained** track provided participants with complete freedom to compress any model of their choice and apply it to any of the 15 language directions covered by the WMT25 General MT task (GenMT) (Kocmi et al., 2025). As in the constrained track, separate rankings were planned for each language direction.

[3] https://huggingface.co/CohereLabs/aya-expanse-8b

2.2 Data

Data usage policies were aligned with those of the GenMT task. Participants were therefore allowed to calibrate and fine-tune their compressed models using the publicly available datasets released for this year's round,[4] as well as test sets from previous WMT editions.

2.3 Evaluation

Submissions were evaluated[5] along three key dimensions:

- **Translation quality** measured using the same automatic metrics employed in the GenMT task;
- **Model size** as disk space footprint;
- **Inference speed** as the average number of output tokens produced per second when processing the test set.

All three were considered both *independently* and *jointly*. We report Pareto frontier rankings to visualize system differences through quality–size, quality–speed and size–speed plots. Since we received multiple submissions only for Czech→German, this type of visualization was only feasible for that language direction.

To ensure a fair and informative evaluation, we create a homogeneous hardware environment for running the submitted systems. We used machines with a single Nvidia A100 GPU having 80GB of VRAM, AMD EPYC CPU with 96 cores, and 866GB RAM.

2.4 Submission

Participating teams were asked to provide a link to a Docker image containing all necessary software and model files for translation, along with basic information about the maximum batch size supported by their model(s) under the specified hardware configuration. Upon request, we also offered storage space to teams who needed it or preferred to upload their models externally to their institutional infrastructure.

3 Participants

Three teams submitted systems to the task, as summarized in Table 1. The organizers also included baseline systems. Below, we provide a brief

overview of the proposed approaches, all developed within the constrained track.

AyaQ[6] This participation employs GPTQ 4-bit quantization (Frantar et al., 2023) with a group size of 32 to enable efficient and scalable LLM inference. The WMT dataset is used as calibration data to guide the quantization process, ensuring the compressed model retains high accuracy on language understanding and generation tasks. The quantized models are integrated through the LLM Compressor framework (AI and vLLM Project, 2024), which streamlines conversion and metadata management. The setup is fully compatible with vLLM (Kwon et al., 2023), a high-throughput inference engine optimized for GPU deployment, enabling fast and memory-efficient execution with minimal performance loss. This approach demonstrates how structured quantization, targeted calibration, and system-level integration can enable practical, production-ready LLM deployment.

LeanAya This participation is based on LeanQuant (Loss-Error-Aware Network Quantization, (Zhang and Shrivastava, 2025)), an accurate, versatile, and scalable quantization method. Existing iterative loss-error-based quantization techniques typically rely on min-max affine grids, which often degrade model quality due to outliers in the inverse Hessian diagonals. LeanQuant overcomes this limitation by learning loss-error-aware quantization grids instead of using fixed, non-adaptive ones. This approach not only improves accuracy but also supports a wider range of quantization schemes, including both affine and non-uniform, enhancing compatibility across diverse deployment frameworks.

TCD-Kreasof (Moslem et al., 2025) This participation employs iterative layer pruning to incrementally identify and remove layers that contribute least to translation quality, one at a time. Layer importance is assessed by measuring translation performance with each layer individually removed. After pruning the least critical layer, the evaluation is repeated on the remaining ones until the target pruning level is reached. The resulting pruned model was then fine-tuned on 100k sentences from the News Commentary dataset. This process produced three submissions: the primary one is a 24-layer model with 6.28B parameters, while the two contrastive submissions are 20-layer and 16-layer models, with 5.41B and 4.54B parameters, respectively.

Vicomtech (Ponce et al., 2025b) This participation employs GeLaCo (Ponce et al., 2025a), an evolutionary approach to LLM compression based on layer merging operations. Models are compressed at three ratios (0.25, 0.50, and 0.75), representing the proportion of original layers collapsed through differential weight merging. To recover performance after compression, over 3 million translation instructions (1 million per language) from a subset of WMT25 translation data are used. For the 0.25 and 0.50 compression levels, models are fine-tuned on this data, while the 0.75 model is trained using General Knowledge Distillation (GKD (Tan et al., 2023)). Additionally, post-training quantization is applied using the `bitsandbytes` library[7] to further reduce model size to 8-bit and 4-bit precision. The primary submission (`gelaco-0.75_gkd_q4`)

[6] We did not receive system description papers for AyaQ and LeanAya submissions.

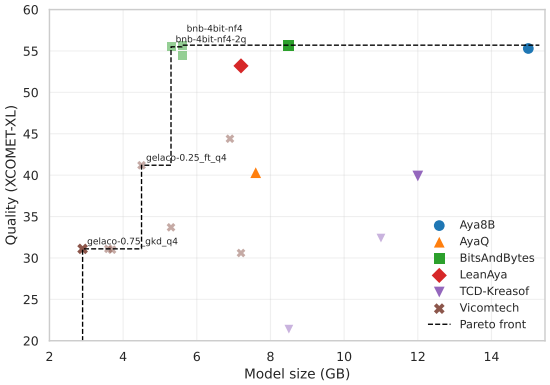
combines evolutionary layer collapse, knowledge distillation, and quantization to achieve substantial size reduction while maintaining reasonable translation performance.

Baselines As a reference system (see Table 2), we included the unmodified Aya Expanse 8B model (FP16, 16.1GB) (Dang et al., 2024) and a family of runtime–quantized variants created using the Hugging Face integration of the `bitsandbytes` library (Dettmers et al., 2022, 2023), without the use of vLLM. The baselines were not fine-tuned or adapted on the task data; their purpose was to anchor the quality–size–speed trade-offs for submitted systems. Quantized versions include 8-bit and 4-bit modes, with two 4-bit quantization data types: NF4 (normal floating point) and FP4.

