NER features. Using lexical features alone, there are a number of words that help indicate OP (*operational*) citations in NLP, e.g., "parser", "tagger", "corpus". We decide to take this a step further and train a named-entity recognition (NER) system to identify NLP named entities. We identify two types of NLP named entities: corpora and tools. First, we create a gazetteer of NLP tools and corpora from an online list of these resources.[5] Next, we tag a portion of our corpus using the gazetteer list to label any occurrence of the words in the list and then manually check those labeled instances to be sure they are correctly labeled. In this way we can expediently create training data, with an emphasis on precision over recall. Finally, we train the SuperSenseTagger (Ciaramita and Altun, 2006)[OEPF] on this annotated portion, and tag the remaining part of the corpus. NER is not central to our task, so we did no direct evaluation of it; we looked only to see if it might lead to improvements in our classification. We include two features, `has-resource` and `has-tool`, for the two types of entities.

The NER features we extract are related only to the NLP domain. However, this approach for acquiring named entities is not domain dependent and can be used to develop a reasonably efficient NER system using lists of tools or resources from any domain.

5 Experiments

In this section we will outline our classification experiments and then discuss the results in Section 6. We use the term *feature set* to describe a collection of features used by us or in previous studies; we use the term *feature class* to describe a collection of similar features as they are organized in Section 4 and in Table 2.

Setup. All our experiments were conducted on the corpus described in Section 3. We trained the Stanford MaxEnt classifier (Manning and Klein, 2003)[OEPF] for each of the four facets

[5] `http://nlp.stanford.edu/links/statnlp.html`

in a 5-fold cross validation setup with default settings except that we set the regularization parameter $\sigma = 10$ based on previous experiments.

Feature set comparison. In our first set of experiments we test our own feature set and the feature sets described in previous studies. Each of these feature sets is a subset of the features described in Section 4 and is identified below by some of its more distinguishing features; e.g., **NgramDep** refers to the feature set that mainly uses n-grams and dependencies.

CueVerbLoc. This feature set is intended to mimic (Teufel et al., 2006b)[CEPF] to the extent this is possible. It includes cue phrase features ($\texttt{cues}_k$), the verbal features `tense`, `voice`, and `modal` as well as `paper-loc`. The cue phrases used in (Teufel et al., 2006b)[CJPF] are not available so we applied automatic feature selection using mutual information (MI) (Manning et al., 2008)[CEPF] to select the most informative unigrams, bigrams, and trigrams for each class label. We borrow from the manual feature selection in (Teufel et al., 2006b)[CEPF] by assigning cue phrases to each of the labels (8 in our case – Teufel et al. used 12) and limiting the number of cue words to 75 per label. Some examples for OP cues are *wordnet*, and *parser*.

NgramDep. This feature set corresponds to (Athar, 2011)[CEPF]. It includes lexical features: unigrams, bigrams, and trigrams (`1+2+3-grams`) and the `dep-rel` features. Athar (2011)[CJPF] tested other features, but we have only reimplemented those that improved results.

CueFreqPOS. This feature set is based on (Dong and Schäfer, 2011)[CEPF]. It includes a list of cue words ($\texttt{cues}_k$), then the frequency features `popularity`, `density`, `avgDensity`, and the syntactic feature $\texttt{POS-pattern}_k$.

PREV. This feature set combines all features previously used for citation classification into one feature set (i.e., CueVerbLoc + NgramDep + CueFreqPOS).

OWN. The feature set OWN includes all the features we have introduced in our work – those marked "own" in Table 2. Some features were designed to help one facet or another, but we use them all together here for all facets.

We note here that by reimplementing features from previous work we claim only to extract the same or similar information as the original authors. Due to sometimes major differences in the corpus, annotation scheme, and classifier used, we are not able to reproduce the same conditions that led to previous results. We are instead more interested in the types of features that seem to perform best on our dataset with our annotation scheme.

Citation context size. The tests just described are run with a fixed context size of one sentence. It is not clear how much context is best for feature extraction, so in another set of experiments we fix the feature set and test the features extracted from different sized context windows. In previous work, different sized context windows were used by different studies, e.g., Athar (2011)[CEPF] used only the sentence containing the citation while Dong and Schäfer (2011)[CEPF] used up to three sentences. Kaplan et al. (2009)[CEPF] and Abu-Jbara and Radev (2012)[CEPF] have illustrated the difficulties in delineating the exact boundary for each individual citation context, while Athar and Teufel (2012)[CEPF] tried different fixed context sizes for citation classification. We follow this general idea and test context lengths of 1, 2, and 3 sentences.

Feature class comparison. In addition to comparing our own feature set with those from previous work, we also want to investigate what feature classes assist most in the classification. We perform this analysis by examining the impact of the seven feature classes described in Section 4. More specifically, we compare the results of their individual performance using *only features in the feature class* (Table 4, top), and their ablation from the entire feature set using *all*

features except those in the feature class (Table 4, center). Finally, we extend the ablation study, *successively removing all feature classes* in order of importance (i.e., by their contribution to F_1 score) (Table 4, bottom).

6 Results and Discussion

Feature set results. The results for the different feature sets when using one sentence of context are found in Table 3. All of the F_1 results presented in this paper are macro-averaged F_1. We have included two baseline experiments. We use a majority baseline (BL) that labels each citation with the label occurring most often in the corpus, e.g., for CONC-OP, all citations are labeled CONC. We also include results for unigram, bigram, and trigram features (Ngram), which is the baseline used by Athar (2011)[CJPN]. The results in Table 3 show that our feature combination outperforms both baselines and all reimplemented feature sets for all four facets. With two exceptions (Ngram for EVOL-JUX and PREV for ORG-PERF), these results are significant.[6]

The greatest improvement over the baseline is with the OWN features for CONC-OP. Several of the other feature sets also do better on CONC-OP than BL, but OWN is still significantly better than PREV, the combination of all other feature sets. Simple BOW features along with our new features (e.g., `has-resource` and `has-tool`) increase F_1 by 7 points over PREV. As an example, in a sentence citing "The Penn TreeBank (Marcus et al., 1993)," the citation is incorrectly classified using PREV. The NER tool recognizes Penn TreeBank as a corpus, which results in the OWN feature `has-resource` to be set to true and a correct classification of the citation as OP.

EVOL-JUX proves to be more difficult than CONC-OP with either no or very small improvements over BL for all feature sets except for Ngram and OWN. The BOW features from our OWN feature set are responsible for most of the improvement of F_1 from 47.3 to 52.9. BOW features contribute to the improvement with OWN features for all four facets.

OWN features improve F_1 by 10.7 (from 47.3 to 58.0) over the BL for ORG-PERF, and are also better by 3.2 (54.8 vs 58.0) than PREV. Some features that contribute to the better results are `root` and `main-verb` with values such as "describe" and "present"; these appear to be useful in identifying ORG citations. In this facet, the feature set CueFreqPOS sees its most significant improvement over BL. This is due in a large part to the frequency features that are not found in other feature sets.

Finally, CONF-NEG is the most difficult facet. All feature sets except our own performed only as well as or even worse than BL. OWN features improve F_1 by 3.3 (from 47.8 to 51.1), which is due in part to the location feature that finds citations in the middle of sentences to be CONF, while NEG citations are more likely to come at the beginning.

To get an idea of a possible upper bound for this task, we include a *human classifier* ("Human" in Table 3): we take the annotation from the most experienced annotator and consider it as classification output. CONC-OP is the "easiest" facet for the human classifier to label, similar to automatic classification. However, the most difficult facet for automatic classification, CONF-NEG, appears to be straightforward for the human classifier. This is consistent with the high observed agreement for CONF-NEG (.91, footnote 4).

Context size results. For OWN, we tested three different context sizes c: $c \in \{1, 2, 3\}$ sentences. We found that $c = 1$ is best for CONC-OP (significant) and ORG-PERF; and $c > 1$ is better for

[6] $p < .05$. All significance tests in this paper use the approximate randomization test (Noreen, 1989)[CEPF].

	CONC-OP	EVOL-JUX	ORG-PERF	CONF-NEG
baseline (BL)	*47.2	*47.3	*47.3	*47.8
Ngram	*53.2	50.7	*51.3	*47.8
CueFreqPOS	*48.4	*49.4	*54.1	*47.7
NgramDep	*53.3	*47.3	*50.5	*47.8
CueVerbLoc	*51.1	*47.3	*47.3	*47.8
PREV	*61.2	*48.5	54.8	*47.5
OWN	68.2	52.9	58.0	51.1
Human	94.7	91.1	91.7	93.5

Table 3: F_1 for different feature sets. Marked with $*$: significantly worse than OWN ($p < .05$). Underlined: best performing feature set per facet.

CONF-NEG (significant) and EVOL-JUX. These results suggest that context size is an important factor, but one that does not have a uniform effect on the four facets. The online appendix describes these experiments in more detail.[2]

Feature class results. In the discussion of the feature class results we will refer to the line numbers in Table 4. The table presents F_1 results using only a single feature class (lines 1–7); F_1 using all features ("All") and F_1 using all features except the listed feature class (lines 8–14); and finally, extended ablation results where a feature class is successively removed from "All" (seven classes) until one feature class remains (lines 15–21). Our goal is to get a better idea of which feature classes are informative for a given facet.

CONC-OP. LEXICAL features appear to be the most important for this facet. Alone they do well against the baseline (61.6 vs 47.2, line 1) and when removed from the entire feature set F_1 drops more than for any other feature class (from 64.5 to 58.2, line 8). Both of these Δ's are significant. The feature class NER has the second highest F_1 (54.1, line 7) when used alone, which makes sense as it was designed for this facet. Removing NER features hurts F_1 (down to 64.0, line 14), but not significantly. Using only WORD-LEVEL or STRUCTURE features also leads to significant improvement: increases of 4.8 (line 2) and 4.3 (line 3). After that, SENTIMENT features improve F_1 but not significantly (line 6), while the LOCATION and FREQUENCY features show no difference from the BL (lines 4–5). The ablation results show that after the significant contributions of the LEXICAL features, the removal of other feature classes does not affect the results much: Removing STRUCTURE, LOCATION, and SENTIMENT features actually increases F_1 (lines 10, 11, 13), and the ablation of WORD-LEVEL, FREQUENCY, and NER features shows no significant change (lines 9, 12, 14).

EVOL-JUX. For this facet, three of the seven feature classes, LOCATION, FREQUENCY, and NER, lead to no change from the baseline when run alone (lines 4, 5, 7). Another three feature classes, LEXICAL, WORD-LEVEL, and SENTIMENT, significantly improve over BL (lines 1, 2, 6). Conversely, the FREQUENCY features, with no improvement alone, help improve results of the entire feature set; when those features are removed, F_1 drops by 2.2 (from 53.4 to 51.2, line 12). Also, the SENTIMENT features, which do well against the baseline (line 6), hurt F_1 when added to the full feature set (decrease by -0.7, line 13).

ORG-PERF. Individually, the feature classes LEXICAL, WORD-LEVEL, and STRUCTURE all had significant improvements (lines 1–3). The other four classes do not help for this facet (lines 4–7). However, in the ablation results, omitting these feature classes also *increases* F_1 (lines 8–10). Only removing LOCATION significantly decreases F_1 (line 11). This result indicates that several of the feature classes are correlated for classifying this facet. They contain useful information for the task (as indicated by good performance when used individually), but mutual correlation has

the effect of bad generalization when all of them are used together. The results show that this type of analysis (which has not been performed before for citation classification) is important to understand how features impact performance and what steps are needed to achieve better performance.

		CONC-OP		EVOL-JUX		ORG-PERF		CONF-NEG	
	BL	47.2		47.3		47.3		47.8

Table 4: **Top.** Results when a single feature class is used. **Middle.** Ablation results: F_1 and decrease in F_1 when each feature class is ablated; i.e., each result shown is a classification result using six feature classes. **Bottom.** Extended ablation results: Left columns indicate the feature class removed. Marked with †: significantly better than BL ($p < .05$); marked with $*$: significantly lower than All ($p < .05$). Underlined: best performing feature class per facet (largest Δ).

CONF-NEG. Only SENTIMENT (line 6) and WORD-LEVEL (line 2) improve over BL and the remaining five feature classes do only as well as BL. Removing four of the seven feature classes actually seems to improve F_1 (lines 8, 11, 12, 14), with F_1 only increasing by adding WORD-LEVEL or STRUCTURE features (lines 9–10).[7] In fact, it seems that including the feature classes LEXICAL, STRUCTURE, LOCATION, FREQUENCY, and NER might only be detrimental for this facet, as F_1 using only SENTIMENT features is 49.9 (line 6) compared to using all features at 48.9 ("All").

To further analyze the relative importance of a feature class for a facet we extend the ablation results by successively removing that feature class whose removal results in the lowest F_1, among the possible ablations, until all have been removed (Table 4, lines 15–21). E.g., in CONC-OP we start with all features ($F_1 = 64.5$) and calculate F_1 after removing each of the feature classes individually. In this case, removing LEXICAL leads to the largest drop in F_1, from

[7] Lines 9–10 have different F_1 (48.9 vs 48.8) but the same $\Delta = 0.1$ due to rounding.

64.5 to 58.2 (line 15). In the next iteration, we again compare F_1 after removing each of the six remaining feature classes. Removing NER features results in the lowest F_1 (now 53.6, line 16), and we proceed by removing one of the five remaining feature classes, etc. These results support what was discussed for the top and middle portions of Table 4, but present it as a list of the feature classes in descending order of importance. This table helps us to compare different facets; we can easily see that LEXICAL and NER features are important for CONC-OP, while LOCATION features are not. Compare this to CONF-NEG where LEXICAL and NER features are not important and WORD-LEVEL is higher in the list. Note also, that F_1 does not always decrease (e.g., removing LEXICAL for EVOL-JUX). Some combinations of subsets of features will perform better than the previous superset. In this case, we see that after having removed STRUCTURE, removing any other feature class can only improve results.

The results in this section give us some valuable insight into how to design features for citation classification. First, we consider the first three feature classes, LEXICAL, WORD-LEVEL, and STRUCTURE. All three contain quite general text classification features, and consequently are quite robust and informative across the four facets of citations that we consider. WORD-LEVEL seems to be the most robust across all four facets, while LEXICAL has the largest Δ BL values for three of the four facets (i.e., CONC-OP, EVOL-JUX, and ORG-PERF). The last four feature classes – LOCATION, FREQUENCY, SENTIMENT, NER – represent different citation features which seem to impact certain citation facets. NER was designed particularly for CONC-OP and does in fact contribute most to that facet; LOCATION helps only ORG-PERF (i.e., the position of the citation indicates its importance) where it contributes significantly to a combination of features; similarly FREQUENCY contributes significantly to a combination of features for EVOL-JUX; and finally, SENTIMENT is important for EVOL-JUX and CONF-NEG, as expected. There is no single feature class that is the most important for all facets, which lends credence to the claim that these facets capture different properties of citations. We conclude that our multi-faceted scheme benefits from a diverse feature set and that although general, easily-extractable features help classification more consistently, the extraction of more specific features is important for improvements on certain classification tasks.

7 Related Work

Information scientists started labeling and studying citations long before automatic text classification became a reality. Garfield (1964)[CEPF] originally introduced 15 different motivations for why an author might cite a paper; Weinstock (1971)[CEPF] then revisited this classification as he explored the emergence of citation indexes. Several studies following Weinstock also aimed to characterize the *function* of citations (as opposed to the motivation). One example is the MM scheme we adopt here. Chubin and Moitra (1975)[CEPF] attempted to simplify and flatten MM using six categories. Spiegel-Rösing (1977)[CEPF] produces another classification scheme with 13 categories that she uses to evaluate one journal's scholarly contributions. Further comparison of previous citation studies can be found in (Liu, 1993)[CEPF] and more recently in (Bornmann and Daniel, 2008)[CEPF]. We note that several other studies (Cano, 1989; McCain and Turner, 1989)[CEPF] have also reused or refined MM in some way, which reinforces our choice. As stated earlier in Section 2, we feel that the multi-faceted composition of MM provides us with a more flexible annotation scheme and a powerful one that can easily represent the quality of a citation as well as its relation to the citing author.

These early annotation schemes were manually applied to a limited amount of scientific literature and did not consider automatic application on large amounts of text. One early

application of automatic citation classification (Nanba and Okumura, 1999)[CEPF] used an annotation scheme with only three classes (Basis, Compare, Other) that are reportedly based on the 15 classes from Weinstock (1971)[CEPF]. Teufel et al. (2006a)[CEPF] introduce a much more complete annotation scheme with 12 classes designed for IR. They thoroughly motivate and analyze their annotation scheme and report inter-annotator agreement of κ=.72. More recently, sentiment analysis has been applied to citations. Athar (2011)[CEPF] classifies citations as *positive*, *negative*, and *objective*, and finds marked improvement in classification using dependency relation features. Athar and Teufel (2012)[CEPF] extend this work and consider context windows of different widths. For each of these three studies the largest class is the one with the least informative label: Nanba and Okumura's *Other* is 52% of citations; Teufel et al.'s *Neutral* is 63%; and Athar's *objective* is 86%. This means that an application receives little information about a majority of citations. In contrast, our annotation scheme does not have a neutral label and always assigns a multi-faceted label that will contain some useful information as no facet can be left undefined.

Dong and Schäfer (2011)[CEPF] conducted a classification study using their own classification scheme with four labels relating to the function of the MM *organic/perfunctory* facet. In addition to adding new syntactic features (`POS-pattern`$_k$, see above), they tested ensemble-style self-training to overcome the problem of limited annotated data. Their paper also included a new dataset with annotated citing sentences. It is important to use previously-tested, publicly-available data, however, their dataset does not contain the full corpus from which they extracted features. Due to this restriction we cannot extract many of the features that they use (e.g., features in the LOCATION and FREQUENCY classes). The annotation in their dataset is also attached to the sentence and not individual citations. This makes it impossible to classify individual citations and prevents us from using the citation-specific features that we have developed (OWN features in STRUCTURE class, e.g., `is-constituent`). We have conducted experiments on the Dong and Schäfer dataset and include those experiments in the online appendix.[2] We believe that annotating and classifying citing sentences (as opposed to citations) is not specific enough for tasks like IR and bibliometrics. Thus, it is essential that we have a citation-annotated corpus for accurate classification.

As we have argued above, the motivation for our work is to provide a generic classification scheme that is established and accepted in information science in the hope that it can be used for a wide range of applications.

Conclusion

In this paper, we address the task of citation classification for applications that access and analyze the scientific literature. Our work uses MM, a standard classification scheme for citations that was developed independently of automatic classification and therefore is not bound to any particular citation application. We introduce new features designed for citation classification and show that they improve performance as measured by F_1. To address the lack of available annotated corpora and reproducible results for citation classification, we are publishing, along with this paper, a manually-annotated corpus as a benchmark for further citation classification research. In future work, we want to further extend the feature set to improve classification and show the benefits of our system for applications like bibliometrics.

Acknowledgments. We thank DFG for funding this work (SPP 1335 *Scalable Visual Analytics*) and Christian Scheible, Wiltrud Kessler, Alex Fraser and the anonymous reviewers for their contributions to the paper.

ABSTRACT

We present an approach to semantics-based statistical machine translation that uses synchronous hyperedge replacement grammars to translate into and from graph-shaped intermediate meaning representations, to our knowledge the first work in NLP to make use of synchronous context free graph grammars. We present algorithms for each step of the semantics-based translation pipeline, including a novel graph-to-word alignment algorithm and two algorithms for synchronous grammar rule extraction. We investigate the influence of syntactic annotations on semantics-based translation by presenting two alternative rule extraction algorithms, one that requires only semantic annotations and another that additionally relies on syntactic annotations, and explore the effect of syntax and language bias in meaning representation structures by running experiments with two different meaning representations, one biased toward an English syntax-like structure and another that is language neutral. While preliminary work, these experiments show promise for semantically-informed machine translation.

TITLE AND ABSTRACT IN GERMAN

Semantikbasierte Maschinelle Übersetzung mit Hyperkantenersetzungsgrammatiken

Wir beschreiben einen Ansatz zur semantikbasierten statistischen maschinellen Übersetzung, der synchrone Hyperkantenersetzungsgrammatiken benutzt um in und aus graphgeformten Zwischenrepräsentationen zu übersetzen. Unseres Wissens ist dies die erste Arbeit in der natürlichen Sprachverarbeitung die synchrone kontextfreie Graphgrammatiken verwendet. Wir beschreiben Algorithmen für jeden Schritt der semantikbasierten Übersetzungskette, inklusive einem neuen Graph-zu-Wort Alinierungsalgorithmus und automatische Regelextraktionsalgorithmen für synchrone Grammatiken. Wir untersuchen den Effekt der syntaktischen Annotation auf semantikbasierte Übersetzung, indem wir zwei verschiedene Regelextraktionsalgorithmen vorstellen, einen, der lediglich semantische Annotationen erfordert und einen, der zusätzlich syntaktische Informationen verwendet. Wir untersuchen ausserdem den Einfluss von semantischen Repräsentationen die auf bestimmte Syntax und Sprache ausgerichted sind indem wir mit zwei verschiedenen Repräsentationen experimentieren: mit einer englischausgerichteten syntaxartigen Struktur und mit einer sprachneutralen Struktur. Unsere Arbeit zeigt dass semantikbasierte maschinelle Übersetzung vielversprechend ist.

1 Introduction

In this paper, we introduce a model for semantic machine translation using a graph-structured meaning representation. While it has been claimed since the inception of machine translation that a semantic model is necessary to achieve human-like translation (Weaver, 1955; Bar-Hillel, 1960), most recent work in MT has instead focused on phrase-based approaches. Statistical phrase-based systems rely on large volumes of parallel training data to learn translation probabilities across two languages; while, given sufficient data, phrase-based systems can cope with some of the ambiguity problems identified by early MT researchers, they are limited by the underlying assumption that surface phrases can be translated without reference to syntax or meaning. Such systems often struggle to generate correct translations that involve non-local phenomena such as argument reorderings across languages, deep embeddings, empty categories and anaphora.

With the increasing availability of syntactically-annotated data in many languages, it has become possible to more directly integrate syntax into data-driven approaches. Such syntax-based SMT systems can automatically extract larger rules, and learn syntactic reorderings for translation (Yamada and Knight, 2001; Venugopal and Zollmann, 2006; Galley et al., 2004; Chiang, 2007; Zollmann et al., 2008; DeNero et al., 2009; Shen et al., 2010; Genzel, 2010).

However, many problems remain unsolved. For illustration of a specific phenomenon difficult to capture without an intermediate meaning representation, consider the following translation example using a state-of-the-art German→English SMT system [1]:

Source	**System output**	**Reference**
Anna fehlt ihrem Kater	**Anna is missing her cat*	Anna's cat is missing her

SMT systems are frequently unable to preserve basic meaning structures (e.g. "who does what to whom") across languages when confronted with verbs that realize their arguments differently. A system using an intermediate meaning representation need not suffer from this problem. Instead of learning many bilingual translation rules over all possible realizations of this pattern, it can rely on monolingual realizations to preserve meaning in translation.

Due to the recent emergence of large, multilingual, semantically annotated resources such as OntoNotes (Hovy et al., 2006), we believe the time is ripe for data-driven, semantics-based machine translation. In this paper we present a pilot statistical, semantic machine translation system which treats MT as a two-step process of analysis into meaning in the source language, and decoding from meaning in the target language.

Our system assumes that meaning representations are directed acyclic graphs; beyond that, it is completely agnostic with respect to the details of the formalism, including the inventory of node and edge labels used. Figure 1 illustrates a pipeline via one possible graph as semantic pivot. The proposed framework is flexible enough to handle numerous existing meaning representations, including the programming language syntax of the GeoQuery corpus (Wong and Mooney, 2006) (used for the experiments in this paper), the PropBank-style structures (Palmer et al., 2005) used for the CoNLL shared task on recognizing semantic dependencies (Hajič et al., 2009), and the Elementary Dependency Structures of the LOGON corpus (Oepen and Lønning, 2006).

[1] Google Translate, 08/31/2012

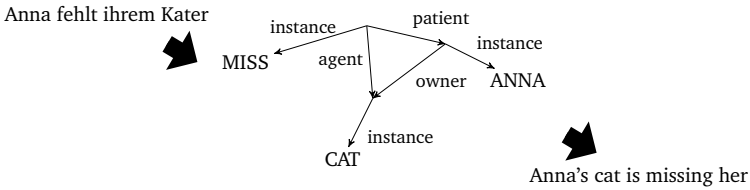

Figure 1: A string to meaning graph to string translation pipeline.

Experimental results demonstrate that our system is capable of learning semantic abstractions, and more specifically, to both analyse text into these abstractions and decode them back into text in multiple languages.

The need to manipulate graph structures adds an additional level of complexity to the standard MT task. While the problems of parsing and rule-extraction are well-studied for strings and trees, there has been considerably less work within the NLP community on the equivalent algorithms for graphs. In this paper, we use hyperedge replacement grammars (HRGs) (Drewes et al., 1997) for the basic machinery of graph manipulation; in particular, we use a synchronous HRG (SHRG) to relate graph and string derivations.

We provide the following contributions:

1. Introduction of string $\Leftrightarrow$ graph transduction with HRGs to NLP
2. Efficient algorithms for
   - string–graph alignment
   - inference of graph grammars from aligned graph/string pairs
3. Empirical results from a working machine translation system, and analysis of that system's performance on the subproblems of semantic parsing and generation.

We proceed as follows: Section 2 explains the SHRG formalism and shows how it is used to derive graph-structured meaning representations. Section 3 introduces two algorithms for learning SHRG rules automatically from semantically-annotated corpora. Section 4 describes the details of our machine translation system, and explains how a SHRG is used to transform a natural language sentence into a meaning representation and vice-versa. Section 6 discusses related work and Section 7 summarizes the main results of the paper.

2 Synchronous Hyperedge Replacement Grammars

Hyperedge replacement grammars (Drewes et al., 1997) are an intuitive generalization of context free grammars (CFGs) from strings to hypergraphs. Where in CFGs strings are built up by successive rewriting of nonterminal *tokens*, in hyperedge replacement grammars (HRGs), nonterminals are *hyperedges*, and rewriting steps replace these nonterminal hyperedges with subgraphs rather than strings.

A hypergraph is a generalization of an graph in which edges may link an arbitrary number of nodes. Formally, a hypergraph over a set of edge labels C is a tuple $H = \langle V, E, l, X \rangle$, where V is a finite set of nodes, E is a finite set of edges, where each edge is a subset of V, $l : E \to C$ is a labeling function. $|e| \in \mathbb{N}$ denotes the *type* of a hyperedge $e \in E$ (the number of nodes connected by the edge). For the directed hypergraphs we are concerned with, each edge contains a distinguished source node and one or more target nodes.

A HRG over a set of labels C is a rewriting system $G = \langle N, T, P, S \rangle$, where N and $T \subset C$ are the finite sets of nonterminal and terminal labels ($T \cap N = \emptyset$), and $S \in N$ is the start symbol. P is a finite set of productions of the form $A \rightarrow R$, where $A \in N$ and R is a hypergraph over C, with a set of distinguished *external nodes*, X_R.

To describe the rewriting mechanism, let $H[e/R]$ be the hypergraph obtained by replacing the edge $e = (v_1 \cdots v_n)$ with the hypergraph R. The external nodes of R "fuse" to the nodes of e, $(v_1 \cdots v_n)$, so that R connects to $H[e/R]$ at the same nodes that e does to H. Note that $H[e/R]$ is undefined if $|e| \neq |X_R|$. Given some hypergraph H with an edge e, if there is a production $p : l_H(e) \rightarrow R \in G_P$ and $|X_R| = |e|$, we write $H \Rightarrow_p H[e/R]$ to indicate that p can derive $H[e/R]$ from H in a single step. We write $H \Rightarrow_G^* R$ to mean that R is derivable from H by G in some finite number of rewriting steps. The grammars we use in this paper do not contain *terminal* hyperedges, thus the yield of each complete derivation is a graph (but note that intermediate steps in the derivation may contain hyperedges).

A *Synchronous Hyperedge Replacement Grammar* (SHRG) is a HRG whose productions have pairs of right hand sides. Productions have the form $(A \rightarrow \langle R, Q \rangle, \sim)$, where $A \in N$ and R and Q are hypergraphs over $N \cup T$. $\sim$ is a bijection linking nonterminal mentions in R and Q. We call the R side of a rule the source and the Q side the target. Isolating each side produces a *projection* HRG of the SHRG. In general the target representation can be any hypergraph, or even a string since string can be represented as monadic (non-branching) graphs. Because we are interested in translation between MRs and natural language we focus on graph-string SHRGs. The target projection of such a SHRG is a context free string grammar. To ensure that source and target projection allow the same derivations, we constrain the relation $\sim$ such that every linked pair of nonterminals has the same label in R and Q.

Figure 2 shows an example SHRG with start symbol $\overset{\text{ROOT}}{\text{S}}$. External nodes are shaded black.

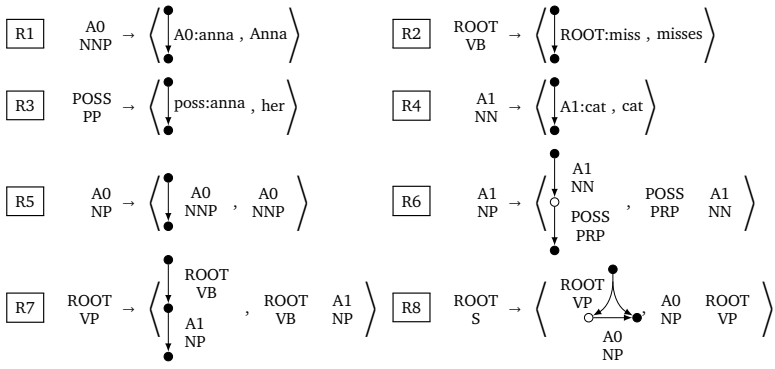

Figure 2: A graph-string SHRG automatically extracted from the meaning representation graph in figure 3a using the SynSem algorithm. Note the hyperedge in rule R8.

The graph language captures a type of meaning representation in which semantic predicates and concepts are connected to their semantic arguments by directed edges. The edges are labeled with PropBank-style semantic roles (A0, A1, poss). Nonterminal symbols in this SHRG are complex symbols consisting of a semantic and a syntactic part, notated with the former above the latter.

Since HRG derivations are context free, we can represent them as trees. As an example, Figure 3c shows a derivation tree using the grammar in Figure 2, Figure 3a shows the resulting graph and Figure 3b the corresponding string. Describing graphs as their SHRG derivation trees allows us to use a number of standard algorithms from the NLP literature.

Finally, an *Adaptive Synchronous Hyperedge Replacement Grammar (ASHRG)* is a SHRG $G = \langle N, T, P^*, S, V \rangle$, where V is a finite set of variables. ASHRG production templates are of the same form as SHRG productions, $(A \rightarrow \langle R, Q \rangle, \sim)$, but $A \in N \cup V$ and $Q, R \in N \cup T \cup V$. A production template $p^* \in P^*$ is realised as a set of rules P by substituting all variables v for any symbol $s \in N \cup T$: $P = \{\forall_{v \in V} \forall_{s \in N \cup T} p^*[v/s]\}$. ASHRGs are a useful formalism for defining canonical grammars over the structure of graphs, with production templates describing graph structure transformations without regard to edge labels. We make use of this formalism in the production template R^* in Figure 4a.

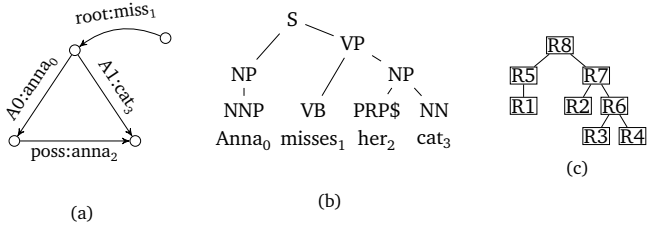

Figure 3: (a) an example meaning representation graph for the sentence *'Anna misses her cat.'*, (b) the corresponding syntax tree. Subscripts indicate which words align to which graph edges. (c) a SHRG derivation tree for (a) using the grammar Figure in 2.

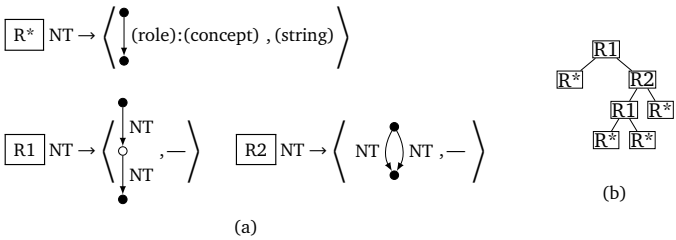

Figure 4: (a) The canonical grammar of width 2. R^* is a production template and values in parentheses denote variables as defined by the ASHRG formalism. (b) A SHRG derivation tree for the MR graph in Figure 3a using the canonical grammar in a, as created by the CanSem algorithm.

3 Learning Grammars from Annotated Data

3.1 Aligning Strings and Graphs

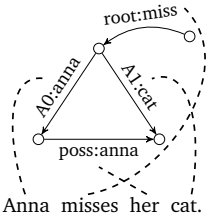

Figure 5: Edge-word alignment example.

Like much of SMT, alignments lie at the center of our semantics-based approach. However, in our case the alignments are between edges of the graph and words of the string. Figure 5 illustrates such an alignment. By listing out edge labels in a linear order, the graph-to-string alignment problem reduces to ordinary token-to-token alignment (Brown et al., 1990). We experiment with two strategies: (1) IBM Model 4 (M4) as implemented in GIZA++ (Och and Ney, 2003), and (2) a novel aligner that relies on the relative structure of the MR graph and the natural language syntax.

For M4, we traverse the graph in a fixed breadth first order to get a sequence of edge labels and feed this, along with the tokenized natural language string, to GIZA++. We then use the edge label order to map the aligned edge labels back to their respective edges.

We also experiment with a novel variant of IBM alignment Model 2 (Brown et al., 1990) that we call the dependency depth based aligner (DEPDEP, or DD for short) which uses depth within the graph and the dependency analysis of the natural language as location. Since the MR and the sentence describe the same thing, it seems reasonable to assume a certain degree of shared structure. To encode this notion, we place a Gaussian distribution over the difference between the depth of the graph edge and words in the dependency tree and weight the alignment choice by this probability. In this way, we favor aligning words to edges that are at a similar depth in the graph j to the depth of the word m in the dependency analysis.

The algorithm is concisely defined with the following equation, where a_i is the index of the edge aligned to the i^{th} word, f is a dependency parse with words f_i, e is a graph comprising edges e_i, and j_{a_i} and k_i are the edge and dependency depth of e_{a_i} and f_i, respectively.

$$p(f, a|e) = \prod_{i=1}^{n} p(j_{a_i}|k_i)p(f_i|e_{a_i}) \quad (1)$$

$$p(j_{a_i}|k_i) = \frac{\mathcal{N}(j_{a_i} - k_i|\mu, \sigma)}{\sum_{j'} \mathcal{N}(j' - k_i|\mu, \sigma)} \quad (2)$$

We estimate the mean μ and variance σ^2 of $p(j_{a_i}|k_i)$ with EM at the same time as the translation probabilities $p(f_i|e_{a_i})$.

3.2 Canonical Semantics Algorithm (CanSem)

Given word–edge alignments, we present two algorithms for rule extraction that both employ the same general strategy for rule extraction: They induce a single context-free derivation for each graph in the training data, and then extract rules from the aligned derivation trees and sentence spans.

Our first strategy for inducing a derivation of each training hypergraph (the "Canonical Semantics" Algorithm, or CanSem) is to specify, *a priori*, a minimal "canonical grammar" which is capable of producing every training example. A theorem by (Lautemann, 1988), proved by (Bodlaender, 1998), guarantees that a canonical grammar of width k is sufficient for graphs of maximum treewidth k. We extract a minimal grammar by incrementally increasing its width until the training data can be fully explained. The canonical grammar rules learned in this algorithm are effectively SHRG rule templates which ignore edge labels. Figure 4a shows a canonical grammar of width 2 needed to parse the graph in Figure 3a.

This grammar then allows us to immediately acquire a derivation tree given a graph alone (see Figure 4b); we can then use a standard technique (Galley et al., 2004) for acquiring a set of rules from an aligned derivation tree-string pair.

3.3 Syntactic Semantics Algorithm (SynSem)

Intuition suggests that additional linguistic information might aid in the selection of general, well-formed rules. Our second algorithm (the "Syntactic Semantics" Algorithm, or SynSem) is based on this assumption.

The procedure is described in Algorithm 1; to describe the notation, let each training example consist of (1) a sentence $S = s_1, s_2, \ldots, s_n$; (2) a constituency parse of S, defined by a set C of constituents; (3) a directed single-source connected hypergraph $H = (V, E)$; and (4) alignments $a : S \rightarrow E \cup \{\texttt{null}\}$. For convenience, denote the subspan of S contained in a constituent $c \in C$ (equivalently, the yield of c) as $S(c)$.

A constituent $c \in C$ is in the *frontier set* F if there exists some connected subgraph h of H such that $s \in S(c)$ if and only if $a(w) \in h$. Let $f(c)$ denote this h. c is in the *minimal frontier set* $\hat{F}$ if $c \in F$ and there exists no $c' \subset c \in F$.

Algorithm 1 EXTRACT-RULE

1: $R \leftarrow \emptyset$
2: **while** $\hat{F} \neq \emptyset$ **do**
3: $\quad c = pop(\hat{F})$
4: $\quad h$ is a new hyperedge with type matching $f(c)$
5: $\quad R = R \cup \{(h, f(c), c)\}$.
6: $\quad H = H[f(c)/h]$
7: $\quad S = S[S(c)/h]$
8: **end while**

On an abstract level, algorithm 1 matches minimal parse constituents to aligned graph components, and incrementally collapses these into nonterminals until the entire graph is consumed. Figure 2 shows the set of rules extracted by this algorithm from the MR graph, parse, and alignments in Figure 4.

In describing both algorithms, we have thus far assumed that every edge E is aligned to at least one word. As this is not always the case in practice, heuristics similar to those used in (Galley et al., 2006) may be used to attach the remaining edges.

4 Parsing and Translating with SHRG

4.1 Translation Pipeline

To build a translation system between two languages, we first extract an SHRG for each language from semantically annotated monolingual data using one of the algorithms from section 3. We then assign weights to each rule in the SHRG to transform it into a *probabilistic* SHRG, using one of the methods described below in Section 4.2.

Given a pair of weighted SHRGs, translation is a two-step process. First, we transform the source language string into an MR graph using the source SHRG (sometimes called "semantic parsing" or "analysis"). This is accomplished by parsing the string with the string projection of the SHRG and then applying the resultant derivation to generate the corresponding graph. The algorithm amounts to standard CKY string parsing with complexity $\mathcal{O}(n^3)$ in the size of the input.

We then transform the 1-best graph into the output string using the target SHRG (the "generation" task). This involves parsing the graph using the graph projection of the SHRG and then constructing the corresponding string yielded by the derivation. While parsing arbitrary graphs with SHRGs is NP-complete, we use a polynomial time chart parsing algorithms (which are exponential in the maximum size of the graph fragments on the rule right hand side) for connected graphs (Drewes et al., 1997).

In the case of the CanSem algorithm, we use a parser specialized for the canonical HRG which can be parsed even more efficiently in $\mathcal{O}(n^c)$, with c the maximum number of rule right hand side nodes (worst case $c = 3$ for experiments in this paper).

Finally, we rerank the natural language output by incorporating a language model (Heafield, 2011; Dyer et al., 2010). For the SynSem algorithm, this is integrated into the parsing algorithm via cube pruning (Chiang, 2007). In the CanSem algorithm reranking is performed on an k-best list of generated natural language output using a standard n-gram language model. Hypothesis meaning representations might be similarly reranked using a 'language model' defined on MR graphs, but we leave this for future work. In our experiments, language model weights were selected empirically based on initial evaluations of the development set.

4.2 Parameter Estimation

As with CFGs, there are two strategies for estimating the parameters of a probabilistic SHRG. One is to treat the derivations induced by the CanSem and SynSem algorithms as observed, and obtain maximum-likelihood estimates for the grammar by simply counting the number of times each production occurs in the training data.

The alternative approach is to employ the EM algorithm given a synchronous parse chart (Oates et al., 2003). Synchronous parsing extends graph parsing by identifying all possible derivations which yield both a specified string and a specified graph; the complexity of synchronous parsing is therefore approximately the product of string and graph parsing.

We initially tested both methods with both rule extraction algorithms on the development set.

For the CANSEM algorithm, EM with a Dirichlet prior of 0.1 performed better, whereas the SYNSEM algorithm obtained better results using counting.

5 Evaluation

5.1 Data

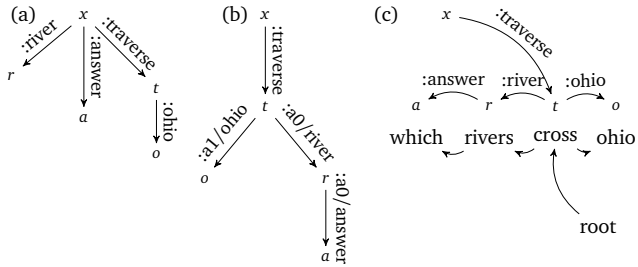

Figure 6: Two different ways of converting the GEOQUERY Prolog expression `answer(A,(river(A),traverse(A,ohio)))` to a MR graph: (a) language-neutral, (b) English-biased and (c) an illustration of how (b) matches the English dependency analysis.

Our experiments use the GEOQUERY data set (Tang and Mooney, 2001), originally a parallel corpus of 880 English questions about US geography paired with Prolog style database queries and later translated into Chinese (Lu and Ng, 2011). For English there are gold Penn Treebank-style syntax annotations as well as gold alignments pairing every word with the best predicate in the query. For Chinese, we make use of automatic parses provided by the Stanford Parser (Levy and Manning, 2003).

The database queries—expressions in an unambiguous formal language—serve as a rough encoding of sentence meaning, which we use as our meaning representation in the machine translation pipeline. Though they do not, strictly speaking, encode a linguistic notion of semantics, a statistical MT system can still learn meaningful associations with this language-independent representation. (For instance the German *'Gib mir die Bevölkerung von Kalifornien!'* [*'Give me the population of California!'*] would match the the same Prolog query as English *'How many people live in California?'*.) For input to our system, we automatically translate the Prolog expressions into graphs.

We are interested in how differences between the syntax and semantic representation might impact the translation process, and we use two different graph representations to test this. One, shown in Figure 6a (corresponding to the question '*Which rivers cross Ohio?*'), is produced by only looking at the query expression itself (GQN). The second (GQE), shown in Figure 6b is a transformation of GQN to more closely match the English syntax using the gold alignments. Note that this reshaped graph better fits the assumptions of the SYNSEM algorithm and should, in theory, produce better SHRGs for English. It is less clear whether an English biased intermediate representation would perform better for translation, as it could conceivably hurt translation to and from other languages.

We use the standard 600 train/280 test sentence split (Kwiatkowski et al., 2010), and run 10

	Prec.	Rec.	f_1
DD	**74.8**	46.9	**57.7**
M4	54.6	**53.7**	54.1

Table 1: Evaluation of English alignment, vs. gold alignments

fold cross-validation on the training data during development. We also use the standard list of named entities paired with the corresponding edges to create some fallback rules for handling previously unseen named entities.

5.2 Alignment

Table 1 shows results for the alignment algorithms described in Section 3.1 on English and the GQN MR. We report precision, recall and f_1-measure on alignment pairs. The DEPDEP algorithm (DD) performs somewhat better than IBM Model 4 (M4) with respect to f_1, and substantially better in terms of precision.

5.3 Analysis: String to Graph

We use the Smatch measure (Cai and Knight, 2012) to evaluate analysis into MR graphs, which is essentially an f_1-score on edge labels under the optimal mapping of hypothesis nodes onto reference nodes. Table 2 shows results for the analysis task in both English and Chinese. We report results of 10-fold cross validation on the training set, reserving the test data for the evaluation of the end-to-end MT system. We apply both rule extraction algorithms to the GQN data set; for English, where we have gold alignments and gold parses (which allow us to obtain DD alignments), we also vary the alignment model. We observe that the SYNSEM procedure uniformly outperforms CANSEM for analysis. These results highlight the importance of alignment quality: Gold alignments unsurprisingly lead to improved analysis, and in accordance with our expectations the syntactically-guided DD alignments appear to help SYNSEM but not CANSEM.

	CANSEM			SYNSEM		
	M4	DD	GOLD	M4	DD	GOLD
EN	67.9	56.4	72.4	81.5	81.8	84.4
ZH	67.8	–	–	76.8	–	–

Table 2: Evaluation of analysis (f_1), vs. gold MRs in development set

	CANSEM			SYNSEM		
	M4	DD	GOLD	M4	DD	GOLD
EN	51.89	48.82	55.24	52.47	42.91	53.3
ZH	50.28	–	–	45.82	–	–

Table 3: Evaluation of generation (BLEU), vs. gold strings in development set

5.4 Generation: Graph to String

We evaluate text generated from gold MR graphs using the well-known BLEU measure (Papineni et al., 2002). Table 3 shows results for English (EN) and Chinese (ZH), varying rule extraction and alignment model as before. As before, M4 alignments help CANSEM more than DD alignments; however, here the trend also carries through to SYNSEM. Also in contrast to the analysis results, the two systems perform comparably on their best English results, and CANSEM outperforms SYNSEM on Chinese.