The organizers' baselines illustrate the performance one can obtain from (i) the full reference model, and (ii) straightforward, widely available post-training quantization strategies, against which more sophisticated compression pipelines can be directly compared in terms of translation quality, memory footprint, and decoding speed.

4 Results

We evaluate systems' performance on the official WMT25 GenMT test sets, which comprise between 332 and 456 paragraphs for each of the three considered language pairs. Because we received submissions to the constrained track only and most



(a) Model size and COMET scores.

submissions focused on Czech→German, we primarily report results for this language pair unless mentioned otherwise.

We noticed that most of the systems may suffer from hallucinated content, which affects both translation quality and decoding speed, and complicates system comparisons. To minimize the impact of hallucinations, we segment the original paragraph-level test data at newline characters and remove empty lines. For Czech-German, this results in a test set with 2,868 segments.

To further investigate the potential impact of hallucinations, we also evaluate on a subset of the test set that only includes 1,928 segments where none of the systems exhibits hallucinations under any batch setting. This subset makes it possible to assess system performance in terms of inference speed more accurately, by excluding the distortions that hallucinations would introduce into cross-system comparisons. For brevity, analysis on the hallucination-free test data is presented in Appendix A.

Below, we briefly discuss the results in terms of quality, model size and speed. The detailed results across more benchmark settings are provided in Appendix B.

4.1 Translation Quality

Following the reference-based automatic evaluation settings proposed by the GenMT task, translation quality is automatically evaluated using XCOMET-XL[8] (Guerreiro et al., 2024) and MetricX-24-Hybrid-XL[9] (Juraska et al., 2024). Results are shown in Table 3, in which we also report the number of potentially hallucinated lines for each system, providing insight into system robustness across evaluation conditions. An output line was considered hallucinated if its output length (measured as number of characters) was at least twice the length of the source. Since we did not observe significant score differences across decoding with various batch sizes, we only report metric scores computed from outputs generated with batch size 1. However, we did observe minor differences in the outputs at different batch sizes, which indicates that the submitted implementations do not account for padding handling e.g., for relative positions (Papi et al., 2024).

The main observation is that BitsAndBytes and LeanAya achieve compression with minimal quality loss, nearly matching the baseline with ≈55 COMET scores. Other compression methods can decrease quality significantly, in particular for Czech→German, with ≈31–44 COMET scores.

4.2 Model Size

For each system variant, we record model size as the on-disk footprint of the submitted model direc-

Table 4: Final results of the WMT25 Model Compression shared task. Primary submission names are bolded.

tory. The size is the sum of parameter shard files, tokenizer, and minimal wrapper scripts, which directly reflects the storage and transfer cost of deploying the model in gigabytes (GB).

We do not measure peak CPU memory usage or GPU VRAM footprint.

The model sizes are reported in Table 4. Organizer's submission BitsAndBytes (4-bit and 8-bit), while maintaining the translation quality, reduces the model size by up to 65%. On the other hand, Vicomtech's systems achieve best compression (81%, down to 2.9 GB from 15.0 GB) but suffer significant quality degradation.

4.3 Inference Speed

Each model was run three times per batch size, and wall-clock time was recorded for each run. Our primary metric, output rate, is defined as the number of output tokens divided by adjusted wall time (tokens/s). Output tokens were counted by retokenizing the generated hypotheses using the Aya Expanse 8B tokenizer. To isolate model initialization overhead, we performed a separate "warmup" run per model, decoding a single short sentence with batch size 1. The average wall time of warmup runs was subtracted from the total wall time to compute an adjusted speed metric. We also tested multiple batch sizes to analyze throughput scaling. The results for primary systems are presented on Figure 1.

As expected, inference speed scales with batch size, but not uniformly. Vicomtech's systems scaled most efficiently from 70 tokens/s at batch size 1 to nearly 1000 tokens/s at 512. Some models saturated early, showing minimal speedup with larger batch sizes or even failing to produce outputs.

5 Conclusion and Future Directions

The final results of the WMT25 shared task on model compression are summarized in Table 4. Figure 2 shows Pareto front comparisons across evaluation criteria.

The key findings can be summarized as follows:

- BitsAndBytes baselines and LeanAya maintained translation quality with moderate speed and model size reduction;
- Vicomtech's systems achieved best compression rates, latency and throughput thanks to efficient batch scaling, but at the cost of translation quality;
- Quantization has emerged as the most popular approach for its simplicity and effectiveness;
- Hallucinations in compressed outputs reveal the fragility of the current approaches and the need for more robust evaluation and compression-aware training techniques.

Overall, despite the moderate participation in this shared task limited the breadth of exploration, several submissions showed promising results. The results of this evaluation campaign highlight that task-specific compression of LLMs still warrants

more research efforts, especially at high compression rates required for running systems on edge devices. The smallest model still requires almost 3GB of disk space, which is incompatible with many edge devices that are equipped with a few hundred MB of memory (Cai et al., 2022). Additionally, high compression rates result in a significant performance drop. We believe that pushing the boundaries of compression rates and reducing the quality degradation in such settings represent the most interesting challenges for future research on the topic and for participants of the future editions of the task.

Looking ahead, future iterations of this task could benefit from expanding the evaluation to more language pairs, aligning more tightly with the evaluation benchmark at the GenMT task, and including human assessments of the outputs.

6 Limitations

This study offers an early glimpse into the landscape of model compression for machine translation, but several limitations constrain the generality of its findings. First, the participation was only modest, all systems compressed the same base model (Aya Expanse 8B) and primarily focused on one language pair (Czech→German). Second, the submissions relied mainly on quantization, with limited exploration of other well-established compression techniques such as parameter pruning or knowledge distillation. Third, only one system used vLLM infrastructure, limiting comparability.