While not targeted directly at the generation task (and not comparable to the existing literature, which reports BLEU scores on the test set), these results are promising: They are close to state-of-the-art for generation on the GEOQUERY data set, and future research might focus on optimizing generation specifically.

5.5 Translation: String to String

Finally, Table 4 shows results for the end-to-end machine translation system for English to Chinese, evaluated on the test set. We again experiment with both rule extraction algorithms in English (because DD alignments are not available for Chinese, Chinese rule extraction always uses M4).

Here CANSEM substantially outperforms SYNSEM, regardless of the data set and the choice of alignment algorithm. Also notable is the fact that the switch from GQN to GQE hurts performance with CANSEM but improves it with SYNSEM.

	CANSEM		SYNSEM	
	M4	DD	M4	DD
GQN	42.74	36.84	28.22	28.34
GQE	38.88	35.14	32.24	31.20

Table 4: Evaluation of translation (BLEU), vs. gold strings in the test set

5.6 Discussion

Several broad trends are apparent from these experimental results. The first is a partial confirmation of our hypothesis that syntactic information (in various forms) is useful in guiding the acquisition and application of semantic grammars: this is apparent in SYNSEM's gains on analysis and possibly generation, and the fact that SYNSEM performs better on GQE.

In this light the fact that CANSEM performs comparatively better on translation is somewhat surprising—we would expect overall translation results to be improved as a result of improved analysis and comparable generation. We hypothesize that the discrepancy in translation scores is due to the consistency of the grammars learned by CANSEM: Because it induces a standard derivation for MRs regardless of the source language, any incorrect rules that it learns are nonetheless shared across languages.

We also observe that the system generates many output sentences that have identical meaning but markedly different syntax and lexical choice from the reference translation (Figure 8). An inspection of the *k*-best list (Figure 7) for one translation input reveals various such candidates. This confirms that the translation pipeline works as expected: Sentences in the

source language are analyzed into a language-independent meaning representation, and that meaning representation is then used to generate a semantically equivalent sentence in the target language.

The scores reported for SYNSEM are especially heartening in light of the fact that a standard phrase-based SMT system (Koehn et al., 2007), trained and tuned on the same corpus, achieves a BLEU score of 45.13 for ZH–EN translation. Note that the semantic translation task (at least as formulated here) is strictly harder than direct translation, as the test set contains numerous sentences annotated with identical meaning representations but different natural language realizations. We are optimistic about the potential for an extended version of the current system in which generation is conditioned on both semantics and source language.

6 Related Work

We view our semantics-based approach to MT as a continuation of recent work in statistical MT (SMT) that abstracts away from the surface string level by capturing syntactic reorderings in translation (Yamada and Knight, 2001; Gildea, 2003; Eisner, 2003; Collins et al., 2005), or using larger syntactic fragments instead of phrases (Galley et al., 2004, 2006; Chiang, 2007). These systems combine the benefits of rule-based MT and SMT by defining their translation model using syntactic translation rules from the source syntax, into the target syntax, or both. Our syntax-driven approach to rule extraction is inspired by (Chiang, 2007, 2010), while the canonical grammar approach is based on (Galley et al., 2004, 2006). However, we induce synchronous graph grammars between surface form and meaning representation, instead of transfer rules between source and target form. As with other translation work using synchronous tree grammars, such as synchronous TSG (Chiang, 2010) and synchronous TAG (DeNeefe and

Knight, 2009), our SHRGs can also be applied in both directions.

However, none of these SMT approaches use an intermediate semantic representation. A lot of research has been done in the early days of MT on translation systems using such representations (Uchida, 1987; Nirenburg, 1989; Landsbergen, 1989). These systems usually required hand-crafted rules and large knowledge bases and do not learn translation models from data automatically. Until recently, because of their good performance especially in narrow domains, rule-based MT was the predominant paradigm in deployed MT systems. In contrast, while our system adopts a semantic transfer based paradigm, we learn weighted transfer rules into and from the meaning representation automatically to build a true statistical semantics-based MT system.

In the semantic parsing literature, there are other learning based approaches to analysis into meaning representations. Zettlemoyer and Collins (2005) use an automatically induced, semantically augmented CCG and a log-linear model to parse into lambda expressions, and Ge and Mooney (2005) integrate syntactic parsing with semantic parsing for recovering Prolog queries. Lu et al. (2008) learn a generative model over tree shaped meaning representation and natural language sentences. Wong and Mooney (2006)'s WASP system is similar to ours because it draws on techniques from SMT, using word alignment algorithms to learn synchronous CFGs which translate between syntax and semantics. In fact, Jones et al. (2012) recasts many semantic parsing approaches as tree transduction, which is closely related to synchronous grammar parsing (Shieber, 2004). To our knowledge we are the first to address semantic parsing into graph-based representations as a learning task using synchronous graph grammars.

In generation, learning the parameters of statistical generation models is popular, but not much attention has been paid to the scenario where no handwritten rules exist or the mapping between semantic structure and output language is unknown in the training data (the scenario we assume in this paper). The WASP system (Wong and Mooney, 2006) can also be used as a generator. Lu and Ng (2011) automatically learn to generate English and Chinese from sentences paired with lambda calculus. Other examples are (Varges and Mellish, 2001) who learn a semantic grammar form a semantically annotated treebank automatically, and (DeVault et al., 2008) who infer a TAG for generation automatically from semantically annotated example sentences.

Formal language approaches to probabilistic tree transformation are popular (e.g. in syntax-based MT) and recently a formulation of such methods as tree transducers (Comon et al., 2007) has gained prominence in NLP (Knight and May, 2009; Graehl and Knight, 2004). In contrast, little work has been done on methods for graphs in NLP. The standard model for graph-shaped meaning representations in NLP are feature structures, which can be constructed from strings using unification grammars (Moore, 1989). However, while powerful in representation, unification grammars have unfavorable algorithmic properties, lack an intuitive probabilistic extension, and require hand-built rules. Other formal devices to accept and transduce feature structure graphs have rarely been discussed. Notable exceptions are Quernheim and Knight (2012) who discuss formal devices to accept and transduce feature structure graphs, and Bohnet and Wanner (2010) who present a toolkit for manually engineering graph-to-string transducer rules for natural language generation. We believe that we are the first to use hyperedge replacement grammars in the NLP literature and can only refer to the formal HRG survey by (Drewes et al., 1997).

7 Conclusion

We have introduced a new model for semantically-driven statistical machine translation using graph-structured meaning representations. Our approach is based on the class of weighted synchronous hyperedge replacement grammars, a rewriting formalism for graph-string pairs that intuitively extends context-free grammars. We have described unsupervised algorithms for string-graph alignment, and two algorithms for automatic SHRG learning given these alignments.

We have evaluated a semantic machine translation system on the GeoQuery data set, using grammars acquired using each of these algorithms. The results of this evaluation provide a working demonstration of the effectiveness of our machine translation model, and a characterization of the extent to which syntactic information may be used to improve the effectiveness semantic MT.

We hope that our work will motivate further research on the applications of graph grammars to basic problems in natural language processing research. Immediate extensions of the research presented here include integration of a re-ranking model for hypothesized MRs (analogous to language modeling for strings), investigation of other corpora and meaning representation formalisms, and more sophisticated probabilistic models for scoring SHRG derivations. More broadly, our results suggest that SHRGs might be an effective tool for the individual problems of semantic parsing and generation, and indeed for any phenomenon in natural language which can be represented with directed graphs.

Abstract

This paper investigates a solution to yes/no question answering, which can be mapped to the task of determining the correctness of a given proposition. Generally it is hard to obtain explicit evidence to conclude a proposition is *false* from an information source, so we convert this task to a set of factoid-style questions and use an existing question answering system as a subsystem. By aggregating the answers and confidence values from a factoid-style question answering system we can determine the correctness of the entire proposition or the substitutions that make the proposition false. We evaluated the system on multiple-choice questions from a university admission test on world history, and found it to be highly accurate.

Keywords: question answering, facts validation, yes/no question, question inversion.

Proceedings of COLING 2012: Technical Papers, pages 1377–1392,
COLING 2012, Mumbai, December 2012.

1 Introduction

Yes/no question answering (Green and Carberry, 1994; Hirschberg, 1984) can be equated to the task of determining the correctness of a given proposition. The target of such a mechanism is not limited to explicit interrogative questions since any general declarative sentences can in principle be validated. For example, consider the following two propositions, where (1) is true and (2) false[1]:

(1) Chirac was the president of France in 2000.

*(2) Chirac was the president of Germany in 2000.

As suggested by this example, a false proposition can often be produced by replacing a part of a true proposition. During a conversation, a human with knowledge of the facts might not only say that the utterance (2) is wrong, but respond with something like "not Germany, but France." Therefore we believe this kind of validation system we are proposing here may have application outside of a strict question-answering framework.

In spite of the importance of the process, yes/no-style question answering has not been intensively studied, compared to other type of question answering, such as the factoid-style question answering (Ravichandran and Hovy, 2002; Bian et al., 2008) and definition question answering (Xu et al., 2003; Cui et al., 2005). Even though there are only two possible answers, yes or no, such questions can be quite hard to answer. Search technologies cannot be applied easily because in many cases we can not rely on the existence of explicit negative evidence in the information source, *e.g.* "Chirac was *not* a president of Germany."

This paper tackles yes/no question answering by exploiting an existing system for factoid-style question answering. The key idea, inspired by *question inversion* (Prager et al., 2006), involves generation of factoid questions by replacing some parts of a given proposition with abstract (*i.e.* ungrounded) expressions. For example, to determine the correctness of (1) and (2), two question sentences are generated for each proposition, with abstracted parts in italics and *anticipated answers* in brackets[2].

(1a) *He* was the president of France in 2000. [Chirac]

(1b) Chirac was the president of *this country* in 2000. [France]

(2a) *He* was the president of Germany in 2000. *[Chirac]

(2b) Chirac was the president of *this country* in 2000. *[Germany]

DeepQA (Ferrucci, 2012), the factoid-style question answering system used here accepts these sentences with focal words (*e.g.* nouns with 'this', or pronouns such as 'he') as input questions, generates a hit-list of candidate answers, and assigns confidence values to candidate answers. Usually the system's output to the question is the top-ranked answer, the answer with the highest confidence value. Our hypothesis is that if an original proposition

[1] '*' denotes a false proposition.

[2] '*' before brackets denotes the anticipated answer should not be answered because the original proposition is false.

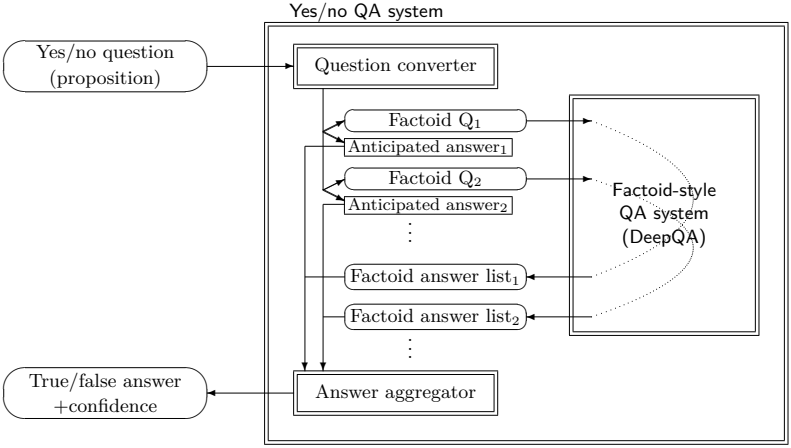

Figure 1: The flow of yes/no question answering using the factoid-style question answering.

is true, then the anticipated answer should be the top-ranked answer from DeepQA, but for false propositions, the anticipated answer should either have a low confidence value, or not be ranked high, or both. Since DeepQA outputs "France" for (1b) and (2b) as the top-ranked answer, we can use that as positive evidence for proposition (1), and negative evidence for proposition (2). The exact formula for processing the results of the generated questions is discussed in Section 4.

There is no natural repository of true and false facts which can be used for evaluation of the fact validation system. It is even difficult to artificially generate wrong facts from the set of correct facts without bias. Therefore we chose to use questions of multiple-choice of true (or false) statements in a university admission test as a reliable benchmark. In this context, wrong statements are carefully produced by the examining board by mixing a correct statement with partially wrong information.

The main contribution of this paper is to provide a novel framework for benchmarking and discussion of a method of processing yes/no questions, and propose a method to appropriately make use of existing technologies of factoid-style question answering and its underlying information sources.

Figure 1 illustrates the overall architecture to solve yes/no questions with an existing factoid-style question answering system, DeepQA. The yes/no question answering system takes a proposition as an input and outputs the correctness of the proposition with a confidence value. DeepQA is used as a subsystem, which takes a factoid-style question as an input and outputs an answer list with confidence values.

The key methods are conversion from yes/no questions into factoid-style questions, and aggregation of the results of factoid answers to determine yes or no. Rather than the implementation of fully automatic system, this study focuses on the methodologies and the headroom analysis of this fact validation. Thus the conversion of questions is done

manually, but it is conducted by using specific algorithms and can be automated using standard techniques and resources. The subsequent stages are automatic and accuracies of several methods will be compared.

Section 2 describes some of the prerequisites for the discussion in this paper, the yes/no type question answering, the existing factoid-style question-answering system, the original idea of question inversion, and the Japanese university admission test that was used for the evaluations. Section 3 shows the method of question conversion and problems in question generation. Section 4 describes the answer aggregation module, which selects the most appropriate answer lists for the fact validation. The experimental results appear in Section 5, and Section 6 provides the further discussion on the results and comparison with another approach. Section 7 concludes this paper.

2 Background

2.1 Yes/no question answering

From linguistic point of view, a yes/no question is defined as an interrogative sentence that is answered by either yes or no. A yes/no question in English language is often generated by placing a positive or negative form of an auxiliary verb (*e.g.* does, can, isn't, etc.) before the subject.

However, yes/no questions are not always correctly answered by just one of two answers, yes or no. Hirschberg (Hirschberg, 1984) pointed out that yes/no questions can have several functions, including *scalar implicature* such as (3Q), where the answer (3A) makes the correction to the proposition in the question.

(3Q) Did you invite Mary?

(3A) I invited Bob.

Green et al. (Green and Carberry, 1994) investigated such indirect answers (*i.e.* other than yes/no) to yes/no questions from discourse representation based on Rhetorical Structure Theory (Mann and Thompson, 1987). They provided an algorithm to generate appropriate answers that fill the gap between the question and the discourse contexts. The process is designed to provide the automatic responses in a dialog system.

This paper aims at fact validation of propositions, so the main outputs are yes or no. Though the initial input in our test domain is not in the form of interrogative question but declarative expressions, the intrinsic task is the same; indeed we will show that our approach has the capability of suggesting the true fact from a factually incorrect input.

2.2 Factoid-style question answering system

We use an open-domain factoid-style question answering system, DeepQA (Ferrucci, 2012), which returns multiple answers with each confidence value ranging from 0 to 1. DeepQA first analyzes the input question sentence, identifies its answer type amongst other question processing, generates candidate answers from searches performed corpora including encyclopedia, news paper articles and thesauri, gathers evidences for each candidate answer by evaluating a collection of feature scorers on it, and calculates each candidate's final confidence value by accumulating these scores and weighting them via a model of learned on trained data.

In the candidate answer generation phase, the candidates are not restricted to terms which have the answer type determined by question analysis, but any term found in returned documents which passes certain filtering criteria can be selected as a candidate. The coincidence between the type of the candidate and the type of question is used as one of the features that support the candidate answer to be correct.

A confidence value is calculated using multiple features computed from some analysis that the candidate answer should be correct. Each feature type is weighed by a model output from a machine learning process trained on a repository of several thousand question-answer pairs. The confidence values, calculated independently for each candidate, estimate the likelihood to be the correct answer (so the sum of confidence values across all answers may exceed 1, reflecting the fact that multiple answers may be correct). Thus there is a strong correlation between the confidence value and the precision of the answer.

According to (unpublished) experiments, DeepQA achieved an accuracy of 67% on TREC 2002 (Voorhees, 2002) question set, trained using about 8,000 QA pairs from other years of TREC and another data source.

2.3 Question Inversion

Question inversion (Prager et al., 2006) is a method to generate new questions from a different point of view to rerank the candidate answers in factoid-style question answering. It can be used with any QA system. For example, when a QA system solves question (4),

(4) What was the capital of Germany in 1985?

the system first generates several candidate answers, like "Berlin", "Moscow", etc. The next step is to generate the abstract inverted question (4i), by removing Germany, the *pivot term*.

(4i) Of what country was *CANDIDATE* the capital in 1985?

A series of grounded inverted questions is generated by replacing *CANDIDATE* in turn with each of the candidate answers to (4i) (*e.g.* "Of what country was Berlin the capital in 1985?"). These inverted questions are processed by the QA system, and the "inverted" answers (*e.g.* "Germany", "Soviet Union" etc.) along with their scores are gathered. Original candidate answers ("Berlin", "Moscow") are given credit when the corresponding inverted question generates the pivot ("Germany", in this case). The candidate's final score is calculated as a function of its original score and the credit from inversion.

2.4 Examination for university admission

For this study we use the National Center Test for University Admission[3], which is the standardized achievement test for high school students who wish to enter universities in Japan. The examination on world history was selected because most of the questions are solvable as fact-validation problems with general knowledge. The questions are provided in a multiple-choice style as exemplified in Table 1, which shows the description of the question and the four candidate statements. In this case only one of four is a correct statement,

[3]http://www.dnc.ac.jp/

From 1-4 below, choose the one sentence that is correct in regard to the person/people that it describes.	
1	Ouyang Xiu and Su Shi were the best known writers of the Tang dynasty.
2	Yen Chen-ching was the best known chirographer in the Sung dynasty.
3	Wang Anshi of the Sung era implemented the reform called the New Policies.
4	Qin Hui fought with the war hawks on the relationship with Yuan.

Table 1: An example of questions in the world-history examination (from 2009 National Center Tests on World History). The correct answer is 3.

and the others are incorrect, so we can frame the individual choices as test cases for fact validation. The original examinations are provided in Japanese, and this paper used their English translation, which was translated by a native speaker with domain knowledge.

This particular examination is also used for evaluating a task of recognition of textual entailment (Miyao et al., 2012; Shima et al., 2011). These true or false statements can be test cases of hypotheses which can be entailed from relevant texts found in encyclopedia articles. The multiple-choice solution using textual entailment will be compared to our approach in Section 6.2.

3 Question conversion

The question conversion module generates multiple factoid-style questions to be input to DeepQA from the original proposition. As described in Section 1, because the component to perform the inversion was not completed in this time, this module's function is performed manually in this study so that we can discuss the intrinsic features of yes/no question answering, but this section gives algorithms for each operation.

3.1 Conversion method

First, *pivot terms*, the key entities to be abstracted are selected from the original proposition. While the original work chose a single pivot per question, there is nothing about the question inversion process that requires there be only one pivot/abstract inverted question per input question, and in fact we use multiple. Since most of questions in the test domain contain proper nouns, often multiple proper nouns, we decided to use proper nouns as pivot terms. A back-off method of choosing common nouns is employed when there are no proper nouns. For example, two pivot terms (underlined) are found in proposition (5), which is the second row in Table 1.

(5) Yen Chen-ching was the best known chirographer in the Sung dynasty.

Next, a *type* is determined for each pivot term. For this algorithm, we define a type to be a common noun which is a hypernym of the pivot term. A thesaurus such as WordNet can be used, but choosing the right level of abstraction can be a problem. An effective approach to making this selection involves mining the corpus to determine co-occurrence counts with each possible hypernym (Prager et al., 2001). A simpler solution, which we adopt here as a guideline, is to select the type from the first sentence of Wikipedia articles about the subject term, from the observation that many opening sentences are of the form "X is Y" where X is the title of the article and Y is its type (Kazama and Torisawa, 2007). In the

example above, “calligrapher” and “dynasty” are assigned as types of “Yen Chen-ching” and “Sung dynasty”, respectively.

The pivot term is then replaced with a noun phrase consisting of “this” and the type. When the type is Person and the pivot term is the subject of the head predicate of the proposition, just “he” or “she” is used. From (5), two factoid questions (5a) and (5b) are generated, the substitutions denoted by italic.

(5a) *He* was the best known chirographer in the Sung dynasty.

(5b) Yen Chen-ching was the best known chirographer in *this dynasty*.

For each question there is the *anticipated answer*, that corresponds to the pivot term in the original proposition. The questions are input to DeepQA and the results will be compared to the anticipated answers, “Yen Chen-ching” for (5a) and “Sung dynasty” for (5b).

This idea of generation of new questions is inspired by question inversion, described in Section 2.3. However, the method in this paper is different from the original question inversion (Prager et al., 2006) mainly in three points:

Multiple inverted questions. Instead of a single pivot term, multiple pivot terms are selected and multiple questions are generated in this study. All of them are input to DeepQA and the results are aggregated in a subsequent module. This usage of multiple questions makes the reliance on DeepQA (both its competence and the coverage of the test domain in its corpora) less brittle.

Generation of sentences. In our method the inverted sentences are generated as natural-language questions, instead of internal structures for a specific system. This process is more general.

No need of candidate answers. When question inversion is used for answer reranking in factoid-style question answering, candidate answers must be generated to fill the slot of the original question. In our method, possible answers for a yes/no question are just yes or no, thus traditional candidate generation is not required in the question conversion module.

The questions generated by the method above are input to DeepQA, and the multiple answers with confidence values are returned for each question. Table 2 shows an example.

Ideally the anticipated answer is at the top of the DeepQA’s answer list when the original proposition is correct, although, we cannot rely on this since DeepQA is not perfect. For example, the third question in Table 2 is an unlucky case: the original proposition is correct, but the anticipated answer was at the second place in DeepQA’s answer list, due to complexity of the responsive text in the corpus. The anticipated answer was not returned for the fourth question in Table 2. This problem will be addressed by the answer aggregation module described in Section 4.

	Generated questions	Anticipated answer	1st	2nd	3rd
q_1	In *this country*, Xuanzang traveled to India and brought home the Buddhist scriptures during the Tang period.	[China]	China 0.702	Nepal 0.513	Burma 0.129
q_2	In China, *he* traveled to India and brought home the Buddhist scriptures during the Tang period.	[Xuanzang]	Xuanzang 0.593	Tang 0.147	Buddhism 0.11
q_3	In China, Xuanzang traveled to *this country* and brought home the Buddhist scriptures during the Tang period.	[India]	monk 0.23	India 0.216	Faxian 0.135
q_4	In China, Xuanzang traveled to India and brought home the Buddhist scriptures during *this period*.	[Tang period]	Buddhism 0.441	monk 0.219	Faxian 0.127

Table 2: Examples of answer lists output by DeepQA, for the original (true) proposition "In China, Xuanzang traveled to India and brought home the Buddhist scriptures during the Tang period." The numbers under the answers indicate the confidence values.

3.2 Problematic questions

Besides failures by DeepQA due to just lack of information in the corpus or inability to process it correctly, there are intrinsic problems in the use of DeepQA as the evidence of a fact validation. We identified two major problematic phenomena: *multiple-answer questions* (*i.e.* questions with more than one answer) which may not return the anticipated answer as the first answer for a true proposition, and *attributive questions* which may produce the anticipated answer for a false proposition.

Multiple-answer questions. Proposition (1) in Section 1 has enough context in it to be correctly validated as-is; however, suppose the phrase "in 2000" were dropped, producing proposition (6), with inverted questions (6a) and (6b).

(6) Chirac was the president of France.

(6a) *He was the president of France.* $^{?}$[Chirac]

(6b) Chirac was the president of this country. [France]

(6b) is not problematic, but (6a) has several possible answers ("Mitterand", "Chirac", "Sarkozy", "Hollande", ...), so even if the original proposition (6) is true, "Chirac" may not be the DeepQA's first answer to (6a).

Attributive questions. Proposition (7) below is false. Structurally, (7) asserts two properties of an entity ("Carlos I"), and whether one uses said entity or one of the properties as a pivot can have very different consequences. Using the entity as a pivot is generally a good choice in such situations, since the two (or however many are present) properties can together triangulate a unique answer. This does not happen so readily when a property is chosen as a pivot.

*(7) Carlos I, the King of Spain, was also the King of Portugal.

(7a) He, the King of Spain, was also the King of Portugal. *[Carlos I]

(7b) *Carlos I, the King of this country, was also the king of Portugal.* *?[Spain]

(7a) is confirmed to be a desirable inverted question because DeepQA actually returns "Philip II of Spain" as the first answer. This generates a correct statement, knowledge of which is the point of the question. However, if (7b) is used as an inverted question, "Spain" is returned by DeepQA as the first answer. This is because there is no country which is more associated with "Carlos I" than "Spain", regardless of other contexts in the sentence. This suggests that the kind of pivot term which is an attribute of a specific named entity may not be suitable for generation of inverted questions. This issue will be addressed in the answer aggregation phase discussed in Section 4.

4 Aggregation of answers

This section describes the answer aggregator which processes the multiple answer lists from the generated questions and decides the correctness of the input proposition.

4.1 Answer matching

The initial operation by the answer aggregator is to compare the anticipated answer and the answer lists output by DeepQA. Here we introduce a function $A(q)$, which stands for the rank where the anticipated answer appears in the answer lists for a question q. If the anticipated answer is not found in the answer list for q, $A(q) = \text{nil}$. For example, the third question in Table 2 is expressed as $A(q_3) = 2$.

There is clearly an important signal in whether the anticipated answer appears on the top of the answer list. When the first answer is the anticipated answer (*i.e.* $A(q) = 1$) it will provide evidence that the original proposition is true. On the other hand, when the first answer is different from the anticipated answer (*i.e.* $A(q) \neq 1$), it provides evidence that the original proposition is false.

Given the importance of this test, the matching of the anticipated answer and each candidate answer should be more robust than exact match. We relax the matching criteria in the following ways:

- Case insensitive matching.
- The existence of type name is optional (*e.g.* "Sung dynasty" and "Sung" can match).
- Synonyms, or transliteration variations (*e.g.* "Sung dynasty" and "Song dynasty") can match. In this study a synonym list is created manually by seeing the pairs of the anticipated answers and the first answers of DeepQA, without seeing the result. This can be replaced by an automatic process, such as using Wikipedia redirects.

4.2 Question/answer selection

Now the question is how to interpret multiple answer lists output by DeepQA to determine the correctness of a given proposition. An ultimate goal of this work is to develop an algorithm that combines the support for/against the truth of the different propositions

from all of the inverted questions used. However, we have found that selecting just one question per proposition requires a simpler algorithm, and can give good results.

For simplicity, we use only the top-ranked answer from the desired inverted question, that is, the system outputs true if $A(q) = 1$ and outputs false if $A(q) \neq 1$. Therefore the problem is reduced to selection of q^*, the question for which DeepQA generates the most representative answer list, from the set of questions Q. If we define $R(q)$ to be the *reliability* of question q, then the decision of true or false of the given proposition is formalized as

$$TF(Q) = \begin{cases} \mathsf{true} & A(q^*) = 1 \\ \mathsf{false} & otherwise \end{cases} \\ where \quad q^* = \underset{q \in Q}{argmax}(R(q)) \tag{8}$$

Then the problem is the design of the reliability function $R(q)$. The basic idea is the use of confidence value, relying on the correlation between the confidence value and the precision of the answer in DeepQA's outputs. Define

$$R_1(q) = C(q, 1) \tag{9}$$

where $C(q, n)$ is DeepQA's confidence value for n-th answer to question q. In Table 2, $q^* = q_1$ because q_1 has the highest confidence value for its first answer, then $TF(Q) = \mathsf{true}$ because q_1's first answer, "China" matches the anticipated answer. The correct answer is true, so it shows the method works well for the decision.

Now remember that in Section 3.2 we found two types of questions that are not suitable for fact validation. To consider multiple-answer questions, we can penalize questions where the first answer and second answer have similar confidence values. We revise (9) to

$$R_2(q) = \begin{cases} p_2 R_1(q) & \frac{C(q,2)}{C(q,1)} > \theta_2 \\ R_1(q) & otherwise \end{cases} \tag{10}$$

where p_2 is a penalty value less than 1.0, and θ_2 is a threshold value between 0.0 and 1.0 to estimate whether q is a multiple-answer question.

To take attributive questions into consideration, another penalty value should be multiplied to $R_2(q)$, when the pivot term of q is an *indirect entity*, which is one of the followings:

- A constituent of a phrase modifying other proper noun or content noun (*e.g.* "Akbar of the Mughal Empire")
- Appositive modifiers (*e.g.* "Tenochtitlan, the capital of Aztec empire")

The updated formula is (11). For example, the pivot term of question (7b) meets the second condition above, so the reliability of the question will be penalized with p_3.

$$R_3(q) = \begin{cases} p_3 R_2(q) & q\text{'s pivot term is indirect entity} \\ R_2(q) & otherwise \end{cases} \tag{11}$$

Besides $TF(Q)$, the decision of true or false, the system returns the confidence value $C^*(Q)$ as well, simply defined as $C^*(Q) = C(q^*, 1)$ *i.e.* DeepQA's confidence value of the first answer for the most reliable question.

Number of proper nouns	0	1	2	3	4
Frequency	0	1	53	48	2

Table 3: Distribution of number of proper nouns in statements of the development set.

5 Experiments

5.1 Experimental setup

For the evaluation of yes/no question answering, we used two sets of world history examination data from National Center Test for University Admission, the set in the year of 2009 for development data, and set in the year of 2007 for open test data. They contain 26 and 23 multiple-choice questions each of which has four sentential statements, thus 104 and 92 predicates can be used for true/false validation as development and test data, respectively. 84% of questions require the answerer to choose a correct statement out of four, and rest of them are to choose an incorrect statement out of four.

Some statements need preprocessing to be self-contained statements, because sometimes necessary information is found in the description of the question, instead of the statements to be chosen. This preprocessing is same as that in the use of the same data for textual entailment (Miyao et al., 2012). For example, when a question description says "choose the most appropriate sentence concerning events that occurred during the period of Ming dynasty", the statement (12) need to be updated to (12m) to determine its correctness.

(12) A Buddhist sect called Zen was created.

*(12m) A Buddhist sect called Zen was created during the period of Ming dynasty.

Table 3 shows the distribution of number of proper nouns in statements of the development set. This shows that most of statements have multiple proper nouns to be ungrounded to produce multiple inverted questions.

The main metrics of this experiment is the accuracy of true/false determination, and we also evaluated the accuracy of 4-way multiple-choice questions, which actually examinees answer. To answer such question types, we introduce the *correctness score* $CS(Q)$ defined as (13).

$$CS(Q) = \begin{cases} C^*(Q) & TF(Q) = \mathsf{true} \\ (-1)C^*(Q) & TF(Q) = \mathsf{false} \end{cases} \tag{13}$$

With this score, "select the correct statement" questions can be solved by selecting the statement with the highest $CS(Q)$, that is, the proposition judged true with the highest confidence value, or the one with the lowest confidence when all propositions are judged false. Also "select the wrong statement" questions can be answered by just selecting the lowest $CS(Q)$.

5.2 Experimental results

First we evaluated the accuracies of true/false determination and 4-way selection using the development data (examination in the year of 2009). Baseline for true/false evaluation is

Method	true/false		p	4-way	
Baseline	65.4%	(68/104)		25%	
Model 1	77.8%	(81/104)	.043	50%	(13/26)
Model 2	79.8%	(83/104)	.029	58%	(15/26)
Model 3	81.7%	(85/104)	.017	62%	(16/26)

Table 4: The result of closed test with the development set (2009).

Method	true/false		p	4-way	
Baseline	68.4%	(63/92)		25%	
Model 1	69.6%	(64/92)	.500	57%	(13/23)
Model 2	71.7%	(66/92)	.418	57%	(13/23)
Model 3	79.3%	(73/92)	.046	65%	(15/23)

Table 5: The result of open test with 2007 question set.

the accuracy when returning always false, and baseline for 4-way evaluation is the random choice (theoretically 25%). The proposed method was evaluated with three models. Model 1 uses $R_1(q)$ in equations (8) and (9). Model 2 addresses the problem of multiple-answer questions with $R_2(q)$ in equation (10), where both p_2 and θ_2 were empirically set to 0.5. Model 3 cares also attributive questions with $R_3(q)$ in equation (11). p_3 is empirically set to 0.1 here.

Table 4 shows the results. According to p-value between the baseline and each model in the true/false determination, all models significantly outperformed the baseline. We set parameters so that Model 3 shows the highest accuracies, but the differences amongst the three models were not significant, due to the small test set.

Table 5 shows the result using the test data (the examination in 2007), using parameters set from the development data. Though Model 1 and Model 2 did not show a significant difference from the baseline in terms of the yes/no determination, Model 3 shows highest accuracy and significantly outperformed both the baseline and Model 1. In the 4-way test, all models apparently outperformed the random choice.

The results with the test set showed that referring to both the multiple-answer questions and attributive questions can be appropriately discouraged. For example, when a wrong statement (14) is converted to (14a), the country which ruled Vardhana dynasty, India, was returned as the first answer by DeepQA with high confidence, regardless of the role of Angkor Wat. When Model 3 is used, (14a) was penalized because the pivot term is a modifier to another proper noun. This gave another question (14b) relatively higher priority, resulting in the answer "Chalukya", which is actually the ruling dynasty when Angkor Wat was built. The resulting mismatch with the anticipated answer successfully supports the conclusion that (14) is false.

*(14) Angkor Wat was built during the same period as the Vardhana dynasty ruled in India.

(14a) Angkor Wat was built during the same period as the Vardhana dynasty ruled in this country. ?[India]

(14b) Angkor Wat was built during the same period as this dynasty ruled in India. *[Vardhana dynasty]

5.3 Error analysis

From unsuccessful cases, we found some difficulties. Here is a typical example of DeepQA's limitation. For the correct statement (15), three questions (15a) to (15c) were generated, but DeepQA's results were $A(q) \neq 1$ for all of them. The difficulty comes from ambiguity in "February Revolution", so "Russia" is answered for (15a) due to more popular revolution, and (15c) is difficult to answer.

(15) French provisional government formed after the February Revolution created National Workshops.

(15a) Provisional government of this country formed after the February Revolution created National Workshops. [France]

(15b) French provisional government formed after this revolution created National Workshops. [February Revolution]

(15c) French provisional government formed after the February Revolution created this place. [National Workshops]

Another interesting case was (16). "Agricultural Adjustment Act" and "United States" were answered for (16a) and (16b), respectively, but this statement was wrong because the prices were *raised*, not *lowered*. This is the limitation of DeepQA that answers the most likely proper nouns assuming there is an answer. To overcome this problem, other questions with opposite meaning (*e.g.* The prices of agricultural products were *raised*...) could be generated and submitted to DeepQA. If DeepQA performs well enough, it might return higher confidence values with questions derived from the correct statement.

*(16) The prices of agricultural products were lowered by the Agricultural Adjustment Act in United States.

(16a) The prices of agricultural products were lowered by this law in United States. ?[Agricultural Adjustment Act]

(16b) The prices of agricultural products were lowered by the Agricultural Adjustment Act in this country. ?[United States]

6 Discussion

6.1 Beyond yes/no answer

This system does not just return yes/no answers. For false propositions, the answer by DeepQA can suggest what element makes the proposition false, as we found in the example (7a) and (14b). We call this task *false trigger identification*.

Table 6 shows the frequency of such triggers found in the answer lists. Among the 68 false propositions in the development data, 11 false triggers were found as the first answer of

Question rank	Answer rank	Frequency
1st	1st	11
2nd to 3rd	1st	6
1st	2nd to 5th	2
2nd to 3rd	2nd to 5th	5

Table 6: The frequencies of false triggers found in the answer lists.

q^*, 6 false triggers were found as the first answer to other questions, and 7 were in the lower-ranked answers to one of the questions. For these incorrect statements, our system thus provides useful hints to make corrections to the input.

In 12 out of 46 unsuccessful cases the time period was incorrect as in Question (17) when the 15th century is the correct date. In these cases it is difficult to identify the false trigger because DeepQA was not particularly good at answering questions seeking the proper century.

*(17) In the 11th century, the ruler of the Malacca Sultanate converted to Islam.

6.2 Comparison with entailment techniques

Recently recognition of textual entailment (RTE) (Dagan et al., 2005) is intensively studied. The same world history question dataset was used in the evaluation of entailment task (Miyao et al., 2012). In their experiments, for a statement H in the choices for a question, a relevant sentence T was manually selected among Wikipedia articles so that H entails T only if statement H is true. They reported that the accuracy of 4-way multiple choice question in a world history examination using the best system was 54% (13/24). Since the prerequisites were different and the languages were also different (they used the original Japanese questions while we used English translations) we cannot directly compare the results. However, the accuracy using entailment is lower than that by our closed test in Table 5, and our method does not require the careful selection of a relevant single text from the corpus, so our approach can be argued that it is closer to a real application scenario.

7 Conclusion

This paper proposed a method to determine the correctness of propositions by leveraging the power of information sources accessed through a factoid-style question answering system. This was done by generating questions to be input to a subsystem and postprocessing the answer list produced by the system. This achieved quite encouraging results in both true and false determination, and hence in the overall examination goal of answering multiple choice questions. In this study, although the first stage of the process was manual, we identified kind of questions that are suitable or problematic for fact validation, and we found that reliable questions can be automatically selected by relying on the confidence values output by the factoid-style question-answering system. Besides yes/no determination, the system indicated an ability to identify why an input statement might be incorrect, suggesting our method can be applied in a dialog system that continuously validates the input utterances, or for semantic document content correction based on general knowledge, amongst others.

ABSTRACT

Despite the existence of many effective methods to solve topic classification tasks for such widely used languages as English, there is no clear answer whether these methods are suitable for languages that are substantially different. We attempt to solve a topic classification task for Lithuanian, a relatively resource-scarce language that is highly inflective, has a rich vocabulary, and a complex word derivation system. We show that classification performance is significantly higher when the inflective character of the language is taken into account by using character n-grams as opposed to the more common bag-of-words approach. These results are not only promising for Lithuanian, but also for other languages with similar properties. We show that the performance of classifiers based on character n-grams even surpasses that of classifiers built on stemmed or lemmatized text. This indicates that topic classification is possible even for languages for which automatic grammatical tools are not available.

TITLE AND ABSTRACT IN LITHUANIAN

Klasifikavimo į temas gerinimas stipriai kaitomoms kalboms

Nepaisant to, jog tokioms plačiai naudojamoms kalboms kaip anglų yra sukurta daug efektyvių metodų, sprendžiančių klasifikavimo į temas uždavinius, neaišku ar šie metodai yra tinkami visiškai skirtingoms kalboms. Siekiame išspręsti klasifikavimo į temas uždavinį gana mažai išteklių šioje srityje turinčiai lietuvių kalbai, kuri yra stipriai kaitoma, turi turtingą žodyną, sudėtingą žodžių darybos sistemą. Pademonstruosime, kad galima pasiekti ženkliai geresnius klasifikavimo rezultatus, kuomet atsižvelgiama į kaitomą kalbos pobūdį: naudojamos simbolių n-gmamos vietoj labiau įprasto žodžių rinkinio. Gauti rezultatai perspektyvūs ne tik lietuvių kalbai, bet taip pat ir kitoms, panašiomis savybėmis pasižyminčioms, kalboms. Pademonstruosime, kad klasifikatorių, naudojančių simbolių n-gramas veikimas netgi efektyvesnis, palyginus su klasifikatoriais, naudojančiais į žodžių kamienus arba lemas transformuotą tekstą. O tai reiškia, kad šį klasifikavimo į temas metodą galima taikyti netgi toms kalboms, kurios neturi specializuotų automatinių gramatinių įrankių.

KEYWORDS : Character n-grams, topic classification, Lithuanian.
KEYWORDS IN LITHUANIAN : Simbolių n-gramos, klasifikavimas į temas, lietuvių kalba.

1 Introduction

With the exponential growth in the number of electronic documents, automatic text categorization has become one of the key techniques to help control and organize the constant influx of information. The ever-increasing amount of articles, e-mails, comments, and other types of texts leaves no opportunity for manual classification.

Initially, the main focus of text categorization research was on proposing and applying supervised text classification methods on different benchmark data collections, such as Reuters-21578 (Lewis, 1992; Lewis et al., 2004), 20 Newsgroups (Lang, 1995), Ohsumed (Hersh et al., 1994; Lewis et al., 2004), etc. When text classification methods achieved sufficient accuracy, research topics started to diversify, focusing instead on integrating different sources of information (semantic information, world knowledge), developing increasingly autonomous classification methods (semi-supervised or unsupervised classification), applying the approach to diverse classification tasks (genre classification, author classification), etc.

Whereas currently proposed methods solve text classification tasks very effectively, they often require information that is not immediately present in the text. Using part-of-speech information, for instance, requires the availability of accurate part-of-speech taggers. The same can be said about world knowledge, which requires the existence of ontologies or common sense databases. For English and other major languages, a wide range of annotated corpora, grammatical tools and databases are available, but this is not the case for other, more resource-scarce languages. Furthermore, most research currently focuses on a limited selection of languages, and there is no guarantee that the techniques that work best to classify English texts will also be most effective for languages that are substantially different.

In this paper, we investigate whether the widely accepted bag-of-words approach that seems to work well for topic classification in English is also the best method for topic classification in Lithuanian, which is a highly inflectional language. We also assess whether it is possible to perform topic classification on Lithuanian without resorting to external resources such as extra grammatical annotation layers or automatic grammatical parsers, since Lithuanian has a limited number of these resources. We posit that our findings can also be applied to other, similar languages (according to such properties as inflectional morphology, complexity of word derivation, etc.) such as Latvian (the only other living Baltic language) or Slavic languages.

Section 2 contains an overview of related work. In Section 3, we describe the Lithuanian language and its properties. We outline the methodology of our topic classification experiments in Section 4 and present the results in Section 5. We discuss these results in Section 6 and evaluate their implications for text classification procedures in general, and for inflectionally rich languages specifically.

2 Related work

In this paper we focus on supervised machine learning methods (for review see Kotsiantis, 2007) applied to a text categorization task (for review see Sebastiani, 2002).

The most important features when performing topic classifications are usually those lexical features that clearly refer to topic-specific terminology. Function words are less important for this task, and so is most grammatical information. Therefore, prior to topic classification, the

documents are usually pre-processed in such a way that this topic-specific lexical information is easily accessible. This may involve the removal of stop words, function words; stemming or lemmatization; spelling normalization; word segmentation; etc. Stemming and lemmatization are advisable for highly inflective languages, spelling normalization for languages having a highly variable orthography (e.g. Arabic), word segmentation is demanded for languages having concatenative compounding (e.g. Swedish or German) and inevitable for the languages that have no whitespace between words (e.g. some Asian languages such as Chinese or Japanese). However, the gain one can expect from pre-processing steps like stemming or lemmatization seems to be strongly dependent on the language of the dataset. Some comparative experiments have revealed that stemming improves the classification performance of various machine learning algorithms on English texts (Radovanovic & Ivanovic, 2006). However, in Gaustad & Bouma (2002)'s experiments on Dutch data, it had no influence on classification results. Stemming can even adversely affect accuracy, as shown by Wahbeh et al. (2011) on Arabic data. As for lemmatization, Leopold & Kindermann (2002) report that it led to no significant classification improvements on German, sometimes even yielding worse results.

Regardless of these pre-processing steps, the most popular feature representation for topic classification seems to be the bag-of-words approach. In some cases, it may be interesting to add word bigrams, on the condition that these are not entirely redundant. Indeed, adding bigrams does not usually help classification performance (on the contrary, performance often drops), since the feature space becomes even more sparse. Boulis & Ostendorf (2005), however, showed that carefully selected token bigrams can offer improvements over the bag-of-words approach. They propose a measure to evaluate the redundancy of token bigrams based only on their related words. Tan et al. (2002) use a lexical analyzer to determine and include the most important token bigrams and demonstrate a positive influence on classification results. Nastase et al. (2007) use syntactically related word pairs (verb + each of its arguments, noun + each of its modifiers) instead of token n-grams and report an improvement over the pure bag-of-words representation.

Stop word removal, stemming, lemmatization and lexical analysis are language dependent, and are therefore necessarily based on external resources –lists of stop words, grammar tools or dictionaries– resources that resource-scarce languages may not always have. It is however also possible to use character level n-grams. Character n-grams can often capture the language-dependent elements without having to resort to external stemmers, lemmatizers or word segmentation tools. Character n-grams will highlight highly relevant word segments, and since each string is decomposed into small parts, any error can affect only a limited number of these parts, which makes character n-grams ideal to use with informal texts containing many typographical errors.

Peng et al. (2003a, 2003b) skipped language dependent pre-processing and feature selection stages and demonstrated that a language modelling approach on character n-grams gives superior classification results for English and competitive results for Chinese and Japanese. For English, the most accurate performance was achieved with n-grams of 3 characters or more, peaking at 6-grams with Witten-Bells smoothing. Bigrams (or higher order) with different smoothing techniques worked best for Chinese, whereas 6-grams (or more) with absolute or Written-Bell smoothing worked best for Japanese. Wei et al. (2008)'s experimented on Chinese texts, showing good performance for combinations of character unigrams and bigrams, or combinations of unigram, bigrams and trigrams. Peng & Schuurmans (2003) demonstrated that a chain-

augmented Naïve Bayes classifier can work equally well on character n-grams as on bag-of-words for Chinese, Japanese, English and Greek.

Sometimes character level n-grams are applied on pre-processed texts. Khreisat (2006) applied character trigrams on Arabic texts after stop word removal and spelling normalization. A similar approach was applied to Farsi by Bina et al. (2008) who report that 4-grams give the best results.

Unfortunately, we cannot give any examples of topic classification experiments for Lithuanian, since no automatic text categorization tasks have yet been described for this language. Consequently, this paper will be the first attempt at finding a good method to perform topic classification on Lithuanian text, taking into account language-specific characteristics, while keeping the use of external information sources to a minimum.

3 The Lithuanian language

Lithuanian is considered one of the most archaic and conservative living Indo-European languages (Gimbutas, 1963) and it has retained a lot of cognates to many words found in such languages as Sanskrit or Latin.

Lithuanian has a rich vocabulary and word derivation system. The Academic Dictionary of Lithuanian (Naktinienė et al., 2005) has more than 0.6 million headwords (e.g. Oxford English Dictionary has about 0.3 million headwords, Deutsches Wörterbuch – the largest lexicon of the German language – has around 0.33 million). As an example of Lithuanian's rich vocabulary, in the Academic Dictionary of Lithuanian, there are more than 1300 synonyms for the Lithuanian word "eiti" (*to go*) (Piročkinas, 2012) – the majority of which are derived from onomatopeias – and for some of these synonyms it is impossible to find equivalents in other languages. Lithuanian has 25 prefixes for nouns and 78 suffixes for diminutives and hypocoristic words (Ulvydas, 1965). Diminutives and hypocoristic words (which are especially frequent in fiction and spoken language) very often have two/three suffixes, and in rare cases the number of suffixes can go as high as six. E.g. the word "sesuo" (*sister*) can be found in texts as "sesutė", "sesužėlė", "seserytė", etc.

Of all living Indo-European languages, Lithuanian has the richest inflectional morphology, making it more complex than even Latvian or Slavic languages (Savickienė et al., 2009). Different parts-of-speech of a word are expressed through inflections and through different endings. As an example of Lithuanian's inflectional complexity, one can calculate all the possible word forms for the Lithuanian word "aukštas" and its English translation, "*high*" (see FIGURE 1).

In Lithuanian, nominal words (nouns, adjectives, numerals, pronouns, and participles) are inflected by 7 (+2) cases, 2 (+1) genders, and 2 numbers. There are 7 "common" cases, and 2 additional forms of locative that are still found in spoken language and idiomatic use. Nouns have 5 declensions (12 inflection paradigms), adjectives have 3 (9 inflection paradigms). E.g. the noun "vanduo" (*water*) of a masculine gender can be found in Lithuanian texts written as "vanduo", "vandens", "vandeniui", "vandenį", "vandeniu", "vandenimi", "vandenyje", "vandenie", "vandenys", "vandenų", "vandenims", "vandenis", "vandenimis", "vandenyse". The word "vanduo" is an example of one of the inflection paradigms, where the part "vand" (i.e. the root of word) always remains stable. Nominal words usually have 2 grammatical genders, except for adjectives, which have an additional neuter gender that is not declined.

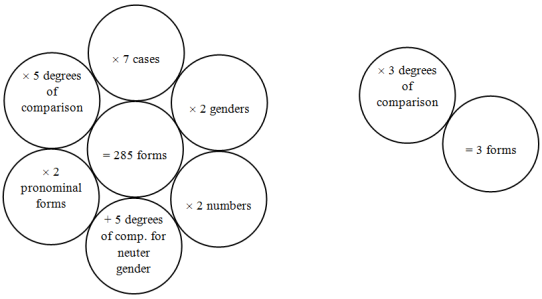

FIGURE 1 – The adjective "aukštas" (*high*) has 285 different forms in Lithuanian (a); and 3 forms in English (b).

Lithuanian also has pronominal forms of adjectives, ordinal numerals, pronouns and active forms of participles. Pronominal forms are unknown to English, German, French, and to hundreds of other languages (they are however present in Russian, for instance). They are used to highlight an object and its properties from other similar objects. Pronominal forms are composed by appending the anaphoric pronoun to the ending of the word and composing more complex dissyllabic endings. E.g., the ordinal number "pirmas" (*the first*) has a simple ending indicating masculine gender in singular number, namely "as". The pronominal form, "pirmasis", is formed by adding an extra ending, "is". Both endings can be inflected further, which can even lead to trisyllabic endings, as is the case of the plural locative "pirmuosiuose", which has an ending made up of three elements: "uos", "iuos" and "e". Despite these extra endings, the root "pirm" is retained.

Adjectives, adverbs, and some forms of verbs have 3 (+2) degrees of comparison, where two of them are usually used only in fiction and spoken language and have no equivalents in English. Degrees of comparison in Lithuanian are expressed by different endings and suffixes, e.g. singular masculine gender noun "gražus" (*beautiful*), "gražesnis" (*more beautiful*), "gražiausias" (*the most beautiful*), where "graž" remains stable.

The most ancient Indo-European languages had 2 or 3 degrees of comparison for demonstratives (pronouns), but in most existing languages only 2 (sometimes 1) are left. Meanwhile, Lithuanian retained 3 degrees of comparison: describing objects located close to the speaker; objects located not close to the speaker, but close to the listener; objects located far from both, i.e. the speaker and the listener. All these words are also inflected, but are too short to retain stable parts longer than one symbol. E.g. the pronoun "šis" (*this/these*) can be found as "šio", "šiam", "šį", "šiuo", "šiame", "šie", "šių", "šiems", "šiuos", "šiais", "šiuose".

Lithuanian language also has compound nouns, consisting of two or even three roots. E.g. "saulėtekis" (*sunrise*) ("saulė", *sun* + "tekėti", *to rise*), "sienlaikraštis" (*wall newspaper*) ("siena", *wall* + "laikas", *time* + "raštas", *writing*), etc. But only the last of the compound words can change its inflection form. E.g. "sienlaikraštis", "sienlaikraščio", "sienlaikraščiui", etc. The same can be said of some fixed combinations of words, e.g. "žemės ūkis" (*agriculture*), "saulės smūgis" (*sunstroke*), where the first word is stable and the second is inflected ("žemės ūkio",

"žemės ūkiui", "žemės ūkį", etc.), whereas both words can be inflected when they occur separately.

Verbs have 3 conjugations, and are inflected by 4 tenses, 3 persons, 2 numbers, and 3 moods. Some conjugated verb forms are also reflexive. This can be expressed by adding particle "si" or "s" at the end of word or after extra added prefixes, e.g. "nusiprausti" (particle "si" after prefix "nu"), "praustis" (*to have a wash*) (particle "s" at the end of word). Both words have the same root "praus". Phrasal verbs in Lithuanian have extra prefixes (14 in total), whereas in English they are expressed by two words: i.e. verb + preposition/adverb. E.g. "nubėgti" (*to run away*), "prabėgti" (*to run by*), "įbėgti" (*to run in*), "išbėgti" (*to run out*), all having different prefixes but the same stable root "bėg". Other forms of verbs are non-conjugative (e.g. participles, adverbial participles, verbal adverbs, and some forms of gerund), but can be inflected by tense, case, gender, number, and have active and passive forms. Non-conjugative forms of verbs retain the same root, but have different suffixes and endings in different inflection forms.

4 Methodology

Our goal is to see if we can carry out automatic topic classification despite the complexity of Lithuanian (and, by extension, of other Baltic and Slavic languages). Since for these relatively resource-scarce languages, we do not always have access to freely available dictionaries, annotated datasets or grammatical tools, we also want to avoid using such external resources and use only the information present in the text's surface representation.

Section 4.1 will describe the datasets we used and Section 4.2 will give a formal description of the classification task. In Section 4.3, we will describe which different feature types we experimented with and formulate two hypotheses we would like to test through these experiments. Section 4.4 describes the actual classification process, including optimization of the classifier and evaluation of the models' performance.

4.1 Datasets

All of our experiments were carried out on three different datasets to make sure our findings generalize over different domains.

- "*Lietuvos rytas*". The information for this dataset was crawled from the internet forum of the largest daily newspaper in Lithuania, "Lietuvos rytas" (Lietuvos rytas, 2012). The structure of the forum is hierarchical: it contains a number of topics (root categories), each of which may contain several sub-topics (sub-categories). Within a topic, the discussion is determined by a collection of posted messages. The data was crawled automatically, resulting in a collection of documents, each containing a single forum post, and grouped according to their root category. Root categories (topics) are very general including such areas as "Business", "Politics", "Sports", etc. The "Lietuvos rytas" dataset is thus composed of 8,936 text documents grouped into 11 topics.
- "*Supermamos*". This dataset contains information from the largest internet forum for women in Lithuania (Supermamos, 2012). The structure of this forum is analogous to the "Lietuvos rytas" forum, and was processed similarly. The root categories are more specific compared to "Lietuvos rytas", and concern topics such as "Parenting and Education", "Maternity and Paternity", "Health and Beauty", etc. The created dataset contains 11,353 text documents grouped into 14 topics.

- "*Rinkimų programos*'04". This dataset contains political information, extracted from the programs of major political parties for the Lithuanian parliamentary elections of 2004. The programs were manually processed by a domain expert following classification rules determined in Volkens (2002): each program was split into small phrases and labeled with appropriate categories indicating policy domains, such as "External Relations", "Freedom and Democracy", "Political system", "Economy", etc. The "Rinkimų programos'04" dataset contains 2,388 text documents grouped into 8 topics (7 are related to policy domains and one is neutral).

As we already mentioned, the "Lietuvos rytas" and "Supermamos" datasets contain messages from internet forums, and thus represent spoken Lithuanian language in written form. "Rinkimų programos'04" contains texts extracted from formal documents and represents normative written Lithuanian.

The classification of "Lietuvos rytas" and "Supermamos" is a challenging task, even for a domain expert, because some posts are very general, and attaching them to any of the possible topics is very difficult. Moreover, internet forums have their own specific jargon full of informal words, foreign language insertions, barbarisms, and other expressions that are outside standard language norms. Besides, "Lietuvos rytas" and especially "Supermamos" are full of diminutives and hypocoristic words. Typographical and grammatical errors can also not be avoided. A particularly difficult problem is that informal written language often imitates spoken language. In the case of Lithuanian, some grammatical forms are very often pronounced without the ending vowel (such as "mergyt" → "mergyte" (*lassie*, in vocative case); "eit" → "eiti" (*to go*, infinitive); "schemoj" → "schemoje", (*schema*, in locative case)). This trend is reflected in informal written language. Moreover, Lithuanian uses the Latin script supplemented with diacritics (ą, č, ę, ė, į, š, ų, ū, ž), but in internet messages, diacritics are very often replaced with matching Latin letters (e.g.: ą → a, č → c, ę → e, etc.) or pairs of letters expressing the same sounds as in English (e.g.: č [tʃ] → ch, š [ʃ]→ sh, etc.). "Rinkimų programos'04", consisting of formal written language only, avoids the above-mentioned problems.

TABLE 1 shows the number of topics (classes) and the majority and random baselines (determined by calculating the sum of the squared probability of the classes, or $\sum_i P(c_i)^2$)) for each dataset.

Dataset	Number of topics	Number of text documents	Random baseline	Majority baseline
Lietuvos rytas	11	8,936	0.145	0.247
Supermamos	14	11,353	0.093	0.137
Rinkimų programos'04	8	2,388	0.167	0.231

TABLE 1 – Number of topics and text documents, random and majority baselines for all datasets.

4.2 Formal description of the task

The mathematical formulation of the topic classification task we are attempting to solve is given below.

Let $d \in D$ be a text document, belonging to a document space D. In our case we have three document spaces, related to different datasets: "Lietuvos rytas", "Supermamos", and "Rinkimų programos'04".

Let C be a finite set of classes (topics): $C=\{c_1, c_2, \ldots, c_N\}$. In our case $2 < N << \infty$ – i.e. we have multi-class classification problem, because "Lietuvos rytas" has N=11 classes; "Supermamos" – N=14 classes; "Rinkimų programos'04" – N=8 classes.

Let D^L be a training set, containing instances I – i.e. document feature vectors d' (where d' corresponds to document d) with their appropriate class labels: $I=\langle d', c\rangle$. "Lietuvos rytas", "Supermamos", "Rinkimų programos'04" contain single-labeled instances only: i.e. the text document d cannot be attached to more than one class c.

Let function γ be a classification function mapping text documents to classes, $\gamma : D \rightarrow C$. Function γ determines how d was labelled with c. In "Lietuvos rytas" and "Supermamos", the labeling was performed automatically by the users by replying to forum messages; in "Rinkimų programos'04", the annotation was performed by a domain expert.

Let Γ denote a supervised learning method which given training D^L as the input, can return a learned classification function γ' (defined as a model) as the output: $\Gamma(D^L)\rightarrow\gamma'$.

4.3 Experimental setup

The datasets "Lietuvos rytas", "Supermamos" and "Rinkimų programos'04" were pre-processed using different pre-processing techniques (TABLE 2):

Dataset	Total number of tokens	Number of distinct tokens	Number of distinct tokens after stemming	Number of distinct tokens after lemmatization
Lietuvos rytas	331,068	70,760	41,291	37,743
Supermamos	703,220	116,144	67,811	63,919
Rinkimų programos'04	29,745	7,426	4,474	3,320

TABLE 2 – Statistics about pre-processed datasets.

- Stemming. This pre-processing technique includes case normalization, the replacement of numbers with a general placeholder, and stemming. Words were stemmed using a Lithuanian stemmer (Krilavičius & Medelis, 2010) based on the Porter stemming algorithm (Porter, 1980; Willett, 2006). The Lithuanian stemmer eliminates endings and some suffixes. It is rule-based and can therefore cope with some irregular words (barbarisms, words with replaced diacritic letters, and words with grammatical errors). In some cases, stemming can cause the loss of meaning (e.g. "sala" (*island*), "salė" (*hall*), and "salti" (*to malt*) will be stemmed to the same "sal"). This pre-processing technique allows reducing the number of distinct tokens by ~42% for "Lietuvos rytas" and "Supermamos", and by ~40% for "Rinkimų programos'04".
- Lemmatization. This preprocessing technique includes the replacement of numbers by a placeholder. Documents were lemmatized using the Lithuanian morphological analyzer-lemmatizer "Lemuoklis" (Zinkevičius, 2000; Daudaravičius et al., 2007), which also solves morphological disambiguation problems. Its accuracy on normative Lithuanian texts is ~94% (Rimkutė & Daudaravičius, 2007). "Lemuoklis" transforms words into their lemmas by replacing the words' endings by their main lemma ending (but it does not touch suffixes and prefixes). However, the lemmatizer is dictionary-based, and can therefore not cope with unknown words. Case normalization was not necessary, because

"Lemuoklis" transforms the letters of generic words into lower case and leaves proper nouns capitalized. Unrecognized words are not modified in any way. "Lemuoklis" was unable to recognize ~15% of tokens in "Lietuvos rytas"; ~26% in "Supermamos", and ~2.5% in "Rinkimų programos'04". These numbers are in line with research by Giesbrecht & Evert (2009), who showed that for German data, every seventh token is incorrectly recognized when working with internet forum data, whereas almost no errors occur in (standard-language) fiction texts. Lemmatization allowed reducing the number of distinct tokens by ~47% for "Lietuvos rytas", by ~45% for "Supermamos", and by ~55% for "Rinkimų programos'04".

It should be noted that even though it is a common pre-processing step, we chose not to remove stop words from our datasets. This choice was made because of the following two reasons: 1) there is no list of stop words available for Lithuanian; 2) stop words are not a big problem in Lithuanian given the inflective nature of the language (e.g. Lithuanian does not have articles; phrasal verbs are expressed with a single token; negations are usually expressed by single token also, where participle "ne" (*not*, *no*) is attached as the prefix, etc.).

We now have three versions of the "Lietuvos rytas", "Supermamos" and "Rinkimų programos'04" datasets: one version with unmodified words, one with stemmed words, and one in which the words are lemmatized. Both the lemmatizer and the stemmer significantly reduce the number of distinct features, mapping several forms of the same word to a single feature. This should improve topic classification accuracy, but both the lemmatizer and the stemmer are in fact external resources, which may not be available for many resource-scarce languages, or which may not be accurate enough. Therefore, we will not only perform experiments with unigrams of lemmatized or stemmed words, but we will also attempt to classify the documents by using character n-grams. It is our expectation that the character n-grams will capture intrinsically what the lemmatizer and stemmer do explicitly, i.e. the terms present in the text, regardless of their inflection or derivational affixes.

The different feature types we will compare for all three datasets are thus the following:

- Unigrams based on word tokens.
- Unigrams based on stemmed words.
- Unigrams based on lemmatized words.
- Character n-grams based on word tokens.

The results of the corresponding experiments are described in Section 5.

Our first hypothesis is that a simple bag-of-words approach, which has shown its efficiency in topic classification tasks in English and in related languages, will not be the best technique for Lithuanian. We expect stemming and lemmatization to improve the classification results for Lithuanian significantly, due to the language's complex morphology and the importance of inflection.

Our second hypothesis is that it may not be necessary to use grammatical tools such as stemmers or lemmatizers – which may not be available for many resource-scarce languages – to capture the influence of this complex morphology and inflectional system. Character n-grams can capture these influences intrinsically. We expect character n-grams to perform significantly better than the bag-of-words approach, and we anticipate they will reach similar performance as the stemmed or lemmatized words.

4.4 Classification

We attempt to find a method Γ which could create the model γ' that best approximates γ. Since topic classification of text has never been solved for Lithuanian, we selected Support Vector Machines (a detailed description of SVMs is presented in Cortes & Vapnik (1995)) as Γ, based on comparative research indicating that SVMs perform best on a variety of text classification experiments. Additionally, SVMs can cope with the following problems which typically occur in text classification tasks:

- High-dimensional feature spaces. A very large feature set is not uncommon when dealing with text documents. E.g. if all token unigrams in a dataset (when $D^L = D$) would be considered as features (following the very common bag-of-words approach), "Lietuvos rytas" would have 70,760 features, "Supermamos" – 116,144; "Rinkimų programos'04" – 7,426.
- Sparseness of feature vectors. Each *d'* usually contains only a small number of features with non-zero values; these vectors are therefore considered sparse. E.g. in a token unigram approach (assuming $D^L = D$), each *d'* would contain ~14 non-zero feature values (among 70,760) in "Lietuvos rytas"; ~18 (among 116,144 features) in "Supermamos"; ~5 (among 7,426 features) in "Rinkimų programos'04".
- Heterogeneous use of features: i.e. when instances belonging to the same class do not share any common features. This is often the case when classifying short texts. Each *I* contains ~36 words in "Lietuvos rytas"; ~60 in "Supermamos"; only ~12 in "Rinkimų programos'04".

Additionally, SVMs do not require one to perform aggressive feature selection, which may result in a loss of information. This is especially important in our case, i.e. when working on Lithuanian, where there may be important information in both its rich vocabulary and in its complex word derivation system. The implementation of Support Vector Machines we use in our experiments is LIBSVM (Chang & Lin, 2011), using the radial basis kernel function. Most parameters were left to their default values, except for the cost parameter and the gamma parameter in the radial basis function, which were optimized using a grid search.

5 Results

All results reported in TABLE 3 – TABLE 5 are based on 10-fold cross-validation. For each experiment, the learner parameters were determined using a grid search, using macro-averaged F-scores as the optimization target.

	Lietuvos rytas		
	acc.	macro-F	micro-F
Tokens-1	0.271	0.190	0.265
Stems-1	0.305	0.221	0.300
Lemmas-1	0.303	0.232	0.300
Characters-4	0.324	0.237	0.317
Random baseline	*0.091*		
Majority baseline	*0.247*		

TABLE 3 – Accuracies, macro-averaged and micro-averaged F-scores for the different feature types on "Lietuvos rytas".

	Supermamos		
	acc.	macro-F	micro-F
Tokens-1	0.327	0.277	0.316
Stems-1	0.360	0.320	0.353
Lemmas-1	0.365	0.323	0.358
Characters-4	0.398	0.356	0.392
Random baseline	*0.071*		
Majority baseline	*0.137*		

TABLE 4 – Classification results for "Supermamos".

	Rinkimų programos'04		
	acc.	macro-F	micro-F
Tokens-1	0.298	0.238	0.282
Stems-1	0.326	0.262	0.306
Lemmas-1	0.363	0.291	0.346
Characters-4	0.376	0.290	0.351
Random baseline	*0.126*		
Majority baseline	*0.231*		

TABLE 5 – Classification results for "Rinkimų programos'04".

To determine whether the performances of the classifiers trained with each feature type were significantly different from each other, we performed approximate randomization testing (Noreen, 1989; Yeh, 2000).

For "Lietuvos rytas", all differences are significant to a very high degree ($p <= 0.0001$), with the following exceptions: the difference between the "Stems-1" and the "Lemmas-1" results are not statistically significant; the difference between "Characters-4" and "Stems-1" is significant to a high degree (accuracy: $p = 0.001$, macro-F: $p = 0.006$, micro-F: $p = 0.003$); the difference between "Characters-4" and "Lemmas-1" is only significant in terms of accuracy ($p = 0.0005$) and micro-F ($p = 0.001$).

For "Supermamos", all differences are significant to a very high degree ($p <= 0.0001$), with the exception of the difference between "Stem-1" and "Lemmas-1", which is not significant.

Finally, for "Rinkimų programos'04", all differences are significant to a very high degree ($p <= 0.0001$), with the following exceptions: the difference between "Token-1" and "Stems-1" in terms of macro-F is slightly less significant ($p = 0.007$), as is the difference between "Characters-4" and "Stem-1" ($p = 0.002$); the differences between "Characters-4" and "Lemmas-1" are not statistically significant.

6 Discussion

Before we could compare the character n-gram performance to the performance of the word unigrams (tokens, stemmed words or lemmatized words), it was necessary to determine the optimal size of the n-grams. As reported by Peng et al. (2003a, 2003b) (see Section 2), for English, the character n-gram performance is competitive starting from trigrams, and peaks at 6-grams. Chinese, on the other hand, performed best with bigrams. For classification of Farsi texts,

character 4-grams seem to be the recommended feature type (Bina et al., 2008). The optimal size of the character n-grams thus appears strongly dependent on the language of the dataset. No research regarding the optimal n-gram size for Lithuanian has yet been published.

We expect word roots to give us the most useful information for a topic classification task, and n-grams of a length that manages to capture these roots most often should therefore be the most powerful. Based on the fact that Lithuanian has an average word length of 6 characters, and that most endings are 2 characters long, we expect that 4-grams will yield the best classification performance.

To test this hypothesis, we carried out experiments on all three datasets using all n-gram sizes ranging from trigrams to 7-grams. FIGURE 2 shows a graph mapping the n-gram performance (in terms of micro-averaged F-score) on all three datasets.

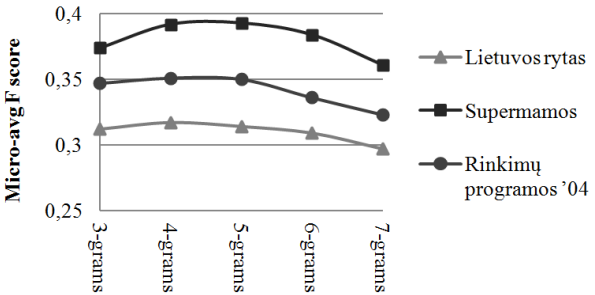

FIGURE 2 – Micro-averaged F-scores for n-gram sizes from 3-grams to 7-grams on all three datasets.

As expected, performance reaches a peak for character 4-grams, though the difference with 5-grams is subtle. Shorter string segments (trigrams) do not appear to capture enough information, while the longer segments (6-grams, 7-grams) fail to generalize sufficiently. TABLE 6 contains a more detailed performance breakdown.

	Lietuvos rytas	Supermamos	Rinkimų programos'04
3-grams	0.312	0.374	0.347
4-grams	0.317	0.392	0.351
5-grams	0.314	0.393	0.350
6-grams	0.309	0.384	0.336
7-grams	0.297	0.361	0.323

TABLE 6 – Micro-averaged F-scores for n-gram sizes from 3-grams to 7-grams on all three datasets.

A glance at TABLE 3 – TABLE 5 in Section 5 shows that our first hypothesis is confirmed: the simple bag-of-words approach (Tokens-1) is easily beaten when using a stemmer or a lemmatizer. For both the "Lietuvos rytas" and "Supermamos" datasets, stemming and lemmatization both account for an increase of 0.04 in micro-averaged F-score. On "Rinkimų programos'04", stemming does cause a small boost in performance, but lemmatization seems to

perform even better. The reason why lemmatization improves performance over stemming on the "Rinkimų programos'04" dataset, while it only matches the stemmer's scores on the other datasets, is that "Rinkimų programos'04" contains formal written text. As we described in Section 4.1, "Lietuvos rytas" and "Supermamos" both contain conversations from Internet forums, which are much more informal and contain non-standard language. The lemmatization package "Lemuoklis" is unable to deal with much of this "chat" data, while it does a better job lemmatizing the formal language in the political dataset.

More interestingly, the results also support our second hypothesis: the character 4-gram scores (which were the best n-gram scores, as shown in TABLE 3) are consistently higher than the scores for the other feature types. This means that not only is it possible to perform topic classification for Lithuanian using features that require no external resources, this approach even outperforms the standard classifiers trained on unigrams of stemmed or lemmatized words. The experiments were performed using different datasets, representing both formal and informal Lithuanian, with different particularities and different topic distributions. It can therefore be concluded that the hypothesis does not depend on the corpus or on a specific set of topics, but that it is applicable to Lithuanian in general. Assuming this pattern holds for other languages with similar properties (Latvian and some Slavic languages), this is good news indeed for resource-scarce languages where external tools such as lemmatizers or stemmers may not be available.

If we look more closely at why character n-grams work, we see that they capture patterns which are not always captured by alternative feature types. The lemmatizer reduces the word ending to their base form, but it does not remove suffixes ("mama", *mother*, and "mamytė", *mother* in diminutive, for instance, have the same root "mam", but are treated differently) and prefixes (e.g. "išbėgti", *to run out*, and "bėgti", *to run*, have the same root "bėg", but are treated differently). This means that phrasal verbs are not decomposed and diminutives or hypocoristic words remain untouched by the algorithm. The stemmer, then, is purely rule-based and captures even less of the intricacies of the Lithuanian language. It does not consider the function or meaning of a word in a sentence, and instead mechanically eliminates word endings (and some of the suffixes), resulting in an output that is all but perfect. The word "sveikas" (*healthy*), for instance, is stemmed to "sve" but should be stemmed to "sveik": i.e. ending "as" is correctly eliminated, but "ik" is erroneously treated as a suffix. With character n-grams, on the other hand, one does not need to explicitly define how words are formed. Character n-grams will implicitly capture the relevant inflectional patterns and the base word forms, which make them excellent features for this topic classification task.

The top character 4-gram features for the "Rinkimų programos'04" dataset, for instance, mostly contain the stable parts of words that are not influenced by inflection. In many cases, even, the n-grams capture the semantics of a term, which is stable over different parts of speech. The n-gram "vald", for instance, corresponds to the root of several, related words: the nouns "valdymas" (*management*), "valdžia" (*authority*) and "pavaldumas" (*subordination*); the verb "valdyti" (*to govern*); the phrasal verbs "įvaldyti" (*to master*), "suvaldyti" (*to manage*), etc. It is also one of the roots in the compound nouns "savivaldybė" (*municipality*) ("savas", *own* + "valdyti", *to govern*) and "žemėvalda" (*land-ownership*) ("žemė", *land* + "valdyti", *to govern*). Similarly, the character n-gram "kari" captures the nouns "karininkas" (*officer*) and "kariuomenė" (*army*); the adjective "karinis" (*military*). It captures the part of the noun "kariai" (*soldiers*) that remains stable in all inflected plural forms.

The examples above are lemmas (with the exception of "kariai", which is the plural of "karys", *soldier*), meaning they would not be transformed further by the lemmatizer. The stemmer would shorten the lemmas by eliminating endings and some suffixes, but prefixes and compound words would still remain.

By capturing those parts of words that are stable over semantically related words across different parts of speech, character n-grams help resolve feature sparseness, which is especially problematic for Lithuanian. Since Lithuanian has such a rich vocabulary, the standard bag-of-words approach results in an extremely sparse feature space, which can significantly complicate the construction of a good classification model. Stemming and lemmatization help reduce sparseness by limiting the number of possible realizations of the same lemma, but they do nothing to reduce the number of lemmas. Character n-grams, however, segment text into more frequent, more general substrings, which results in more reliable models.

Character n-grams also don't throw away valuable information as a stemmer or lemmatizer might. Some character n-grams, such as "emės", capture a string that remains stable in fixed combinations of two words, e.g. "žemės ūkis" (*agriculture*), "žemės grąžinimas" (*land restitution*), "žemės nuosavybė" (*land property*), etc. Both the stemmer and the lemmatizer would change "žemės" to "žemė", thus discarding valuable information.

Conclusion and perspectives

We have formulated and experimentally confirmed two hypotheses regarding topic classification for morphologically rich languages such as Lithuanian:

- The standard bag-of-words approach which works best for English and related languages, is not the best approach for these languages. Where English barely benefits from stemming and lemmatization, Lithuanian (and, by extension, likely also other Baltic and Slavic languages) benefit significantly from these pre-processing steps.
- It is possible to capture the intricate morphology of Baltic and Slavic languages without resorting to external tools such as stemmers or lemmatizers, which may not be available (or which may simply not work sufficiently well). Character n-grams implicitly capture relevant patterns and can outperform classifiers trained on stemmed or lemmatized data.

Our assumptions that these hypotheses also hold for Slavic languages are based on the characteristics that they share with Lithuanian. In future research, it will be interesting to experiment with datasets in these languages to see if these assumptions hold.

ABSTRACT
The phonetic alphabet enables people to dictate letters of the alphabet accurately by using representative words, i.e., A for Alpha. Japanese kanji (idiographic Chinese characters) vastly outnumber the letters of the Roman alphabet, and thus Japanese requires an explanatory reading like a phonetic alphabet. We call the explanatory reading of a kanji a "distinctive explanation." Most kanji characters have their homophones, and the role of the distinctive explanations is to enable users to identify a specific kanji character only by listening to the explanation. In this paper, we propose a corpus-based method for automatically generating distinctive explanations for a kanji, in which information about familiarity and homophones of kanji are taken into consideration. Through the kanji-identification experiments, we show that the quality of the explanations generated by the proposed method is higher than that of the manually crafted distinctive explanations.

KEYWORDS: phonetic alphabet, distinctive explanation for a kanji.

Proceedings of COLING 2012: Technical Papers, pages 1411–1424,
COLING 2012, Mumbai, December 2012.

1 Introduction

Japanese has three types of characters: hiragana, katakana, and kanji (Chinese characters). While hiragana and katakana characters are phonograms, kanjis are ideograms, each of which usually has several readings. Most kanjis have homophones, and thus it is difficult to identify a kanji only by its reading. However, sometimes we need to identify a kanji verbally. For example, screen readers need to enable the users, especially visually impaired people who have difficulty seeing things, to identify a kanji only by sound. When we talk over the telephone, we have to exchange information, such as proper names, only by our voice. In such cases, we explain a kanji by using not only its reading but also its properties, compositions, and so on, to reduce the ambiguity. In this paper, we call such an explanation a "distinctive explanation for a kanji" and propose a method for generating distinctive explanations automatically.

One concept similar to a distinctive explanation is the phonetic alphabet, e.g., A for Alpha, B for Bravo, and C for Charlie. While a distinctive explanation explains kanjis, the phonetic alphabet explains letters and numbers. One of the major differences between them is the number of target characters. Whereas the phonetic alphabet for English deals with only 26 letters and 10 numbers, the distinctive explanation for kanjis deals with thousands of kanji characters.

The distinctive explanation leverages various aspects of the target kanji such as its Chinese reading, its Japanese reading, and its radicals, to reduce ambiguity. Each kanji has several readings, some of which are derived from Chinese readings and the others are Japanese traditional readings. If a kanji has a distinctive reading, the reading can be used to generate the distinctive explanation. Some kanjis can be divided into left and right parts and we can explain a kanji without ambiguity by using them. For example, the kanji "評 (*hyou*)" can be divided into "言 (*gon*)" and "平 (*hei*)." By listening to the information of "言 (*gon*)" and "平 (*hei*)," we can identify "評 (*hyou*)." Words including the target kanji, such as "購入 (*kou-nyū*, purchase)" for "購 (*kou*)," are also effective in identifying the target kanji because they can reduce the ambiguity.

Some screen readers (Lazar et al., 2007) already have functions for outputting distinctive explanations for kanjis. A screen reader is a software application for visually impaired people that reads aloud a text on a computer screen. This function enables visually impaired people to use e-mail, read news, view Web pages, and operate other complex applications. However, the existing screen readers use some distinctive explanations that do not make a target kanji easily identifiable, such as "*aya* for[1] *aya-ori* (綾織, twill)" for "綾 (*aya*)." "綾織 (*aya-ori*, twill)" is not a word with which most people are familiar, and thus we cannot identify the target kanji "綾 (*aya*)" easily. Watanabe et al. (2003) pointed out that the main factors that prevent the users from identifying the target kanji are the low familiarity and the homophones of the words used in the distinctive explanations.

Vocabulary and word familiarity vary among age groups, regions, and social backgrounds. It is hard work to remake a distinctive explanation for each kanji in accordance with changes in the target audience. We try to automate both the acquisition of vocabulary and word familiarity, and the generation of the distinctive explanations.

[1]In fact, distinctive explanations are expressed by using a Japanese word "*no*" as in "*kou-nyū no kou*." "*no*" is a Japanese postposition that can represent a wide range of semantic relations. It is similar to "for" in English. In this paper, we therefore refer to distinctive explanations by using "for" as in "*kou* for *kou-nyū*."

In this paper, we propose a method for automatically generating distinctive explanations for a kanji, and aim to improve the kanji identification rate. Our system automatically generates distinctive explanations using the knowledge of familiarity and homophones derived from a large text corpus. Automatic methods for generating the distinctive explanation can easily adapt to the users.

2 Distinctive explanation for kanji

With the growth of computers, screen readers that have functions for producing voice outputs of distinctive explanations have become popular among visually impaired people. Accordingly, people argued over the problem of what distinctive explanations should be outputted from screen readers.

Ooyama et al. (1996) proposed a spoken explanation generator, PLANET. This system can explain a kanji, especially those used in peoples' names, only by sound. When explaining, the system uses the information such as words containing the target kanji and the components of the kanji.

Watanabe et al. (2005a) manually produced distinctive explanations on the basis of children's vocabulary familiarity obtained by a kanji dictation survey. When producing distinctive explanations, they prioritized words that had higher familiarity than others and no homophones. Moreover, they avoided using negative expressions and English words like "*kin*[2] *for* gold," so that generated distinctive explanations would be suitable for elementary school students. The identification rate for their generated distinctive explanations was 14.1% higher than that for the existing distinctive explanations in the experiments of kanji dictation involving elementary school students.

Nishida et al. (2005) proposed distinctive explanations based on the meanings of a kanji. For example, the traditional distinctive explanation of "情報 (*jou-hou*, information)" was "*jou* for *jou-netsu* (情熱, passion)" and "*hou* for *hou-koku* (報告, report)." On the other hand, in distinctive explanations based on the meanings, "情報 (*jou-hou*, information)" was explained as "*i-n-fo-mē-sho-n* (インフォメーション, information)," "*chou-hou* (諜報, intelligence)," or "*hi-mitsu-jou-hou* (秘密情報, confidential information)." Experimental results showed no differences between the identification rates of the traditional distinctive explanations and explanations based on the semantics. Since those main target words are those that appear in a thesaurus, we cannot easily compare them and our distinctive explanations.

Watanabe et al. (2005b) classified in detail the composition of the traditional distinctive explanations derived from screen readers. Distinctive explanations can be classified into three types in accordance with their configuration:

Type 1 consists of a word that includes the target kanji and the reading of the target kanji in the word.

"*kou* for *kou-nyū* (購入, purchase)" for "購 (*kou*)"

Type 2 consists of the distinctive reading of the target kanji. This type uses the reading that other kanjis never have.

"*sakura* (桜, cherry blossom)" for "桜 (*sakura*)"

[2]In Japanese, *kin* means gold.

Type 3 uses the components of radicals of the target kanji or consists of meanings of the target kanji that forms a word only by itself.

"*kawa* with *sanzui*[3]" for "河 (*kawa*)"

They reported that Type 1 distinctive explanations were most common. Type 1 is suitable for use in statistical treatment, and therefore we aim to generate Type 1 distinctive explanations automatically in this paper.

Watanabe et al. also investigated the factors that make it difficult to identify the target kanji (Watanabe et al., 2003). We enumerate the major factors reported in their work:

Factor 1 The low familiarity of words such as "千代紙 (*chi-yo-gami*, Japanese paper with colored figures)."

Factor 2 The presence of homophones such as "購買 (*kou-bai*, purchase)" and "勾配 (*kou-bai*, gradient)."

Factor 3 The target kanji itself is difficult, such as "爾 (*ji*, thou)."

Factors 1 and 2 can be improved by selecting a suitable word for the distinctive explanation, but Factor 3 cannot because of the difficulty of the target kanji itself. Our study aims to improve the rate of identifying the target kanji from the distinctive explanation, and hence we focus on Factors 1 and 2.

3 Automatic generation of distinctive explanation for kanji

We propose an interactive system that automatically generates distinctive explanations for a kanji. Figure 1 shows the overview of our system. The first step outputs one Type 1 distinctive explanation. If the user cannot recall a kanji, the second step outputs another distinctive explanation.

The first step uses a single word that has high familiarity and few homophones. However, some kanjis are hard to identify from one word unambiguously; for example, "科 (*ka*)." While the most common words that include "科 (*ka*)" are "科学 (*ka-gaku*, science)," "教科 (*kyou-ka*, subject)," and "単科 (*tan-ka*, single subject)," all have several homophones such as "化学 (*ka-gaku*, chemistry)" for "科学 (*ka-gaku*)," "強化 (*kyou-ka*, reinforcement)" for "教科 (*kyou-ka*)," and "炭化 (*tan-ka*, carbonization)" and "単価 (*tan-ka*, unit price)" for "単科 (*tan-ka*, single subject)," and thus it is hard to identify "科 (*ka*)" unambiguously from a Type 1 distinctive explanation. For such a kanji, our system proceeds to the second step, and generates another distinctive explanation for the kanji by using a word that ensures a high kanji identification rate when combined with the word presented by the first step of our system.

The first example of the system's input in Figure 1 is the kanji "購 (*kou*)." The system outputs the distinctive explanation "*kou* for *kou-nyū*" by our first step and describes it to the user. The user identifies the correct kanji "購 (*kou*)" from the distinctive explanation. The second example of the system's input is the kanji "科 (*ka*)." The system outputs the distinctive explanation "*ka* for *ka-gaku*" by our first step and describes it to the user. The user cannot identify

[3] *sanzui* means "氵."

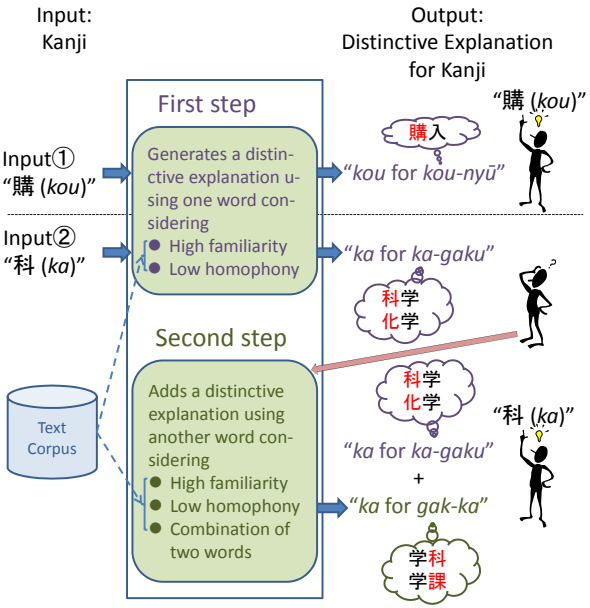

Figure 1: The overview of our system. If “購 (*kou*)” is input, the first step outputs “*kou* for *kou-nyū*.” In this case, the user will think of the correct kanji since there is no ambiguity. If “科 (*ka*)” is input, the first step outputs “*ka* for *ka-gaku*.” However, there are plural candidates such as “科 (*ka*)” and “化 (*ka*).” In such case, the user asks our system to generate an additional distinctive explanation. The second step then outputs "*ka* for *gak-ka*," and the user can identify the correct kanji.

the correct kanji because the reading “*ka-gaku*” has many homophones. Then the user asks our system to generate an additional distinctive explanation. Our system outputs the second distinctive explanation “*ka* for *gak-ka*,” and the user identifies the correct kanji “科 (*ka*)” from the two distinctive explanations.

3.1 Generation of distinctive explanations in the first step

The first step generates a Type 1 distinctive explanation as follows:

i. Extract words from the corpus that have more than two characters and include the target kanji.

ii. Calculate the score for each word w:

$$score_1(w) \triangleq p(w)^{\alpha} \cdot u_1(w)^{\beta}, \tag{1}$$

where

$p(w)$: the probability of w in the corpus,

$u_1(w)$: the ratio of the frequency of w to the frequency of all words in the corpus that have the same reading as w,

α: a parameter that reflects the importance of familiarity ($\in [0, 1]$),

β: a parameter that reflects the importance of not having homophones ($\in [0, 1]$).

The probability $p(w)$ is calculated as follows:

$$p(w) \triangleq \frac{c(w)}{\sum_{w' \in W} c(w')}, \tag{2}$$

where

$c(w)$: the frequency of w in the corpus,

W: the set of words that appear in the corpus.

The ratio $u_1(w)$ is calculated in the following way:

$$u_1(w) \triangleq \frac{c(w)}{\sum_{w' \in H(w)} c(w')}, \tag{3}$$

where

$H(w)$: the set of words that have the same reading as w.

iii. Select the word with the highest score and then use it to generate a Type 1 distinctive explanation.

In Equation (1), $p(w)$ represents the degree of familiarity and $u_1(w)$ represents the degree of uniqueness. For example, the most common words that include "購 (*kou*)" are "購読 (*kou-doku*, subscription)," "購入 (*kou-nyū*, purchase)," and "購買 (*kou-bai*, purchase)." While "購読 (*kou-doku*, subscription)" has higher probability than the other words, it has homophones such as "鉱毒 (mining pollution)." $u_1(w)$ functions to reduce the score of such ambiguous words. As a result, our system prioritizes the output of the distinctive explanation using the word "購入 (*kou-nyū*, purchase)" rather than "購読 (*kou-doku*, subscription)."

3.2 Generation of distinctive explanations in the second step

The second step generates an additional distinctive explanation that reduces ambiguity when combined with the distinctive explanation by the first step.

i. Extract words from the corpus that have more than two characters and include the target kanji.

ii. Give a score for each pair of the word selected in the first step w_1, and a word extracted in i. The score is calculated in the following way:

$$score_2(w_1, w) \triangleq score_1(w_1) \cdot score_1(w) \cdot u_2(w_1, w)^{\gamma}, \tag{4}$$

where

$u_2(w_1, w)$: the ratio of the number of the target kanjis to the number of the kanjis that we can recall from the pairs composed of w_1 and w,

γ: a parameter that reflects the importance of combination ambiguity ($\in [0, 1]$).

The ratio $u_2(w_1, w)$ is calculated in the following way:

$$u_2(w_1, w) \triangleq \frac{\min(c(w_1), c(w))}{\sum_{(w_1', w') \in C} \min(c(w_1'), c(w'))}, \tag{5}$$

where

C: the set of candidate pairs of words that have the same reading as w_1 and w and can make the user recall a kanji.

iii. Select the word with the highest score and then generate a distinctive explanation by using w besides w_1.

Equation (4) consists of a product of $score_1(w_1)$, $score_1(w)$, and $u_2(w_1, w)^{\gamma}$. $u_2(w_1, w)^{\gamma}$ represents the uniqueness when using two words. For example, the distinctive explanation "*ka* for *ka-gaku*" and "*ka* for *tan-ka*" evoke at least two kanjis: "科 (*ka*)" and "化 (*ka*)." The candidate kanjis for the distinctive explanation "*ka* for *ka-gaku*" are "科 (*ka*)" from "科学 (*ka-gaku*, science)" and "化 (*ka*)" from "化学 (*ka-gaku*, chemistry)." Similarly, those for "*ka* for *tan-ka*" are "科 (*ka*)" from "単科 (*tan-ka*, single subject)" and "化 (*ka*)" from "炭化 (*tan-ka*, carbonization)" and "価 (*ka*)" from "単価 (*tan-ka*, unit price)." Thus we have $C = \{($ 科学, 単科 $), ($ 化学, 炭化 $)\}$. The term $u_2(x, y)^{\gamma}$ reduces the scores of such ambiguous distinctive explanations. Our system outputs distinctive explanations that are less ambiguous, such as "*ka* for *ka-gaku*" and "*ka* for *gak-ka*."