Lastly, quality assessment depended solely on automatic metrics (COMET and MetricX). We did not conduct human evaluation or cross-language validation. We also did not present some important deployment metrics (e.g., memory usage, latency, energy consumption), which narrows the conclusions.

Acknowledgments

We would like to thank all participants for submitting their systems to the shared task. Marco Gaido's work has been funded by the PNRR project FAIR - Future AI Research (PE00000013), under the NRRP MUR program funded by the NextGenerationEU.

A Hallucinations

To understand if the potential hallucinations impacted the results, we benchmarked the participating systems on a subset of the Czech→German WMT25 test set. This subset includes only segments where none of the systems exhibits hallucinations under any batch setting. An output line was considered hallucinated if its tokenized output length was at least twice the length of the tokenized source. This version of the Czech-German test set reduces the number of input segments from 2,686 to 1,928 segments. Table 5 illustrates quality comparisons across systems for both versions of the test set using a reference-less metric, WMT23-CometKiwi-XL (Rei et al., 2023), computed using Pymarian (Gowda et al., 2024). Inference speed metrics across different settings are presented in Figures 3 and 4.

Abstract

We present the results of the WMT 2025 shared task of the Open Language Data Initiative (OLDI). Participants were invited to contribute to the existing massively multilingual open datasets supported by OLDI (FLORES+, OLDI-Seed, WMT24++), or create new resources in line with OLDI's aims. We accepted eight submissions: seven extensions or revisions of the existing datasets and one submission with a new massively parallel training dataset, SMOL. These contributions advance the coverage and quality of multilingual datasets, especially since for many languages, they are the first publicly-available training or evaluation data for machine translation. All contributions are released under permissive open-source licenses.

1 Introduction

Recent advances in machine translation (MT) have resulted in system output which is indistinguishable from that of human translators (Kocmi et al., 2024). However, even if we assume that the task of MT is 'solved', this would be true only for a small number of well-resourced language pairs. Achieving such high task performance requires abundant parallel training data specific to the language pair and domain of interest, either as explicit parallel datasets, or as incidental bilingual signals in generic web data (Briakou et al., 2023). For the majority of the world's languages, we lack both the parallel training data necessary to train MT models, as well as the evaluation data to assess their translation capabilities.

One way to address this bottleneck is creation of massively multilingual parallel datasets and their extension to new languages. In this paper, we describe the second Shared Task for Open Language Data Initiative (OLDI) which invited language communities to contribute to high-quality, massively parallel and open-source datasets. Contributions could involve either extending existing datasets to new language varieties, making substantial improvements to existing datasets, or creating new massively multilingual parallel datasets. The datasets of interest to the shared task include (but are not limited to) FLORES+, OLDI-Seed (NLLB Team et al., 2024; Maillard et al., 2024), and WMT24++ (Deutsch et al., 2025). The OLDI itself is a community of researchers that maintains the former two datasets and promotes better language resources for under-served languages in general.[1]

This year, we received eight submissions, including six extensions of datasets to new language varieties, two revisions of existing translations, and one entirely new massively parallel dataset. All the data will be made available online under permissive open-source licenses.[2]

2 Datasets

2.1 FLORES+

FLORES is a family of datasets designed to benchmark multilingual translation, with many-to-many alignment across over 200 languages. The first iteration of this dataset covered only three languages (Guzmán et al., 2019), but following iterations increased coverage first to 101 languages (FLORES-101, Goyal et al., 2022) and then to over 200 languages as part of the "No Language Left Behind" project (NLLB Team et al., 2024). Finally, as part

of the previous edition of this shared task, an additional 8 languages were included on top of several corrections to existing datasets (Abdulmumin et al., 2024; Ali et al., 2024; Gordeev et al., 2024; Kuzhuget et al., 2024; Mamasaidov and Shopulatov, 2024; Perez-Ortiz et al., 2024; Yu et al., 2024). This new, living version of the FLORES benchmark is released under the name FLORES+.

2.2 OLDI-Seed

The NLLB-Seed dataset of NLLB Team et al. (2024) was created as a source of starter data for languages without publicly-available high-quality bitext in sufficient quantity for training natural language processing (NLP) models. This dataset consists of around 6000 sentences sampled from the Wikipedia articles listed in English Wikimedia's "List of articles every Wikipedia should have".[3] These were professionally translated into each of the 38 languages covered by the first iteration of this dataset (39 if including English), and experiments by Maillard et al. (2023) demonstrated the gains of including these datasets in the training mix of MT models.

[3] https://meta.wikimedia.org/wiki/List_of_articles_every_Wikipedia_should_have

Participants to last year's edition of this shared task contributed three new languages (Ahmed et al., 2024; Cols, 2024; Ferrante, 2024). To reflect the continuously updating nature of this dataset, and to distinguish it from prior iterations, it is released as OLDI-Seed.

2.3 WMT24++

The WMT24++ dataset (Deutsch et al., 2025) was created by translating the test dataset from the WMT24 General MT shared task (Kocmi et al., 2024) from English to 54 other languages. The 998 paragraph-sized English source documents come from four different domains: literary, news, social, and transcribed speech. Thus, WMT24++ is mostly complementary to FLORES+ in document sizes and domains (though news is an overlapping domain). Unlike the two previous datasets, WMT24++ is managed by Google Research and not by OLDI, but in common with all datasets promoted by OLDI, it is released under a permissive license (Apache License 2.0).

2.4 Other datasets

There are other massively parallel datasets that could have been potential targets for extension

in the OLDI shared task. They include MT evaluation benchmarks such as NTREX-128 (Federmann et al., 2022) and BOUQuET (Andrews et al., 2025), as well as other parallel datasets that could be reused for MT like Global MMLU (Singh et al., 2025) or MCS-350 (Agarwal et al., 2023). FLEURS, a parallel datasets of speech (Conneau et al., 2023) and signed language (Tanzer, 2025; Costa-jussà et al., 2025) could also have been considered. Finally, there is the massively parallel GATITOS dataset (Jones et al., 2023) of 4000 frequently used words and phrases translated from English that served as a foundation for SMOL (Caswell et al., 2025), one of the contributions of the current shared task.