4 Experiments

4.1 Experimental Settings

We used three corpora in experiments:

- Google Japanese N-gram corpus (Google corpus)
- Yomiuri newspaper corpus (Yomiuri corpus)
- Balanced Corpus of Contemporary Written Japanese (BCCWJ)

The Google Japanese N-gram corpus (Kudo and Kazawa, 2007) was constructed from 20 billion Japanese sentences on the Web and consists of 255 billion words. The Yomiuri newspaper corpus consists of 400 million words in Yomiuri newspaper articles from 1991 to 2004. The

BCCWJ (Maekawa, 2008) is a balanced corpus of 100 million words of contemporary written Japanese.

We used MeCab (Kudo et al., 2004), an open-source morphological analyzer, to separate the corpus into words. We applied the IPA dictionary with the parameter estimated by Conditional Random Fields (CRF) based on IPA corpus[4]. We also used the Simple Kana to Kanji conversion program (SKK) dictionary[5] to utilize words longer than those in the IPA dictionary. This is because the words in the IPA dictionary tend to be too short for our method. For example, although we want to use "炒め物 (*ita-me-mono*, fried food)" to generate a distinctive explanation for "炒 (*ita*)," there is no entry for "炒め物" in the IPA dictionary, and thus "炒め物" is divided into two words: "炒め (*ita-me*, fried)" and "物 (*mono*, object)." On the other hand, there is an entry for "炒め物" in the SKK dictionary, and in such cases we consider the word as a candidate word for generating distinctive explanations.

We used the kanjis selected from top 2,000 frequently occurring kanjis in the Google corpus for experiments. This is because we want to focus on the performance of generating distinctive explanations, and thus we want to ignore errors caused by Factor 3: the target kanji itself is difficult. Note that since the total frequency of the 2,000 kanjis covered more than 99% kanji occurrences, our experimental setting is very practical. We set the parameters (α, β, γ) to $(0.1, 1.0, 1.0)$ in accordance with the results of a preliminary experiment.

4.2 Comparison of the three corpora

We first conducted a preliminary experiment to evaluate distinctive explanations generated by the first step to examine which corpus is the most preferable for our method. We prepared four distinctive explanations for each kanji: three are generated by using each corpus (Google corpus, Yomiuri corpus, and BCCWJ) and one is the distinctive explanation used in the screen reader PC-Talker XP for comparison. We randomly selected 100 kanjis for an evaluation from the 2,000 most frequently occurring kanjis that had Type 1 distinctive explanations in PC-Talker XP such as "*kou* for *kou-nyū* (購入, purchase)" for "購 (*kou*)."

The distinctive explanations were evaluated by eight human subjects. These distinctive explanations were written on paper, randomly shuffled, and shown to the subjects. Each subject was shown only one distinctive explanation for each kanji. Since there were eight human subjects and four types of distinctive explanations were generated for each kanji, each distinctive explanation was evaluated by two subjects. The subjects were requested to think of the most likely kanji from the presented distinctive explanation and to choose one from the following choices:

a. I thought of a kanji that matched the target kanji.

b. I thought of a kanji that did not match the target kanji.

c. I could not think of any kanji.

We did not conduct a kanji dictation test when we evaluated the distinctive explanations. Japanese speakers cannot always write out kanjis that they can identify, probably because of

[4]http://en.sourceforge.jp/projects/ipadic/
[5]http://openlab.ring.gr.jp/skk/index.html

	Google corpus	Yomiuri corpus	BCCWJ	PC-Talker XP
a	179	170	185	185
b	15	15	9	9
c	6	15	6	6
IR[%]	89.5	85.0	92.5	92.5

Table 1: The identification rates for three corpora.

the spread of computers, which let us input kanjis simply by selecting the correct one instead of actually writing it. This situation is similar to the fact that some English speakers cannot always spell familiar words correctly.

We calculated the identification rate (IR), i.e., the percentage of successfully identified kanji, for each corpus, as follows:

$$\mathrm{IR} = \frac{n(\mathbf{a})}{n(\mathbf{a}) + n(\mathbf{b}) + n(\mathbf{c})} \times 100\ [\%] \tag{6}$$

where $n(x)$ is the number of times choice x is selected.

Table 1 shows the identification rates for three corpora. PC-Talker XP and our system based on BCCWJ achieved the highest identification rate (92.5%). We conducted the McNemar's test and confirmed that there were significant differences at the 0.05 significance level between our system with Yomiuri corpus and PC-Talker XP, and between our system with Yomiuri corpus and with BCCWJ.

Table 2 shows the examples of distinctive explanations and their evaluation. Distinctive explanations generated by the Yomiuri corpus (newspaper articles) tend to use difficult words such as "*gai* for *gai-bou* (外貌, exterior)" generated for "貌 (*bou*)" and "*gi* for *yo-gi-nai* (余儀無い, unavoidable)" generated for "儀 (*gi*)," while there are easier words such as "美貌 (*bi-bou*, beauty)" and "儀式 (*gi-shiki*, ceremony)." This tendency would be one of the factors of the lower identification rate of distinctive explanations generated by the Yomiuri corpus.

4.3 Evaluation of the proposed method

We then evaluated the proposed method with both steps. We used the output of PC-Talker XP as a comparison. On the basis of the results in Sec. 4.2, we used BCCWJ as the corpus in this experiment. We used 100 kanjis randomly selected from the 2,000 most frequent kanjis that were not limited to kanjis that had Type 1 distinctive explanations in PC-Talker XP. Table 3 shows the number of kanjis for each type used in PC-Talker XP.

We evaluated 200 distinctive explanations: 100 generated from our method and 100 extracted from PC-Talker XP. Sixty subjects were each shown 50 distinctive explanations. Thus each distinctive explanation was evaluated by 15 subjects.

When evaluating our system, we first asked the subjects to think of a kanji from the distinctive explanation generated by the first step described in the paper. If the subjects could not think of a kanji, we asked the subjects to look at the distinctive explanation generated by the second step and to think of a kanji. After that, we asked the subjects to choose one from the following:

Kanji	Google corpus	Yomiuri corpus	BCCWJ	PC-Talker XP
儀	"*gi* for *sou-gi*" 葬儀 (2/2) funeral	"*gi* for *yo-gi-na-i*" 余儀無い (0/2) unavoidable	"*gi* for *gi-shiki*" 儀式 (2/2) ceremony	"*gi* for *gi-shiki*" 儀式 (2/2) ceremony
貌	"*bou* for *bi-bou*" 美貌 (2/2) beauty	"*bou* for *gai-bou*" 外貌 (0/2) exterior	"*bou* for *bi-bou*" 美貌 (2/2) beauty	"*bou* for *bi-bou*" 美貌 (2/2) beauty
感	"*kan* for *kan-ji*" 感じ (0/2) feeling	"*kan* for *kan-jiru*" 感じる (2/2) feel	"*kan* for *kan-jiru*" 感じる (2/2) feel	"*kan* for *kan-shin-suru*" 感心する (2/2) be impressed
遥	"*you* for *you-hai*" 遥拝 (0/2) worshipping from afar	"*you* for *you-hai*" 遥拝 (0/2) worshipping from afar	"*you* for *you-hai*" 遥拝 (0/2) worshipping from afar	"*haru* for *haru-ka-kanata*" 遥か彼方 (2/2) far away
餅	"*hei* for *sen-bei*" 煎餅 (1/2) rice cracker	"*mochi* for *kiri-mochi*" 切餅 (1/2) sliced cracker	"*hei* for *sen-bei*" 煎餅 (2/2) rice cracker	"*mochi* for *mochi-tsuki*" 餅つき (1/2) mochi pounding
欄	"*ran* for *kū-ran*" 空欄 (2/2) blank	"*ran* for *ran-kan*" 欄干 (0/2) parapet	"*ran* for *ran-kan*" 欄干 (1/2) parapet	"*ran* for *ran-gai*" 欄外 (2/2) margin
点	"*ten* for *kyo-ten*" 拠点 (1/2) stronghold	"*ten* for *kyo-ten*" 拠点 (1/2) stronghold	"*ten* for *kan-ten*" 観点 (0/2) standpoint	"*ten* for *ten-sū*" 点数 (2/2) score
輸	"*yu* for *yu-nyū*" 輸入 (2/2) importation	"*yu* for *yu-nyū*" 輸入 (2/2) importation	"*yu* for *yu-nyū*" 輸入 (2/2) importation	"*yu* for *yu-shutu-su-ru*" 輸出する (2/2) export

Table 2: Examples of distinctive explanations and their evaluation. "$(n/2)$" means n subjects out of two chose **a**.

- I thought of a specific kanji from only the first distinctive explanation, and the kanji was
  $\mathbf{a_1}$. correct, $\mathbf{b_1}$. wrong.
- I thought of a specific kanji from the first and the second distinctive explanation, and the kanji was
  $\mathbf{a_2}$. correct, $\mathbf{b_2}$. wrong.
- **c**. I could not think of any kanji.

To evaluate our whole system, we regarded $\mathbf{a_1}$ and $\mathbf{a_2}$ as positive answers and calculated the identification rate (IR_2) as follows:

$$\mathrm{IR}_2 = \frac{n(\mathbf{a_1}) + n(\mathbf{a_2})}{n(\mathbf{a_1}) + n(\mathbf{b_1}) + n(\mathbf{a_2}) + n(\mathbf{b_2}) + n(\mathbf{c})} \times 100.\ [\%] \tag{7}$$

We also evaluated the distinctive explanations generated only by the first step in our system for comparison. For this evaluation, we regarded $\mathbf{a_1}$ as a positive answer and calculated the identification rate (IR_1) as follows:

$$\mathrm{IR}_1 = \frac{n(\mathbf{a_1})}{n(\mathbf{a_1}) + n(\mathbf{b_1}) + n(\mathbf{a_2}) + n(\mathbf{b_2}) + n(\mathbf{c})} \times 100.\ [\%] \tag{8}$$

Type	#	Example
Type 1	93	"*ka* for *ka-zei-su-ru* (課税する, tax)" "*ken* for *ken-ka-su-ru* (喧嘩する, fight)"
Type 2	0	-
Type 3	7	"*yorokobi-wo-imi-suruka* (happiness)" "*tsuchi-wo-hutatu-kasaneta kei* (to stack soil on soil)"

Table 3: The number of kanjis for each type used in PC-Talker XP.

	Our system using BCCWJ	PC-Talker XP
$\mathbf{a_1}$	1,181	1,301
$\mathbf{b_1}$	28	58
$\mathbf{a_2}$	163	-
$\mathbf{b_2}$	22	-
c	106	141
IR[%]	IR_1: 78.7, IR_2: 89.6	IR_{SR}: 86.7

Table 4: Evaluation results of our system outputs and distinctive explanations in screen reader.

To evaluate the distinctive explanations in PC-Talker XP, we asked the subjects to choose one from the following options:

a. I thought of a specific kanji that was correct.

b. I thought of a specific kanji that was wrong.

c. I could not think of any kanji.

For evaluating the screen reader, we regarded **a** as a positive answer and calculated the identification rate (IR_{SR}) as follows:

$$IR_{SR} = \frac{n(\mathbf{a})}{n(\mathbf{a}) + n(\mathbf{b}) + n(\mathbf{c})} \times 100. \ [\%] \tag{9}$$

Table 4 shows the results. We confirmed that our whole system outperformed PC-Talker XP. We conducted the McNemar's test and confirmed that our whole system (IR_2) and PC-Talker XP significantly differed at the 0.05 level. Distinctive explanations generated by our system seem to be longer and take more time to listen to than those of PC-Talker XP. However, users do not always need to hear the entire distinctive explanation of our system to think of a kanji. Table 5 shows the average length of distinctive explanations shown to the subjects. In 80.6 %[6] of cases, the target kanjis were correctly thought of in the first step. In addition, the average length of the first step's output was shorter than that of distinctive explanations of PC-Talker XP. The average length of our system output was 8.14, which was shorter than that of PC-Talker XP, and thus the comparison of (IR_2) and (IR_{SR}) is fair.

The identification rate of the first step (IR_1) was lower than both those of the screen reader (IR_{SR}) and the rate in Sec. 4.2 (IR). We think there are two reasons for this. The first

[6] $(1,181 + 28)/1,500 = 0.806$

	First step	Second step	The average length
Our system	6.80	13.93	8.14
PC-Talker XP	-	-	8.96

Table 5: The average lengths of distinctive explanations shown to the subjects.

Kanji	Our system		PC-Talker XP
	First step	Second step	
悟	"*go* for *kaku-go*" 覚悟 (9/15) preparation	"*sato* for *sato-ri*" 悟り (14/15) enlightenment	"*go* for *kaku-go, sato-ru*" 覚悟; 悟る (13/15) preparation; to realize
課	"*ka* for *ka-dai*" 課題 (13/15) assignment	"*ka* for *ka-zei*" 課税 (15/15) taxation	"*ka* for *ka-zei-suru*" 課税する (6/15) tax
灌	"*kan* for *yu-kan*" 湯灌 (1/15) wash a dead body	"*kan* for *kan-gai-you-sui*" 灌漑用水 (7/15) irrigation	"*kan* for *kan-gai-suru, soso-gu*" 灌漑する; 灌ぐ (1/15) irrigate; pour
藍	"*ran* for *ga-ran*" 伽藍 (0/15) temple	"*ai* for *ai-hara*" 藍原 (4/15) family name	"*ai* for *ai-iro*" 藍色 (12/15) indigo blue
圭	"*kei* for *kei-ji-rou*" 圭二郎 (2/15) first name	"*kei* for *kei-ichi*" 圭一 (4/15) first name	"*tsuchi-wo-hutatu-kasaneta kei*" (11/15) to stack soil on soil
嘩	"*ka* for *hū-hu-gen-ka*" 夫婦喧嘩 (4/15) marital quarrel	"*ka* for *ō-gen-ka*" 大喧嘩 (5/15) big fight	"*ken* for *ken-ka-suru*" 喧嘩する (1/15) fight
嘉	"*ka* for *ka-ei*" 嘉永 (0/15) era name	"*ka* for *ka-de-na*" 嘉手納 (0/15) place-name	"*yoroko-bi-wo-i-mi-suru ka*" 嘉 (1/15) that means happiness

Table 6: Examples of distinctive explanations generated by the whole our system and distinctive explanations in PC-Talker XP and their evaluation. "$(n/15)$" means n subjects out of 15 chose a positive answer.

is the differences between evaluation methods. While the prior evaluation (IR) contained the possibility of positive evaluation when subjects thought of multiple kanjis, this evaluation (IR_1) did not. The second is the use of different kanjis. While kanjis are limited to those that have Type 1 distinctive explanations in PC-Talker XP in the prior evaluation (IR), all kanjis were allowed in this evaluation. Even for the kanji unsuitable for the Type 1 distinctive explanation, our system has to output Type 1 distinctive explanations.

Table 6 shows examples of distinctive explanations and their evaluation. We confirmed that our system generates a better distinctive explanation for "課 (*ka*)" and "灌 (*kan*)." In the case of "課 (*ka*)," 13 subjects out of 15 successfully identified "課 (*ka*)" from distinctive explanations generated by the first step. However, two subjects could not identify the target kanji. This would be because our system outputted the distinctive explanation using the word "課題 (*ka-dai*, assignment)," which has homophones such as "過大 (*ka-dai*, excessive)" and "仮題 (*ka-dai*, a tentative title)." Since the remaining two identified the correct kanji by using distinctive explanations generated by the second step, we confirmed the effectiveness of the

proposed two-step method. On the other hand, only six subjects identified kanji from distinctive explanations of the screen reader. The cause of the low identification rate of the screen reader may be that subjects thought of "*ka-sei-suru* (加勢する, assist)" instead of "*ka-zei-suru* (課税する, tax)." In the case of "灌 (*kan*)," only one subject out of 15 identified "灌 (*kan*)" from our first step or the screen reader. However, when other subjects looked at distinctive explanations generated by the second step, seven identified "灌 (*kan*)." It can be inferred from these results that "灌 (*kan*)" is difficult to identify but our two-step approach is effective in such a case.

Conversely, the examples where our system was worse than the screen reader were the cases of "藍 (*ai* or *ran*)" and "圭 (*kei*)." In the case of "藍 (*ai* or *ran*)," our first step could not make anyone identify the kanji. In addition, even our second step made only four subjects identify the kanji. However, the screen reader succeeded in making 12 subjects identify the kanji. This is because our system cannot capture the specific features of "藍 (*ai* or *ran*):" in Japanese, "藍色 (*ai-iro*, indigo blue)" is a color. While the screen reader used words related to the color, our system used "伽藍 (*ga-ran*, temple)" and "藍原 (*ai-hara*, which is a Japanese family name)." The neither word includes information about the color. Such kanji-specific information is important but our system cannot use it well. For "圭 (*kei*)," our system used ambiguous words, and most subjects failed to identify the kanji[7]. In contrast, the screen reader achieved a high identification rate for this kanji, by using the distinctive explanation "Write 土 on top of 土 (*tsu-chi*, soil)." The use of kanji components or radicals as in this example by the screen reader, on top of our method, will further improve the identification performance.

Although we selected the top 2,000 frequent kanjis for the candidates of evaluation in order to eliminate the difficult kanji, some difficult kanjis still appeared. For example, in the case of "嘉[8] (*ka*)," our system and the screen reader made barely any subjects identify the kanji. We think that this is because "嘉 (*ka*)" itself is difficult.

Conclusion

In this paper, we proposed a method for automatically generating distinctive explanations for a kanji using a text corpus. The proposed method took into account familiarity and homophones of kanjis. As a result of human evaluation, we confirmed that distinctive explanations generated by our system outperformed those in existing screen readers.

Our future work involves incorporation of intonation, application to Chinese, and user adaptation. Intonation of words can help generate good distinctive explanations. For example, "橋 (*hashi*, bridge)" and "箸 (*hashi*, chopstick)" have the same readings but different intonations, so we think intonation can be a clue for identifying a kanji. Kanjis are used in not only Japanese but also Chinese. Since our proposed method is language-independent, our method can be applied to distinctive explanations for Chinese. Finally, we are considering generating distinctive explanations that consider the user attributes. For example, users who have studied the law will be familiar with legal terms but not medical terms. To adapt our system to different users, we can select a corpus that is suitable for them.

[7] "*Kei-ji-rou*" has homophones such as "慶二郎," "敬二郎," and "啓二郎" and "*kei-ichi*" have homophones such as "恵一," "慶一," and "啓一." All are Japanese male names.

[8] "嘉 (*ka*)" means happiness, but this kanji is rarely used.

ABSTRACT
Extracting biomedical named entities is one of the major challenges in automatic processing of biomedical literature. This paper proposes a machine learning approach for finding phenotype names in text. Features are included in a machine learning infrastructure to implement the rules found in our previously developed rule-based system. The system also uses two available resources: MetaMap and HPO. As we are not aware of any available corpus for phenotype names, a corpus has been constructed. Since manual tagging of the corpus was not possible for us, we started tagging only HPO phenotypes in the corpus and then using a semi-supervised learning method, the tagging process improved. The evaluation results (F-Score 92.25) suggest that the system achieved good performance and it outperforms the rule-based system.

KEYWORDS: Phenotype, Named Entity Recognition, MetaMap, Human Phenotype Ontology.

COLING 2012, Mumbai, December 2012.

1 Introduction

A large amount of biomedical knowledge is available in the biomedical literature. So, automatic processing of biomedical literature to capture and formalize this embedded information is very demanding. Current Natural Language Processing (NLP) systems try to extract from the biomedical literature different types of knowledge such as, protein–protein interactions (Leroy et al., 2003) (He and DiMarco, 2005) (Fundel et al., 2007) (kiong Ng and Wong, 1999) (Yu et al., 2005) (Bui et al., 2011), new hypotheses(Swanson, 1986) (Hristovski et al., 2005) (Hristovski et al., 2006), relations between drugs, genes, and cells (Rindflesch et al., 2000) (Friedman et al., 2001) (Tanabe et al., 1999), relations between genes and diseases (Rindflesch et al., 2003) (Coulet et al., 2010), protein structure (Humphreys et al., 2000) (Gaizauskas et al., 2003), and protein function (Andrade and Valencia, 1998) (Valencia, 2005).

Fundamental to each of these applications is the Named Entity Recognition and Classification (NERC) task. Research over the past years has shown that recognizing the names of biomedical objects is not a simple task. Factors that preclude a straightforward procedure include the existence of an ever-increasing large (millions) set of entity names, a penchant for the use of abbreviations, the use of synonyms, and the fact that some biological entities have complex names consisting of many words, like "increased erythrocyte adenosine deaminase activity", and lacking agreement on the name boundaries, even among biologists (Leser and Hakenberg, 2005).

Named Entity Recognition and Classification in the biomedical domain has been extensively studied. As a consequence, many methods have been proposed. Generic methods, like MetaMap (Aronson, 2001) and mgrep (Dai et al., 2008) recognize and classify many kinds of entities in text. Some methods, however, are specialized to recognize particular types of entities like gene or protein names (Krauthammer et al., 2000) (Gaizauskas et al., 2003), diseases and drugs (Rindflesch et al., 2000) (Xu et al., 2008) (Segura-Bedmar et al., 2008), mutations (Horn et al., 2004), and properties of protein structures (Gaizauskas et al., 2003). Each method employs one or more of the following techniques (Leser and Hakenberg, 2005): (1) dictionary-based techniques (like (Krauthammer et al., 2000)) which match phrases from the text against existing dictionary entries, (2) rule-based techniques ((Fukuda et al., 1998), for instance) which make use of lexical and linguistic rules to find entity names in the text, and (3) machine learning techniques (for example, (Nobata et al., 1999)) which treat the NER task as a classification problem. Some methods use hybrid approaches to find named entities: ChemSpot (Rocktäschel et al., 2012) blends Conditional Random Fields with dictionary matching to identify chemicals in texts, a biomedical name entity recognizer (Gong et al., 2009) uses POS tagging, rules and a dictionary, and a protein name recognizer (Seki and Mostafa, 2005) uses rules, a probabilistic model and a dictionary to find protein names in biomedical text.

Every day many research experiments are performed to discover the role of DNA sequence variants in human health and disease and the results of these experiments are published in the biomedical literature. Because of the large quantity of information, a reliable automatic system to extract this information for future organization is desirable. Human phenotypes comprise a very important part of this knowledge. Phenotypes are the observable characteristics of a cell or organism, including its appearance, its morphology, physiology and ways of life. A phenotype of an organism is determined by the interaction of its genetic constitution and the environment. Skin colour, height and behaviour are some examples of phenotypes.

Currently, many systems which use phenotypes to find information like phenotype-genotype re-

lations (for instance, (Coulet et al., 2010)) use only dictionary-based techniques to recognize the phenotypes in the text. Although many biomedical-term-specialized dictionaries are available, we are not aware of a dictionary which is both comprehensive and ideally suited for phenotype name recognition. For example, the Unified Medical Language System (UMLS) Metathesaurus (Humphreys et al., 1998) is a very large, multi-purpose, and multi-lingual vocabulary database that contains more than 1.8 million concepts. All concepts in the Metathesaurus are assigned to at least one semantic type, but *Phenotype* is not one of them. So, it alone is not adequate to distinguish between phenotypes and other objects in text. In addition, some phenotype names do not exist in the UMLS MetaThesaurus. The Pharmacogenetics Knowledge Base (PharmGKB) (Klein et al., 2001) attempts to collect all knowledge of how human genetic variation impacts drug–response phenotypes. It is a high quality database queried by clinicians and bioinformaticians. It is a manually curated database that summarizes published gene–drug–phenotype relationships. Nevertheless this manual curation process is not sustainable considering the growth of the scientific literature in this domain. The Online Mendelian Inheritance in Man (OMIM) (McKusick, 2007) is the most important single information source about human genes and genetic phenotypes (Robinson and Mundlos, 2010). Nonetheless, OMIM does not use a controlled vocabulary to describe the phenotypic features in its clinical synopsis section making it inappropriate for data mining purposes (Robinson and Mundlos, 2010). And, it is manually curated. The Human Phenotype Ontology (HPO) (Robinson and Mundlos, 2010) has been developed using information from OMIM. Although it contains approximately 10,000 terms, it is incomplete. Also, new phenotypes are being constantly introduced to the biomedical world and HPO currently is being refined, corrected, and expanded manually, meaning that it will have difficulty keeping pace with all the new phenotypes.

To our knowledge the only method to extract phenotype names automatically from text is the rule-based system we proposed in (Khordad et al., 2011). In the current paper we discuss a machine-learning-and-dictionary-based NER system that recognizes the human phenotype names in molecular biology literature which has been inspired by the rule-based method mentioned above. We have integrated existing databases (UMLS Metathesaurus(Humphreys et al., 1998) and the Human Phenotype Ontology (HPO) (Robinson and Mundlos, 2010)) and tools (MetaMap (Aronson, 2001) and BANNER (Leaman and Gonzalez, 2008)) to achieve our goal.

2 Background

2.1 MetaMap

MetaMap, a program developed by the National Library of Medicine (NLM) (Aronson, 2001), provides a link between biomedical text and the structured knowledge in the Unified Medical Language System (UMLS) Metathesaurus. To map phrases in the text to concepts in the UMLS Metathesaurus, MetaMap analyzes the input text lexically and semantically. First, MetaMap tokenizes the input text. In the tokenization process the input text is broken into meaningful elements, like words. After part of speech tagging and shallow parsing using the Specialist Lexicon, the text has been broken into phrases. Phrases then undergo further analysis: Each phrase is mapped to a set of candidate UMLS concepts, each candidate being given a score that represents how well the phrase matches the candidates. An optional last step is word sense disambiguation (WSD) which chooses the best candidate with respect to the surrounding text (Aronson, 2001).

MetaMap is configurable with options for vocabularies and data models in use, output format

and algorithmic computations. An example of the human-readable output format for the text “at diagnosis.” is shown in Figure 1. MetaMap finds 6 candidates for this phrase and after WSD it maps the phrase to the “diagnosis aspect” concept. In UMLS each Metathesaurus concept is assigned to at least one semantic type. In Figure 1 the semantic type of each concept is given in the square brackets. Semantic types are categorized into groups, called Semantic Groups (SG), that are subdomains of biomedicine such as Anatomy, Living Beings and Disorders (McCray et al., 2001). Each semantic type belongs to exactly one SG.

2.2 The Human Phenotype Ontology (HPO)

The Human Phenotype Ontology (HPO) (Robinson and Mundlos, 2010) provides a standardized vocabulary of phenotypic abnormalities encountered in human disease. The HPO was constructed using information initially obtained from the Online Mendelian Inheritance in Man (OMIM) (McKusick, 2007) expanded with synonym terms. The hierarchical structure in the HPO represents the subclass relationship. The HPO currently contains over 9500 terms.

2.3 The Rule-Based Method

In (Khordad et al., 2011) we proposed a rule-enhanced dictionary-based named entity recognition system based on MetaMap. The block diagram of the system is shown in Figure 2. In this system the input text is processed and each Noun Phrase is tagged by MetaMap. The UMLS semantic types are categorized into 15 more general and comprehensive categories called Semantic Groups (SG) (McCray et al., 2001). The definition of the SG *Disorders* is close to the meaning of Phenotype. SG *Disorders* contains 12 semantic types. (Khordad et al., 2011) categorized these semantic types into two categories : *Phenotypes* and *Phenotype Candidates*. Using the MetaMap output, Disorder Recognizer considers noun phrases in the Phenotype category as phenotypes and searches for the Phenotype Candidates in HPO to see whether they are phenotypes or not. OBO-Edit (an open source Java program) (Day-Richter et al., 2007)

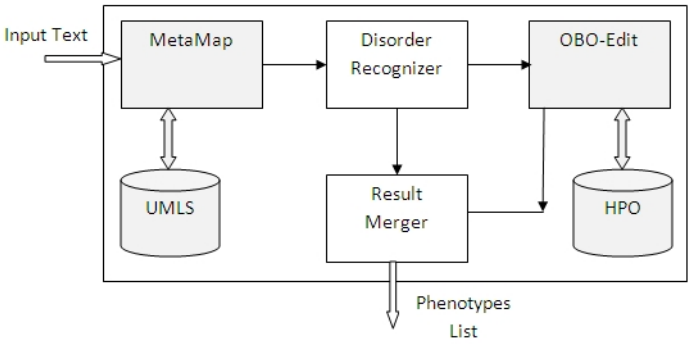

Figure 2: Rule-Based System Block Diagram.

has been used for searching in HPO. To improve the results 5 stylistic and linguistic rules are employed. These rules include:

- Rule 1: Resolve the acronym referencing problem by making and using a list of acronyms occurring in a paper.
  Often the names of phenotypes are used in acronym form. This makes it difficult to recognise them. However we can find the full form of them in their first usage.
- Rule 2: The semantic type of a noun phrase is the semantic type assigned by Metamap to its head.
  Sometimes MetaMap breaks a noun phrase to different parts with different Semantic Types. Using this rule it is possible to assign one semantic type to the whole noun phrase.
- Rule 3: If a phrase is "modifier (from the list of special modifiers (Burgun et al., 2009)) + [Anatomy] or [Physiology]" it is a phenotype.
  Some phenotypes follow a special pattern. There is a list of special modifiers (Burgun et al., 2009) which if come before a Noun Phrase in the SG *Anatomy* or *Physiology* make a phenotype.
- Rule 4: If the single form of a phrase is a phenotype, the plural form is a phenotype, too.
  This rule applies while searching in HPO, when the phenotype number in HPO is not in agreement with the noun phrase number in text.
- Rule 5: If the head of a phenotype candidate phrase is a phenotype, the whole phrase is a phenotype.
  This rule is also useful for searching in HPO. Sometimes a noun phrase in text contains a word in HPO but it is surronding with adjective and adverbs.

2.4 BANNER

BANNER (Leaman and Gonzalez, 2008) is an open-source biomedical named entity recognition system implemented using second order conditional random fields (CRF), a machine learning technique. The BANNER architecture is illustrated in Figure 3. A BANNER input file contains a text which has been separated into sentences. Each sentence is taken individually and is tokenized. The tokenization process in BANNER breaks tokens into either a contiguous block of

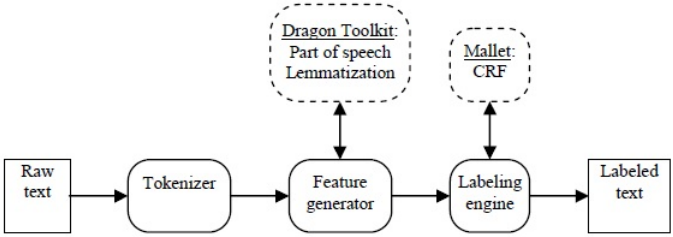

Figure 3: BANNER Architecture (Leaman and Gonzalez, 2008)

letters and/or digits or a single punctuation mark. As an example, the string "Bub2p-dependent" is broken into 3 tokens: "Bub2p", "-", and "dependent". In the next step features are assigned to each individual token. Each feature is a name/value pair for use by the machine learning algorithm. And finally in the labeling process, each feature gets exactly one label. BANNER makes use of the Mallet CRF (McCallum, 2002) in both feature generation and labeling. The set of machine learning features used in BANNNER is listed in Table 1.

Feature set definition	Description
The part of speech which the token plays in the sentence	Provided by the Dragon toolkit implementation of the Hepple tagger.
The lemma for the word represented by the token, if any	Provided by the Dragon toolkit.
A set of regular expression features	Includes variations on capitalization and letter/digit combinations.
2, 3 and 4-character prefixes and suffixes	
2 and 3 character n-grams	Including start-of-token and end-of-token Indicators
Word class Convert	upper-case letters to "A", lowercase letters to "a", digits to "0" and other characters to "x"
Numeric normalization	Convert digits to "0"
Roman numerals	
The names of the Greek letters	

Table 1: Set of features in BANNER (Leaman and Gonzalez, 2008)

BANNER considers a token window of 2 to make features, meaning that the features of each token contains the features of the two previous and the two following tokens.

BANNER has been used for NER in the Gene names and the disease names domains, and it has achieved results comparable with other NER systems in these domains.

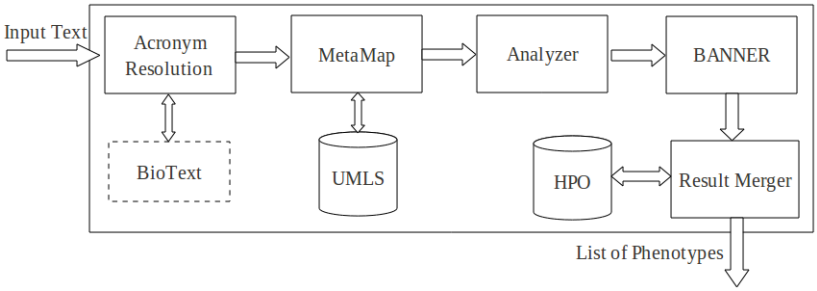

Figure 4: System Block Diagram

3 Proposed Method

The rule-based system described in Section 2.3 achieves good results. However, it, like other rule-based methods, has some shortcomings. As the rules are extracted from a small corpus, they may be overfitted to that corpus and cannot cover new phenotypes in other texts. And if we wish to use it on a larger corpus, we may need to add extra rules. It is not easy to analyse the errors manually to generate the new rules. So, we decided to extend the capabilities of our rule-based system using machine learning methods.

BANNER is open-source and it provides a good infrastructure for NER. Its results are convincing and features can be easily added. Therefore starting with BANNER and its CRF method, the rule-based method was incorporated to it.

The block diagram of the system is illustrated in Figure 4. The first phase in this system is finding acronyms in the input text and resolving them. Usually, papers indicate the local unambiguous reference for each acronym used at its first usage. So acronym resolution is done, making a list of local full forms for acronyms (according to rule 1 of the rule-based method). Then the output which does not contain any acronym is processed by MetaMap. According to our settings, MetaMap finds composite noun phrases with up to 3 simple phrases and prints out the syntax of each noun phrase. Each noun phrase is also tagged with a semantic type. The Analyzer analyses the MetaMap output and changes it to BANNER input format. Our feature-enhanced BANNER takes each sentence separately and using the features, finds some phenotypes. In the last step the system searches for the HPO phenotypes in the text and found phenotypes are added to our list of phenotypes. The details of how we made use of rules and features in our machine learning method are explained in the following sections.

3.1 Incorporating the rules

Rule 1 *Acronym Resolution* implements Rule 1. It finds the full forms of acronyms using their local unambiguous reference in the text and replaces acronyms with their unabbreviated forms. BioText (Schwartz and Hearst, 2003) has been used to make a list of acronyms and their full forms in the text.

Rule 2 This rule is implemented in *Analyzer*. Analyzer finds the noun phrases and their heads from the MetaMap output. If Metamap breaks a noun phrase into different parts and

assigns different semantic types to them, the Analyzer assigns the semantic type of the head to the whole phrase. An example of such a phrase and the Analyzer output is shown in Figure 5. The phrase "of Diamond-Blackfan anemia patients" is broken into two noun phrases "Diamond-Blackfan anemia" and "patients", each with a different semantic type. MetaMap output shows that the head of the whole phrase is "patients" so analyzer assigns its semantic type, i.e. *Patient or Disabled Group*, to the whole phrase.

Rule 3 To help our machine learning method learn this rule, three binary features were added to the system: *Special Modifier*, *Anatomy* and *Physiology* to indicate whether a noun phrase is in the Special Modifier, Anatomy or Physiology classes. Furthermore, some sentences containing this class of phenotypes (*Special Modifier* + [Anatomy] Or [Physiology]) were added to our training set.

Rule 4 When the Result Merger searches for HPO phenotypes in the text, it searches for their singular and plural forms.

Rule 5 This rule is considered in Result Merger: if the head of a noun phrase is found in HPO the whole noun phrase is tagged as a phenotype.

3.2 Adding features

To implement the rule-based system completely, Rule 3 was added as three features to the CRF, in addition to the features already possessed by BANNER. Finally, some other features which seemed to be helpful were added to the system. These features were tested several times and finally the best set of features were selected. These features include:

1. Phenotype: This feature comes from the rule-based method (see Section 2.3). In this method semantic types in SG *Disorders* are categorized into two categories. This feature is a binary feature that indicates whether a noun phrase is in the *Phenotypes* category.
2. Phenotype Candidates: This feature is a binary feature that indicates whether a noun phrase is in the *Phenotype Candidates* category of SG *Disorders*.
3. Special Modifier: A binary feature that indicates whether a noun phrase is in the list of special modifiers (Burgun et al., 2009).
4. Anatomy: A binary feature which means a noun phrase is in SG *Anatomy* or not.
5. Physiology: A binary feature which means a noun phrase is in SG *Physiology* or not.
6. List Separator: We found out that usually in biomedical literature when a number of elements in a list are phenotypes, there is a good chance that the other elements are phenotypes too. The List Separator feature was added to designate the availability of list indicators (*and* or *comma*) in the sentence.
7. Semantic type: The semantic type which is assigned by MetaMap to noun phrases. This feature is null for other phrases.
8. NP: A binary feature which indicates whether a token is a part of a noun phrase.
9. POS: The part of speech of a token. This feature is available in BANNER.
10. Lemma: The lemma of each token. This is available in BANNER.
11. NPstart: A binary feature to indicate whether a token is the first token in a noun phrase.
12. NPend: A binary feature to designate whether a token is the last token in a noun phrase.
13. 2, 3 and 4-character prefixes and suffixes: This is a part of BANNER.
14. 2 and 3 character n-grams: This is a part of BANNER.

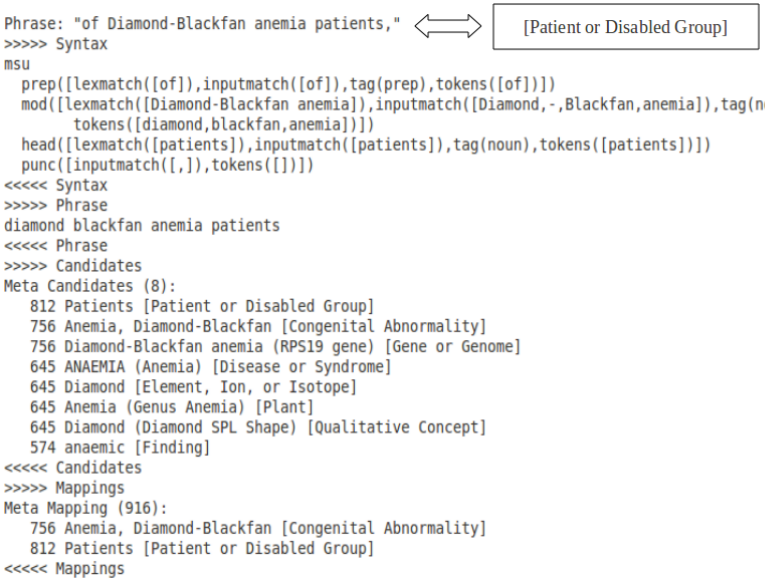

Figure 5: Analyzer Example

Also, it should be remembered that BANNER makes a window of size 2 for each token, i.e. features of each token contain features of the 2 tokens before and the 2 tokens after it. We used the default configuration of BANNER. The NP feature comes from the MetaMap results and the POS feature is provided by BANNER. They do not align perfectly, but it is the task of the CRF to find a solution using these conflicting features.

3.3 Corpus

The most significant problem for us in using the machine learning method was the lack of an annotated specialized corpus of sufficient size. As no one before has used machine learning on phenotype name recognition, no corpus was available for us to train and test our system with. Therefore we had to make our own corpus with a sufficient number of sentences. However, making a large corpus is a very difficult and time consuming task. So we decided to use semi-supervised learning to make our corpus.

3.3.1 Collecting the papers

To find the papers which are relevant to phenotypes, we started with two available databases: PubMed (2009) and BioMedCentral (2004). All HPO phenotypes were searched for in these databases and every paper which contained at least three different phenotypes was added to our collection. In this way we found 100 papers which were used to train the system. We had another 13 papers which had been collected for the development of the rule-based method (see Section 2.3) and were annotated manually. These 13 papers were used to test the system.

3.3.2 Annotating the corpus

As it was not possible for us to annotate the 100 papers manually, we used a semi-supervised learning method starting with the information provided by HPO. First, HPO phenotypes were searched for in the set of papers and were tagged as phenotypes. These papers along with their tags made our initial training corpus. When annotating the corpus, it should be noted that the last phase of the system (the Result Merger) was omitted because all HPO-annotated phenotypes were already annotated.

The trained model was used to annotate the training set again. The newly found phenotypes were analysed manually and the correct ones were added as annotations to the training set. Also, on each iteration, the system was tested using the test set to find out how many iterations would be sufficient for training the system. This process was repeated several times until we reached the results that we were satisfied with when testing the last model on the test set.

One important point to mention is that we only included positive sentences (sentences with at least one phenotype) in our training set, because the number of negative sentences was far greater than positive sentences and it prevented the system from training efficiently. Therefore, whenever new phenotype names were found, the number of sentences in the training set increased for the next iteration.

4 Evaluation

We compared the performance of our system against the rule-based system (Khordad et al., 2011), which is the only specialized system for phenotype name recognition that we are aware of. The final training corpus which is made from 100 papers contains 2755 sentences and 4233 annotated phenotypes. All sentences in this corpus include at least one phenotype. A test set is collected from 13 papers and includes 216 sentences and 373 phenotypes.

To evaluate the system, 10-fold cross validation has been used. Also the system has been tested using a separate test set. Table 2 gives the details of the results. The base system is our machine learning method ignoring the Result Merger. Result Merger finds HPO phenotypes in text and adds them to the list of phenotypes. The results after using Result Merger are mentioned in the column labelled *HPO added*. The rule-based system has been tested using the test set and the results are displayed in Table 3. To calculate these results, a returned phrase is considered to be a true phenotype if its head contains a phenotype. For example, in the phrase “acute myloid leukemia” the head is “leukemia”, a phenotype that is confirmed by its inclusion in HPO. However, in the phrase“Diamond-Blackfan anemia patients” the correct phenotype is: “Diamond-Blackfan anemia”. If the system returns “Diamond-Blackfan anemia patients” as the phenotype, it is deemed false.

As this table demonstrates, the results are comparable with other named entity recognition systems which are specialized for finding other biomedical entities even though they may have larger training corpora. For example BANNER has been trained and tested for finding gene names, using BioCreative 2 GM corpus containing 15,000 sentences (7500 for training and 7500 for testing) which is much larger than our current corpus. However our results are really better than Banner’s (Precision 85.09, Recall 79.06 and F-measure 81.96)(Leaman and Gonzalez, 2008). Although our task is different these results mean that our system is performing well.

In addition the machine learning method outperformed the rule-based method, even though the corpus is not fully annotated. We believe that if we had a fully annotated corpus the system would achieve an even better performance.

	Base system			HPO Added		
	Precision	Recall	F-measure	Precision	Recall	F-measure
10-Fold	82.83	68.13	74.35	86.89	98.33	92.25
Test Set	93.44	57.37	71.09	95.76	90.88	93.25

Table 2: System Evaluation Results

	Precision	Recall	F-measure
Machine Learning Method	95.76	90.88	93.25
Rule-Based Method	88.34	73.19	80.05

Table 3: Comparing the system with the Rule-Based Method

To have an idea of how well our annotation process works, we selected 100 random sentences from our corpus. Then, we tagged these sentences manually. There were 157 phenotypes in these 100 sentences. Our semi-supervised machine learning method found 142 phenotypes and 1 of its phenotypes was incorrect, i.e. it missed 16 phenotypes. So, the annotation process misses about 10 percent of the phenotypes.

5 Discussion

Finding the best set of features is one of the most important parts of developing the system. Tables 4 and 5 show the role and importance of each feature. To illustrate the contribution of each feature in Table 4 we considered a small set of features as the basic set of features for our system. These features came from the rule-based system and are very important in signifying phenotype names in the text. Then, in each line a feature is added to the basic feature set until we have the complete feature set in the last line. Adding some features (Phenotype candidates, List separators, Semantic Types, and Lemma) drops the results slightly but the results of the last feature set is better than the previous feature sets.

Analysing Table 4, it may seem that including some features is not necessary. Table 5 illustrates the role of each feature in a different way. In each line of Table 5 only one feature is ignored from the feature set and the system is tested using the separate test set. Note that the results are calculated without adding the HPO. As one can see, removing each feature reduces the results slightly. The exception to this modest reduction in performance is the removal of the NP feature which causes a significant drop in precision and recall, because not having NP information causes errors in finding NP end and NP start. In some cases (Lemma, Phenotype candidates, NP start and NP end, and Physiology) ignoring the feature causes small improvement in precision or recall. However the F-score is always less than the F-score of final results.

Reviewing the results, it has been found that both the rule-based and machine learning methods are dependent on MetaMap. MetaMap does make mistakes. MetaMap makes some errors in finding the boundaries of NPs and in determining the semantic types. NP boundaries and semantic types are features used by both methodologies, so the errors made by MetaMap have effects on the performance of each system. However the rule-based system is more dependent on MetaMap output and errors in MetaMap output changes the results completely. But the machine learning system is more robust and it sometimes finds the correct phenotype names despite Metamap errors. For example consider the sentence *"Diamond-Blackfan anemia is a rare inherited bone marrow failure syndrome."*. The phrase *Diamond-Blackfan anemia* is a phenotype but MetaMap assigns the [Gene or Genome] semantic type to it, which is not in the SG *Disorders*.

Features	Precision	Recall	F-Score
Phenotype, Anatomy, Physiology, Special Modifier	89.89	47.72	62.34
+Phenotype candidates	90.72	47.18	62.07
+List Separator	90.41	40.48	55.92
+Semantic type	90.24	49.59	64
+NP	90.24	49.59	64
+POS	91.15	55.22	68.77
+Lemma	92.72	54.69	68.79
+NP start, NP end	93.44	57.37	71.09

Table 4: Contribution of each additional feature

Ignored Feature	Precision	Recall	F-Score
Anatomy	92.82	55.49	69.45
Lemma	93.57	54.69	69.03
List Separator	91.66	56.03	69.54
Phenotype	92.54	56.56	70.20
NP	81.81	38.6	52.45
Phenotype Candidate	92.64	57.37	70.85
NP start and NP end	93.18	54.95	69.13
Physiology	93.21	55.22	69.35
POS	92.05	52.81	67.11
Semantic Type	91.89	54.69	68.56
Special Modifier	92.44	55.76	69.56

Table 5: Contribution of each feature

So the rule-based system does not tag it as a phenotype. The phrase *missing vertebrae* is another example of MetaMap errors. MetaMap does not consider this phenotype name as one NP. It separates this phenotype name into two phrases *missing* and *vertebrae*.

In addition determining the boundary of an NP is very important in the rule-based system. MetaMap has an option to make larger NPs by merging simpler NPs. If we only use simple NPs, we cannot get larger phenotype names as one NP and the system will miss them. The phrase *Partial hypoplasia of the corpus callosum* is an example of a phenotype name with composite NPs. On the other hand if we use composite NPs, the head of the NP may change and the semantic type of the NP may change as a result. This is problematic for the rule-based system. The phrase *the associations of facial dysmorphism* is an example. The word "associations" is the head of this phrase, so the semantic type [Mental Process] is assigned to it and it is not tagged as a phenotype name by the rule-based system.

On the other hand, there are some cases in which MetaMap assigns the correct semantic type to a phrase and found a good boundary for a phenotype name but the machine learning method does not mark it as a phenotype. For example "arhinia" is not tagged as a phenotype by the machine learning method in the following sentence *"These phenotypes may resemble that of the only confirmed case of an individual with a lethal compound heterozygous PAX6 mutation and may include anophthalmia, arhinia and severe central nervous system defects"* although MetaMap assigns the semantic type [Congenital Abnormality] (which is in the category of Phenotypes) to it.

Table 6 shows how many false negatives and true positives are available in the final results for both the machine learning and the rule-based methods. And Table 7 illustrates the percent of these errors caused by MetaMap or the boundary of noun phrases.

	Rule-based	Machine Learning
True positives	273	339
False negatives	100	34

Table 6: number of TPs and FNs in each method

	Rule-based	Machine Learning
MetaMap errors	37%	11.76%
NP boundary errors	26%	8.82%

Table 7: Analysis of NPs

Comparing the precision errors gave interesting observations. There are no common errors between the two systems. False positive errors in the rule-based system were caused by the rules not being discriminating enough. For each returned phrase, one of the rules produced that phrase. But there are exceptions to each rule that can cause these false positive errors. The exceptions to the rules do not cause any problem for the machine learning system. The machine learning system was able to learn all of these exceptions. For the false phenotypes returned by the machine learning system, analysis indicates that none of these would be suggested by application of a rule in the rule-based system, explainging why there are no common errors.

Conclusion

In this paper we discussed the development of a named entity recognition system which is specialized to find phenotype names in biomedical literature. The system has been generated using machine learning. Some of its features are based on the rules found in our previous rule-based method (Khordad et al., 2011). We added some other features. The system makes use of MetaMap and HPO.

As there was no annotated corpus available for training the machine learning system, a corpus was annotated using a semi-supervised learning method and HPO. The corpus does not fully annotate all phenotype names. About 10 percent of the phenotype names are missed.

The system has been evaluated using both a 10-fold cross validation and a separate test set and the results are really promising.

The current system is extremely dependent on MetaMap output, although it is less dependent than the rule-based system. Still, when MetaMap gives erroneous output, it makes it difficult for our system to work correctly. In addition the corpus is not completely annotated and its annotation has some errors.

Despite these problems, the system achieved an F-Score of 92.25 and its performance is comparable to other NER systems which are specialized for finding other entities in biomedical literature.

To improve the system performance, it is imperative to overcome the phenotype name recognition errors initiated by MetaMap parsing errors. Using a more reliable partial parser to provide the NPs for MetaMap's mapping to UMLS concepts, instead of using the Metamap embedded

parser, may fix this problem. Furthermore, adding more features to the machine learning system can be considered. Finally, a machine learning method other than CRF might achieve better results.

ABSTRACT
This paper presents a novel method of improving Combinatory Categorial Grammar (CCG) parsing using features generated from Dependency Grammar (DG) parses and combined using reranking. Different grammar formalisms have different strengths and different parsing models have consequently divergent views of the data. More specifically, dependency parsers are sensitive to linguistic generalisations that differ from the generalisations that the CCG parser is sensitive to, and which the reranker exploits to identify the parse most likely to be correct. We propose DG-derived reranking features, which are obtained by comparing dependencies from the CCG parser with DG dependencies, and demonstrate how they improve the performance of a CCG parser and reranker in a variety of settings. We record a final labeled F-score of 87.93% on section 23 of CCGbank, 0.5% and 0.35% improvements over the base parser (87.43%) and reranker (87.58%), respectively.

KEYWORDS: Combinatory Categorial Grammar (CCG), Dependency Grammar (DG), Reranking, Dependency Grammar-derived features, parsing, syntax.

Proceedings of COLING 2012: Technical Papers, pages 1441–1458,
COLING 2012, Mumbai, December 2012.

1 Introduction

Reranking is the process of rescoring an *n*-best list with an external model, and it is an effective method for improving performance in NLP tasks. In parsing, rerankers are able to incorporate arbitrary global features from the entire parse tree that would be intractable in a base parser. More informative features can be considered in reranking as the entire parse tree is available, as opposed to the fragments considered in parsing.

In this paper, we propose a simple method for improving the performance of the C&C Combinatory Categorial Grammar (CCG) parser (Clark and Curran, 2007). We parse sentences using the C&C *n*-best parser and a 1-best dependency grammar (DG) parser, and generate DG-derived features by comparing the extracted dependencies from the C&C parser with the DG dependencies. We then incorporate the DG-derived features into the CCG reranker of Ng et al. (2010) to reorder the *n*-best CCG parses using the external parse information. We experiment with both the Maltparser (Nivre et al., 2007b) and the MSTparser (McDonald et al., 2005) as the DG parser. This is the first cross-formalism parser combination experiment for CCG parsing that we are aware of, combining the features and strengths of two different formalisms together.

Previous work has shown that dependency parsers such as the Maltparser perform better on short-range dependencies (McDonald and Nivre, 2007), whereas the C&C parser deals with long-range dependencies more reliably (Clark et al., 2002; Rimell et al., 2009). Short-range dependency information has also been shown to improve parser accuracy (Chen et al., 2009). We show how our new DG-derived features substantially improve parser performance by 0.35% to 87.93%, and improve the accuracy of the C&C parser on both short and long-range dependencies. These results demonstrate how rerankers can successfully combine diverse features from different formalisms for better parsing accuracy.

2 Background

2.1 Reranking and Cross-formalism Parser Combination

Collins (2000) describes reranking for the Collins (Model 2) parser and defined the general approach that has been used for the task since. Reranker training data is produced by parsing 36,000 sentences from sections 02-21 of the Penn Treebank WSJ data (Marcus et al., 1993) using an *n*-best version of the base parser. The parser model used for this process is trained using cross-validation to ensure that overly optimistic parses are not produced. Global features calculated over the whole tree such as context-free rules, *n*-gram ancestors, parent and grandparent relationships, and lexical heads and the distances between them are extracted from the parses and fed into a boosting-based reranker. Collins reports a final PARSEVAL F-score of 89.75%, a 1.55% improvement compared to the baseline parser.

The oracle F-score (given a perfect reranker that always chooses the best *n*-best parse for a sentence) is used to measure the quality of *n*-best parses. Huang and Chiang (2005) describe efficient *n*-best parsing algorithms that have become widely used in the field, including in the Charniak and Johnson (2005) reranker. This system uses a similar setup to the Collins reranker, but adopts a maximum-entropy model along with additional features, including features for subject-verb agreement, *n*-gram local trees, and right-branching factors. In 50-best mode the parser has an oracle F-score of 96.80%, and the reranker produces a final F-score of 91.40% compared to an 89.70% baseline.

Farkas et al. (2011) rerank BitPar, an unlexicalised generative PCFG parser for German (Schmid,

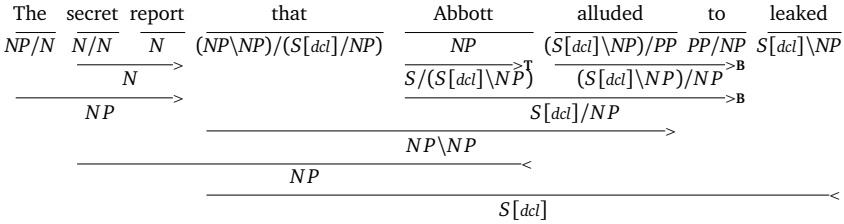

Figure 1: An example CCG derivation using application, composition, type-raising, and unary rules. A long-range dependency is created between *report* and *to*, mediated by *that*.

2004) using dependency grammar features and forest-based rerankers. Bohnet (2010), which is a second order dependency parser, was used to generate parses for feature extraction. Their experimental results show a 0.8% F-score improvement. However, their work was only concerned with extracting additional features from the dependency parses, and does not generate features based on a comparison between the extracted dependency parses and the constituency parses that are being reranked.

Øvrelid et al. (2009) describe a two-stage system where the output of an LFG parser is used to provide features for the Maltparser in English and German. They observe a 0.15% improvement in Maltparser unlabeled attachment scores for English, and 1.81% improvement in German. This work exploits analyses from different formalisms, but it completely retrains the Maltparser with additional features based on a conversion of the LFG analyses to a dependency representation. It also targets improved dependency parsing rather than improved grammar-driven parsing. Sagae et al. (2007) used the output of dependency parser to disambiguate Head-driven Phrase Structure Grammar (HPSG) parses. This work used a single penalty parameter for each mismatch between the DG and HPSG parses that was set via a parameter sweep on held-out data.

2.2 Combinatory Categorial Grammar

Combinatory Categorial Grammar (CCG; Steedman, 2000) is a lexicalised grammar formalism based on combinatory logic. Lexical categories govern the syntactic behaviour of each word, and generic combinatory rules combine categories together to form an analysis of a sentence.

Atomic categories such as noun phrases (*NP*) and sentences (*S*) represent syntactically complete constituents. Complex categories are binary functors of the form A/B or $A\backslash B$, and subcategorize for an argument category B to the right or left respectively to form an A. For example, transitive verbs ($(S\backslash NP)/NP$) subcategorize for an object *NP* to the right to form a verb phrase $S\backslash NP$, which in turn expects a subject *NP* to the left to form a sentence *S*.

The simplest combinatory rules are forward and backward application, where complex categories acquire their outermost argument and return their result. Additional combinators are based on composition and unary category type-changing, increasing the generative power of the formalism and enabling the analysis of phenomena such as *wh*-movement and right-node raising. Figure 1 gives an example CCG derivation using these combinators.

We will use the CCG dependency representation of CCGbank (Hockenmaier and Steedman,

2007) in this work. Each dependency expresses a word-word relationship between a head and a dependent, generated when the assigned categories are combined. Additionally, CCG allows for the production of long-range dependencies mediated by intermediate words in the sentence. This allows a clear representation of function and trace information that would require co-indexation in phrase-structure parses. These dependencies have the following form: $\langle to, PP/NP_1, 1, report, (NP\backslash NP)/(S[dcl]/NP)\rangle$, which includes the head word, its category, the argument slot, argument word, and the mediating category for long-range dependencies.

2.3 CCG parsing

The C&C parser is a fast and accurate wide-coverage CCG parser. It is a two-stage system, where a supertagger assigns probable categories to words in a sentence and the parser combines them using the CKY algorithm. The parser has been found to be particularly accurate at recovering long-range dependencies (Clark et al., 2002; Rimell et al., 2009).

C&C is trained on CCGbank, a conversion of the Penn Treebank WSJ data to CCG derivations and dependencies (Hockenmaier and Steedman, 2007). We use the normal-form model described in Clark and Curran (2007), which models the probability of derivations. We also follow the convention of using section 00 of CCGbank as development data, sections 02-21 as training data, and section 23 for final testing. The standard evaluation metric is labeled dependency recovery, as described by Clark and Hockenmaier (2002).

Clark and Curran (2007) develop a conversion from CCG dependencies to Briscoe and Carroll-style grammatical relations (GRS) (King et al., 2003; Briscoe and Carroll, 2006). GRS provide a useful abstraction as they allow the conflation of many CCG dependencies that are semantically similar but structurally different. For example, since subcategorization information is fully specified in categories, the verb-subject relationship is expressed in many different forms in CCG depending on the transitivity of the verb. In the GR scheme, they map to a general `ncsubj` dependency, echoing the underlying similarity between the CCG dependencies.

Rimell and Clark (2009) adapt the C&C parsing for the biomedical domain, and in the process they developed a mapping from CCG dependencies to Stanford dependencies based on the GR conversion. We generate DG-derived features based on this Stanford dependency output of the C&C parser to maximise the potential overlaps between the representations; this differs from the existing C&C reranking features, which use the CCG dependency format (Ng et al., 2010).

Figure 2 shows the CCG derivation and corresponding Stanford dependencies for the example sentence, *We are about to see if advertising works*, taken from WSJ section 22.

2.4 Dependency parsing

Dependency Grammars (DG) describe the syntactic structure of a sentence in terms of head-dependent relations between words. The set of dependency relations for a sentence forms a dependency tree with a special root head word. Unlike CCG, DG directly model relationships between pairs of words, and do not easily account for mediated long-range dependencies. CCG categories encoded detailed subcategorization information that is not present in DG labels, and the restrictions in combinator application constrain the way CCG derivations can be built, whereas dependency arcs may appear between any pair of words under a DG. Thus, we expect that CCG and DG analyses will provide markedly different insights, despite both producing dependency-style output.

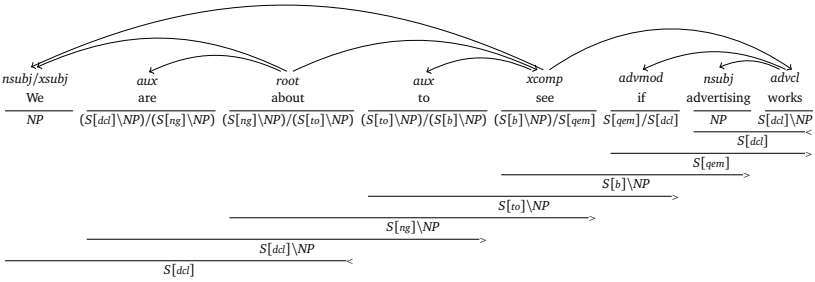

Figure 2: A CCG derivation and the Stanford dependencies produced by applying the Rimell and Clark (2009) conversion on the parse.

2.5 DG Representation Schemes

We experimented with four different dependency schemes; for each scheme, we retrained the Maltparser and the MSTparser over the extracted dependencies from the Penn Treebank WSJ data. 20-fold cross-validation was used to generate the parses corresponding to the reranker training data (sections 02-21); sections 02-21 was used to create a model for use at test time.

CoNLL: The CoNLL DG was used in the CoNLL 2007 dependency parsing shared task (Nivre et al., 2007a). Penn2Malt, a publicly available conversion utility[1], was used to generate CoNLL dependencies for our experiments. In contrast to other grammars used in this paper, this dependency scheme contains only unlabeled word-word arcs.

Stanford: de Marneffe and Manning (2008) introduced the dependency scheme used in the Stanford parser[2]. We used the Stanford parser's built-in converter to transform Penn Treebank trees into dependencies. The Stanford scheme has different variants; for this work we use the basic projective tree schema.

LTH: The LTH dependency scheme was developed with the aim of making better use of the linguistic information present in the Penn Treebank from version II onwards (Johansson and Nugues, 2007). We generated these dependencies using the LTH converter[3] over the NP-bracketed version of the Penn Treebank described by Vadas and Curran (2007). The converter was configured to produce a functional rather than lexical DG.

Fanse: Another conversion of the Penn Treebank with more fine-grained labels was presented in Tratz and Hovy (2011). The Fanse scheme is linguistically rich, featuring both non-projective dependencies and shallow semantic interpretation in its analyses. We used the freely available converter[4], which also requires the Vadas and Curran (2007) NP-bracketed Penn Treebank.

Figures 3 and 4 demonstrate some of the differences between the four dependency schemes. For instance, auxiliaries take the lexical verb as a dependent in all schemes except for Stanford,

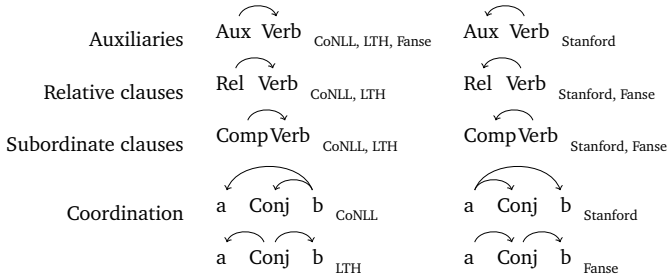

Figure 3: Analyses of auxiliaries, relative/subordinate clauses and coordination in the DG schemes.

where the lexical verb is the head of a *VP*. The characteristics of each scheme mean that each one produces an analysis that is quite different to the others as well as to CCG; by investigating a variety of schemes we hope to identify characteristics which are useful in our cross-formalism experiment.

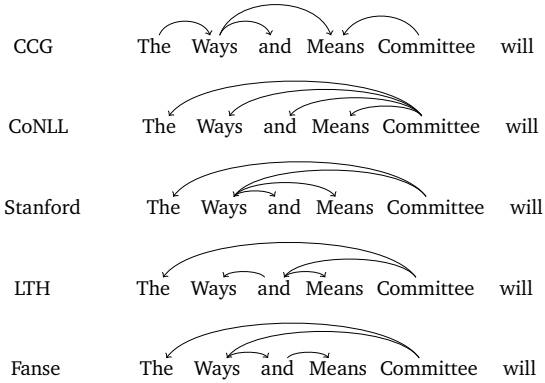

Figure 4: Example of divergence on the interpretation of the coordination by each scheme.

2.6 Maltparser and MSTparser

DG schemes	Maltparser	MSTparser
CoNLL	**90.46**	88.77
Stanford	89.82	87.27
LTH	84.54	86.67
Fanse	89.96	**89.61**

Table 1: Unlabeled Attachment Scores for each scheme over WSJ section 22.

In this work we use the Maltparser, a transition-based dependency parser (Nivre et al., 2007b),

and the MSTparser, a graph-based dependency parser (McDonald et al., 2005). The Maltparser uses an incremental shift-reduce algorithm, with actions guided by a classifier trained over parse history information. In contrast, the MSTparser builds a weighted graph for sentences, and finds the parse corresponding to the maximum spanning tree of the graph.

Table 1 shows the Unlabeled Attachment Scores (UASs) over WSJ section 22 for the Maltparser and the MSTparser with respect to four DG schemes[5]. The Maltparser has the highest UAS (90.46%) with the CoNLL DG, while the MSTparser performs best (89.61%) using the Fanse DG. Both parsers perform the worst with the LTH DG and by a substantial margin: 6% F-score for the Maltparser and 3% for the MSTparser compared with the best result. These results lead us to expect that features generated from Maltparser output will perform better than those from the MSTparser, LTH scheme notwithstanding.

3 CCG reranking

We follow the CCG reranker implementation described in Ng et al. (2010) and use the *n*-best C&C parser described in Brennan (2008); Ng and Curran (2012). This reranker is inspired by Charniak and Johnson (2005), with many new features designed to address specifics of the CCG formalism and evaluation process. For each *n*-best parse, the reranker uses a regression model to predict its expected F-score, and chooses the model with the highest predicted score. The log score and rank assigned to each derivation by the parser were encoded as core features in the reranker, and here we briefly summarise the other feature groups:

Tree Topology features describe the overall shape of the parse tree, to capture the fact that English generally favours right-branching parse trees, with heavy constituents generally occurring in the sentence-final position.

Local Context features represent fragments of the tree as well as layers of vertical and horizontal context that are difficult to encode in the parser model.

Argument-Adjunct features represent different attachment points for arguments and adjuncts and their wider context. Incorrect argument-adjunct distinctions can cause multiple CCG dependency errors due to the subcategorization information encoded in CCG categories.

Grammar-based features encode combinator sequences or combinations that may indicate an overly complicated or undesirable derivation. Additionally, these features encode the actual dependencies as these are the target of the evaluation.

C&C features from the parser are also incorporated as described in Clark and Curran (2007). These features encode combinations of word-category, word-POS, root-word, CCG rule, distance, and dependency information.

4 DG-derived Features

This section describes the DG-derived features. For convenience, we refer to the converted Stanford dependency output of an *n*-best CCG parse as the CCG *Dependency Parse* (CDP), as opposed to the *Malt/MST Dependency Parse* (MDP).

Our DG features are designed to capture the desirable and undesirable characteristics of the CDP and MDP, as well as the ways in which dependencies match and mismatch between the two. The dependencies from each *n*-best CDP are compared pairwise with the dependencies from the

[5] 20-fold cross-validation on sections 02-21 is used to create reranker training data.

1-best MDP for the corresponding sentence. *Matching* dependencies are those where the head and dependent are the same in the CDP and MDP. These dependencies also have a directionality component: whether the match occurs in the *same* direction (head and dependent are the same in CDP and MDP), or in the *reverse* direction (head and dependent are in opposition in the CDP and MDP). *Mismatching* dependencies are classified as being a head-dependent pair existing only in the CDP, or only in the MDP.

Our intuition is that the reranker should learn to prefer or disprefer particular properties of matching and mismatching dependencies. For example, it may learn that a particular CCG dependency is usually expressed in the same or opposite direction in the dependency parse. It may learn that a particular dependency is always expected to be mismatching, or that particular heads tend to take the same pairs of dependents in both parses.

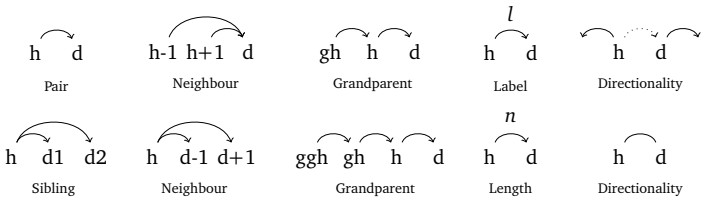

Figure 5: Dependency representations for each feature group. The letters ggh, gh, h, d refer to great grandparent head, grandparent head, head and dependent respectively.

For each matching dependency, binary indicator features were generated based on our feature templates (depicted in Figure 5). These features represent fragments of one or more dependency arcs that the reranker learns to favour or disprefer. Each feature includes components specified by the template, a directionality marker, and all four combinations of the word and POS tag for the head and dependent. Some of our templates also generate additional features for each mismatching dependency, conjoined with a label indicating whether the dependency existed only in the CDP or the MDP.

This approach differs from that of Sagae et al. (2007) since our reranker learns a separate penalty parameter for each combination of DG and CCG constructions as a feature of our regularised MaxEnt reranker model; these weights are learnt as part of the reranker training procedure. This enables our reranker to learn which DG constructions are most reliable and informative for CCG parsing, and which DG constructions should be ignored.

Following are descriptions of our DG-derived feature templates, which correspond to various dependency relations shown in Figure 5:

Pair-dependency features encode the head-dependent pair and a flag indicating a matching or mismatching dependency.

Sibling-dependency features encode matching sets of heads and pairs of dependents between the CDP and MDP. Multiple features are generated for each additional pair of matching dependents per head.

Neighbour-dependency features encode the linear context of heads and dependents in a sentence. For each matching dependency, the head is encoded with the word and POS tag in

turn of words immediately to the left and right of its dependent. This procedure is repeated for the dependent with the neighbours of its head.

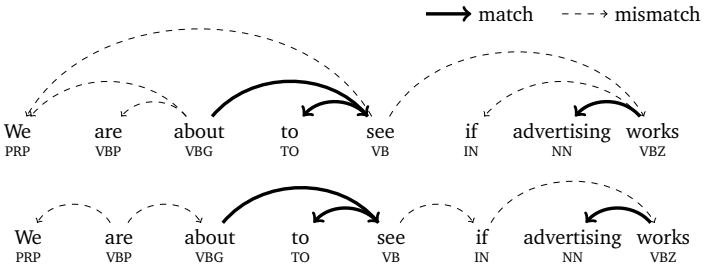
Grandparent-dependency features encode matching relationships of a great-grandparent head, grandparent head, head, and dependent between the CDP and MDP.

We also developed features that included further arc-level information from the dependency parses. These included:

Label-dependency features mimic the pair dependency features, but also include the label assigned by the dependency parser to the arc. This feature was not used for the CoNLL scheme (as this scheme does not include labels), but was active for each of the others.

Length-dependency features encode matching dependencies conjoined with the bucketed length of the dependency with respect to intervening tokens between head and dependent. The bucket intervals were set at 1, 2, 5, and 8 based on an analysis of typical lengths.

Directionality-dependency features consider, given a matching dependency, the additional matching dependencies that the head or dependent are part of. We term the dependencies in this set that are headed by the head or dependent as *out arcs*, and all others as *in arcs*. This feature template encodes the number of out arcs for each matching dependency, as well as a real value feature encoding the ratio of out arcs to in arcs.



Match: (about, see) (see, to) (works, advertising)
Mismatch^{CDP}: (about, are) (about, We) (see, We) (see, works) (works, if)
Mismatch^{MDP}: (are, We) (are, about) (see, if) (if, works)

Figure 6: Matching and mismatching pair dependencies between a CCG parse (top) and CoNLL parse (bottom) for the sentence *We are about to see if advertising works*.

Figure 6 illustrates matching and mismatching pair dependencies for the sentence shown in Figure 2, with dependencies involving punctuation ignored. There are three matching dependencies, five mismatching dependencies from to the CCG parse, and four mismatching dependencies from the DG parse. Table 2 lists examples of the pair-dependency features generated from these parses.

5 Results

We ran two classes of reranker experiments for each dependency scheme: one using gold-standard DG dependencies that were directly converted from the treebank data, and one using

Dependency	Features
(about, see)	`match:about:see, match:about:VB, match:VBG:see, match:VBG:VB`
(see, We)	`nomatch-ccg:see:We, nomatch-ccg:VB:We, nomatch-ccg:see:PRP, nomatch-ccg:VB:PRP`
(see, if)	`nomatch-malt:see:if, nomatch-malt:VB:if, nomatch-malt:see:IN, nomatch-malt:VB:IN`

Table 2: The generation process for pair-dependency features. Each feature template follows a similar pattern.

parser-predicted DG dependencies. The gold experiment allowed us to investigate the upper performance bound of our reranking technique and of our DG-derived features. We evaluate using the standard CCG dependency recovery metric over section 00 of CCGbank.

We use the reranker settings that Ng et al. (2010) found to provide best performance: regression learning, 10-best mode, and no feature pruning. We use the same experimental settings reported in Nivre et al. (2010) and McDonald et al. (2005) for the Maltparser and MSTparser respectively. This means that both parsers will produce a projective dependency tree for each scheme that we experimented with.

	Fanse features	87.61	86.72	87.17

Table 3: Parsing performance for the four DG schemes in gold and predicted configurations over section 00 of CCGbank

Table 3 records the labeled precision (LP), recall (LR) and F-score (LF) per system over section 00 of CCGbank. We compare our results to that of the C&C'07 baseline and the Reranker '10 baseline of Ng et al. (2010); the latter uses only the features defined in Ng et al. (2010), whereas our work includes the DG-derived features previous described. Each dependency scheme was tested in turn with the same feature set.

The gold results show that performance improvements of over 2% F-score are possible with

perfect DG-derived features. Each of the DG schemes performs similarly, with the exception of the Fanse scheme, which provides roughly 0.5% higher F-score than the others. The Fanse scheme is generated with the NP-bracketed version of the Penn Treebank, and also incorporates deeper linguistic analysis than the other schemes. However, it is interesting that the LTH dependencies generated from the same enriched corpus have the lowest upper bound.

The Maltparser-predicted results show that, with the exception of the LTH DG, the DG-derived features perform roughly on par with each other and generally better than the Reranker '10. However, the LTH features perform substantially worse than the others and also worse than Reranker '10; this corresponds with the Maltparser performing worst with respect to unlabeled attachment on that scheme. In contrast, the MSTparser feature results are each indistinguishable from one another, despite the very different performance of the baseline with respect to each scheme. The MSTparser results are also indistinguishable from the Reranker '10 system; this shows that the MSTparser does not produce enough useful variations compared with CCG for our procedure to work.

5.2 Isolation experiments

We took our best performing systems, which used the Fanse and CoNLL-based features for the Maltparser and MSTparser respectively, and investigated the individual impact of the DG-derived features. We did this by running the reranker with DG-derived features only over section 00 of CCGbank, and comparing our results with those of Reranker '10 (CCG features only) and the full system. Table 4 summarises the results; DG denotes our new features, and CCG denotes the CCG features.

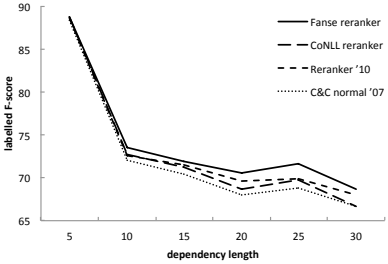
section 00 (dev)		LP	LR	LF
Reranker '10	CCG	87.57	86.69	87.13
Gold	Fanse DG	89.43	88.44	88.93
	CCG +Fanse DG	**89.61**	**88.72**	**89.16**
Malt Predicted	Fanse DG	86.79	85.79	86.29
	CCG +Fanse DG	**87.82**	**86.93**	**87.37**
MST Predicted	CoNLL DG	85.94	84.80	85.36
	CCG +CoNLL DG	**87.65**	**86.77**	**87.21**

Table 4: A comparison of DG-derived features in isolation and in combination with CCG reranker features over section 00 of CCGbank.

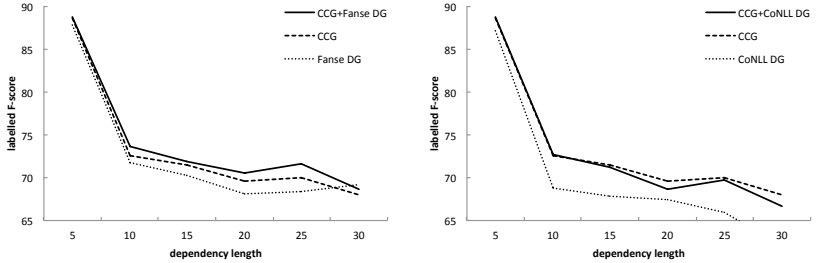
The gold results show that the DG-derived features perform strongly in isolation and outperform Reranker '10. However, performance is much worse using automatic DG parses compared to Reranker '10; F-score drops from 88.93% to 86.29% for the Maltparser-predicted experiment, and to 85.35% for MSTparser-predicted. These experiments are simply the result of removing the CCG features from the best performing system, and show that automatically produced DG features in isolation are harmful for reranking. However, the abstraction provided by automatic DG features prove useful in combination with CCG features and lead to a performance improvement.

5.3 Dependency lengths

Figure 7-(a) plots the labeled F-scores with respect to dependency length (number of words between the head and dependent) on section 00 for the best Fanse and CoNLL features. Our



(a) System comparison



(b) Feature comparison

Figure 7: Labeled F-score performance by bucketed dependency lengths for the Maltparser-predicted Fanse and MSTparser-predicted CoNLL experiments. Test conducted over CCGbank section 00.

new DG-derived features improve the Fanse performance across all dependency lengths compared to the C&C baseline and Reranker '10. In particular, we have improvements of 2.86% and 1.67% over the C&C baseline and Reranker '10 respectively when the dependency length is between 21 and 25, though the number of these dependencies is relatively small. In contrast, the MSTparser-predicted CoNLL features perform worse than the Reranker '10 as the dependency length grows though even though the CoNLL features perform better than the C&C'07 baseline for all dependency lengths.

We repeated the dependency length analysis with DG-derived features in isolation, as per the previous section. As can be seen from Figure 7-(b), Fanse DG-derived features in isolation perform poorly, while combining CCG and DG features gives an overall performance improvement over CCG features alone for all dependency lengths. Our CCG +Fanse DG reranker performs well for dependency lengths 21-25, with an F-score difference of 1.67% compared to Reranker '10. However, the F-score of CCG +CoNLL DG starts falling below the performance of CCG features beyond the dependency length 10.

These results all show a similar pattern, where F-score is very high for short dependencies, drops sharply up to length 6-10 words, and levels out for longer lengths. Interestingly, we

notice that the performance using only Fanse DG-derived features slightly increases as the dependency length grows beyond 15. For dependencies of length 25 and longer, the Fanse features in isolation actually outperform CCG features in isolation. Additionally, the performance improvement for the CCG +Fanse features over Reranker '10 is more substantial at longer dependency lengths – contrary to our initial expectations given the relative strengths of the parsers we used. One possible reason may be due to the generation of the Fanse scheme over the NP-enriched Penn Treebank. In contrast, the C&C parser was trained over a non-enriched version of CCGbank where all the noun phrases are right-branching. More errors may have crept into the noun phrase results as they typically contain short dependencies.

Table 5: Subtractive analysis of each DG feature for the Fanse and CoNLL schemes on CCGbank section 00. Bolded rows indicate the most substantial performance drops.

We performed a subtractive analysis to investigate the individual contribution of each feature type. We can see in Table 5 that different features are important for the gold and predicted experiments. Removing the length or directionality-dependency features causes a substantial performance decrease in the gold-standard experiment. This seems to suggest that certain dependencies between words will only exist with a certain length between head and dependent, and that words also have a relatively predictable number of incoming and outgoing arcs in the gold standard.

In contrast, the removal of no individual feature causes a significant change in F-score in either the Maltparser-predicted or MSTparser-predicted experiments. The introduction of parse errors has reduced the reliance of the reranker on length and directionality features, and caused it to smooth out the weights to other features. In this setting it is the combination of small

contributions from many features that is important.

5.5 Final results

We used the Fanse and CoNLL features, as these performed best on the development data for the Maltparser and MSTparser respectively, for a single run on the final test set of section 23 of CCGbank. Table 7 shows that the Fanse features with the Maltparser improve F-score relative to the C&C baseline and Reranker '10 systems. In particular, our final result of 87.93% F-score is a 0.5% improvement over the baseline parser, and a 0.35% gain over Reranker '10. These results are significant at $p < 0.05$, as tested using Bikel's approximate randomisation procedure [6].

Conclusion

In this paper we proposed new DG-derived features, generated by a dependency parser and incorporated into a CCG parser using reranking. We observe significant performance improvements using the DG-derived features from the Maltparser, and also show that there remains substantial potential in the DG-derived features with improved dependency parsing.

The LTH and Fanse dependency schemes were created from the NP-bracketed Penn Treebank of Vadas and Curran (2007). While the Fanse features performed the best in our experiments with the Maltparser, the LTH features performed poorly, further work should experiment with the standard Penn Treebank as the basis for conversion, as well as generating the CoNLL and Stanford schemes with the enriched corpus.

We plan to develop features to address more specific linguistic phenomena such as coordination and prepositional phrase attachment. The dependency schemes each represent these phenomena differently (see Section 2.5), and they are a particular issue in parsing. New features that compare the way different schemes represent these phenomena may allow us to better represent and reproduce them in parsing.

Our work focused on English parsing and we used the Maltparser and MSTparser independently of one another to generate features. It would be interesting to examine the effect of our features on parsing and reranking in different languages, as well as developing new features that compare the output of both dependency parsers. Additionally, we did not use higher order features for the Maltparser and MSTparser. Since these features are not present in the C&C parser, further work should explore whether enabling these features helps reranking.

We have developed a technique for incorporating parse information from one formalism as features for reranking another. This allows us to exploit the strengths of each formalism in a flexible framework with arbitrarily complex features.

Inducing Crosslingual Distributed Representations of Words

ABSTRACT
Distributed representations of words have proven extremely useful in numerous natural language processing tasks. Their appeal is that they can help alleviate data sparsity problems common to supervised learning. Methods for inducing these representations require only unlabeled language data, which are plentiful for many natural languages. In this work, we induce distributed representations for a pair of languages jointly. We treat it as a multitask learning problem where each task corresponds to a single word, and task relatedness is derived from co-occurrence statistics in bilingual parallel data. These representations can be used for a number of crosslingual learning tasks, where a learner can be trained on annotations present in one language and applied to test data in another. We show that our representations are informative by using them for crosslingual document classification, where classifiers trained on these representations substantially outperform strong baselines (e.g. machine translation) when applied to a new language.

KEYWORDS: distributed representations, multilingual learning, direct transfer of annotation.

Proceedings of COLING 2012: Technical Papers, pages 1459–1474,
COLING 2012, Mumbai, December 2012.

1 Introduction

Word representations induced to capture syntactic and semantic properties of words have been extremely useful for numerous natural language processing applications (Collobert and Weston, 2007; Turian et al., 2010). Their primary appeal is that they can be induced using abundant unsupervised data and then used directly or as additional features to alleviate the data sparsity problem common in the supervised learning scenario.

Most of the prior work on inducing these representations has focused on a single language, English, which enjoys the largest repository of available annotated resources. In this work, we focus on a single representation for a pair of languages such that semantically similar words are closer to one another in the induced representation irrespective of the language. Learning with these representations for a task where annotation is available for one language would induce a classifier which could be used in another language lacking sufficient resources for this task. We pick one example of such a task, document classification, to show that a classifier trained using these representations in one language achieves high accuracy in another language where no annotation is available (the set-up called *direct transfer of annotation*).

Our main contribution is a general technique for inducing crosslingual distributed representations. We use an existing model for learning distributed representations in individual languages; however, motivated by the multitask learning (MTL) setting of Cavallanti et al. (2010), we propose a method to jointly induce and align these representations. We use word co-occurrence statistics from parallel data to define a signal for aligning the latent representations in both languages as we induce them. In MTL terminology, we treat words as individual tasks; words that are likely to be translations of one another (based on bitext statistics) are treated as related tasks and effectively help to align representations in both languages during learning.

We use a variant of a neural network language model of Bengio et al. (2003) to induce the latent representations in individual languages. These models learn a lower-dimensional embedding of words arguably capturing their syntactic and semantic properties (Socher et al., 2011a).

In sum, the contributions of this work are:

- we frame induction of crosslingual distributed word representations as joint induction and alignment of distributed representations in individual languages;
- we apply our framework to the neural network language modeling approach of Bengio et al. (2003);
- although our goal is not to beat the state of the art in crosslingual document classification, we use this task to show that the crosslingual embeddings we induce enable us to transfer a classifier trained on one language to another without any adaptation.

The crosslingual representation induction set-up we propose is motivated by the multitask learning (MTL) setting of Cavallanti et al. (2010), so we begin with a brief overview in Section 2, in part to introduce terminology and notation. In our set-up, we do not commit to a particular technique for learning representations in individual languages, but rather propose a general technique for jointly inducing and aligning representations in multiple languages. However, since we apply the setup to a neural probabilistic language model in this work, we also give a short overview of a variant of the method from Bengio et al. (2003) in Section 3. In Section 4,

we define the crosslingual distributed representation induction as the joint task of learning distributed representations in two languages. Finally, Section 5 gives experimental evaluation of the induced crosslingual representations on the crosslingual document classification task.

2 Multitask Learning

The goal of multitask learning (MTL) is to improve generalization performance across a set of related tasks by learning them jointly. MTL is particularly relevant when sufficient annotation is not available for (some of) these tasks.

In the multitask set-up of Cavallanti et al. (2010), at time t a multitask learner receives an example relevant to one of K tasks it is learning. Along with the example $x_t \in \mathbb{R}^m$, and the correct binary label $y_t \in \{-1,+1\}$, the learner is supplied with the task index $i_t \in [1,K]$. It then considers a compound multitask instance $\phi_{x_t} \in \mathbb{R}^{mK}$:

$$\phi_{x_t} = (\underbrace{0,\ldots,0}_{(i_t-1)m}, x_t^\top, \underbrace{0,\ldots,0}_{(K-i_t)m})^\top$$

A multitask version of the perceptron algorithm they propose keeps a weight vector for each task. Assuming that at time t the algorithm has made s mistakes, the compound weight vector at t is $v_s = (v_{1,s}^\top, \ldots, v_{K,s}^\top)^\top$, where $v_{j,s} \in \mathbb{R}^m$ is the weight vector for task j. When a mistake is made at time t, updates are performed not only for the weight vector of task i_t, but also for the remaining $K-1$ tasks. The rate of the update for each task is defined by a $K \times K$ *interaction matrix* A, which, intuitively, encodes relatedness between the tasks. When a learner makes a mistake, the compound weight vector update rule applied is $v_s \leftarrow v_{s-1} + (A \otimes I_m)^{-1}\phi_{x_t}$, where $\otimes$ is the Kronecker product and I_m is the identity matrix of size m. This update can be rewritten as separate updates for each task:

$$v_{j,s} \leftarrow v_{j,s-1} + y_t A^{-1}_{j,i_t} x_t \qquad \forall j \in [1,K]$$

This learning algorithm directly corresponds to the minimization of the following objective:

$$L(v) = \sum_t L^{(t)}(v) + \frac{1}{2} v^\top (A \otimes I_m) v \tag{1}$$

where $L^{(t)}(v) = \left[1 - y_t v^\top \phi_{x_t}\right]_+$ is the hinge loss on the example at time t. Consequently, this setup can be naturally extended to other loss function and to non-linear models. We will use it to formalize the crosslingual representation induction task in Section 4.

2.1 Encoding Prior Knowledge in Interaction Matrix A

Let us consider the following simple interaction matrix with the corresponding inverse:

$$A = \begin{pmatrix} K & -1 & \cdots & -1 \\ -1 & K & \cdots & -1 \\ \vdots & \vdots & \ddots & \vdots \\ -1 & -1 & \cdots & K \end{pmatrix} \qquad A^{-1} = \frac{1}{K+1} \begin{pmatrix} 2 & 1 & \cdots & 1 \\ 1 & 2 & \cdots & 1 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & \cdots & 2 \end{pmatrix}$$

That is, when a mistake is made at time t, the rate of update is $2/(K+1)$ for task i_t and half as large for the other $K-1$ tasks. In other words, A defines all tasks as "equally related" to any other task.

Cavallanti et al. (2010) propose an elegant way of encoding richer prior knowledge in the interaction matrix. Relatedness between tasks can be naturally represented by an undirected graph $G=(R,E)$. The vertices R of the graph are tasks, and a pair of vertices are connected by an edge in E only if we believe that the corresponding tasks are related. The interaction matrix can then be defined as:

$$A = I + L \tag{2}$$

where I is the identity matrix and L is the Laplacian of graph G, defined as a $K \times K$ matrix:

$$L_{i,j}(G) = \begin{cases} \deg(i) & \text{if } i = j \\ -1 & \text{if } (i,j) \in E \\ 0 & \text{otherwise} \end{cases}$$

where $\deg(i)$ is the number of edges involving the vertex i.

This definition of the task interaction matrix A naturally generalizes to weighted graphs $H=(R,E,S)$, where S are weights associated with edges E. The graph Laplacian becomes:

$$L_{i,j}(H) = \begin{cases} \sum_{(i,k)\in E} s(i,k) & \text{if } i = j \\ -s(i,j) & \text{if } (i,j) \in E \\ 0 & \text{otherwise} \end{cases}$$

where $s(i,j)$ is the weight of $(i,j) \in E$. We will use these extended definitions in this work to include prior knowledge about the *degree* of relatedness between tasks. Note that the matrix A is invertible: a graph Laplacian is always positive semi-definite and consequently adding an identity matrix is guaranteed to yield a positive-definite matrix.

3 Neural Language Models

The goal of statistical language modeling methods is to estimate the joint probability distribution of word sequences occurring in a natural language. Neural probabilistic models learn a latent multi-dimensional representation of words and use them to estimate the probability distribution of word sequences. An important side-effect of training neural language models is the fact that the learned latent representations capture syntactic and semantic properties of context words, because these properties are predictive of a possible next word.

Lets us assume that a word sequence is a string of words $w_1,\ldots,w_T$, and $w_i \in V, i \in (1,\ldots,T)$ for some vocabulary V. For notational convenience, we will assume that the $|V|$ types are indexed, and w_i could refer to either the i-th token in the sequence or the corresponding index, depending on the context in which it is used.