3 Shared task definition

The goal of the shared task was to expand high-quality, massively-parallel and open-source datasets to improve the resources available for multilingual applications like MT. Contributions could consist of the addition of new language varieties to existing datasets, substantial improvements to existing datasets, or novel datasets compatible with the aims of OLDI. Most contributions were to the datasets managed by OLDI: FLORES+ and OLDI-Seed.

3.1 Contributing to FLORES+ and OLDI-Seed

We encouraged the contributors of new languages to FLORES+ and OLDI-Seed to start from the original English data; using a different pivot language was also possible, if clearly documented. We required the translations to be performed, wherever possible, by qualified, native speakers of the target language, and encouraged verification of the data by at least one additional native speaker. More recommendations were described in the OLDI contribution guidelines.[4]

For FLORES+ translation, we did not allow using or even referencing MT output, including post-editing, to avoid introducing any machine bias in this evaluation dataset. For OLDI-Seed data, the use of post-edited machine translated content was allowed, as long as all data was manually verified and the MT system allowed reusing their outputs to train other models (which is not the case for the major commercial LLMs). This is because OLDI-Seed is intended as MT training data rather than evaluation data and so is subject to less strict requirements.

We asked the participants to attach dataset cards to new data submissions, detailing precise language information and the translation workflow that was employed. In particular, we asked them to identify the language with both an ISO 639-3 individual language tag and a Glottocode, and identify the script with an ISO 15924 script code. For example, the Rumantsch Grischun variety was identified as `roh_Latn_ruma1247`.

Participants were encouraged to provide experimental validation of the quality of the data they were submitting.

3.2 Contributing other data

We also accepted extensions and improvements to other foundational multilingual datasets (e.g. WMT24+) that are massively parallel, open source, and useful to under-served language communities. We suggested that contribution workflow should follow that for FLORES and OLDI-Seed as closely as possible to ensure data quality and documentation. We required contributed data to be released under an open license (allowing free research use as a minimum).

4 Submissions

4.1 Shared task submissions

Table 1 summarises the contributions accepted as part of the shared task and the languages that were involved. In the rest of this section, we briefly describe each submission.

Caswell et al. (2025) created the SMOL dataset: a multiway parallel training dataset with high lexical coverage. The first part of the dataset, SMOLSENT, is based on 863 English sentences semi-manually selected from Common Crawl data[5] to cover 5.5k of the most common English words (obtained by joining the GATITOS wordlist and the most frequent words in Common Crawl). The second part of the dataset, SMOLDOC, is based on 584 English documents generated with LLMs using prompt templates that ensured diversity of topics and styles. The dataset was professionally translated from English into 115 languages, mostly under-resourced. Subsequently, additional volunteer translations were contributed, bringing the total number of languages to 123.

[4] https://oldi.org/guidelines

[5] https://commoncrawl.org/

To demonstrate the value of the dataset, the authors used it for in-context learning of several commercial LLMs and for fine-tuning of a GEMINI LLM for translation out of English into the 80 languages for which evaluation data were available. For most language subsets and models, in-context learning with SMOL examples was found to be superior to zero-shot translation. Fine-tuning demonstrated positive effect of both SMOL dataset parts and their combination with GATITOS.

Frontull et al. (2025) translated FLORES+ into Val Badia and Gherdëina, two varieties of the Ladin language which is spoken in Northern Italy. The paper gives a detailed overview of Ladin and the resources available for it. The FLORES sentences were first manually translated into the Val Badia variety, using German, Italian, Friulian, and English references, then into the Gherdëina variant, using Val Badia as an additional reference. The authors additionally released training datasets for Gherdëina–Italian and Val Badia–Gherdëina pairs and used them to fine-tune an NLLB model to translate between the three languages. They used the newly translated FLORES dataset to benchmark the MT performance of this model and four LLMs (with and without retrieval of few-shot examples from the parallel training dataset). They found that even though retrieval helps, translation into the Ladin variants remains a clear challenge for current LLMs.

Jumashev et al. (2025) expand OLDI-Seed to Kyrgyz by post-editing LLM-based translations from English (using also Kazakh and Russian lexical resources) with a subsequent review to ensure term consistency throughout the dataset. Two post-editing techniques that the authors highlight are breaking a complex English sentence into two or more Kyrgyz sentences to be more fluent under the Kyrgyz SOV sentence structure, and a careful choice between native Kyrgyz words and Russian or English calques for scientific terms.

To demonstrate the effectiveness of the resulting parallel dataset, the authors finetuned four multilingual models on it and demonstrate gains in translation performance of each model on FLORES+ and X-WMT (Mirzakhalov et al., 2021).

Mæhlum et al. (2025) revise the FLORES+ dataset in Norvegian Bokmål and create a new version of it in Radical Bokmål, a sub-variety that is closer to spoken Norwegian dialects than the more Danish-like conservative Bokmål that dominates formal discourse. The authors provide a detailed explanation of the difference between the varieties, followed by an overview of the grammatical and lexical mistakes present in the original Bokmål FLORES+ dataset, such as anglicisms, word-by-word translations and problems in agreement. The necessary revisions affected two thirds of the FLORES+ sentences. The authors demonstrate that the new version of the dataset, cleaned from anglicisms and overly literal translations, serves as a more challenging reference set for English-Bokmål translation than the previous version.