When building a statistical n-gram language model, the aim is to estimate a conditional distribution of the next word given the preceding $n-1$ words, i.e. $P(w_t|w_{t-n+1:t-1})$, where

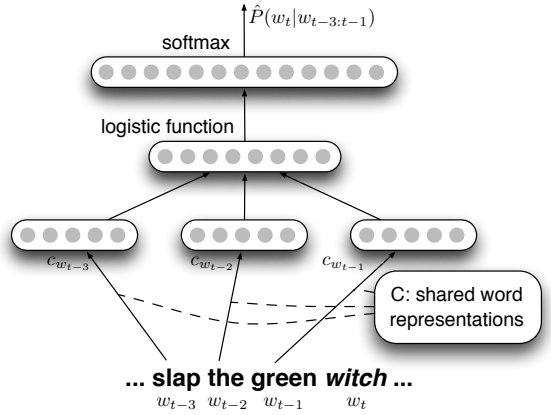

Figure 1: Neural architecture (3-gram language model) for inducing word representations in a single language.

$w_{t-n+1:t} = (w_{t-n+1}, \ldots, w_{t-1}, w_t)$ is a subsequence of n words. The language model of Bengio et al. (2003) estimates the distribution over the next word $w_t \in V_{out}$ in the sequence (see Figure 1) as follows[1]:

1. Uses a shared representation vector $c \in \mathbb{R}^{|V_{in}|d}$, a concatenation of representations of all vocabulary words $c = (c_1^\top; \ldots; c_{|V_{in}|}^\top)^\top$, to map each of the context words $w_i, i \in [t-1, \ldots, t-n+1]$ to its distributed representation c_{w_i}.

2. Concatenates all of the word representations of context $w_{t-n+1:t-1}$ preserving the order, $(c_{w_{t-n+1}}^\top; \ldots c_{w_{t-2}}^\top; c_{w_{t-1}}^\top)$.

3. The hidden layer applies a linear transformation followed by the logistic function on the concatenated embeddings.

4. Finally, the output layer separates out the classes (words in V_{out}) and applies the softmax function to ensure that the network outputs can be interpreted as a probability distribution. We will call W all network weights other than the embedding c.

The key component of the architecture is the *shared* embedding c, which is learned along with the rest of the network parameters using backpropagation. The model captures local context, so that the induced d-dimensional distributed vectors for words in the vocabulary V_{out} are "closer" for more semantically "similar" words. Thus, the induced representation can help alleviate sparsity issues in a supervised learning setup (Turian et al., 2010).

[1]Note that we make a distinction between the input (V_{in}) and output (V_{out}) vocabularies. It will be relevant in the experimental section to speed up learning, but in the rest of the paper they can be assumed the same,$V_{in} = V_{out} = V$.

Learning maximizes the data likelihood objective with respect to model parameters $\theta = (W, c)$:

$$L(\theta) = \sum_{t=1}^{T} \log \hat{P}_\theta(w_t | w_{t-n+1:t-1}) \tag{3}$$

The training procedure uses stochastic gradient descent: it iteratively updates parameters using a gradient at each training subsequence $w_{t-n+1:t}$. Specifically, for the word representations c, the updates have the form:

$$c_w \leftarrow c_w + \eta \frac{\partial L^{(t)}(\theta)}{\partial c_w}, \tag{4}$$

where η is the learning rate and $L^{(t)}(\theta) = \log \hat{P}_\theta(w_t | w_{t-n+1:t-1})$ is the contribution of the example to the data likelihood objective. Note that only the representations of words in the contextual window (i.e. their corresponding parts of c) are modified during each step.

4 Crosslingual Representation Induction

The neural language model we described in Section 3 induces an embedding c, so that words which are semantically similar are close to one another in c. In this work, our goal is to have the same property hold across two languages.[2] We train neural language models jointly for both languages and induce a common embedding.

We cast crosslingual distributed representation induction as a multitask learning problem by treating each word w in our languages' vocabularies as a separate task. The set of related tasks for each w are then the possible translations of the word in the other language. When encoding relatedness and defining an interaction matrix A, we make use of parallel data (a set of sentences and their translations). These resources are available for many language pairs and include large volumes of multilingual parliamentary proceedings, book translations, etc. Standard Machine Translation tools (e.g. GIZA++ (Och and Ney, 2003)) can be used to induce alignments between words on both sides of the bitext.

Assuming that word alignments are available, we first define a complete undirected bipartite weighted graph H with two disjoint sets of vertices corresponding to the input vocabularies V_{in} of the two languages, and edges labeled with the number of alignments between each pair of words in the two sets. The edge weights indicate the fit of a pair of words as translations, and thus encode the degree of relatedness between the two corresponding tasks. We can now directly apply the definition of the interaction matrix from Section 2, defining $s(w, \tilde{w})$ as the number of alignments between words w and $\tilde{w}$.

We use a separate neural language model for each language l, parameterized by $\theta^{(l)} = (W^{(l)}, c)$. Although the notation might suggest that embedding c is shared across languages, this is not the case, as we distinguish between word types of the two languages: for example, the word *handy* in English and the word *Handy* in German (meaning a mobile phone) would be treated as two different word types. Given an interaction matrix A, we can extend the MTL formalization (1)

[2] Our methods can be trivially extended to more than two languages.

and reformulate the monolingual learning objective (3) as:

$$L(\theta) = \sum_{l=1}^{2} \sum_{t=1}^{T^{(l)}} \log \hat{P}_{\theta^{(l)}}(w_t^{(l)} | w_{t-n+1:t-1}^{(l)}) + \frac{1}{2} c^\top (A \otimes I_d) c \tag{5}$$

where $T^{(l)}$ and $w_t^{(l)}$ are the number of words in the data set for language l and a word at position t in this corpus, respectively. As before, $\otimes$ denotes the Kronecker product and I_d is the identity matrix of size d.

Intuitively, the first (language modeling) part of the learning objective (5) captures the syntactic and semantic similarities between words in each of the two languages, while the second (MTL regularization term) ensures that the learned representations are aligned across the two languages. Note that additional information such as WordNet synsets could in principle be used to also encode relatedness between words within each language into A. However, these resources are unavailable for most languages. Also, similar type of information is already induced by the neural language model.

The stochastic gradient descent procedure would now iteratively update parameters using a gradient at each training subsequence $w_{t-n+1:t}^{(l)}$ in both languages. The monolingual update formula (4) now becomes:

$$c_w \leftarrow c_w + \eta \sum_{w'} A^{-1}_{w',w} \frac{\partial L^{(l,t)}(\theta)}{\partial c_{w'}}, \tag{6}$$

where η is the learning rate and $L^{(l,t)}(\theta) = \log \hat{P}_{\theta^{(l)}}(w_t^{(l)} | w_{t-n+1:t-1}^{(l)})$ is the contribution of the training example. In this formulation, both representations of the words in the contextual window $c_{t-n+1:t-1}$ and words w' "related" to them (i.e. those w' for which $A^{-1}_{w,w'} \neq 0$ for any contextual word w) are modified on each training step. These updates can be computed efficiently as long as A^{-1} is sufficiently sparse.

Computing these learning updates requires the inverse of the interaction matrix A. However, the dimensionality of the matrix is equal to the total number of word types in both languages, so the standard cubic-time Gaussian elimination is infeasible even for moderately sized datasets. Direct computation of A^{-1} can be made more efficient if we compute it separately for each of the connected components in our graph. Still, because of large sizes of the input vocabularies and the noise in word alignments, this computation remains impractical. A future direction could be to explore faster algorithms which could take advantage of our particular setup (i.e., sparse matrices corresponding to bipartite graphs (Li, 2009)), or to use approximate iterative algorithms (Fouss et al., 2007). In our experiments, we approximate A^{-1} directly with the following heuristic:

$$\hat{A}^{-1}_{w,w} = \frac{m_w + 1}{m_w + 1 + \sum_{\tilde{w}} s(w, \tilde{w})}$$

$$\hat{A}^{-1}_{w,w'} = \frac{s(w, w')}{m_w + 1 + \sum_{\tilde{w}} s(w, \tilde{w})}$$

where $m_w = \max_{\tilde{w}} s(w, \tilde{w})$. Intuitively, the effective update rate for a word w' "related" to a contextual word w is proportional to their alignment count. The rate applied to a context word itself is only slightly larger than the rate used for the word w' most frequently aligned to it if the corresponding alignment frequency $m_w = s(w, w')$ is high. However, if m_w were 1 and w were not aligned to other words, the self update rate $\hat{A}^{-1}_{w,w}$ would be twice as large. Consequently, the $+1$ term reduces the effect of potentially noisy counts. While this heuristic does not quite correspond to the exact computation of the inverse of the interaction matrix A as we defined it for weighted graphs, it plays a similar role, has a similar form (compare with the example in section Section 2), and is easy to compute.[3]

5 Experiments

The technique we propose induces crosslingual representations capturing relatedness of words in a pair of languages. We use a particular supervised learning task, crosslingual document classification, and show that a classifier trained using these representations in one language achieves high accuracy in another language where no annotation is available. Note that our goal is not to induce a state-of-the-art classifier, but rather to examine the informativeness of the induced representations.[4] Thus, we keep the classification experiments simple: we chose a learning algorithm requiring no parameter tuning and used simple features.

5.1 Data

In our experiments, we induce crosslingual embeddings and use them for multilinigual document classification for the English-German language pair. We use the following resources:

- English (**en**) and German (**de**) sections of the Europarl v7 parallel corpus (Koehn, 2005) to induce our baseline systems and to compute the interaction matrix A (see Section 4). We used GIZA++ (Och and Ney, 2003) to induce word alignments, keeping only bidirectional alignments. In the context of our model, parallel data is only used to estimate the interaction matrix A. When constructing A, we discard word pairs aligned only once in order to reduce the number of effective updates during gradient descent (see equation (6)).

- A subset of the English and German sections of the Reuters RCV1/RCV2 corpora (Lewis et al., 2004) to induce crosslingual embeddings and for the crosslingual document classification experiments. The corpus contains documents (news stories) in several languages which are assigned topics capturing the major subjects of the story. In the English dataset, there are four topics (each with hierarchy of sub-topics): `CCAT` (Corporate/Industrial), `ECAT` (Economics), `GCAT` (Government/Social), and `MCAT` (Markets). Note that these documents are not parallel.

  Each document can be labeled with multiple topics, however, since we do not want to consider multi-label classification in our experiments, we only select documents assigned to single topics. Of those, we sampled 34,000 **en** and 42,753 **de** documents (they were selected with the goal of keeping roughly 8 million tokens for each language). which we used for unsupervised induction of crosslingual representations.

[3] In preliminary small scale experiments we did not observe a significant advantage from using the true inverse matrix, and therefore we chose not to resort to more accurate approximations.

[4] An embedding specifically learned for the classification task would require modifications of the learning objective. While it is likely to improve the performance on this specific task, it is not the aim of this work.

For our classification experiments, we randomly selected 15,000 documents from our sampled dataset and used a third of them as a test set, with the remainder used to construct training sets of sizes between 100 and 10,000 documents. We repeated this procedure for both **en** and **de**; for both languages, the majority class was `MCAT` with roughly 46.8% of the documents.

All datasets were normalized with the tools distributed by the 2012 SMT workshop (Callison-Burch et al., 2012). The list of RCV1/RCV2 document names we used in our experiments along with the crosslingual word representations we induced are available at `http://www.ml4nlp.de/code-and-data`.

5.2 Our Model and Baselines

Our neural language model architecture (Section 3) was the same for both languages with 25 hidden units, and the context size of 4. We induced representations of $d = 40$ dimensions for input vocabularies of $|V_{in}^{\mathbf{en}}| = 43,614$ and $|V_{in}^{\mathbf{de}}| = 50,110$ words (filtering out words which occur fewer than five times in our dataset). However, to speed up training,[5] we learn on a subset of training sequences choosing the 3,000 most frequent words in **en** and **de** for their output vocabularies $V_{out}^{\mathbf{en}}$ and $V_{out}^{\mathbf{de}}$, respectively. The representations were induced from our subset of RCV1/RCV2 dataset using word alignments from Europarl v7 (see Section 5.1). We ran the learning procedure for 40 iterations, which took about 10 CPU days and is linearly parallelizable. Learning rate was set to 0.005 and was reduced when the training data likelihood went up, as is common when training neural networks.

We used the averaged version of the perceptron algorithm (Collins, 2002) to train a multiclass document classifier, so that we do not need to tune any parameters, with the exception of the the number of epochs, which we set to 10 in all experiments (the results were not sensitive to this parameter). Our goal is to train a classifier in one language and test it on data in another, so we compared the following classifiers:

- A classifier which used features based on the crosslingual representations we induced (*DistribReps*) and was trained on supervised training data in one language and *directly* tested on documents in the other. We represent each document as an average of d-dimensional representations of all of its tokens weighted by their *idf* score (Huang et al., 2012).
- A classifier with word count features which was trained and tested on the second language documents translated into the original language. Translations are done by replacing each word in a test document by the word most frequently aligned to it in the parallel data (*Glossed*). Unaligned words were left as is.
- Using a machine translation system instead of simple glossing would provide a natural baseline (Fortuna and Shawe-Taylor, 2005; Shi et al., 2010). So, another baseline (*MT*) is similar to the previous with the exception that the second language documents were translated by the standard phrase-based machine translation model (Koehn et al., 2007) using default parameters and a 5-gram language model trained on Europarl v7 data.
- For reference, we also include majority class predictions (*Majority Class*).

[5] In particular, computing the normalization in the softmax function, is linear in $|V_{out}|$.

5.3 Classification Results

Before looking at the classification results, let us examine the distributed representations we induce with a small experiment. Table 1 shows six English words, each along with ten words in English and German ranked by the Euclidean distance in the induced embedding. With few exceptions, all six end up being near semantically similar words in both languages. Identical ranking of months in both languages in the first example suggest that aligned data brought translations very close to one another in the induced embedding.

We ran crosslingual classification experiments training on English and testing on German documents, varying the training data size from 100 to 10,000 documents, then repeated the same experiments going from German to English. Classification results are summarized on Figure 2 and a single point is detailed in Table 2. Classifiers based on distributed representations substantially outperform all baselines. They are especially beneficial when the amount of training data is small, effectively taking advantage of plentiful unsupervised data used for inducing crosslingual word representations. While their performance is high relative to the baselines, it does not change significantly with the training data size. We believe that is likely due to relatively low embedding dimensionality ($d = 40$); 100 examples were sufficient to learn a good classifier for this representation. Increasing the size of the hidden representation is likely to improve the results. Note that these embeddings were not induced specifically for this task. It is likely that these results would improve if we reformulate the objective with the classification task in mind (see e.g. (Titov, 2011; Glorot et al., 2011)).

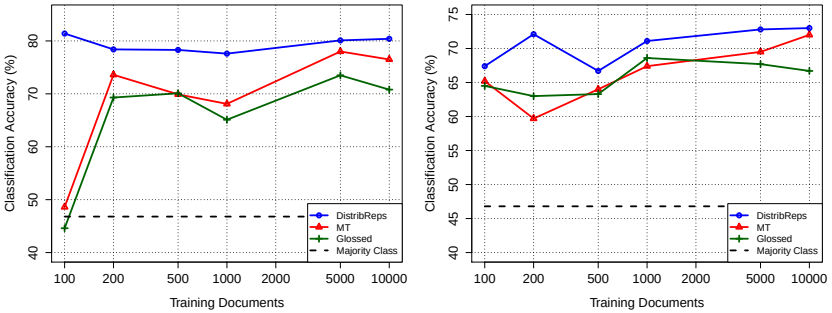

Figure 2: Classification accuracy with three types of features: crosslingual distributed representations (*DistribReps*), translated (*MT*), and glossed (*Glossed*) words, and the majority class baseline (*Majority Class*). The results are for training on English and testing on German documents (left) and vice versa (right).

6 Additional Related Work

In the last decade crosslingual methods have attracted a lot of attention both in NLP and closely related communities such as information retrieval (Lavrenko et al., 2002) and information management (Frederking et al., 2001). Much of this work has focused on techniques for porting methods and resources from one language to another (see, e.g., crosslingual document classification (Fortuna and Shawe-Taylor, 2005; Shi et al., 2010)). Development of crosslingual models (e.g., topic models (Zhang et al., 2010; Mimno et al., 2009)) has also attracted some attention. However, these approaches either do not induce representations of individual words and, as such, may not be very useful for methods dealing with richer linguistic structures (such as syntactic parsing or semantic role labeling) or they focus on porting a specific method (e.g., named entity recognizer (Steinberger and Pouliquen, 2007)). This contrasts significantly with our objective: inducing fine-grain distributed word representation useful in virtually arbitrary NLP problems.

Possibly the most related work to ours is the method for inducing crosslingual Brown clusterings (Täckström et al., 2012). They also use multi-lingual parallel data to enforce a form of crosslingual agreement in the induced representations. However, atomic cluster labels arguably are not capable of encoding multiple factors or views on the syntactic and semantic properties of words, and, consequently, may be less informative for many applications. For a detailed comparison of properties of distributed representations and Brown clustering we refer the reader to Turian et al. (2010).

Construction of crosslingual representations and similarity functions has also been considered in the related area of distributional semantics (van der Plas and Tiedemann, 2006; Agirre et al., 2009) where a word is represented as a vector and each of its components encodes the strength of co-occurrence with a specific lexical or syntactic context (Rapp, 1995). These representations again have very different properties from the ones considered here: for example, they are typically very highly dimensional and, consequently, may be less useful as features in

	en → de	de → en
DistribReps	77.6	71.1
MT	68.1	67.4
Glossed	65.1	68.6
Majority-Class	46.8	46.8

Table 2: Classification accuracy for training on English and German with 1000 labeled examples.

classifiers. Also they generally cannot be created with a specific application in mind, whereas word representations can be learned to be useful for a specific problem (Collobert and Weston, 2007).

7 Conclusions and Future Work

In this work, we propose a general method for inducing crosslingual distributed representations for a pair of languages. We treat it as a multitask learning problem, where each task corresponds to a word in the vocabularies of the two languages, and relatedness information between them is estimated from word alignments in parallel data. Intuitively, task relatedness information encoded in the interaction matrix A is used to align the representations in both languages as we learn them. Words in either language that are similar to each other end up being "close" in the joint representation. However, since aligned resources may not be available for a given language pair, an investigation of robustness of our setup to the amount of parallel data as well as using alternative resources to define A is an interesting future direction.

Distributed representations of multi-word expressions (phrases) have recently been shown very useful for sentiment analysis (Socher et al., 2011b). Inducing these representations in multiple languages is likely to benefit tasks like low-resource machine translation (Klementiev et al., 2012) where it could potentially be used to both induce phrase tables and score them with little parallel data.

We showed that crosslingual representations are very informative for crosslingual document classification, where they can be used to directly apply a classifier trained on data in one language to test data in another. Classification accuracy is likely to improve if we were to learn these representations specifically for the task, which would require a small change to the learning objective. Applying our framework with the specific goal of building a state-of-the-art classifier is also an interesting future direction.

ABSTRACT

Event anaphora resolution plays a critical role in discourse analysis. This paper focuses on improving event pronoun resolution using both local and global semantic information. In particular, a predicate-argument structure is proposed to represent the local semantic information about an event while the global semantic information is represented by the entity coreference chains related with various arguments in the predicate-argument structure to complement its locality. Evaluation on the OntoNotes English corpus shows the effectiveness of local and global semantic information for event pronoun resolution.

KEYWORDS: event pronoun, semantic information, corefernce resolution, predicate-argument structure

COLING 2012, Mumbai, December 2012.

1 Introduction

As one of the most important techniques in discourse analysis, anaphora resolution aims to resolve a given mention to its referred expression in a text and has been a focus of research in Natural Language Processing (NLP) for decades. According to the nature of the referred expression, anaphora resolution can be categorized into entity anaphora resolution and event anaphora resolution. While most studies focus on entity anaphora resolution and have achieved much success recently (e.g. Soon et al. 2001; Ng and Cardie 2002; Ng 2007, 2009; Yang et al.2004, 2006, 2008; Kong et al. 2009,2010), there are only a few studies on event anaphora resolution (Byron, 2002; Pradhan et al., 2007; Chen et al. 2010a, 2010b; Kong and Zhou, 2011).

In this paper, we address event pronoun resolution, the most difficult type of event anaphora resolution due to the least discriminative information that an event pronoun can provide. Here, an event pronoun is a pronoun whose antecedent refers to an event. In particular, we focus on improving event pronoun resolution using both local and global semantic information. For local semantic information, we employ a shallow semantic parser to extract the predicate-argument structure in a sentence to represent an involved event. In order to complement the locality of the predicate-argument structure, we consider the global semantic information via the entity coreference chains related with various arguments in the predicate-argument structure.

The rest of this paper is organized as follows. Section 2 describes the event anaphora resolution task. Section 3 briefly introduces the related work on event anaphora resolution. Section 4 presents our baseline framework which combines various kinds of flat features and a structured parse tree for event pronoun resolution. Section 5 explores both local and global semantic information for event pronoun resolution. Section 6 reports the experimental results. Finally, we conclude our work in Section 7.

2 Task Description

While entity anaphora focuses on mentions of an entity, event anaphora looks into mentions that refer to an event. In this paper, we consider event anaphora resolution. Consider the following examples:

a) In Yemen today, where the ship was ***[attacked]***$_1$, the deliberate, well-organized familiar effort to find out who did *[it]*$_2$, and how ***[it]***$_3$ happened.

b) Two F Tomcats ***[struck]***$_1$ the targets. After ***[today's air strikes]***$_2$, 13 Iraqi soldiers abandoned their posts and surrendered to Kurdish fighters.

c) Yes, it took a while last night to sort out precisely what the court had ***[decided]***$_1$ by such a narrow margin. ***[This]***$_2$ was a stabilizing decision that restored order to a very chaotic situation.

Example (a) shows the importance of event anaphora resolution in understanding the discourse. In example (a), the three mentions in italic and bold font form a chain of event "the ship was attacked". While entity anaphora resolution is capable of linking up mention 2 and mention 3, e.g. using the default proximity preference rule as widely adopted in the literature (Soon et al. 2001), this chain will only contain two pronouns without linking mention 2 to actual event mention 1. Event anaphora resolution provides an essential role to bridge the understanding gap

in such a discourse by linking mention 2 to actual event mention 1. Here, we employ the predicate of a clause to represent an event mention.

Similarly, in example (b), the anaphor of NP "today's air strikes" refers to event "Two F Tomcats struck the targets" while in example (c), the anaphor of pronoun "this" refers to event "what the court had decided by such a narrow margin". Obviously, compared with noun phrases, pronouns carry little information of their own. This indicates the difficulty of event pronoun resolution in event anaphora resolution. Besides, our statistics on the OntoNotes English corpus (Release 3.0) shows that event pronouns occupy about 40% of event anaphors. This indicates the importance of event pronoun resolution in event anaphora resolution.

For better understanding the paper, here we give some related terminologies:

- ***Entity***: an object or a set of objects in one of the semantic categories of interest, referred by one or more coreferential entity mentions in the document.
- ***Entity mention***: a reference to an entity (typically, a noun phrase).
- ***Event trigger***: the key word that most clearly expresses the occurrence of an event. In this paper, as mostly adopted in the literature, we take the main predicate (either verbal or nominal) of a clause as the event trigger to represent the corresponding event.
- ***Event arguments***: the entity mentions involved in an event.
- ***Event mention***: a clause within which an event is described, including event trigger and event arguments. Although some event pronouns can actually refer to a paragraph or larger chunks of texts, in this paper we only consider the cases taking clauses as antecedents.

3 Related Work

In comparison with entity anaphora resolution, there are few linguistic studies on event anaphora (e.g. Asher, 1993) and very initial explorations on event anaphora resolution. It was only until recently, with the increasing interest in discourse analysis, event anaphora resolution has begun to draw more and more attention for the natural language processing community. While some of them focus on hand-crafted constraints to resolve event anaphora of normally limited kinds of predicates (e.g. Byron, 2002), most of previous studies adopt a learning-based framework (e.g. Muller, 2007; Pradhan et al., 2007; Chen et al. 2010a, 2010b; Kong and Zhou, 2011).

As a representative to linguistic studies on event anaphora, Asher (1993) proposed a discourse representation theory to resolve the references to events. However, no computational system was proposed in his work.

As a representative of using hand-crafted knowledge to resolve specific kinds of predicates, Byron (2002) proposed a semantic filter as a complement to salience calculation in resolving event pronouns. However, since the semantic filter was constructed by using a set of hand-crafted constraints on some specific domains, this approach is not suitable for general event pronoun resolution.

Among learning-based methods to event anaphora resolution, Chen et al. (2010a) explored various kinds of positional, lexical and syntactic features for event pronoun resolution, which turned out quite different from entity pronoun resolution. Besides, they studied the importance of structured syntactic information by incorporating it into event pronoun resolution via a composite kernel. Finally, they explored the incorporation of negative instances from non-event anaphoric

pronouns, the fine-tuning of the SVM model and the employment of the twin-candidate model (Yang et al. 2003) in event pronoun resolution. Chen et al. (2010b) extended their previous work from event pronoun resolution to general event anaphora resolution by considering other types of event anaphors. Kong and Zhou (2011) proposed a new tree expansion scheme to automatically determine a proper parse tree structure for event pronoun resolution by considering various kinds of competitive information related with the anaphor and the antecedent candidate and achieved a much better performance on the OntoNotes English corpus than Chen et al (2010a).

Besides, there are some studies which integrate event anaphora resolution with entity anaphora resolution. For example, Pradhan et al. (2007) proposed a unified event and entity anaphora resolution framework based on a set of widely-used features which have been proven to be effective for entity anaphora resolution. Evaluation on the OntoNotes English corpus shows that their unified framework achieved the performance of 51.2 in F1-measure on overall entity and event anaphora resolution. However, they did not report the performance of their unified framework on event anaphora resolution. Alternatively, Muller (2007) constructed a logistic regression model to resolve event and entity pronouns together. For event pronoun resolution, he achieved 11.94 in F1-measure and found that the types of information effective for event pronoun resolution were very different from those for entity pronoun resolution. From this aspect, it seems better to independently explore event anaphora resolution first and then explore its possible integration (e.g. joint learning) with entity anaphora resolution.

In this paper, we focus on improving event pronoun resolution by exploring both local and global semantic information.

4 Baseline System

Our event pronoun resolution framework adopts the common learning-based one for entity anaphora resolution, as described by Soon et al. (2001). Specially, the way generating instances during training and testing procedures of event pronoun resolution is similar to Kong and Zhou (2011).

4.1 Flat Features

For entity pronoun resolution, Yang et al. (2004, 2005, 2006) explored various kinds of syntactic and semantic features to describe the information related with the antecedent candidate and the anaphor from their own and the relationship between them. However, few of these features can be adopted in event pronoun resolution. On one hand, since the antecedent candidate is an event trigger and the anaphor is a pronoun, both carry little obvious information about their own. On the other hand, the event anaphor and candidate pair in event pronoun resolution consists of a predicate and a pronoun. The difference in syntactic categories introduces extra difficulties. The features, such as number agreement, gender agreement, name alias, string matching and head matching, which have been proven to be effective for entity pronoun resolution, will no longer function here. Instead, we employ a list of flat features as shown in Table 1, inspired by Chen et al. (2010a).

In principle, the features in Table 1 can be grouped into three categories:

1) *Positional features*: the intuition is that the antecedent of an event pronoun should be close to each other. In particular, different kinds of distances between the anaphor and

the antecedent candidate are explored, i.e. over sentence, word, pronoun, predicate and main predicate.

2) *Grammatical features*: mainly used to describe the grammatical roles of the anaphor and the antecedent candidate.
3) *Similarity feature*: There is no doubt that semantic information is important for event pronoun resolution. However, since both event pronouns and event triggers carry little obvious semantics of their own, the context similarity is employed to measure the semantic compatibility between the anaphor and its antecedent candidate. In our baseline system, the similarity is calculated based on a list of nearby 10 contextual words (including previous 5 words and following 5 words) with proper stemming using the Porter stemmer and stop words (such as "in", "the" and etc.) filtered out.

	Features	Description
Positional Features	SenDist	Sentence distance between event anaphor and antecedent candidate
	WordDist	Word distance between event anaphor and antecedent candidate
	PredDist	Number of predicates between event anaphor and antecedent candidate
	PronDist	Number of pronouns between event anaphor and antecedent candidate
	MPredDist	Number of main predicate between event anaphor and antecedent candidate
Grammatical Features	isAnaInMC	Whether event anaphor occurs in main clause
	isAnaSub	Whether event anaphor is at subject position
	isPredInMC	Whether antecedent candidate occurs in main clause
	isMPred	Whether antecedent candidate is main predicate
Similarity Feature	ContextSim	Similarity between event anaphor's context and antecedent candidate's context

TABLE 1 – FLAT FEATURES FOR EVENT PRONOUN RESOLUTION

4.2 Structured Parse Tree

Besides various kinds of flat features described above, we also explore structured syntactic information via a parse tree structure. The commonly-used syntactic knowledge for anaphora resolution, such as the governing relations, can be directly described by the parse tree structure. Other syntactic knowledge that may be helpful for anaphora resolution could also be implicitly represented in the parse tree structure. Furthermore, tree kernel-based methods have been explored in entity anaphora resolution and achieved comparable performance with the dominated feature-based methods (Yang et al. 2006; Zhou et al. 2008). For structured syntactic information, we adopt the Dynamic Competitive Tree, as proposed in Kong and Zhou (2011), which takes the related competitive information, such as the event pronoun predicate (i.e. the predicate of the event pronoun), event antecedent competitors and event pronoun competitors between the anaphor and the considered antecedent candidate into consideration. For more details, please refer to Kong and Zhou (2011).

4.3 Polynomial Kernel, Tree Kernel and Composite Kernel

For two vectors of flat features, we compute their similarity using a polynomial kernel, while given any parse tree structure, e.g. the one as described above, the similarity between two parse trees is calculated using a convolution tree kernel. For more details about this kernel, please refer to Collins and Duffy (2002) and Moschitti (2004).

In order to combine flat features and structured parse trees, a linear-interpolated composite kernel is adopted in this paper:

$$K_{comp}(x_1, x_2) = \frac{K_{tree}(x1, x2)}{|K_{tree}(x1, x2)|} + \frac{K_{flat}(x1, x2)}{|K_{flat}(x1, x2)|}$$

For simplicity, this paper equally weights the convolution tree kernel K_{tree} for the parse tree structure and the polynomial kernel K_{flat} (d=2) for flat features with proper normalization.

5 Incorporating Semantic Information

It is well proven that the semantic compatibility between the anaphor and the antecedent candidate is important for entity anaphora resolution. For event pronoun resolution, since the anaphor is a pronoun and the antecedent candidate is an event trigger, both carry little obvious semantic information about themselves. Therefore, it is more difficult to measure the semantic compatibility between the anaphor and the antecedent candidate in event pronoun resolution. A possible way to measure it is to explore the contexts where the event pronoun and the antecedent candidate occur.

In our baseline system, we use a bag-of-words method to represent the contexts of the anaphor and the candidate. However, such a bag-of-words method suffers from the dilemma between the noise and the necessary information covered in a context window. In order to resolve this problem, we propose a predicate-argument structure representation to capture the local semantic information related with an event. Besides, we explore the global semantic information via entity coreference chains related with various arguments of the predicate-argument structure to complement its locality.

5.1 Local Semantic Information

Obviously, various arguments closely related with an event trigger contain necessary semantic information for event pronoun resolution. Therefore, it is reasonable to represent an event mention using the event trigger and corresponding event arguments. Since the event trigger is normally the predicate of a clause and event arguments correspond to the arguments driven by the predicate of a clause, we employ a shallow semantic parser to extract the predicate-argument structure of a clause as the representation of the local semantic information of the event. Especially for an event pronoun, we retrieve its governing predicate and related arguments as its local representation.

Figure1 shows the algorithm for computing the semantic compatibility between an event pronoun and an antecedent candidate. In particular, only those core arguments as defined in the Propbank (Palmer et al. 2005) are included in the computation. Consider following example:

a) ***Both President Gore and President Bush$_1$*** have held a flurry of news conferences in recent weeks and with each one ***they$_1$*** have ***[increased]*** *the* number of Stars and Stripes ***they$_1$*** use as a backdrop. I think ***they$_1$*** think ***[it]*** makes ***them$_1$*** look patriotic and presidential.

which includes an inter-sentence event anaphora with pronoun "it" referring to event "they have increased the number of Stars and Stripes". For this pair of event pronoun and antecedent, the algorithm in Figure1 returns {makes, it, them} and {increased, they, the number of Stars and Stripes} as AnaSet and CandSet, respectively.

Algorithm:

computing the semantic compatibility between an anaphor and an antecedent candidate

Input:

an anaphor: current event anaphor, a pronoun
an antecedent candidate: an event trigger, a predicate

Steps:

1) Initialize Score, CandSet and AnaSet
2) Use a semantic role labeling (SRL) toolkit to get all the core arguments of the antecedent candidate (i.e., event arguments) and add the antecedent candidate (i.e., the event trigger) and all the core arguments to CandSet (except pronouns).
3) Get the governing predicate of the anaphor and use a SRL toolkit to get all the core arguments of the predicate. Add the governing predicate of the anaphor and all the core arguments to AnaSet (except pronouns).
4) For every element pair from CandSet (candi) and AnaSet (anaj), compute the similarity between them using WordNet as described in Satanjeev and Ted (2002). If the similarity is larger than a threshold (0.5 in this paper), increase Score by 1.
5) Return Score/sqrt(|CandSet|*|AnaSet|) as the semantic compatibility between the given anaphor and the given antecedent candidate

FIGURE1– ALGORITHM FOR COMPUTING THE SEMANTIC SIMILARITY BETWEEN AN ANAPHOR AND AN ANTECEDENT CANDIDATE

5.2 Global Semantic Information

Obviously, the algorithm in Figure1 can only retrieve local descriptions of an event mention. It may be difficult to correctly measure the global semantic compatibility between the anaphor and the antecedent candidate using the predicate-argument structure due to its locality, e.g. considering example (d) due to the occurrence of various pronouns.

In order to complement the locality of the predicate-argument structure in representing the anaphor and the antecedent candidate, we further explore the global semantic information via entity coreference chains related with various arguments for event pronoun resolution.

The basic idea is that, when measuring the semantic compatibility between the anaphor and the antecedent candidate, we not only consider the event trigger and involved arguments, but also include different entity mentions (except pronouns) related with those involved arguments. Consider CandSet={increased, they, the number of Stars and Stripes} in the above example. Although we can retrieve little semantic information from argument "they" itself, we can find that it actually refers to "Both President Gore and President Bush" via entity anaphora resolution.

Similarly, we can find the referred expressions of other pronouns in CandSet and AnaSet. In this way, CandSet and AnaSet can be better represented.

6 Evaluation and Discussion

This section systematically evaluates the performance of our event pronoun resolution framework on the OntoNotes English corpus (Release 3.0).

6.1 Experimental Setting

The OntoNotes English corpus (Release 3.0) contains 300K words of English newswire data (from the Wall Street Journal) and 200K words of English broadcast news data (from ABC, CNN, NBC, Public Radio International and Voice of America). Table 2 shows the statistics of the corpus. From Table 2 we can find that about 9% of coreference chains are event related. Among 3550 event pronoun candidates (i.e. all the occurrences of "this", "that" and "it", which function as pronoun), 504 are event pronouns, accounting for about 14%. This indicates the difficulty of identifying event pronouns.

Category	Num
Coreference chains	8154
Coreference chains related with events	737
Event pronoun candidates	3550
Event pronouns	504

TABLE 2 – STATISTICS ON ONTONOTES 3.0 ENGLISH CORPUS

System	P(%)	R(%)	F
Polynomial kernel(flat features)	34.84	53.08	42.07
Tree kernel(structured)	47.06	65.71	54.84
Composite kernel(flat+structured)	49.78	69.17	57.89

TABLE 3 – PERFORMANCE OF THE BASELINE SYSTEM

For preparation, all the documents in the corpus are pre-processed automatically using a pipeline of NLP components. In addition, the corpus is parsed using the Charniak parser, and a state-of-the-art semantic role labelling (SRL) toolkit as proposed by Li et al. (2009) is employed to extract the predicate-argument structure (i.e. various arguments of a predicate)[1]. Finally, we use the SVM-light toolkit (Joakim, 1998)[2] with the convolution tree kernel SVMlight–TK (Moschitti, 2004)[3] for computing the similarity between two parse trees, and the polynomial kernel (d=2) for computing the similarity between two vectors of flat features, with learning parameters same as Chen et al. (2010a). For performance evaluation, we report the performance of event pronoun resolution with 10-fold cross validation in terms of recall, precision, and F1-measure.

[1] In this paper, we only consider verbal predicates, since 97.3% of events in the OntoNotes English corpus (Release 3.0) are triggered by verbal predicates. Besides, only those core arguments as defined in the Propbank are explored in this paper. For reference, the toolkit developed by Li et al. (2009) achieved the performance of 81.8 in F1-measure on the CoNLL'2005 version of the Propbank.

6.2 Experimental Results

6.2.1 Performance of baseline system

Table 3 shows the performance of our baseline system. It shows that the polynomial kernel with the flat features yields 42.07 in F1-measure while the convolution tree kernel with the parse tree structure achieves a much better performance of 54.84 in F1-measure due to direct modeling of commonly used syntactic knowledge and implicit including of other knowledge helpful for event pronoun resolution. It also shows that the flat features and the parse tree structure are quite complementary that their combination via a simple composite kernel achieves 57.89 in F1-measure. Although the employed dynamic competitive tree may lose some important contextual information, it prunes out potential noise as much as possible. At the same time, the flat features used in our baseline system mainly describe positional and grammatical information. This suggests the complementary nature of the flat features and the parse tree structure, which is justified by the effective use of the composite kernel. In all the following experiments, we only report the performance employing the composite kernel.

6.2.2 Contribution of local semantic information

Table 4 shows the contribution of local semantic information on the composite kernel. It shows that the local semantic information via the predicate-argument structure can significantly improve the performance on the composite kernel by 1.7 in F1-measure. This justifies the usefulness of the predicate-argument structure in representing the local semantic information of the anaphor and the antecedent candidate. It also shows that the inclusion of A0 (i.e. agent) improves the performance by 1.29 in F1-measure and further inclusion of A1 (i.e. recipient) contributes 0.36 in F1-measure while the effectiveness of other kinds of arguments is very limited due to their less number and their less possibility of being referred in a text.

System	P(%)	R(%)	F
Flat+Structured	49.78	69.17	57.89
+A0	53.04	66.92	59.18(+1.29)
++A1	53.59	66.98	59.54(+0.36)
+++Others	53.64	67.02	59.59(+0.05)

TABLE 4 – INCREMENTAL CONTRIBUTION OF DIFFERENT KINDS OF LOCAL SEMANTIC INFORMATION ON THE COMPOSITE KERNEL [4]

6.2.3 Contribution of global semantic information

While the global semantic information via entity coreference chains can complement the locality of the predicate-argument structure, entity anaphora resolution itself is a difficult task. Obviously, the effectiveness of the global semantic information will largely depend on the performance of entity anaphora resolution.

[4] Significance tests are conducted between each of them and the previous one. The *p*-values are all smaller than 0.01.

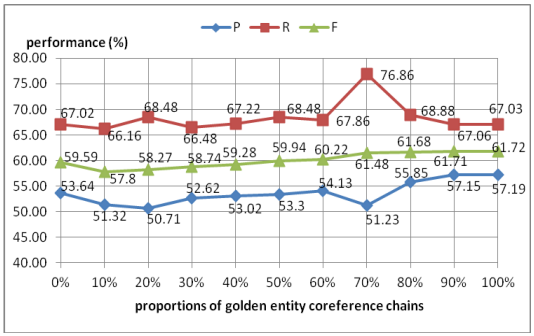

FIGURE 2– CONTRIBUTION OF GLOBAL SEMANTIC INFORMATION BY RANDOMLY CHOOSING DIFFERENT PROPORTIONS OF GOLDEN ENTITY COREFERENCE CHAINS

Figure 2 shows the contribution of global semantic information by randomly choosing different proportions of golden entity coreference chains. From Figure 2, we can find that:

1) Only considering a small proportion of even golden entity coreference chains (<50%) may harm the performance of event pronoun resolution. That is to say, only a small proportion of even golden entity coreference chains cannot complement the locality of the predicate-argument structure. In contrast, it may introduce too much uneven distribution across different events and thus harm the performance.
2) For golden entity coreference chains, including at least 50% begins to contribute.
3) When the used proportion of golden entity chains reaches a threshold (about 80%), the performance of event pronoun resolution stabilizes.

Systems	P(%)	R(%)	F
Soon et al. (2001) (duplicated)	61.5	45.9	52.57
Kong et al. (2009) (duplicated)	73.5	54.2	62.39

TABLE 5 – PERFORMANCE OF ENTITY ANAPHORA RESOLUTION

System	P(%)	R(%)	F
Flat+Structured+Local Semantic	53.64	67.02	59.59
+Global Semantic (Soon et al 2001)	53.6	67.36	59.70
+Global Semantic (Kong et al. 2009)	54.65	68.6	60.84

TABLE 6 – CONTRIBUTION OF AUTO ENTITY COREFERENCE CHAINS

In order to measure the effectiveness of global semantic information in practical environment, i.e. using automatic entity anaphora resolution, we duplicate two entity anaphora resolution systems with different levels of performance: the one proposed by Soon et al. (2001) and the other proposed by Kong et al. (2009). Table 5 shows the performance of these two duplicated systems on the OntoNote English corpus. Table 6 shows the contribution of global semantic information via entity coreference chains returned by the two automatic anaphora resolution systems. It shows

that the effectiveness of global semantic information largely depends on the performance of an entity anaphora resolution system. Using the duplicated system proposed by Soon et al.(2001), we can only get a performance improvement of only 0.11 in F1-measure for event pronoun resolution while applying the duplicated system proposed by Kong et al. (2009) improve the performance by 1.25 in F1-measure. That is to say, the state-of-the-art entity anaphora resolution system can improve the performance of event pronoun resolution by filling the gap by about 50% (60.84-59.59 vs. 61.72-59.59). While most of the contribution of golden entity chains comes from gain in precision, the contribution of automatic entity chains comes from gain in both precision and recall.

6.2.4 Comparison with the State-of-the-Art

For comparison, Table 7 illustrates the performance of the state-of-the-art event pronoun resolution system developed by Chen et al. (2010a) using different schemes. From Table 7, we can find that Chen et al (2010a) achieved the performance of 40.6 in F1-measure via a feature-based method, and the best performance of 44.4 in F1-measure using the min-expansion tree via a tree kernel-based method. They further studied different ways of combining flat features and a parse tree structure to improve the performance and achieved the best performance of 47.2 in F1-measure when combining flat features with the simple-expansion tree structure. In our study, our feature-based system achieves 42.07 in F1-measure, and our tree kernel-based method with the dynamic competitive tree achieves the performance of 54.84 in F1-measure. By combining the flat features with the structured parse tree via a composite kernel, our system achieved the performance of 57.89 in F1-measure. The much better performance of our baseline system is mainly due to two reasons: 1) our better preprocessing in filtering out unnecessary negative instances by employing a set of constraints as described in Byron (2002). In Chen et al. (2010a), each event pronoun will generate 6.93 candidates while the number in our system is reduced to about 3; 2) employing the more effective structured tree span.

System	P(%)	R(%)	F
Flat	40.6	40.6	40.6
Min-Expansion	35.5	59.6	44.4
Simple-Expansion +Flat	42.3	53.4	47.2
+Negative Instances w/ Sampling	59.9	50.6	54.9
++SVM Fine-tuning	65.2	49.2	56.1
+++Twin-Candidate Modelling	62.6	54.0	57.9

TABLE 7 – PERFORMANCE OF CHEN ET AL. (2010A) ON EVENT PRONOUN RESOLUTION

Besides, Chen et al. (2010a) looked into the incorporation of negative instances from non-event anaphoric pronouns and achieved the best performance of 54.9 in F1-measure. They further improved the performance by keeping certain training data as the development data to help SVM select a more accurate hyper plane and achieved the performance of 56.1 in F1-measure. Finally, they proceeded to apply the twin-candidate model as proposed in Yang et al. (2003) to event pronoun resolution and achieved the performance of 57.9 in F1-measure. After employing so many strategies, Chen et al. (2010a) achieved the comparable performance with our baseline system. This justifies the strength of our baseline system.

We further improve the performance of event pronoun resolution by combining local and global semantic information via the predicate-argument structure and entity coreference chains and achieve the outstanding performance of 60.84 in F1-measure using automatic semantic role labelling and entity anaphora resolution.

Conclusion and Further Work

This paper studies the impact of both local and global semantic information for event pronoun resolution. In particular, a predicate-argument structure is proposed to represent the local semantic information related with an event while the global semantic information via entity coreference chains is further incorporated to complement the locality of the predicate-argument structure. Experimental results show that both the local and global semantic information are very effective for event pronoun resolution. We also study the influence of the performance of entity anaphora resolution on event pronoun resolution.

For further work, we will explore more structured syntactic information and semantic information in event anaphora resolution. In addition, we will study joint learning of entity anaphora resolution and event anaphora resolution.

ABSTRACT
Compounds occur very frequently in Indian Languages. There are no strict orthographic conventions for compounds in modern Indian Languages. In this paper, Sanskrit compounding system is examined thoroughly and the insight gained from the Sanskrit grammar is applied for the analysis of compounds in Hindi and Marathi. It is interesting to note that compounding in Hindi deviates from that in Sanskrit in two aspects. The data analysed for Hindi does not contain any instance of Bahuvrīhi (exo-centric) compound. Second, Hindi data presents many cases where quite a lot of compounds require a verb as well as vibhakti(a case marker) for its paraphrasing. Compounds requiring a verb for paraphrasing are termed as madhyama-pada-lopī in Sanskrit, and they are found to be rare in Sanskrit.