Mamasaidov et al. (2025) extended FLORES+ to Southern Uzbek, a variety spoken in Afghanistan and written in Arabic script. It is substantially different from Northern Uzbek, which is spoken in Uzbekistan and written in Latin. The challenges of understanding and generating Southern Uzbek include the ambiguity of Arabic vowel characters and the use of a zero-width non-joiner character (U+200C) to separate the words' suffixes. Apart from the FLORES+ dev set translation into Southern Uzbek performed by a single native linguist, the paper also contributes an automatically aligned parallel dataset of the Southern and Northern Uzbek sentences, a NLLB model fine-tuned with this data and evaluated with FLORES+, and scripts for transliteration of Southern Uzbek into Latin and for post-correction of missing U+200C characters. The newly finetuned model outperforms the strong LLM baselines on translation into Southern Uzbek, demonstrating the lack of previous support for this language.

Marmonier et al. (2025) expand OLDI-Seed to French with the purpose of serving as a pivot language for the under-resourced regional languages of France. Each OLDI-Seed sentence has been translated from English with 9 different MT systems, and two native French speakers selected and post-edited the most promising translation candidate from each such set. Finally, the translations were processed through a grammar checker. For validating the post-edited translations, the authors use MetricX-24 quality estimation system (Juraska et al., 2024), demonstrating that the human translations result in lower predicted error rates than any of the MT candidates. The paper emphasizes the terminological complexity of the OLDI-Seed dataset and the challenges of producing fluent French translations as a result of the issues sometimes found in the English source sentences.

Oktem et al. (2025) revised FLORES+ and OLDI-Seed sentences in Standard Moroccan

Tamazight as a part of the Awal initiative. The FLORES sentences were revised by two linguists using English as reference whilst OLDI-Seed was revised by three professional Tamazight translators with English and Arabic references. 36% of FLORES and overall and 40% of OLDI-Seed sentences required correction of spelling mistakes, transliteration errors, unnecessary or malformed loanwords, and mistranslations.

The authors fine-tuned an NLLB-based model with the corrected OLDI-Seed dataset and other Tamazight-English parallel datasets and evaluated it alongside with the original NLLB models and commercial LLMs on the original and corrected FLORES dataset. They found that the corrected FLORES dataset yields better MT evaluation metrics, and that fine-tuning with the OLDI-Seed data improves NLLB performance, making the model outperform the LLMs in the English-Tamazight direction.

Vamvas et al. (2025) expanded the WMT24++ benchmark with six varieties of the Romansh language: Rumantsch Grischun, a supra-regional variety, and five regional varieties: Sursilvan, Sutsilvan, Surmiran, Puter, and Vallader. The benchmark texts were translated from German by hired professionals who are native speakers of both German and a Romansh variety. The translations were then reviewed by two expert linguists. For automatic validation of the translations, the authors used language identification with a FastText model and cross-variety ChrF++ scores, demonstrating that the texts in the Romansh varieties are similar but distinguishable from each other. The resulting benchmark was used to assess the performance of MT system and LLMs on translation between German and Romansh, demonstrating that although some models already understand Romansh fairly well, translation into it is still challenging.

4.2 Other dataset extensions

It should be noted that not all contributors to the OLDI datasets submitted shared task papers. In the last year, FLORES+ has also received new translations in Chuvash, Dargwa, and Meadow Mari, regional languages in Russia, and incorporated the translations into Nko (Doumbouya et al., 2023) and five Indic languages (Gala et al., 2023): Bodo, Dogri, Konkani, Sindhi and Manipuri. OLDI-Seed has been extended with the Nko language (Doumbouya et al., 2023).[6]

5 Discussion

Creating and maintaining language resources and technologies is hard, especially massively multilingual ones. There are tradeoffs and compromises: between the number of language varieties covered and the depth of the support of each variety, between the difficulty of benchmarks and the ease of translating them into new languages, between the naturalness of the translation in the target language and its faithfulness to the source content. Without the active interest of the communities actually speaking the language, advancing the NLP technologies for many of the world's under-served languages is hardly possible.

The contributions of this year's OLDI shared task highlight some of the issues with existing multilingual datasets and put forward suggestions as to how these might be solved. One issue which was highlighted repeatedly by the teams translating OLDI-Seed is its terminological complexity and the requirement of specialized knowledge for translating it. However, the emergence of SMOL as an alternative seed training dataset for MT helps circumvent this issue. An additional issue is that many popular multilingual datasets are English-centric. This is a barrier for extension into languages whose speakers use other languages as a lingua franca. Contributions like French OLDI-Seed by Marmonier et al. (2025) mitigate this. Finally, the work of Mæhlum et al. (2025) and Oktem et al. (2025) on revising the OLDI datasets in Norvegian Bokmål and Tamazight, respectively, show the need for continuous improvement of massive parallel datasets, especially with the direct involvement of the community of speakers.

Since the previous round of the OLDI shared task, contributions to FLORES+ and OLDI-Seed have already propagated to massively multilingual NLP benchmarks (e.g. Luo et al. (2025)) and to the extension of foundation models to new languages (e.g. Tsiamas et al. (2025)). We hope that the new datasets, languages and revisions contributed in the current shared task will similarly lead to further improvements in NLP resources and MT research for under-resourced languages.

[6] See the detailed list of changes and their attributions in the `CHANGELOG.md` files and dataset cards in the FLORES+ and OLDI-Seed repositories.

6 Conclusion

We presented the results of the WMT 2025 OLDI shared task. We accepted 8 submissions covering 16 languages, including the new SMOL dataset covering 123 languages, and extensions or revisions of the existing foundational datasets, FLORES+, OLDI-Seed, and WMT24++, in 14 language varieties. We are truly grateful to all participants for their work and we hope that these contributions are soon adopted by the research community, enhancing a positive feedback loop between the developers of language technologies and the communities of language speakers.

Acknowledgments

OLDI functions on volunteer time and community contributions. We are grateful to the language communities, researchers, and reviewers that contributed to this shared task with new resources for under-served languages. AA also acknowledges support from the US National Science Foundation under award CIRC-2346334.