1 Introduction

Noun compounds represent a linguistic device of encrypting information that makes their analysis a challenging NLP task. For example, consider a compound 'ballpoint pen'. It is made up of two nouns: a modifier 'ballpoint' and a head 'pen'. The modifier is again a compound that is composed of two nouns 'ball' and 'point'. The relation between 'ball' and 'point' and in turn between 'ballpoint' and 'pen' is not encoded anywhere on the surface although a user of the language can decodify the meaning correctly. The study of compounds involves two major tasks: 1) automatic identification and extraction of compounds from natural language texts and 2) syntactic and semantic analysis of compounds. The task of identification of compounds becomes significant because of orthographic vagaries. Orthographic conventions for writing compounds may vary from language to language and even within the same language. For example, in Sanskrit a compound is a single word, while in English (as exemplified above) as well as in modern Indian Languages (ILs) we find the following conventions of writing: components written with or without a space and components separated by a hyphen. When compounds are written without a space, the adjoining phonemes undergo euphonic changes as in *gaṅgā-udaka* changing to *gaṅgodaka*. Analysis of compounds primarily involves the expansion of these syntactically condensed constructs with an aim to unfold the meaning of the constructions (Butnariu and Veale, 2008; Girju et al., 2007; Kim and Baldwin, 2006; Kumar, 2012; Nakov, 2008; Nastase and Szpakowicz, 2009; Séaghdha and Copestake, 2007). Semantic analysis of compound is significant for various NLP applications including machine translation, information extraction and so on. Here we discuss one example to show how semantic analysis helps in machine translation. For example, let us consider the English compounds *cancer death* and *room temperature*. Lexical substitution of components of these compounds into Hindi would produce the following result: *kainsara mauta* and *kamarā tāpamāna* which are not legitimate constructions in Hindi. However, the semantic paraphrase of the two compounds, namely, *death from cancer* and *temperature of room* will be helpful for achieving the correct translations of the compounds: *kainsara se* (or *ke kāraṇa*) *mauta* and *kamare kā tāpamāna*. Currently there exist two different approaches in Computational Linguistics to deal with this phenomenon (Paul et al., 2010). They are (a) Labeling the semantics of compound with a set of abstract relations (Girju et al., 2003) and (b) Paraphrasing the compound in terms of syntactic constructs. Paraphrasing is again done in three ways: (i) with prepositions (*war story* vs *story about war*) (Lauer, 1995) (ii) with verb+preposition nexus (*war story* vs *story pertaining to war*, *noise pollution* vs *pollution caused by noise* (Finin, 1980) (iii) with Copula (*tuna fish* vs *fish that is tuna*) (Vanderwende, 1995).

Detailed study of Sanskrit compound processing had been taken up recently (Kumar, 2012), and the insights gained there were found useful for processing the compounds in ILs. After looking at the features of Sanskrit as described in the Sanskrit grammar, in the third section we describe the automatic Sanskrit compound processor, followed by the insights we gained from this processor to identify the compound tags and also the semantic categories necessary to carry out the compound analysis automatically. The fourth section discusses as a case study, use of these tags for Hindi and Marathi compound types. Conclusion follows in the fifth section.

2 Sanskrit Compounds

Pāṇini (500 BCE approximately) has described the process of compound formation in Sanskrit in his grammar called Aṣṭādhyāyī. He used the term Samāsa for Compound. The word Samāsa literally means "Throwing out together" which in the context means "throwing out the words

together". This concept implies that words are thrown out of mouth by human beings in syntactically related structures. There are three main features of a Compound: 1. One word (*aikapadya*), 2. One meaning (*aikārthya*) and 3. One accent (*aikasvarya*). According to Pāṇini, two words within a sentence can form a compound if and only if there is syntactic compatibility (sāmarthya) amongst them. Mere adjacency of words does not allow them to get compounded. The words should be first syntactically related and further should possess the quality of being used by the native speakers as one unit. Further, what distinguishes a compound from a non compounded word group within a sentence are various morphological as well as syntactical features such as a) loss of case, b) absence of intervention of other words, c) no possibility of relation of a non-head word within a compound with another word in the sentence, d) absence of expression of number of the first component.

There are broadly speaking four types of compounds in Sanskrit: 1. Avyayībhāva, 2. Tatpuruṣa, 3. Dvandva and 4. Bahuvrīhi. Semantically, Avyayībhāva and Tatpuruṣa are endocentric compounds with the head typically to the left and right respectively. Dvandva is a copulative compound while Bahuvrīhi is an exocentric compound. Many of the compounds are compositional and hence can be generated with the help of a rule base. However, there are some compounds which are non-compositional and they are treated separately in Pāṇini's grammar. These compounds are called nitya samāsa (obligatory compounds), that is they are always used in compounding form. Such compounds either can not be paraphrased at all (*Avigraha*) or involve extra words other than the components for their paraphrase (*Asvapadavigraha*). Following two examples will illustrate this point:

i) *aśvakarṇa* (name of a medicinal plant) is a compound made up of two words, *aśva* 'a horse' and *karṇa* 'an ear'. When both these words are joined together, they result into a compound, *aśvakarṇa*; but, this compound has no traces of the meanings of it's components. Therefore, this compound can not be paraphrased in terms of its components.

ii) *Kākapeyā* (meaning: a river which contains water potable only by crows). This compound is made up of two components, namely, *kāka* 'a crow' and *peya* 'potable'. As we see, there is an additional semantic element of censure which goes to make this compound. This additional meaning is obviously not a part of the component meanings.

The meaning of compounds may or may not be compositional. Based on the discussions in traditional Sanskrit grammar sources, we see a spectrum of compositionality as illustrated below (Shastri, 2006).
i) purely compositional (*sambaddhārtha*)
ex: *rāja-puruṣaḥ*
gloss: King - man
meaning: King's man

ii) compositionality with fixity of expression (*samprekṣita*)
ex: *khaṭvā-āruḍhaḥ*
gloss: Bed - one who climbs
meaning: One who climbs the bed without completing the education

iii) Non compositionality (with some predictability) (*samgatārtha*)
ex: *citra-gu*
gloss: colorful - cow
meaning: One who has a colorful cow

iv) Non compositionality (*samsṛṣṭārtha*)
ex: *aṣva-karṇa*
gloss: horse - ear
meaning: Name of a medicinal plant.

In Sanskrit compounds are always written without any space in between. But modern Indian languages do allow space in between. Therefore, this spectrum of meanings makes it difficult to decide whether a group of words written with space in between is a compound or not, making the identification of a compound a challenging task for these languages.

3 Sanskrit Compound Processing

Sanskrit is rich in compound formation. Almost every fifth or sixth word in a randomly chosen Sanskrit text is a compound. Compound formation being very productive, we can not list all the compounds in a dictionary. An automatic compound processor was developed (Kumar, 2012) as a part of Computational Toolkit for Sanskrit. This compound processor provides a general architecture for processing compounds.

Analysing a Sanskrit compound involves
i) Segmentation,
ii) Deciding the constituency structure,
iii) Identification of relations between the constituents, and
iv) paraphrasing it.

3.1 Segmentation

In Sanskrit a compound is always written without any space. Moreover, the phonemes of the adjoining components necessarily undergo euphonic changes. Splitting involves reversing these euphonic changes. For instance, the compound *gaṅgodaka* is segmented as *gaṅgā-udaka*. It is possible that a word is ambiguous leading to multiple possible splitting. In Sanskrit the authors have taken advantage of this ambiguity which resulted in many texts with pun. The splitter should be able to produce all possible splits and also rank them if possible. A splitter needs sandhi rules and also a morphological analyser to validate the splits. Two different methods have been followed for building a Sanskrit splitter (Mittal, 2010). In the first approach FST built for morphological analyser is augmented with the sandhi rules (Huet, 2009). In the second approach a given string is split in all possible ways following the sandhi rules, and then the splits are validated through the morphological analyser. This is closer to the GENerate-CONstrain-EVALuate model of Optimality theory (Prince and Smolensky, 1993). The sandhi rules split the given string into all possible ways, then constraints, such as every component of the split should be a valid morph, are applied, and finally the possible splits are ranked using the language and split model. The results of this splitter are quite good, with 93% of cases the first split is correct. This method, though sounds good, practically ends up generating thousands of splits 90% of which are not validated morphologically. Thus this method is computationally less efficient. On the other hand a splitter built by augmenting the FST with sandhi rules is computationally very efficient, since it splits the string only if it is morphologically valid thereby avoiding unnecessary splits. If this FST is further augmented with a proper model for sandhi rules and the lexicon, better results are expected.

3.2 Constituency Parser

Constituency parser takes an output of the segmenter and produces a binary tree showing the syntactic composition of a compound corresponding to each of the possible segmentations. Each of these compositions shows the possible ways various segments can be grouped. To illustrate various possible parses that result from a single segmentation, consider the segmentation a-b-c of a compound. A compound being binary[1], the three components a-b-c may be grouped in two ways as <*a*-< *b*-*c*>> or <<*a*-*b*>-*c*>. Only one of the ways of grouping may be correct in a given context (unless the text has intended pun) as illustrated by the following two examples. Parse of *three-meter-wide* is <<*three-meter*>-*wide*>, and that of *iron water pump* is <*iron*-<*water-pump*>>. The number of possible parses increase exponentially as the number of components increase. The problem of constituency parsing is similar to the problem of completely parenthesizing *n+1* factors in all possible ways. Thus the total possible ways of parsing a compound with $n+1$ constituents is equal to a *Catalan number,* C_n (Huet, 2009). In the absence of any morpheme marking the relation between the components, the constituency structure is governed by the compatibility of meanings of the components involved. Hence to decide the constituent structure, a semantically rich lexicon is needed. In the absence of any such lexicon, the statistical properties of the manually tagged corpus were used (Kulkarni and Kumar, 2011) to decide the constituency structure. For compounds with 3 components, it had a F-measure of 93.66, in case of compounds with 4 components, the F-measure dropped to 65.4. The corpus had compounds with as many as 10 components. On average in 86.5% of cases, the machine could produce the correct parse. Pāṇini has also provided certain rules with morphological constraints on the final component[2], or certain group of words as an initial component[3]. These rules help in prioritising the grouping. These rules, though are written for Sanskrit, hold good across languages. Here is an example of a rule which deals with three components. The sūtra *(diksaṅkhye) taddhitārthottarapadasamāhāre ca (2.1.50)* says that in case of a compound with three components with number or direction indicating word as the first component, the first two components combine first. This holds good for other languages as well. For example, *one day cricket match* is <<*one-day*>-<*cricket-match* >> and *South Indian Association* is <<*South-Indian*>-*Association*>. However, since the surface forms for adjectival usage and compounding forms in English being the same, one may have ambiguous expressions such as *South sea route.* But in Marathi which distinguishes between the adjectival and compounding usage, *dakṣiṇa sumudrī mārga* (<<south-sea>-route>) is different from *dakṣiṇī sumudrī mārga* (<south-<sea-route>>).

3.3 Type Identifier

The semantic classification of compounds given by Pāṇini is not only restricted to Sanskrit language per se, but is more general. For example, the Cambridge Grammar of the English language (Huddleston and Pullum, 2002) uses this classification to describe compounds in English. *Water pump* is an endocentric compound. An endo-centric compound typically shows a hyponymic relation with the head noun. An *egghead* is a bahuvrīhi compound meaning a person whose head resembles the shape of an egg, i.e. a high forehead, and hence intellectual. An example of a coordinative compound is *Hewlett-Packard* meaning a company whose owners are both Hewlett and Packard, or *secretary-treasurer* which stands for a person who is both a

[1] With a possible exceptions of coordinative and certain other rare compounds.
[2] for example, non-finite verbs ending in 'kta' suffix.
[3] for example sūtras corresponding to the 'avyayībhāva' type.

secretary as well as a treasurer. The type of a compound thus is useful in deciding the meaning of a compound. In order to decide the type of a compound, an access to the semantic content of its constituents, and possibly even to the wider context is needed. Now the immediate question is whether this classification of compounds into four classes is sufficient, or do we need further sub-classification. The grammatical texts sub-divide the Tatpuruṣa compounds further into sub-classes based on the case marker the first component takes when the compound is paraphrased. As an illustration, a compound *vidyānipuṇa* 'one who is sharp in the studies', when paraphrased, the first component takes a locative case marker, another compound *Daśarathaputraḥ* 'son of Dasharatha' takes a genitive marker, while the compound *vyāghrabhaya* 'fear of a tiger' takes an ablative case marker in Sanskrit. Based on the paraphrase, a set of 56 fine-grain tags was identified (Kumar et al., 2009) for Sanskrit.

It is important to note the level of semantics the compound tags deal with. Consider the compounds *rājapuruṣaḥ* 'King's servant', *Daśarathaputraḥ* 'son of Dasharatha', and *vṛkṣaśākhā* 'branch of a tree'. In the first case the relation between *rājan* 'king' and *puruṣa* 'man' is that of servant-master (*sevya-sevaka*), in the second the relation between *Daśaratha* and *putraḥ* 'son' is of father-son (*pitā-putra*) and in the third case the relation between *vṛkṣa* 'tree' and *śākhā* 'branch' is part-of (*avayava-avayavi*). However, in all the three cases instead of specifying these deeper relations, relation between the components is expressed through the genitive case suffix in the paraphrase of these compounds as *rājñaḥ puruṣaḥ* 'King's servant', *Daśarathasya putraḥ* 'son of Dasharatha', and *vṛkṣasya śākhā* 'branch of a tree', and thus these are classified as *Ṣaṣṭhī-Tatpuruṣa* 'genitive endocentric compounds with head to the right'. In other words, the classification is not guided by the deeper semantics, but by the paraphrase of a given compound, or by what the language expresses. Thus, on the one hand, to decide the meaning of a compound, we need a fine-grain tagset, at the same time, it should not be as fine-grained as to distinguish between the meaning of genitive cases in *rājñaḥ puruṣaḥ, Daṣarathasya putraḥ* and *vṛkṣasya śākhā*.

Assuming that we follow the fine-grained classification of compounds as dictated by the paraphrase, the question is, to what extent is it possible to decide the relation between the words only on the basis of components involved? For classification, a manually tagged corpus was used as a training data. A corpus of size 800K is tagged manually for the compounds in context by the Sanskrit Consortium. This had 92K instances of compound words. The distribution of frequent compounds is given in Table 1.

Type	Percentage
Endocentric	58.70
Karmadhāraya (IS_A)	18.11
Exocentric	11.04
copulative	5.67

Table 1: Distribution of Sanskrit Compounds

The endocentric compounds were further classified on the basis of missing case marker in the paraphrase. It was found that 55% of these compounds required genitive case marker. (Kumar et al., 2010) reported that the precision of a statistical classifier on this data considering only the major classification, is 72.7%. Allowing sub-divisions resulting into fine-grained tagset

lowers the performance to 63%. Statistical taggers perform well provided the training data is sufficient. So their performance goes down on compounds of rare type. Pāṇini has provided several sūtras in Aṣṭādhyāyī which deal with rare compound types. These sūtras provide various kind of semantic conditions under which a particular type of compound formation takes place. After going through the relevant sūtras, we observe that the conditions stated by Pāṇini fall under the following categories.

1. A restricted list of allowed components in certain type of compounds is provided.
2. A restriction in terms of special inflectional suffix / derivational suffix / category is mentioned.
3. A restriction is stated in terms of special technical terms, which are theory internal.
4. A restriction in terms of semantic relations between the components is mentioned.
5. Semantic property of the component is stated as a condition.

Out of these, the fourth and fifth category are important. The fourth category provides us clues for the important types of relations. Efforts such as Sanskrit WordNet (Kulkarni et al., 2010) or on marking semantic information in various kośas such as Amarakośa (Nair and Kulkarni, 2010) are concerned about lexical as well as semantic relations. In the sūtras related to compounds, we found the mention of following semantic relations.
i) *viśeṣaṇa-viśeṣya-bhāva* 'modifier-modified relation'
ii) *upamāna-upameya-bhāva* 'analogy or comparison'
iii) *avayava-avayavī-bhāva* 'part-whole relation'
iv) instrument-action relation.

The fifth category of conditions puts certain restrictions on the component in terms of semantic properties such as the component should be either a number or a direction or a color or a class indicating word or an adjective. This provides us a clue that the lexicon should have these semantic properties marked to enable automatic compound processing.

3.4 Paraphrase

The tagset for Sanskrit is dictated by the paraphrase. So except for some rare compound types with irregular paraphrases, typically each tag correspond to a well defined paraphrase (Kumar et al., 2009), distinct from the other, and one can then generate the paraphrase automatically. For example, the paraphrase rule for a *Ṣaṣṭhī Tatpuruśa* (T6) 'genitive compound' is given as below.

<x-y>T6 = x{6} y

where x{6} stands for the nominal form of x in genitive case. The paraphrase rules for the complete tagset along with the paraphrase generation is discussed in (Kumar et al., 2009). The problematic cases were those with an elision of certain terms called *madhyampadalopī*. For example, the paraphrase of *Śākapārthivaḥ* 'vegetable - human' is *Śākapriyaḥ pārthivaḥ* 'a human who likes vegetables'. In order to get this paraphrase, we need to insert appropriate content word. Such compounds are rare in Sanskrit, and are listed as exceptions.

3.5 Insights Gained

This detailed study of Sanskrit compounds has helped us in getting a good insight into the compound processing. To understand the meaning of a compound, or to translate a compound into another language, first one needs to understand the underlying constituency structure. For example,
South Indian Cricket Association = <<*South-Indian*>-<*Cricket-Association*>>,
South Indian Food Plaza = <<<*South-Indian*>-*Food*>-*Plaza*>, and
Colon Cancer Tumor Suppressor Protein = <<<<*Colon-Cancer*>-*Tumor*>-*Suppressor*>-*Protein*>.

The second important step in understanding of a compound is to identify the relation between the component pairs. These relations are classified broadly into four categories depending upon the position of the head in the compound. The four major types of compounds were further sub-divided taking into account the differences in their paraphrases. Manual tagging of the Sanskrit compounds revealed that only few of the compounds are very frequent. They include *Tatpuruṣa*, *Bahuvrīhi* and the *Karmadhāraya*. In case of *Tatpuruṣa* compounds, the paraphrase requires appropriate case marker which shows the relation between the components. Among the *Tatpuruṣa* compounds *Ṣaṣṭhī Tatpuruṣa* 'genitive' were most frequent. The *Karmadhāraya* marking the relation of co-referentiality was also frequent. The Sanskrit grammar also provided us certain clues for identifying a compound and its types based on its components.

Finally an important observation from Pāṇini's treatment of Sanskrit grammar was the following. Pāṇini has strived hard to make his grammar as exhaustive as possible by providing rules to handle very rare compounds. So we could take the advantage of both the statistical techniques which perform better with frequent cases and the rule based approach to cover the rare cases.

4 Nominal Compounds in Marathi and Hindi

We used these insights for processing nominal compounds in two major Indian Languages, namely, Hindi and Marathi. Both languages do not have any specific convention for writing the compounds. We find instances of compounds written with components joined together, with a hyphen in between and also with a space in between. Compounds when written as a single word need a segmenter to split it into valid components.

It was observed that a special type of compounds termed as 'Avyayībhāva' are always written as a single word in these languages. Examples of such compounds are *yathāśakti* 'as per the capability', *anurūpa* 'in accordance with'. These are statistically found to be rare in Sanskrit Corpus. We also observe that in Hindi as well as Marathi also such compounds are rare. There could be two ways of accounting for such rare compounds:
1. To have them stored in the lexicon.
2. To have rules with the help of which such compounds can be analysed.
Pāṇini has accounted for such rare compounds with rules which we may use for Hindi and Marathi as well.

In what follows we concentrated only on the compounds written with a space in between. The study was undertaken only to decide the tagset for marking the relation between the components. The tagset for Sanskrit is very exhaustive, covering even the rare compounds. However the purpose of this study was to identify only those tags which are frequent in Hindi and Marathi.

The researchers working on the Cross Lingual Information Retrieval systems among Indian

Languages at IIT Bombay have developed a tool for automatic extraction of Multi Word Expressions from a corpus that uses minimum linguistic tools such as morphological analysers, and POS taggers. The candidates were ranked using Point-wise Mutual Information (PMI) method. Marathi corpus from Tourism domain consisting of 15,925 sentences with 0.325M words was chosen for the experiment. The Multi Word Expression extraction tool gave an initial set of Multi Word Expressions. From these Multi Word Expressions for Marathi, noun compounds were extracted manually, and a study was undertaken to identify the relations between the components. Table 2 lists the identified relations with examples from Marathi.

Dependence relation	Example	Gloss	Meaning
Tādarthya (Purpose)	Praveśa dvāra	Entry door	Door for entry
Karaṇa (Instrument)	Hasta shilpa	Hand Architechture	Architecture made by Hand
adhikaraṇa (Location)	Bhitti chitra	Wall painting	Painting on the wall
samānādhikaraṇa (co-referentiality)	Bauddha dharma	Buddhist religion	Buddhist religion
	sāhasika paryaṭana	adventurous Tourism	adventurous Tourism
	dara varṣī	Every in year	Every year
śeṣa (genitive)	samudra taṭa	Sea bank/shore	Shore of sea
	pāka kalā	Cooking art	Art of cooking
	paryaṭana sthala	tourism place	place of tourism
	upāhāra gṛha	little food house	restaurant

Table 2: Relations in Marathi Noun compounds

As observed in Sanskrit, in Marathi as well we found compounds with genitive case marker, compounds with co-referential components and compounds involving various kinds of dependency relation amongst the components were dominant.

In order to make sure that these relations are sufficient across other ILs, we repeated this study with Hindi. However, this time the compounds were extracted from a Hindi-Urdu dependency treebank being developed at IIIT Hyderabad. Pāṇinian grammar formalism is being followed for the annotation. The treebank has 10,799 sentences consisting of approximately 0.25M words. The compounds in this treebank form a chunk and are annotated with a special label. This made it easy to extract the sentences with compounds. We have examined around 827 sentences and identified 895 noun compounds with two components. Number of unique compounds is 597. Among them 20 are dvandva (copulative) compounds and 15 are cases of reduplication. We observe that compounds can be analysed with genitive (*ṣaṣṭhī sambandha*) for around 45% of times even though we understand that paraphrasing with genitives does not necessarily capture deep semantic relations (see section 3.3 for examples). Nevertheless for the purpose of machine translation genitive paraphrasing may be sufficient because a genitive construct in one language can be mostly translated into a genitive construct in another language whereas a source language compound need not remain a compound in the target language. For example, both the compound *room temperature* and the corresponding genitive construction *temperature of room* can only be translated into *kamare kā tāpamāna* in Hindi. In case of

English-Hindi language pairs, it was observed that in 59% of cases an English Noun compound can be translated into genitive construction in Hindi (Paul et al., 2010). However, for other NLP tasks such as information extraction, question answering etc., genitive relation will not be sufficient and one needs to look for deeper semantic relation. In the present work, we have attempted annotation of deeper semantic relation only when the paraphrase with genitive is illegitimate. The paraphrases were of the following types.

a) with vibhakti (equivalent to post-positions)
b) verb + vibhakti (and not with vibhakti alone)
c) Subtype relation (hyponymy relation)
d) Other kinds of paraphrase

We will discuss each case with suitable examples:

(I) Paraphrasing with vibhakti alone
We come across six classes of vibhaktis[4] which are used for paraphrasing other than the genitive one. Table 3 provides the examples.

(II) Paraphrasing with verb + vibhakti
We find many cases where a meaningful paraphrase is not possible with post-position alone. We have used verbal form along with post-position for meaningful paraphrasing for such cases. For example:

- antarīkṣa yāna vs antarīkṣa meṁ jāne vālā (or ke lie) yāna
  gloss: space ship vs ship that goes into space
- rela saḍaka vs rela calane ke lie saḍaka
  gloss: railway track vs track for the running of train
- rājya sarakāra vs rājya ke lie cunī gayī sarakāra
  gloss: state government vs a government to run the state affairs
- nirvāṇa sthala vs nirvāṇa prāpti (or pāne) ke lie sthala (which according to some annotators can be tagged as nirvāṇa ke lie sthala)
  gloss: nirvāṇa place vs a place where nirvāṇa is attained
- garbha gṛha vs garbha meṁ sthita gṛha
  gloss: inside room vs a room situated inside

(III) Hyponymic Relation
This relation is quite common apart from vibhakti paraphrasing. Hyponymic relations can again be of different nature as exemplified below.

(i) A hyponymic relation which is similar to samānādhikarana (see section 3.3). For example,
a. kāngresa dala vs kāngresa IS_A (nāmaka) dala
gloss: Congress Party
b. taṭarakṣaka bala vs taṭarakṣaka IS_A (nāmka) bala
gloss: Post guard

[4] Vibhakti or post-position can be multi word in Hindi; for example: ke viṣaya meṁ, ke bAre meṁ etc. These multi word expressions are treated as one post-position.

Vibhakti	Meaning	Instances		
		Compound	Gloss	English Translation
se, ke dvārā	With	rimoṭ kanṭrola	Remote Control	Remote Control
		gaisa pīḍita	Gas Victim	Gas Victim
		phoṭo pahacāna	Photo Identity	Identity Card
		dhvani pradūṣaṇa	Noise Pollution	Noise Pollution
		dūrasaṁchāra sevā	Telecom Service	Telecom Service
se	From	sevā nivṛtta	Service Retired	Retired from Service
		karma nivṛtti	Work Retired	Retired from Work
ke lie	For	surakshā bala	Security Forces	Security Forces
		samanvaya samiti	Sensation Committee	Sensation Committee
		ṭurisṭa hāusa	Tourist House	Tourist House
		prajanana aṁga	Reproductive Organs	Reproductive Organs
		śoka saṁvedanā	Mourning Sensation	Condolence
meṁ, para	In, On, At	besa kāmpa	Base Camp	Base Camp
		bāla aparādha	Child Crime	Juvenile Delinquency
ke viṣaya meṁ	About	vidhi śikṣā	Legal Education	Legal Education
		śramika mudde	Labour Issues	Labour Issues
ke sambandha meṁ, sambandhita	About (with regard to)	videśa nīti	Foreign Policy	Foreign Policy
		anusandhāna vibhāga	Research Department	Research Department

Table 3: Paraphrasing Hindi compounds with vibhakti alone

(ii) A hyponymic relation which refers the whole Multi Word Expression as a type of the entity that the head denotes; for example:
a. moṭara boṭa vs moṭara boṭa IS_A (Type of) boṭa (unlike (i), moṭara is not a boṭa)

gloss: Motor Boat
b. prashna cinha vs prashna cinha IS_A (Type of) cinha
gloss:question mark

(IV) Other kinds of paraphrases
We come across some cases where the genitive paraphrase is possible if and only if the modifier can be pluralized. For example,

(a) film abhinetā vs filmoṁ kā abhinetā
gloss: film actor vs actor of film

(b) pujārī samudāya vs pujārīyoṁ kā samudāya
gloss: priest group vs group of priests

(c) cālaka dala vs cālakoṁ kā dala
gloss: driver group vs group of drivers

The heads of (b) and (c) are aggregate nouns and therefore the modifier acquires plural meaning. In case of (a), *film (sg.) kā abhinetā* would mean actor of a particular film; whereas *film abhinetā* as a compound conveys the meaning of 'profession' as in *amitābha eka film abhinetā haiṁ*. The other suitable paraphrase would be *film meṁ kāma karane vālā abhinetā*, where *film* remains singular.

There are institutionalized terms such as *pulisa āyukta*, *vikāsa saciva* and so on and also borrowed compounds such as *ḍāyala up* 'dial up', *kebal cār* 'cable car', which we have left out of the scope of paraphrasing. Table 4 presents number of occurrence of various paraphrases in the data that we have analysed.

Type	No of Instances	Percentage
Genitive	270	47.12
Paraphrasing with Vibhakti alone	80	13.96
Hyponymic Relation	68	11.86
Paraphrasing with verb + Vibhakti	40	6.98
Copulative	20	3.49
Reduplications	15	2.62
Other kinds of Paraphrases	14	2.44
Difficulty in annotation	66	11.51

Table 4: Analysis of Hindi data for various types of paraphrases

This table further supports our intuition from analysis of Marathi data that the tatpuruṣa 'endocentric with missing case markers' and the copulative compounds are more frequent, providing a very strong empirical support for the development of tagset for semantic annotation of noun compounds. In Hindi we also found a considerable number of compounds which require an additional verb and a post position marker for paraphrasing. It is necessary to study the last

category of compounds further in order to enable machines to carry out the analysis and 'guess' the missing verb automatically.

5 Conclusion

It is clear from the data analysed for Sanskrit and Hindi that the most dominating type of compounds is the Ṣaṣṭhī Tatpuruṣa (genitive), in both languages. There are cases of Tatpuruṣa which cannot be analysed with genitive and they are paraphrased with various vibhaktis (case markers). We come across quite a number of cases of Karmadhāraya 'hyponymic' compounds. It is interesting to note that compounding in Hindi deviates from that in Sanskrit in two aspects. Data analysed for Hindi does not contain any instance of Bahuvrīhi (exo-centric) compound. Second, Hindi data presents many cases where quite a lot of compounds requires a verb as well as vibhakti for its paraphrasing. Such compounds are termed as madhyama-pada-lopī in Sanskrit, and they are found to be rare in Sanskrit. The compounds which were found to be difficult for the annotators should form the part of a lexicon.

ABSTRACT

Online shoppers depend on customer reviews when evaluating products or services. However, in the international online marketplace, reviews in a user's language may not be available. Translation of online customer reviews is therefore an important service. A crucial aspect of this task is translating opinion words, key words that capture the reviewers' sentiments. This is challenging because opinion words often have multiple translations. We propose an unsupervised opinion word translation disambiguation scoring method using dependency distance and feature-opinion association as weighting factors. The scores of an opinion word's translation and its surrounding words' translations are estimated using Google snippets. We focus on Japanese-Chinese translation of hotel reviews from Rakutan Travel, using the 10 most common polysemous Japanese opinion words to evaluate system performance. Results show our weighting factors significantly improve translation accuracy compared to Google and Excite.

KEYWORDS : Opinion Word Translation Disambiguation, Dependency Distance, Feature-Opinion Association

Proceedings of COLING 2012: Technical Papers, pages 1503–1518,
COLING 2012, Mumbai, December 2012.

1 Introduction

The development of Web 2.0 has made it easier for internet users to post their reviews or comments about products or services on structured websites. Online shoppers are increasingly likely to look at these reviews before deciding on a purchase. In recent years, the research field of sentiment analysis has focused on analyzing this form of textual-information, particularly opinions or sentiments expressed by internet users.

However, given the international nature of the web and online shopping, opinions in a user's mother language may not be available. Translation of online customer reviews is therefore an important service sought after in many markets. A crucial aspect of customer review translation is translating opinion words, key words that capture the sentiments. At present, machine translation (MT) systems can translate whole sentences or even complete paragraphs. This not a trivial task, however, because opinion words usually have multiple possible translations and the MT systems have low accuracy on polysemous words (Carpuat & Wu, 2005).

This paper proposes an unsupervised method of selecting the most appropriate Chinese translation for an opinion word in a given Japanese sentence. Candidate translations are retrieved from a bilingual dictionary. Consider the following Japanese sentence:

綺麗な夜景とともに食事を楽しむことができました。

(I was able to enjoy a nice meal with a beautiful night view.)

The target opinion word 綺麗 has three candidate translations: 漂亮 (beautiful), 乾淨 (clean), and 清楚 (clear) in Chinese. In this example, the most appropriate translation is 漂亮 (beautiful). This disambiguation problem is known as Word Translation Disambiguation (WTD).

One way to solve the WTD problem is to calculate the sum of association scores of pairs among translation of the target word and all its surrounding words' translations, and then select the one with the highest score. However, since the different surrounding words have different amounts of influence on the target word, it is necessary to add some weighting factors (e.g., word distance). Since our goal is disambiguating opinion words in opinionated sentences, the product features (or aspect expressions) should have direct influence on translation selection. In the above example, 夜景 (night view) and 食事 (meal) are product features, the former having the greatest influence on the opinion word 綺麗 (beautiful).

Our proposed unsupervised opinion word translation disambiguation scoring method uses the dependency distance and feature-opinion association as weighting factors. The scores of an opinion word's translation and its surrounding words' translations are estimated using Google search snippets. In our experiments, we focused on opinion word translation of hotel reviews from Japanese to traditional Chinese. From a dataset of hotel reviews compiled from Rakuten Travel, we selected the top-10 most common polysemous Japanese opinion words to evaluate the performance of our system. The results show that our weighting factors have significantly improved translation accuracy. Compared to Google Translate and Excite translation system, our system can translate opinions more accurately, which could be a boon for Chinese online shoppers seeking accommodations in Japan.

The remainder of this paper is organized as follows: Section 2 introduces some related work while Section 3 describes our proposed method in detail. The experimental results are given in Section 4. The error analysis discussed in Section 5. Finally, conclusion gives in the last section.

2 Related Work

In this section, we introduce some previous works related to our method.

Word translation disambiguation (WTD) (Marsi, Lynum, Bungum, & Gambäck, 2011), also called cross-lingual word sense disambiguation (CL-WSD), which is the task of selecting the most appropriate translation of a polysemous word in a given context. This task can be seen as a special variant of WSD.

The best-known open task in this specialty is the Multilingual Lexical Sample/CL-WSD task, held by the Senseval/SemEval workshop (Chklovski, Mihalcea, Pedersen, & Purandare, 2004; Jin, Wu, & Yu, 2007; Lefever & Hoste, 2010). This task provides a framework for the evaluation of systems that perform machine translation, with a focus on the translation of ambiguous words. Unlike in other lexical sample tasks, the sense inventory for CL-WSD is the set of translations from a bilingual dictionary or a parallel corpus instead of human-defined sense labels.

There have been several studies that use cross-lingual evidence to deal with the WSD problem: (Chan & Ng, 2005; Chklovski et al., 2004; Ng, Wang, & Chan, 2003). These approaches rely on large parallel corpora to train a WSD classifier. However, for some language pairs (e.g., Japanese-Chinese), such corpora are not available. To overcome this problem, Dagan and Itai (1994) used a bilingual lexicon and statistical data from a monolingual corpus of the target language for disambiguation. Tsunakawa and Kaji (2010) proposed a method for using a bilingual dictionary with a correlation matrix to select an appropriate translation word. An item in the matrix is the correlation score between associated words and candidate translations.

The Web is increasingly being used as a data source in a wide range of natural language processing tasks including WSD. Liu and Zhao (2009) presented a fully unsupervised WTD method which selects the maximum sum of Web Bilingual Relatedness (WBR) between a translation and all context words. The WBR is calculated by four association measures based on mixed-language webpage counts from the Baidu search engine. Their WBR model outperformed the best unsupervised SemEval-2007 participant system in the Multilingual Chinese-English Lexical Sample Task. Another work using the Web as a knowledge resource is (Liu, Xue, Li, & Liu, 2010), which is based on minimum Normalized Google Distance and also outperformed the best unsupervised participant system in SemEval-2007.

Most of these studies use the corpus statistics to measure the association between a candidate translation and its context words to disambiguate polysemous words. They tend to consider that all context words have equal influence on a target word. However, since our work is a special case of WTD that focuses on translating polysemous opinion words for a given opinionated sentence, we need give more weight to words that are closely related to opinion words, such as the product features.

3 Opinion Word Translation Disambiguation

In this section, we introduce our method for selecting the translation of a given opinion word in a sentence. The procedure consists of six parts: (1) related word extraction, (2) related word translation, (3) translation corpus, (4) Japanese dependency analysis, (5) related product feature identification, and (6) word translation disambiguation scoring method. The procedures are described in detail in the following sections.

For related word extraction, we apply Japanese compound combination rules to extract nearby words related to the target word. Then, the extracted related words are translated from Japanese to Chinese by our dictionary-based system, which uses an online bilingual dictionary. The translation corpus is compiled from snippets returned by Google Search. To obtain dependency distances among the target word and related words, we feed the given sentence into a Japanese dependency analyzer. We also identify all product features appearing in the given sentence and estimate the association between the target word and each feature. Finally, the disambiguation scoring method calculates scores for each candidate translation to determine the appropriate one.

3.1 Related Word Extraction

We use the following procedure to extract nearby words related to the target word: First, the test sentences are analyzed by a Japanese part-of-speech (POS) and morphological analyzer, MeCab (Kudo, 2005). The MeCab output contains not only the segmented words with POS tags but also detailed information on the *katsuyou* form, root form, and pronunciation of each word. The *katsuyou* is the inflection of the *yougen* (a verb, an adjective, or an auxiliary verb). According to its tense and voice, the *yougen* may have different inflections. For example, 美味しい (delicious) should inflect to 美味しかった in the past tense and 美味しくない (not delicious) in the negative. However, dictionaries usually do not include all these inflections. So we use the root forms instead of the original segmented words in subsequent processing steps.

In addition, we found one difficulty using MeCab: due to the annotation standards of its training corpus, MeCab sometimes treats one compound or loanword as many morphemes. For example, 従業員 (staff) is separated into 従業 (work) and 員 (member), and the loanword エントランス (entrance) is separated into エン (dollar) and トランス (transformer). In both cases, the original meaning is lost. To solve this problem, we apply the Japanese compound combination rules shown in TABLE 1. Most of these morphological rules are based on POS tags. For example, a compound adjective (*comadj*) is composed of a verb (main) followed by an adjective (sub).

noun → noun-verbal | noun-common | noun-proper-misc
prefix → prefix-nominal
suffix → noun-suffix-misc
noun' → *noun'* + *noun*
| *noun* + *noun*
comnoun → *prefix* + *noun* + *suffix*
| *prefix* + *noun'*
| *noun* + *suffix*
| *noun'* + *suffix*
| *noun'*
comadj → verb-main + adjective-sub
location → noun-proper-place-misc + noun-suffix-place
comword → *comnoun* | *comadj* | *location*

comadj: compound adjective
comnoun: compound noun
comword: compound word

TABLE 1 – Japanese Compound Combination Rules

Finally, we filter out irrelevant words using a list of stop words. From the remaining words, we retain only adjectives, verbs and nouns with the following POS tags, as shown in TABLE 2.

Type	POS tags
adjective	adjective-main, adjective-suffix, adjective-sub
verb	verb-main
noun	noun-verbal, noun-common, noun-adjective-base, noun-proper-misc, noun-proper-organization

TABLE 2 – The list of POS tags for retained words

3.2 Related Word Translation

The extracted related words are translated by our dictionary-based system, which uses the Sanseido Japanese-Chinese dictionary[1]. Japanese words are input and Chinese translations are output. Given a Japanese word w_j, all translations of w_j in the dictionary are regarded as potential translations. The Sanseido dictionary includes a total of 28,000 entries and provides the majority of Chinese translations for this study. For few related words that do not appear in this dictionary, we use results from Google Translate.

Since the Sanseido dictionary's Chinese translations are in simplified Chinese, our system must convert the output to traditional Chinese characters. Direct conversion by table lookup may result in mistranslations since the usage of some terms is quite different in mainland China and Taiwan. We use a mapping table of common synonymous words provided by China Biz[2] to improve conversion accuracy.

One translation difficulty that is often encountered in informal-style online user reviews is varying use of common words or expressions. For example, the word すごい (very) can be expressed by the hiragana terms すごーい (terrible) or すっごい (terrific) and the katakana term スゴイ (amazing). Ikeda, Yanagihara, Matsumoto, and Takishima (2009) proposed a normalization algorithm to reduce the number of variant expressions. We apply some of their conversion rules to improve the recall of our translation system. For example, if words are written in all katakana (e.g., スゴイ, the above example), it may imply emphatic use. In this case, we convert the words to hiragana (e.g., スゴイ → すごい). In polite usage, the honorific prefixes (e.g., お, ご, and 御) are used in words such as お手洗い (toilet). In these cases, we remove the prefixes (e.g., お手洗い → 手洗い).

3.3 Translation Corpus

We compiled our translation corpus from snippets returned by Google Search for conjunctive queries of word pairs. These snippets provide useful clues related to the semantic relations that exist between two words. First, we take Chinese word pairs in which one word is a candidate translation of the target word and the other is a translation of a related word. Then, we submit each word pair joined by the Boolean operator "AND" to Google Search and collect the first 500 snippets for our text corpus.

[1] http://www.excite.co.jp/dictionary/japanese_chinese/
[2] http://www.chinabiz.org.tw/

3.4 Japanese Dependency Analysis

In order to obtain the dependency distance between the target word and a related word, we use CaboCha, a Japanese dependency structure analyzer based on Support Vector Machines (SVMs) and the most accurate publicly available system to date, with a reported accuracy of 89.29% (Kudo & Matsumoto, 2002). CaboCha uses a parsing algorithm based on the Cascaded Chunking Model.

FIGURE 1 – An example of Japanese dependency parsing

The basic syntactic unit used in Japanese parsing is the *bunsetsu*, which consists of one or more words followed by either nothing or function words such as particles and auxiliary verbs. FIGURE 1 shows an example of Japanese dependency parsing for a sentence お部屋の照明の照度は大変明るいです！ (The illumination of the lighting of the room is very bright!). In this example sentence, we first find the last node which contains the target word 明るい (bright). Then we calculate all dependency distances from other nodes which contain a related word. For example, the distance from the target word's node to the third node containing the related word 照度 (illumination) is one and the distance to the second node containing 照明 (lighting) is two.

3.5 Related Product Feature Identification

In opinionated sentences, opinion words often describe product attributes or features, such as cleanliness, staff attitude, food quality, etc. in the hotel domain. We believe that considering the product feature(s) related to the target opinion word is helpful for disambiguation of the opinion word. To implement this feature, we enumerated product features[3] for the hotel domain.

3.6 Word Translation Disambiguation Scoring Method

This section describes the word translation disambiguation scoring method. Assume the target opinion word is *o*. One way to select the appropriate translation of *o* is to first calculate the association scores for pairs of each candidate translation and each of its related words' translations, and then select the translation with highest sum of these scores. Consider the following formula (Assume *t* is a candidate translation for *o*):

$$Translation(t \mid o) = \sum_{s_i \in S} \sum_{t' \in translations(s_i)} \frac{Association_T(t, t') \cdot Association_S(o, s_i)}{|translations(s_i)|} \quad (1)$$

where $Translation(t \mid o)$ is the score of the candidate translation *t*, *S* is the set of all related words, and $translations(s_i)$ is the set of s_i's translations (for convenience, hereafter referred to as related translations). For instance, *o* has two candidate translations (t_1 and t_2) and two related words (s_1 and s_2). The translations of s_1 are $t'_{1,1}$, $t'_{1,2}$ and $t'_{1,3}$, and s_2 can be translated to $t'_{2,1}$. Using the above notation, $translations(s_1) = \{t'_{1,1}, t'_{1,2}, t'_{1,3}\}$ and $translations(s_2) = \{t'_{2,1}\}$. $Association_T(t, t')$

[3] The product feature list is available at http://iisr.cse.yzu.edu.tw/~guohau/coling/feature.list

is the association score between a candidate translation t and a related translation t'. $Association_S(o, s_i)$ is the association score between the target opinion word o and a related word s_i—this weighting factor is primarily designed to model their association in the Japanese context. Notice that the final score is divided by the size of $translations(s_i)$. The purpose of adding this term is to balance out the extra influence of s_i's multiple possible translations. In the next two parts, we will introduce the terms $Association_T(t, t')$ and $Association_S(o, s_i)$ in detail.

3.6.1 Association Score between Translations in the Target Language

In this section, we describe how we estimate $Association_T(t, t')$. There are many ways to measure the correlation between two words: one simple way is to calculate the mutual information score in the corpus. First, the snippets described in Section 3.3 are split into segments using punctuation. Their similarity is estimated by Pointwise Mutual Information (PMI) (Church & Hanks, 1990), which is defined as:

$$Association_T(t, t') = PMI(t, t') = \log_2 \frac{p(t, t')}{p(t) \cdot p(t')} \tag{2}$$

where $p(t)$ and $p(t')$ are the probability of word t and t' appearing separately in the corpus, and $p(t, t')$ is the probability of the co-occurrence of word t and t' in the corpus, which is estimated by the number of co-occurring segments for t and t' divided by the total number of segments. However, using PMI does not yield the expected $Association_T(t, t')$ measurements, because the corpus is compiled from the search snippet results of sending all candidate-/related-translation pairs to Google Search. The very low or zero co-occurrence frequencies of some pairs cause difficulty in calculating their values. For instance:

if $\tilde{p}(t, t') \to 0$, then $PMI(t, t') \to -\infty$.

In addition, according to Formula 1, each term in the summation is the product of two scores: $Association_T$ and $Association_S$. For two related words s_1 and s_2 and any of their translations $t'_{1,j}$ and $t'_{2,k}$, if $Association_T(t, t'_{1,j})$ is greater than $Association_T(t, t'_{2,k})$ and $Association_S(o, s_1)$ is greater than $Association_S(o, s_2)$, but $Association_T(t, t'_{1,j})$ and $Association_T(t, t'_{2,k})$ are both negative (PMI score), $Association_T(t, t'_{1,j}) * Association_S(o, s_1)$ is not guaranteed to be larger than $Association_T(t, t'_{2,k}) * Association_S(o, s_2)$. Such a result is not appropriate for our application here.