Abstract

We present the findings of the WMT 2025 Shared Task *LLMs with Limited Resources for Slavic Languages*. This shared task focuses on training LLMs using limited data and compute resources for three Slavic languages: Upper Sorbian (hsb), Lower Sorbian (dsb), and Ukrainian (uk), with the objective to develop and improve LLMs for these languages. We consider two tasks which are to be evaluated jointly: Machine Translation (MT) and Multiple-Choice Question Answering (QA).

In total, three teams participated in this shared task, with submissions from all three teams for the Sorbian languages and one submission for Ukrainian. All submissions led to an improvement compared to the baseline Qwen2.5-3B model through varying fine-tuning strategies. We note, however, that training purely on MT degrades original QA capabilities. We also report further analyses on the submissions, including MT evaluation using advanced neural metrics for Ukrainian, as well as manual annotation and comparison to the current Sorbian machine translator.

1 Introduction

For a large majority of the world's languages, only limited resources are available for training NLP tools, but modern large language models (LLMs) need large amounts of both labelled and unlabelled data to function well. Improving the coverage of low-resource languages in LLMs is an active research area. Recent examples include Nag et al. (2025) for Indic languages and Tonja et al. (2024) for Ethiopian languages. Similarly, there is active work on low-resource machine translation, with recent shared tasks and datasets covering translation for low-resource Indic languages (Pakray et al., 2024), Creole languages (Robinson et al., 2024) as well as Indigenous Languages of the Americas (De Gibert et al., 2025).

Although commercial LLMs increasingly show high performance on both general tasks and machine translation, specialised MT models are still typically required for best results. Our challenge to participants in this shared task is to build a model under low-resource conditions to jointly optimise machine translation and question answering. We aim to study potential synergy effects between these two tasks, as well as to explore whether optimising for one task in a low-resource setting will negatively impact the other task. We are one of the first WMT shared tasks to focus on joint optimisation of Machine Translation (MT) and Question Answering (QA). The Multilingual Instruction Shared Task in the same year took a similar approach, but allowed significantly larger models.

Our task focuses on three Slavic languages: Upper Sorbian, Lower Sorbian, and Ukrainian. Thus, we aim to highlight both truly low-resource settings and mid-resource language scenarios in the context of modern language technologies. As our goal is to evaluate LLMs as general-purpose tools for a given language, we designed our setup to mirror widely adopted benchmarks such as GLUE (Wang et al., 2019) and MMLU (Hendrycks et al., 2021). Since Sorbian languages and Ukrainian currently lack such comprehensive language understanding benchmarks, we approximated a multitask evaluation by selecting two representative tasks: Machine Translation and Question Answering.

Previous iterations of the WMT Shared Tasks on translating low-resource languages (Weller-Di Marco and Fraser, 2022; Libovický and Fraser, 2021; Fraser, 2020) compared supervised and unsupervised translation in various data settings. For both Sorbian languages, the WITAJ-Sprachzentrum provided new machine translation and question answering datasets for this shared task. For Ukrainian, the MT portion of the dataset corresponds to that of the WMT 2025 general translation

Proceedings of the Tenth Conference on Machine Translation, pages 503–519
November 8-9, 2025

task,[1] and the QA portion is based on the dataset from the UNLP 2024 Shared Task on fine-tuning LLMs for Ukrainian (Romanyshyn et al., 2024).

Our research questions are as follows:

- In a low-resource scenario, how does training a model for machine translation impact its performance on a secondary task such as question answering?
- Is it possible to improve capabilities on both machine translation and question-answering in a small LLM?

This article is structured as follows: Section 2 describes the shared task rules, while Section 3 details the MT and QA datasets provided for both development and test phases. Section 4 presents the systems devised by the three participating teams. Section 5 displays the official leaderboard for the primary submissions in all three tracks. Section 6 analyses the model outputs with some additional experiments.

2 Shared Task Description

2.1 Languages

Upper Sorbian (ISO code: `hsb`; Glottocode:[2] `uppe1395`) and Lower Sorbian (`dsb`; `lowe1385`) are minority languages spoken in the eastern part of Germany in the federal states of Saxony and Brandenburg, with only 30k and 7k native speakers, respectively. As western Slavic languages, Upper and Lower Sorbian are closely related to Polish and Czech. There is an active language community working on the preservation of these languages, namely the WITAJ-Sprachzentrum[3] (WITAJ Language Center) who also provided parts of the data used in this shared task. Previously, the WMT Shared Tasks in Unsupervised MT and Very Low Resource Supervised MT (Weller-Di Marco and Fraser, 2022; Libovický and Fraser, 2021; Fraser, 2020) focused on both languages.

Ukrainian (`ukr`; `ukra1253`), spoken by approximately 40 million L1 speakers worldwide, is considered a mid-resource language in NLP with already several language-specific pre-training corpora (Chaplynskyi, 2023) and LLMs (Yukhymenko et al., 2025) available. With a significant number of Ukrainians currently living abroad, the demand for high-quality machine translation systems to support integration into new environments is greater than ever. Machine translation, complemented by cross-lingual knowledge transfer and robust question answering capabilities, can play a crucial role in addressing this need.

2.2 Task Description

Our main goal is to observe the synergy between the two different tasks in an LLM. Therefore, models are tested *jointly* on two tasks: **machine translation** and **multiple-choice question answering**. All participating systems must submit outputs for both tasks of a track.

For Machine Translation, we focus on the following translation directions:

- German to Upper Sorbian (de→hsb)
- German to Lower Sorbian (de→dsb)
- English to Ukrainian (en→uk)
- Czech to Ukrainian (cs→uk)

All these pairs focus on the more challenging—and needed—direction, from the higher-resourced language to the shared task languages.

For Question Answering, we use multiple-choice datasets from education and language certification. For Ukrainian, we evaluated on multiple-choice exam questions from the UNLP 2024 Shared Task on LLM Instruction-Tuning for Ukrainian, which is compiled from school graduation examinations on various subjects. For Upper and Lower Sorbian, we evaluated on language certificate exercises which follow the CEFR (Common European Framework of Reference for Languages) scheme.

2.3 Models and Restrictions

We set this shared task in a restricted context with limited resources: The base LLM is fixed to the Qwen 2.5 family (Qwen Team et al., 2025; Yang et al., 2024) and a maximum of 3B parameters. We chose a small model size in order to enable teams with fewer compute resources to participate, and limited models to one family so that results would be more readily comparable. The Qwen 2.5 model family was selected based on zero-shot performance on the Sorbian QA development sets.

Regarding data resources, we suggested training data and provided development sets for all languages (§3). However, the participants were not restricted to the provided datasets. Additional

[1] https://www2.statmt.org/wmt25/translation-task.html

[2] https://glottolog.org

[3] https://www.witaj-sprachzentrum.de

datasets were permitted under the condition that the used resources were open source.

2.4 Phases

The shared task was held in two phases: the development phase started with the release of training and development datasets (when available), and the test phase began when the respective test datasets were made available. The latter also featured a leaderboard on OCELoT where participants could submit their outputs to compare against other teams.

3 Datasets

In the following, we describe the datasets provided for the development and test phases.[4]

3.1 Sorbian Languages

We release the new data for both Sorbian languages under the CC BY-NC-SA licence.

MT For Machine Translation, the WITAJ-Sprachzentrum provided new monolingual and parallel datasets compared to the previous shared task editions for both Sorbian languages. The development dataset is a combination of both old and new sentence pairs. Table 1 lists the number of sentences or sentence pairs with German translations.

The test sets contain 4,000 sentences for each language. The sentence pairs are from the same domain as the training and development datasets.

	Upper Sorbian	Lower Sorbian
parallel train	187,270	171,964
parallel dev	4,000	4,000
parallel test	4,000	4,000
monolingual	47,758 (wiki) 1,071,723 (witaj)	120,501

Table 1: Number of sentences in the newly released mono- and bilingual (paired with German) data for both Upper and Lower Sorbian.

QA The WITAJ-Sprachzentrum organises language examinations for both Upper and Lower Sorbian, from the A1 to C1 levels, according to the CEFR scheme. We use a mix of questions from all five available levels (A1, A2, B1, B2, and C1, from beginner to advanced) for our Question Answering task—more specifically from the reading, grammar, and listening parts. For the listening questions, we rely on the reference transcription of the audio material to convert the exercises; this can lead to comparatively easier questions.

Each language level differs in terms of exercise formats, which can add another level of complexity to the task. While the beginner levels (e.g., A1) often have true-or-false questions on a short text, the advanced exercises (e.g., B2 or C1) typically consist of multiple-choice questions with longer texts and statements, sometimes with up to 16 possible answers.[5]

While the provided development set only contained questions from the A1 to the B2 levels, the test dataset additionally features questions from the C1 certification level. Table 2 shows the number of questions per difficulty level for both data splits.

split	lang	A1	A2	B1	B2	C1	total
dev	hsb	30	28	44	56	0	158
dev	dsb	30	28	44	56	0	158
test	hsb	30	28	44	56	52	210
test	dsb	29	28	44	56	48	205

Table 2: Number of questions in the Sorbian QA datasets per language level.

3.2 Ukrainian

The Ukrainian language track data was sourced from previous editions of MT and QA shared tasks, with the MT test set aligned with this year's General MT competition.

MT For the machine translation subtask, we focused on translation into Ukrainian from two languages: English→Ukrainian (en→uk) and Czech→Ukrainian (cs→uk).

The suggested development data were the combined WMT datasets from the 2022–2024 editions (Kocmi et al., 2022, 2023, 2024). Our test phase was aligned with the WMT 2025 General Machine Translation task for translation into Ukrainian. Parallel data statistics per language pair are shown in Table 3.

The primary difference in dataset sizes comes from the fact that most training and development sets were sentence-based, whereas the test set was

[4]Available at: https://github.com/TUM-NLP/llms-limited-resources2025

[5]More details are available in our shared task repository.

language pair	dev	test
cs→uk	6,263	230
en→uk	5,108	86

Table 3: Datasets statistics per language pair for the Ukrainian MT track.

designed at the paragraph level. This dissimilarity introduced additional challenges for both shared task participants and the evaluation process.

QA We utilised the dataset from the UNLP2024 shared task (Romanyshyn et al., 2024), focusing exclusively on multiple-choice questions. The original data splits were retained, ensuring balanced coverage of all topics across training, development, and test sets, as shown in Table 4.

split	Ukrainian history	Ukrainian lang. and lit.	total
train	910	1,540	2,450
dev	228	385	613
test	348	403	751

Table 4: Datasets statistics per splits and subjects for the Ukrainian QA track.

This dataset comprises machine-readable questions and answers from the Ukrainian External Independent Evaluation (transl. ZNO), the standardized examination required for university admission in Ukraine. It includes exam materials from 2006 to 2023, covering two subjects: History of Ukraine and Ukrainian Language and Literature.

3.3 Relative Difficulty of the Tracks

While we compiled the same task types for both tracks, there are different challenges for our selected languages.

For Ukrainian MT, natural parallel training data is already available, and a variety of both open-source and proprietary translation systems exist. Participants were therefore encouraged to leverage available resources to whatever extent they find appropriate. In contrast, Sorbian resources include parallel and monolingual sentences but are fewer in comparison. NLP tools, more generally, are not available for the two Sorbian languages.

For the QA task, the Sorbian dataset was derived from language certification exams across different levels. Given the languages' low-resource status, the focus is on evaluating whether models can adequately comprehend the language and answer typical document-understanding or grammatical questions. For Ukrainian, the challenge extends further: Models are tasked not only with answering general language questions but also with addressing deeper questions related to Ukrainian literature and history.

4 System Descriptions

Submissions are language-specific; participants could submit to one or more language tracks. However, participants had to submit both the QA and the MT outputs, which had to be generated by the same model.

In addition to our baseline outputs, three teams submitted to the Upper and Lower Sorbian tracks, and one team also submitted to the Ukrainian track. For the final evaluation, each team was asked to choose a primary submission and provide a short description of their approach. Based on these descriptions, we provide an overview of the participating systems here. Table 5 summarises the main characteristics of the three participating primary submissions. For more details, please refer to the respective system description papers.

Baseline (TUM Organisers) Our simple baseline prompts Qwen2.5-3B-Instruct (Qwen Team et al., 2025) with no fine-tuning. The prompts are zero-shot, and an example is shown in Appendix A. We implemented our tasks in the LLM Evaluation Harness framework (Gao et al., 2024) and provided this code to participants for reference.[6]

Team NRC (National Research Council Canada) (Larkin et al., 2025) The NRC submissions focused primarily on the machine translation (MT) component of the shared task. The team explored the impacts of training on Upper Sorbian and Lower Sorbian data separately and together. They also experimented with direct preference optimisation using pairs of correct and incorrect responses to the question answering (QA) set, with limited success. Their submitted systems are based on the Qwen2.5-1.5B-Instruct model, trained using supervised fine-tuning on full model weights using LLaMa-Factory and 4 GPUs (Tesla V100-SXM2-32GB).

		Instruction tuning	✗	✗	✓

Table 5: Summary of the three **primary** submissions.

Team SDKM (JGU Mainz) (Saadi et al., 2025) Team SDKM trained three separate Qwen2.5-3B-Instruct models for three languages: Lower Sorbian, Upper Sorbian, and Ukrainian. For Lower Sorbian, the team trained a Qwen2.5-3B-Instruct model by combining both machine translation (MT) and question answering (QA) data. Then, they fine-tuned a joint model on a combined MT and QA dataset. After this fine-tuning, they fine-tuned the model on all the provided QA data and 3k MT data for a second round of fine-tuning. This final fine-tuned model was used for both MT and QA tasks. For Upper Sorbian (hsb), the team followed the same overall approach as with Lower Sorbian. During the QA evaluation of dsb and hsb, they made multiple versions of the same MCQ question with different possible orders and averaged the likelihood of each option, then selected the option with the maximum likelihood. For Ukrainian, they also followed a similar approach, but for QA, they employed retrieval-augmented generation (RAG). The team will make all the data and code they used for pre-processing, training, and their trained model publicly available shortly after the deadline. They used the Qwen2.5-3B-Instruct model as all translation models, for semantic similarity calculation to incorporate retrieval augmented generation.

Team TartuNLP (TartuNLP) (Purason and Fishel, 2025) The TartuNLP system fine-tuned Qwen2.5-3B-Instruct (Qwen Team et al., 2025) on a mixture of monolingual, parallel, and instruction data to support both Lower and Upper Sorbian. The monolingual set included all sentence-level Sorbian data from current and past WMT Shared Tasks, Upper and Lower Sorbian Wikipedia articles (Foundation, 20250520 dump), and Upper and Lower Sorbian documents from Fineweb-2 (Penedo et al., 2025). Parallel data, sourced from WMT (current and past), was reformatted as chat-style instruction pairs, with four epochs of German-to-Sorbian and one epoch of Sorbian-to-German translations. Both monolingual and parallel Sorbian data were repeated four times. The instruction data was collected from Magpie (Xu et al., 2024), Aya (Singh et al., 2024), EuroBlocks (Martins et al., 2025), OpenAssistant (Köpf et al., 2023), and FLAN v2 (Longpre et al., 2023), covering multiple languages. All datasets were deduplicated and packed into 4096-token sequences, with loss applied only to assistant responses in instruction-formatted data. For the final submission, they used beam search with a beam size of 4 for machine translation and one-shot prompting with development set examples for question answering. The final model is published on HuggingFace.[7]

5 Primary Submission Results

5.1 Evaluation Methodology

We evaluate MT with chrF++ (Popović, 2015), computed using SacreBLEU (Post, 2018),[8] and QA with accuracy. ChrF++ ranked slightly higher than BLEU (Papineni et al., 2002) in the WMT 2024 Metrics Shared Task (Freitag et al., 2024). Although neural metrics such as COMET are gen-

[7] https://huggingface.co/tartuNLP/Qwen2.5-3B-Instruct-hsb-dsb

[8] SacreBLEU chrF++ signature: `nrefs:1 | case:mixed | eff:yes | nc:6 | nw:2 | space:no | version:2.5.1`.

erally known to better correlate with human judgements, we could not consider them as the main ranking criterion because they do not support the Sorbian languages. However, we do consider xCOMET (Guerreiro et al., 2024) for Ukrainian in Section 6.1.

Since our goal is to evaluate the *joint* performance of LLMs on both MT and QA, the ranking in the leaderboard takes into account the scores from all tasks of the track equally. For the final ranking, points are given according to the ranking of the submission in the MT and QA tasks, with the highest-ranked system obtaining the maximum number of points (4 for the Sorbian tracks, 2 for the Ukrainian track). In case of ties, we ranked according to the MT results.

5.2 Leaderboard Results

Tables 6, 7, and 8 show the results of the participating teams' primary submissions for the three tracks: Upper Sorbian, Lower Sorbian, and Ukrainian. The winning team per track and the best submission per task are in bold.

	de→hsb		hsb-QA		final
	chrF++	pts	acc.	pts	pts
TartuNLP	86.33	4	**58.10**	4	8