To solve this problem, PMI is mapped to an exponential function where the value is always positive, which is defined as:

$$PMI_{Exp}(t, t') = e^{PMI(t, t')} \tag{3}$$

3.6.2 Association Score between the Opinion Word and Related Words in the Source Language

We aim to determine the translation of an opinion word by scoring its association to its related words in the source language. Different related words have different influence on the target word, so added weighting factors are necessary. There are two factors that we consider: dependency distance and feature-opinion association.

Distance weighting has been used in several studies (Beeferman, Berger, & Lafferty, 1997; Brosseau-Villeneuve, Nie, & Kando, 2010; Gao, Zhou, Nie, He, & Chen, 2002) as a means of estimating the association between two words. The exponential model, in which association between two words decreases exponentially when the distance between them increases, is a commonly used approach. We employ Beeferman et al. (1997)'s distance weighting approach. Therefore, the association score of o and s_i is defined as:

$$Association_S(o, s_i) = \mu \cdot e^{-\mu \cdot distance(o, s_i)} \tag{4}$$

where $distance(o, s_i)$ is the dependency distance (see Section 3.4 for the details) between o and s_i; and μ is the parameter for decay rate determined by maximum likelihood estimate:

$$\mu = \log_2 \left(1 - \frac{1}{E_{\tilde{p}}[k]} \right) \approx E_{\tilde{p}}[k] - \sum_{k \geq 0} k \tilde{p}(k) \tag{5}$$

where $\tilde{p}(k)$ is the probability of the distance between o and s_i being k.

Since our goal is disambiguating opinion words in opinionated sentences, we should give product-feature words more influence on the translation selection than normal words. To do this automatically, we modify Formula 4 by introducing the feature-opinion association (FOA) score, which is defined as:

$$FOA(o, s_i) = \begin{cases} \min\left[J(o, s_i), \frac{1}{\lambda} \right] & \text{, if } s_i \text{ is a predefined product feature} \\ \frac{1}{\lambda} & \text{, if } s_i \text{ is not a predefined product feature} \end{cases} \tag{6}$$

where the constant value λ is determined empirically to be 1500. The purpose of introducing the minimal function is to set the lower bound of FOA to be $1 / \lambda$, which is a reasonably small value. $J(o, s_i)$ is the Jaccard coefficient, which is defined as:

$$J(o, s_i) = \frac{|o \cap s_i|}{|o \cup s_i|} = \frac{freq(o, s_i)}{freq(o) + freq(s_i) - freq(o, s_i)} \tag{7}$$

Then, we can modify $Association_S(o, s_i)$ as follows:

$$\begin{aligned} &Association_S(o, s_i) = \mu \cdot e^{-\mu \cdot IFOA(o, s_i) \cdot distance(o, s_i)}, \\ &IFOA(o, s_i) = \frac{1}{\lambda \cdot FOA(o, s_i)} \end{aligned} \tag{8}$$

where $IFOA$ is the abbreviation of the inversed FOA score.

In Formula 6, we mentioned that when s_i is not a predefined product feature, $FOA(o, s_i)$ is $1 / \lambda$, making the $IFOA(o, s_i)$ 1, which implies that $IFOA(o, s_i)$ does not have any effect. This increases the influence of related product-feature words while having no influence on regular related words.

3.7 Application of Our WTD Formulae

Let us consider the following example to demonstrate our proposed WTD scoring method:

お部屋もお風呂も綺麗に掃除がされている。

(The room and bathroom have been swept clean.)

The target opinion word **綺麗** has three candidate translations: 漂亮 (beautiful), 乾淨 (clean), and 清楚 (clear). For convenience, we consider only the first two: 漂亮 (beautiful) and 乾淨 (clean). The steps of our WTD method are as follows:

1. Related Word Extraction
   Three related words are extracted from the input sentence: **部屋** (room), **風呂** (bathroom), and **掃除** (sweep).

2. Related Word Translation
   The related words are translated into Chinese (called related translations): 房間 (room) and 屋子 (house) for **部屋**, 浴室 (bathroom) for **風呂**, 打掃 (sweep) for **掃除**. TABLE 3 lists Japanese words and their Chinese translations used in this application.

Japanese word	Chinese translations
綺麗	漂亮 (beautiful), 乾淨 (clean), 清楚 (clear)
部屋	房間 (room), 屋子 (house)
風呂	浴室 (bathroom)
掃除	打掃 (sweep)

TABLE 3 – Japanese word and its Chinese translations

3. Translation Corpus
   We look up the Chinese word pairs (e.g., "漂亮" AND "房間", "乾淨" AND "房間") in our Google Search translation corpus (Section 3.3) and collect the snippets.

4. Japanese Dependency Analysis
   After dependency analysis, the dependency distances between each target opinion word and the related word are acquired:
   {**綺麗-部屋**: 3, **綺麗-風呂**: 2, **綺麗-掃除**: 2}

5. Related Product Features Identification
   The product features are **部屋** (room) and **風呂** (bathroom).

6. Word Translation Disambiguation Scoring Method
   Consider Formula 1:

$$Translation(t \mid o) = \sum_{s_i \in S} \sum_{t' \in translations(s_i)} \frac{Association_T(t, t') \cdot Association_S(o, s_i)}{\left| translations(s_i) \right|}$$

   o: the target opinion word **綺麗**
   s_i: any related word in {**部屋**, **風呂**, **掃除**}
   t: any candidate translation in {漂亮, 乾淨}
   t': any related translation in {房間, 屋子, 浴室, 打掃}

   Consider Formula 2:
   Assume the $Association_T(t, t')$ for each candidate translation-related translation pair is:
   {漂亮-房間: 0.5, 漂亮-屋子: 0.55, 漂亮-浴室: 0.4, 漂亮-打掃: 0.35,
   乾淨-房間: 0.6, 乾淨-屋子: 0.45, 乾淨-浴室: 0.7, 乾淨-打掃: 0.75}

Consider Formula 5:

$$\mu = \log_2\left(1+\frac{3}{3+2+2}\right) = 0.51$$

Consider Formulae 6 to 8:
We assume the feature-opinion association scores [$FOA(o, s_i)$] are:
FOA(綺麗, 部屋) = 0.0025, $IFOA$(綺麗, 部屋) = 0.27
FOA(綺麗, 風呂) = 0.0032, $IFOA$(綺麗, 風呂) = 0.21

Then, the $Association_S(o, s_i)$ between the target opinion word and each related word is:
$Association_S$(綺麗, 部屋) = $0.51 * e^{-0.51 * 0.27 * 3} = 0.34$
$Association_S$(綺麗, 風呂) = $0.51 * e^{-0.51 * 0.21 * 2} = 0.41$
$Association_S$(綺麗, 掃除) = $0.51 * e^{-0.51 * 1 * 2} = 0.18$

Now, we can calculate the weighted score for each candidate translation:
Translation(漂亮 | 綺麗)
= $Association_S$(綺麗, 部屋) * $Association_T$(漂亮, 房間) / |*translations*(部屋)| +
$Association_S$(綺麗, 部屋) * $Association_T$(漂亮, 屋子) / |*translations*(部屋)| +
$Association_S$(綺麗, 風呂) * $Association_T$(漂亮, 浴室) / |*translations*(風呂)| +
$Association_S$(綺麗, 掃除) * $Association_T$(漂亮, 打掃) / |*translations*(掃除)|
= 0.34 * 0.5 / 2 + 0.34 * 0.55 / 2 + 0.41 * 0.4 / 1 + 0.18 * 0.35 / 1
= 0.41

Translation(乾淨 | 綺麗)
= $Association_S$(綺麗, 部屋) * $Association_T$(乾淨, 房間) / |*translations*(部屋)| +
$Association_S$(綺麗, 部屋) * $Association_T$(乾淨, 屋子) / |*translations*(部屋)| +
$Association_S$(綺麗, 風呂) * $Association_T$(乾淨, 浴室) / |*translations*(風呂)| +
$Association_S$(綺麗, 掃除) * $Association_T$(乾淨, 打掃) / |*translations*(掃除)|
= 0.34 * 0.6 / 0.5 + 0.34 * 0.45 / 0.5 + 0.41 * 0.7 / 1 + 0.18 * 0.75 / 1
= **0.6**

So, the chosen translation is 乾淨 (clean).

4 Experiments

We conducted experiments with our Japanese hotel review corpus to empirically evaluate the translation accuracy of our WTD scoring method using different sets of weighting factors and the modified PMI formula. We also compared our system's performance to that of Google Translate and the Excite translation system.

4.1 Dataset

Our dataset consists of 956,892 reviews of 15,291 hotels from the Rakutan Travel website[4], the largest hotel-booking/review website in Japan. The sentences are segmented and duplicate content is removed. After processing, the dataset contains 4,341,266 sentences. We also use this data to create the product feature list for Section 3.5.

[4] http://travel.rakuten.co.jp/

4.2 Experiment Design

We selected the top-10 most common polysemous opinion words and annotated each of their occurrences in the dataset with their translations. For each of the ten opinion words, we constructed test examples by randomly selecting 1,200 sentences from the dataset. Each test example contains only one opinion word. The ground truth of each translation was assigned by two human annotators. Statistics for the gold standard dataset are presented in TABLE 4.

Word	#Sense	#Instance	Avg length	Min length	Max length
明るい (bright)	2	992	36.3	7	135
甘い (sweet)	2	808	40.3	7	145
暖かい (warm)	2	979	41.6	6	147
丁寧 (polite)	2	1,057	37.9	11	125
冷たい (cool)	2	957	44.0	6	174
薄い (thin)	2	1,041	38.3	6	141
綺麗 (beautiful)	3	736	35.2	9	113
きつい (tiring)	3	755	41.9	10	136
寂しい (lonely)	3	794	38.7	8	120
厳しい (strict)	4	506	45.0	7	141
Avg.	**2.5**	**862.5**	**39.9**	**7.7**	**137.7**

TABLE 4 – Statistics for the gold standard dataset

As shown in TABLE 4, our gold standard dataset contains a total of 8,625 test examples with an average of 2.5 senses per word. The average length of the test examples is 39.9 Japanese characters.

In order to measure the impact of different sets of weighting factors and modified PMI formula on translation accuracy, we ran a set of 30 experiments for each configuration. For each experiment, we randomly chose 85% of the test examples for each opinion word. After running all the experiments, we performed a two-tailed paired T-test on the average accuracies of different sets of weighting factors to prove our weighting approach significantly improved translation accuracy. We also compared our system's performance with that of Google Translate and the Excite translation system using the same test method. The online translation systems' performance was checked by two annotators (only for the correctness of the opinion word translation, but ignoring translation of surrounding words).

4.3 Evaluation Metrics

For each opinion word, the results are given in terms of translation accuracy, which is defined as:

$$accuracy = \frac{\#\ of\ correct\ translations}{\#\ of\ test\ sentences} \tag{9}$$

We also calculated macro and micro averages to measure the overall performance across all opinion words. The macro average is simply the average of the accuracies of all ten opinion words. In contrast, micro average is the sum of correct occurrences divided by the sum of all occurrences.

4.4 Results

TABLE 5 shows the experimental results for the different configurations of our WTD scoring method. The value in each cell indicates the average accuracy. For our baseline system, we used the most frequent sense (MFS) method:

$$MFS = \frac{\#most\ \ frequent\ sense}{\#test\ sentence} \tag{10}$$

In TABLE 5, A_T(PMI) stands for the configuration in which $Association_T$ (t, t') is estimated by the original PMI (Formula 2) and $Association_S$ (o, s_i) is set to 1. $A_T(PMI_{Exp})$ means that the modified PMI formula (Formula 3) is used to replace Formula 2. $A_T(PMI_{Exp})+A_S(D)$ means that $Association_S$ (o, s_i) is estimated by Formula 4, which considers the dependency distance. $A_T(PMI_{Exp})+A_S(D+F)$ means that Formula 8, which considers both dependency distance and feature-opinion association, is used to replace Formula 4. TABLE 5 shows that $A_T(PMI_{Exp})$ significantly improves overall accuracy by about 7.6% over A_T(PMI). $A_T(PMI_{Exp})+A_S(D)$ improves overall performance by about 9.6% from A_T(PMI), and $A_T(PMI_{Exp})+A_S(D+F)$ achieved the best result, improving overall accuracy by about 11% over A_T(PMI). It should be noted that $A_T(PMI_{Exp})+A_S(D+F)$ also has a positive impact on performance of every opinion word individually.

Compared with the online translation systems, TABLE 5 shows our system outperforms Excite and Google for opinion word translation. The two online translation systems perform even worse than MFS on average.

Word	MFS	Excite	Google	A_T(PMI)	$A_T(PMI_{Exp})$	$A_T(PMI_{Exp})$ $+A_S(D)$	$A_T(PMI_{Exp})$ $+A_S(D+F)$

TABLE 6 – T-tests on the average accuracies of different weighting factors

5 Discussion

In this section, we discuss the causes of some common errors that our system made.

5.1 Errors caused by Japanese homonyms

Japanese has many homonyms—words that share the same pronunciation but have different meanings and kanji. For example, the words 蜜柑 (orange), 未完 (unfinished), and 未刊 (unpublished) all share the same hiragana spelling みかん (orange) but are represented by different kanji. When calculating the *Association*$_T$ of hiragana words, the co-occurrence frequency of opinion word/related word pairs may be overestimated.

5.2 Limitations of single word-pair association scores

In the sentence, 暑い時期は駅からの距離が**きつい**です (When it is hot, walking the distance from the station is tiring.), which describes the hotel location, the two most likely Chinese translations for the opinion word きつい are 累人 (tiring) and 擁擠 (crowd), the former being the correct choice. The *Association*$_T$ between 累人 (tiring) and 距離 (distance) is incorrectly calculated as being lower than that between 擁擠 (crowd) and 距離 (distance). To determine the correct translation in cases like this, we should calculate *Association*$_T$ between pairs of related words and the opinion word. In the above example, if we consider 暑い (hot) and きつい (tiring) as one entity and calculate the *Association*$_T$ between 距離 (distance) and 暑い-きつい (hot-tiring), we get the correct translation.

5.3 Target opinion word associated with multiple feature words

If the target opinion word can apply to multiple product feature words in a sentence, the incorrect pairing may end up with the highest *FOA*. For example, in the sentence エントランスが**明るく**て従業員の対応も素敵でした。 (The entrance was bright and the staff's attitude was also friendly.), the opinion word 明るい (bright) can describe both feature words エントランス

(entrance) and 従業員 (staff). In this case our system calculates a higher *FOA* for the 明るい-従業員 (staff-bright) pair.

Conclusion

In this paper, we propose an unsupervised opinion word translation disambiguation scoring method which uses dependency distance and feature-opinion association as weighting factors. The scores of an opinion word's translation and its surrounding words' translations are estimated using Google search snippets. In our experiments, we focused on translation of hotel reviews from Japanese to Chinese. From a dataset of hotel reviews compiled from Rakutan Travel, we selected the top-10 most common polysemous Japanese opinion words to evaluate the performance of our system. The results show that our scoring method for representing the influence of product features and dependency distance improves translation accuracy effectively. Compared to Google Translate and Excite translation system, our system can translate opinion words more accurately, which could be of benefit to Chinese online shoppers seeking accommodations in Japan.

Acknowledgments

We would like to thank the two anonymous reviewers for their valuable comments, which have greatly improved the presentation of this paper. This work was supported in part by the Taiwan National Science Council under Grants NSC 98-2221-E-155-047 and NSC 99-2628-E-155-004.

ABSTRACT
We present a novel topic modelling-based methodology to track emerging events in microblogs such as Twitter. Our topic model has an in-built update mechanism based on time slices and implements a dynamic vocabulary. We first show that the method is robust in detecting events using a range of datasets with injected novel events, and then demonstrate its application in identifying trending topics in Twitter.

KEYWORDS: Topic Model, Twitter, Trend Detection, Topic Evolution, Online Processing.

COLING 2012, Mumbai, December 2012.

1 Introduction

In recent years, microblogs such as Twitter (http://www.twitter.com/) have emerged as a highly popular form of social media. Microblogs provide a platform for users to post short messages (a.k.a. "tweets") for followers to read in an on- or off-line fashion. One of the major attractions of microblogs is their contextual immediacy, i.e. they provide "here and now" access to users, including the potential to geotag tweets for the location of the post. Twitter is used in a variety of ways, from posting about personal daily life events to finding jobs to keeping up to date with news events.[1]

As microblogging services have gained in popularity, a myriad of applications that perform analysis of what is "trending" at a given point in time have emerged, with examples including Trendsmap (http://trendsmap.com/), What the Trend (http://whatthetrend.com/), twinitor (http://www.twinitor.com/) and Twendr (http://twendr.com/). There are a number of reasons for tracking trends. At the end-user level, it provides a way for users to identify popular discussions to follow or participate in. From a social science perspective, it provides insights into how new trends emerge, the half-life of trends, and the types of topics commonly discussed in the Twittersphere, etc.

Applications that track trends commonly use a keyword-based approach, and provide output in the form of simple terms, hashtags or term *n*-grams. While these keywords are indicative of the subject of the trending topic, ultimately they fall short in providing users with a fine-grained insights into the nature of the event. This motivated us to look for an alternative means of analysing and presenting trends, and ultimately led us to look at topic models as a potential solution.

Our contributions in this work are as follows. We first describe a topic model that processes documents in an on-line fashion. The model has the important properties that it does not grow over time, and can cope with dynamic changes in vocabulary. We then describe a method to measure shifts in the topic model, in order to track emerging events. We demonstrate the robustness and accuracy of the model using a suite of synthetic datasets based on Twitter and data from the TREC Topic Detection and Tracking (TDT) corpus, and then apply it to a series of Twitter feeds to detect popular topics in particular locations, which we find closely track local and global news events. The associated topics, in the form of a multinomial distribution over terms, are also more descriptive than single hashtags or strings.

2 Background

In recent years, there has been a surge of interest in event detection, due to the ready accessibility of document streams from newswire sources and social media. It has seen applications in many areas, such as the tracking of influenza (Signorini et al., 2011) and harvesting of spatio-temporal information for forest fires (De Longueville et al., 2009). Event detection occurs in two forms: (1) retrospectively, assuming the full document collection as input; and (2) on-line, processing documents dynamically as they arrive.

Retrospective event detection in microblogs provides insights about events that occurred in static sets of historical data. Much of the early work on retrospective event detection took place in the context of the TREC Topic Detection and Tracking (TDT) task (Allan, 2002), e.g. using document clustering and anomaly detection methods. If we wish to detect events happening presently in

[1] http://webtrends.about.com/od/twitter/a/why_twitter_uses_for_twitter.htm

our time, however, we require on-line event detection models. An example application where real-time responsiveness is critical is earthquake detection (Sakaki et al., 2010), and trend analysis also clearly requires on-line processing in order to be of use (Mathioudakis and Koudas, 2010). Most on-line approaches, however, use a relatively simple keyword-based methodology over a pre-defined set of keywords (Culotta, 2010; Lampos and Cristianini, 2010; Weng and Lee, 2011; Zhao et al., 2012) rather than tackling the more challenging task of open-world event detection.

Real-time first story detection (Petrović et al., 2010; Osborne et al., 2012) is the task of detecting the mentions of a breaking story as close as possible in time to its first mention. Here, the system should ideally pick up on the breaking story within seconds or minutes of its first mention in order to have impact, e.g. as an alert system for a newswire agency or intelligence organisation. As such, the methods that are standardly applied to the task tend to be based on analysis of local "burstiness" in the data, e.g. through locality sensitive hashing. Our work differs from theirs in that we wish to identify trends or topics that occur with a significant proportion in the data—which is different from trying to detect the very first mention of these topics. In our case, timeliness of detection is not as critical.

Bursty term analysis has obvious limitations in identifying events, both in that it fails to capture the fact that multiple terms may be involved with the same event (Zanzotto et al., 2011), and requires that at least one term undergoes a sufficiently high jump in relative frequency that the event can be identified. Topic models have been proposed as a means of better capturing events, by way of learning *clusters* of terms that are associated with a given event, as well as modelling changes in term co-occurrence rather than just term frequency. Most work based on topic modelling has been in the form of retrospective event detection models, however (Kireyev et al., 2009; Diao et al., 2012).

Moving to the more general area of the machine learning, several online topic models have been proposed (Hoffman et al., 2010; AlSumait et al., 2008). Hoffman et al. (2010) introduced an online LDA variant that uses variational Bayes as the approximate posterior inference algorithm. The model that is closest in spirit to what we propose is On-Line LDA (OLDA) (AlSumait et al., 2008). Using collapsed Gibbs sampling for approximate inference, OLDA processes documents in an on-line fashion by resampling topic assignments for new documents using parameters from a previously learnt model. We return to compare OLDA with our proposed method in Section 3.3.

3 Methodology

We first provide background on LDA topic modelling in Section 3.1. Next we describe our proposed online variant of LDA in Section 3.2, and contrast it with Online LDA in Section 3.3. Lastly, we explain how our topic model can be used to detect emerging topics in Section 3.4.

3.1 LDA Topic Model

LDA is a generative model that learns a set of latent topics for a document collection (Blei et al., 2003). The input to LDA is a bag-of-words representation of the individual documents, and the output is a set of latent topics and an assignment of topics to every document in the collection. Formally, a topic is a multinomial distribution of words, and a document is associated with a multinomial distribution of topics. A summary of LDA variables is presented in Table 1.

In topic models, the generative process for a word is as follows: first choose a topic, then sample

Variable	Dimension and Type	Description
T	Integer	Number of topics
W	Integer	Number of unique words (vocabulary)
D	Integer	Number of documents
N	Integer	Number of tokens
θ	$D \times T$ of probabilities	Topic distribution in documents
ϕ	$T \times W$ of probabilities	Word distribution in topics
$\boldsymbol{\alpha}$	$D \times T$ of α priors	Dirichlet prior for θ
$\boldsymbol{\beta}$	$T \times W$ of β priors	Dirichlet prior for ϕ
$\boldsymbol{w}$	N-Vector of word identity w	Words in documents
$\boldsymbol{z}$	N-Vector of topic assignment z	Topic Assignment of Words

Table 1: A summary of variables used in LDA.

a word from the given topic. Blei et al. (2003) introduced Dirichlet priors to the generative model, and used variational Bayes to learn θ and ϕ by maximising the probability of words in the collection. Griffiths and Steyvers (2004) proposed using collapsed Gibbs sampling to do approximate inference by considering the posterior distribution over the assignments of words to topics ($P(\boldsymbol{z}|\boldsymbol{w})$). Summarising the derivation steps, the update function in the sampling process for a new topic assignment of a word can be expressed as follows:

$$P(z = t|\boldsymbol{z}, \boldsymbol{w}, \boldsymbol{\alpha}, \boldsymbol{\beta}) \propto \frac{n(d,t) + \alpha}{n(d,\cdot) + T\alpha} \frac{n(t,w) + \beta}{n(t,\cdot) + W\beta}$$

where $n(d,t)$ is the number of assignments of topic t in document d, and $n(t,w)$ is the number of assignments of word w to topic t; all counts exclude the current assignment z.

3.2 Online Processing Variant

LDA processes the data in a single batch to learn the topic assignments. To facilitate the processing of streamed text, we need a model that: (1) processes the input and updates the model periodically; (2) produces topics that are comparable for different periods so that topic shift/evolution is measurable; and (3) does not grow in size with time (to ensure that it stays sensitive to topic changes over time).

We first introduce a few concepts needed for the model. Time in the model is discretised into slices, and documents (i.e. the input data) are partitioned into time slices. For example, a time slice can be an hour, a day, or a year. Denoting each time slice as k_t, k_0 is the first time slice. L is a sliding window that keeps documents for a fixed number of time slices. As documents in the new time slice arrive, documents in older time slices are discarded, so that length of the window, $|L|$, remains constant. The rationale of this approach is that we require a model that is constant in size; storing the complete document stream history data would cause the model to grow indefinitely over time, and become increasingly insensitive to topic changes.

At the arrival of new documents for time slice k_{t+1}, we update the model by resampling the topic assignments $\boldsymbol{z}$ for all documents in window L (Equation 1), using θ and ϕ from the previous model in slice k_t to serve as Dirichlet priors $\boldsymbol{\alpha}'$ and $\boldsymbol{\beta}'$ in the new model in slice k_{t+1}. The contribution factor, c, determines the degree of contribution of learnt parameters to the priors of the new model. c ranges from 0 to 1: $c = 0$ means the model is run without using any previously learnt parameters. The introduction of c is key in enabling the model to have a set of constantly evolving topics. In other words, it dampens the rich-gets-richer dynamic of the Chinese Restaurant Process in LDA.

1. Initial step:
   (a) Set Dirichlet priors α_0 and β_0; topic number T; contribution factor c; time slice k; and window size $|L|$;
   (b) Given $|L| = l$, window L contains documents from slices $k_0, ..., k_{l-1}$;
   (c) Run LDA for documents in window L;
2. Iterative step for each k_{l+i}:
   (a) Add documents in slice k_{l+i} to window L;
   (b) Remove documents in slice k_i from window L, updating θ and ϕ from the previous model as necessary;
   (c) Re-generate vocabulary for documents in window L;
   (d) Calculate priors $\boldsymbol{\alpha}'$ and $\boldsymbol{\beta}'$ as per Section 3.2;
   (e) Resample $\boldsymbol{z}$ using $\boldsymbol{\alpha}'$ and $\boldsymbol{\beta}'$ for documents in window L as per Equation 1.

Table 2: Work flow of the online processing model.

As a true online model, it would not be appropriate to assume a fixed vocabulary across time. The importance of having a dynamic vocabulary is motivated by the fact that we are interested in detecting emerging events in the data stream, where new words are likely to appear and be associated with new events (e.g. in the form of names of key people or places). To accommodate this, at every update we process the documents in the time window to re-generate the vocabulary, removing words that fall below a pre-defined frequency threshold and adding new words that now satisfy it.[2]

The Dirichlet priors $\boldsymbol{\alpha}'$ and $\boldsymbol{\beta}'$ in the new model in slice k_{t+1} are calculated as follows:

For previously seen documents and words:

$$\alpha'_{dt} = \frac{n(d,t)}{N_{old}} \times D_{old} \times T \times \alpha_0; \qquad \beta'_{tw} = \beta_0 \times (1-c) + \frac{n(t,w)}{N_{old}} \times T \times W_{new} \times \beta_0 \times c \tag{1}$$

For new documents and words:

$$\alpha'_{dt} = \alpha_0; \qquad \beta'_{tw} = \beta_0$$

where α'_{dt} is the prior for topic t in document d; β'_{tw} is the prior for word w in topic t; $n(d,t)$ and $n(t,w)$ are counts from the previous model in slice k_t; α_0 and β_0 are the default uniform prior values for θ and ϕ; and D_{old}, N_{old} and W_{new} are the number of previously processed documents, number of tokens in those documents and number of vocabulary, respectively, in time window L. The rationale behind the normalisation approach is to maintain a constant sum of priors across different batches of processing, i.e. $\sum \boldsymbol{\alpha}' = \sum \boldsymbol{\alpha} = D \times T \times \alpha_0$, and $\sum \boldsymbol{\beta}' = \sum \boldsymbol{\beta} = T \times W \times \beta_0$.

The work flow of the model is presented in Table 2.

3.3 Comparison with On-line LDA

One key difference between our proposed model and On-line LDA (OLDA) is the transfer of parameters from a previously learnt model to the updated model. In OLDA, ϕ counts from the

[2] In all our experiments, we filter our all words that occur less than 10 times across all documents in the window.

previous model are used directly or normalised as priors in the new model. To avoid topics converging after a number of iterations, OLDA removes the the $\boldsymbol{\beta}$ prior counts in ϕ of the previous model before importing them into the new model. Our model handles the converging issue in a more elegant way, by introducing a parameter (contribution factor, c) to dampen the influence from the previous model.

The second difference is that OLDA assumes a fixed vocabulary. While this is a convention in topic models, it is not an appropriate assumption for a genuinely online application, where it is impossible to pre-calculate the vocabulary ahead of time. As emerging events are likely to contain critically-relevant phrases and terms (e.g. the name of a hitherto-unknown key figure in an event, the name of a natural disaster, or the little-known location of an event), the vocabulary of our proposed model is re-generated at each update: new words are added and previously-seen words that drop below our frequency threshold are removed.

3.4 Detection of Novel Topics

At every model update, the word distribution in topics (i.e. ϕ) changes, however a one-to-one correspondence between topics is maintained across adjacent updates (provided that $c \neq 0$). Topics can thus be viewed as constantly evolving as new documents are processed: topics that are rarely or not observed in the updated document set will fade away, replaced by newly-emerged topics.

To detect these novel topics, we calculate the degree of change, or, the *evolution* of a topic using the Jensen-Shannon divergence measure between the word distribution of each topic t before and after an update, and classify a topic as being *novel* if the measure exceeds a threshold.

4 Synthetic Dataset Experiments

4.1 Generation of Synthetic Data

Ultimately we are interested in applying our method to real-world document streams, ideally based on a microblog such as Twitter. For evaluation purposes, however, we require a document stream where we have document-level annotations of: (1) whether it mentions an event of potential interest; and (2) if it mentions an event, what that event is (in the form of an event ID, potentially shared across multiple documents over a time period). In the absence of such a dataset, and given the prohibitive expense in exhaustively annotating such a dataset over the volume of data that comes through Twitter, we created a suite of synthetic datasets. Other than annotation cost, one advantage of using a synthetic dataset is that it gives us the flexibility to generate events with different distributional properties.

Having said that we are resigned to generating a synthetic dataset, we want the data to mimic as closely as possible the actuality of event mentions on Twitter. To this end, we take a document stream from Twitter and replace the message content of tweets nominally relating to a particular event (based on hashtag analysis) with distinct tweet-length mentions of events from the Topic Detection and Tracking corpus (TDT3)[3] dataset. That is, our datasets contain "background events" in the original Twitter document stream that we don't have annotations for, and "novel events" from TDT that we do have annotations for, and that form the basis of our evaluation.

In detail, the following steps were taken to generate the background event dataset:

[3] `http://projects.ldc.upenn.edu/TDT3/`

Event Type	Document Content
Background	@allabouttaurus : be realist we see thing for what they be not what they could be .
Background	ugh i be go to be so sore tomorrow
Background	rt @pagswagxo : next status i see about m . burn and i be gonna go insane .
Background	! ! saatnya mencarus wifi supaya ipod touch gw conect ke internet , dan ngetweet via twitter for iph one ,
Novel	the kosovo information center claim serb police be pass out weapon to serb civilian in the region .

Background	had2let it be know ! & thanks for txtn back -___ - rt @phliwidapencil lmfao rt @skrillafoccapo : all big booty aint good big booty ! !
Background	rt @desintadict_cb : rtif u want follower (cont) http ://t.co/joej7wfz
Background	well i know where all my christmas money be go . municipal court of jasper .

Table 3: An example of 10 documents in the synthetic dataset for KIM-MILOSEVIC (mapped TDT3 Topic: Holbrooke-Milosevic Meeting).

1. Collect Tweets from September 2011 to January 2012.[4]
2. Identify a set of hashtags that occur over 80% of the days in this 5-month period.[5]
3. Designate these hashtags as the set of candidates for the background events. The treatment of these hashtags as background events is based on the assumption that hashtags are generally associated with events or topics in Twitter.
4. Randomly select a subset of hashtags from the candidate set, biased according to frequency, i.e. popular hashtags are more likely to be selected than rarely-used hashtags.
5. Extract out all messages tagged with the selected hashtags for a given time period (see below), and remove the hashtag.

The novel events were embedded into the dataset as follows:

1. Select a news event that occurred during the time of the crawl, across a range of genres ranging from natural disasters to celebrity deaths to terrorist attacks (see Table 4 for details).
2. Identify a set of Twitter hashtags that correspond to the particular news event. Tweets that contain these hashtags constitute the individual novel documents.
3. Select a TDT3 topic that is of a similar genre to the news event (to keep the injected documents as similar as possible in content to the messages they replace). All topics were events that took place in 1999.
4. Replace each identified tweet with a sentence sampled randomly from the TDT3 documents labelled with the selected event topic (removing the original hashtag in the process).

Our justification for this procedure is two-fold:

- *to generate tweet-level annotations for each event, across a range of event genres* — While the original tweets had one of the pre-identified hashtags, they could have been spam or hijacking the primary topic associated with the hashtag (i.e. we are attempting to ensure the *precision* of the annotations relative to a given event);

[4]We collected the Tweets via the Twitter Streaming API: `https://dev.twitter.com/docs/streaming-api/methods`. The corpus contains approximately 12 million tweets, spanning 1.39 million users.

[5]In this case, we assume that hashtags represent events or topics. This assumption is used only as a means to simplify the process for synthesising dataset. Note that these hashtags (that occur over 80% of the days in the period) are generally popular topics that are frequently discussed and may not necessarily be news events.

- *to guard against the possibility that the background tweets relate to injected event* — In the original dataset, it is highly likely that there are tweets which mention the original news event but aren't tagged with one of the pre-identified hashtags. It is unlikely, however, that there would be background tweets which mention an event from 1999 (i.e. we are attempting to ensure the *recall* of the annotations relative to a given event).

In doing a one-for-one replacement of an original tweet with a TDT3 sentence and maintaining the original timestamp of the tweet, we are additionally achieving an event propagation distribution which is as faithful as possible to actual event mentions in Twitter.

In total, we created 5 datasets, each with a single novel event and 25–150 background events. We initially experimented with 50 background events but later varied the number of background events—hence the variation in the number of background events in the synthetic dataset. Each dataset spans over a period of 9 days, with the novel event injected on the 5th day (and subsequent days at a level defined by the frequency of the original hashtags).[6]All documents are stopped and lemmatised.[7] An example of a sample of generated documents is displayed in Table 3.[8] A summary of the novel events, mapped TDT3 topics and other metadata is presented in Table 4.

4.2 Experiments

In all experiments, we set the time slice to 1 day and length of window $|L|$ to 2 days. Note, however, that the time slice setting is flexible: should more temporally fine-grained analysis be required, the time slice can be set to a shorter time frame, e.g. 1 hour.[9] We set the contribution factor c to 0.5, meaning old and new documents have approximately equal weighting in the 2-day window. We set α_0 to 0.001; a low value is preferred to produce a very sparse topic distribution over documents (each document, i.e. tweet or sentence from TDT3, should be assigned to no more than a few topics). For β_0, we use 0.01. We vary the setting of T, as detailed in Section 4.2.1.

On a daily basis, a new batch of documents is added to window L and the model is updated. At the end of every update, we calculate the topic evolution score for every topic (as per Section 3.4), and identify topics that exceed a set threshold as *novel topics*.[10] Each document in the model is associated with a distribution of topics. To determine the *novel documents*—documents that contain novel topics—we select those that have a novel topic (i.e. topics which have a topic evolution score above the threshold) assigned as its highest-probability topic. Note that only documents from the new time slice can be novel documents.

As the true set of documents that contain the injected novel event are known — they are all

[6]By injecting the novel event on the 5th day we mean to select a period such that the first occurrence of the novel event will always fall on the 5th day in the period. As such, the natural distribution for the novel event is preserved.

[7]We use OpenNLP for POS tagging and Morpha for lemmatisation (Minnen et al., 2001).

[8]The "language" of the novel event may seem different from a standard tweet, but we contend that the topic model does not gain any real advantage from this as the model is not attuned to the quality of the language in the documents. Also, the Twitter stream contains news releases from news and government organisations.

[9]The main bottleneck for shorter time slices is simply the number of documents, in that if the number of documents becomes too few, the topic model is unlikely to model the data well. Note that the time taken to process a 24-hour time slice on a somewhat high-end single-processor Linux machine is of the order of 15 minutes.

[10]We additionally introduce the constraint that novel topics must not contain user mention tokens (i.e. words of @XXXX format) in their top-10 topic words. This constraint is created on the observation that topics that contain user mentions in their top-10 topic words are usually not semantically coherent and hence do not constitute novel topics.

Event Name	VAN-MITCH			
News Event	Van Earthquake, Turkey

Table 4: Metadata for the 5 synthetic datasets. Numbers in parentheses indicate the total number of documents on the day the event occurred.

TDT3 sentences — we can assess the effectiveness of the model by calculating the "tweet"-level precision, recall and F-score on the day the novel event occurred.

4.2.1 Detection of Novel Event over Varying Numbers of Topics T

The number of topics, T, is a key parameter in the model that affects the granularity of the topics. A high value of T allows the model to generate more specialised topics, while a low value of T generates higher level, more general concepts. We experiment with a range of T values to ascertain how sensitive the topic model is to the T setting, and attempt to arrive at a recommendation for an appropriate T setting for general-purpose applications.

In our initial experiments, we vary T and keep the number of background events constant at 50. A summary of the F-scores for the classification of novel documents is presented in Table 5. Encouragingly, we see that the topic model is able to detect the novel event with relatively high reliability when T is greater than 25 for all datasets. Bear in mind that these F-scores are at the message level not the topic level, and are predicated on the detection of the novel event via

Number of Topics T	VAN-MITCH	WASHI-MITCH	LIÈGE-PINOCHET	KIM-MILOSEVIC	COSTA-SWISSAIR
25	0.50	0.00	0.00	0.51	0.00
50	0.74	0.62	0.47	0.72	0.37
100	0.63	0.61	0.55	0.62	0.47
150	0.65	0.45	0.59	0.76	0.46

Table 5: F-scores with varying T (the number of background events is kept constant at 50).

Number of Background Events	VAN-MITCH	WASHI-MITCH	LIÈGE-PINOCHET	KIM-MILOSEVIC	COSTA-SWISSAIR
25	0.77	0.55	0.81	0.80	0.62
50	0.74	0.62	0.47	0.72	0.37
100	0.61	0.53	0.00	0.82	0.45
150	0.45	0.34	0.00	0.70	0.46

Table 6: F-scores with varying number of background events (T is kept constant at 50).

topic shifts. Beyond $T = 50$, the F-scores are largely similar, indicating the model's insensitivity to small changes in the T setting.

4.2.2 Detection of Novel Event with Varying Number of Background Events

In Section 4.2.1, we can observe that the F-scores are generally higher for datasets that have a greater proportion of novel documents (VAN-MITCH, KIM-MILOSEVIC). We similarly see the same trend in topic evolution score: VAN-MITCH and KIM-MILOSEVIC have higher $e(t)$ than LIÈGE-PINOCHET and COSTA-SWISSAIR. This implies that the proportion of novel documents in the data stream has an influence on the detection of topic(s) associated with the novel event.

To better understand this, we next keep T constant at 50 and vary the number of background events. Increasing the number of background events decreases the proportion of novel documents; effectively there will be more mixtures of topics in the data stream and thus it will be harder to detect the novel event.[11] F-scores for classifying the novel documents with varying number of background events are presented in Table 6.

We see that the injected novel event in all datasets except LIÈGE-PINOCHET is detected for all settings of the number of background events.[12] The proportion of novel documents in the LIÈGE-PINOCHET dataset is particularly low—0.0245 at 50 background events (Table 4). It is thus not surprising that the novel event is not detected when the number of background events is increased to 100: the proportion of novel documents drops to a mere 0.0106, the lowest out of all the datasets. Overall, the results are positive and the model has demonstrated its ability to detect novel events, even when the proportion of novel documents is as low as 0.0182 (COSTA-SWISSAIR at 150 background events).

For all the F-scores presented, a threshold over the topic evolution score $e(t)$ is required to determine the set of novel topics on each update. The threshold facilitates the classification of documents that are novel, and impacts directly on the F-score. To choose a suitable setting for the topic evolution score threshold, we plot a graph of F-scores of all datasets with varying number of topics T (Section 4.2.1) and background events (Section 4.2.2) against a range of topic evolution score threshold values in Figure 1. Based on Figure 1, we set the topic evolution

[11] The proportion of novel documents with varying number of background events is summarised in Table 4.

[12] We observe some fluctuation in the F-scores; this is quite possible as the background events are selected independently for each background event setting, i.e. the set of background events in BG=25 is not a subset of those in BG=50.

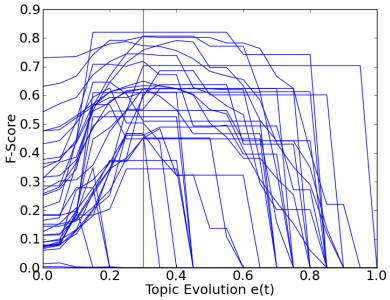

Figure 1: F-scores for the classification of novel documents against threshold values of topic evolution score $e(t)$. Each line represents a single dataset with a fixed number of topics T and background events. The vertical red line indicates the threshold at $e(t) = 0.3$

Injected Novel Events	WASHI-MITCH, LIÈGE-PINOCHET, KIM-MILOSEVIC

Proportion of Novel Documents	0.0452	0.0245	0.1433
on Date of Occurrence	(/26681)	(/31312)	(/40386)

Table 7: Metadata for the synthetic dataset with multiple novel events.

score threshold to 0.3 based on the observation that it provides for consistent and generally optimal performance across all datasets. Note that the F-score results presented thus far are all based on this threshold value.

4.2.3 Detection of Multiple Novel Events

In the previous sets of experiments, each dataset had a single injected novel event. In a real-word setting, however, the number of novel events is unknown and multiple novel events can occur in a single time period. To further test the robustness of our system, and also test our claims about the "fluidity" of the topics under out model, we created another synthetic dataset with a number of novel events injected over a single time period, based on the dates of occurrence of the original events; details of the multi-novel-event dataset are presented in Table 7.

Setting the number of topics T to 50 and using 0.3 for the topic evolution score threshold, we obtain F-scores for novel document classification which are only slightly lower than those for the single-event experiments: 0.49, 0.60, and 0.59 for WASHI-MITCH, LIÈGE-PINOCHET and KIM-MILOSEVIC, respectively, on each event's date of occurrence.

5 Trend Detection in Twitter

The experiments to date have demonstrated the robustness and effectiveness of our methodology in detecting artificially-injected novel events. Ultimately, we are interested in applying the method to online analysis over a microblog such as Twitter to detect emerging trends or events in real-time. To this end, we ran our system for a month in February 2012, over tweets that

Table 8: Top-15 trending topics in London in February 2012.

were returned for a geospatially-bound crawl of data from London and New York. We took the two sets of tweets and calculated the topic evolution score $e(t)$ to discover trending topics each day. We set $T = 300$ in each case (to deal with the larger volume of messages as compared to our synthetic experiments). Other parameter values were identical to those used in the synthetic dataset experiments in Section 4.

We display the top-15 February 2012 trending topics in London and New York in Tables 8 and 9, respectively. We filtered out any topics that occurred over less than 0.7% of the stream to show only the popular trends. Note that it is significant that we present both a date and a topic ID: it is possible for the same topic to shift significantly in content at multiple time slices across the topic-modelled time period, although we don't observe this in our limited display of results in Tables 8 and 9.

In London, there is much discussion about soccer (topic IDs 95, 256, 49, 74, 289). A search using the topic words reveal that these topics correspond to real soccer news events. To give a few examples, topic ID 256 is about the controversial penalties awarded by Howard Webb to Chelsea in a Manchester United vs. Chelsea match, topic ID 49 relates to the the resignation of Fabio Capello as England's manager, topic ID 74 is about Suárez refusing to shake Evra's hand before kick off, and topic ID 49 corresponds to Zambia's first victory in the Africa Cup of Nations.

Whitney Houston's death also triggered a massive reaction from Twitter users in London, so much so that it appears in multiple topics (topic IDs 160, 168, 197, 137). Reading over the topics, the difference in these topics seem indistinguishable, and the fact that it occurs across topics is a function of the sheer volume of traffic that mentioned the event; in a deployed setting, it would be relatively trivial to pick up on the fact that the topics are almost identical (Newman et al., 2010; Mimno et al., 2011). Lastly, entertainment award shows are another popular topic in the Twittersphere (topic ID 91, 17, 251), in the form of the BAFTA and Brits awards.

In New York, rather than soccer, American football is the dominant sport and there was a lot of talk of the Super Bowl (topic IDs 267, 50, 88, 60, 207). Similarly to London, Whitney Houston's death drew much attention, split across a number of largely-indistinguishable topics (topic IDs 51, 223, 45), with the exception of topic ID 250, which is related to her funeral. Entertainment award shows are again a popular topic, although New Yorkers are more interested in the Grammy's and Oscars (topic IDs 265, 227, 4, 290, 246).

In both locations, a new topic for Valentine's Day emerged on February 14th (topic IDs 81 (London) and 273 (New York)).

6 Discussion

The motivation for using a topic model-based approach as opposed to a keyword-based approach is borne out in looking at the detected Twitter trends in Section 5. Some of the detected topics, such as the London football news event examples, would be difficult to capture in a single string of one to three words as used in conventional keyword-based approaches. With our topic model-based detection system, however, the details of an event are summarised more appropriately with a list of associated words.

We note that we did not compare our methodology against existing approaches, such as OLDA or keyword-based approaches. The reasoning for excluding a comparison against OLDA is that in preliminary experiments we found that OLDA was not very effective in detecting the novel topics, as the model uses a fixed vocabulary. Keyword-based approaches are incompatible with our task set up, as they assume knowledge of a fixed information need, which we don't have—our model is looking for the *unknown* in detecting novel events. It is possible to use bursty term analysis (in which case the keywords don't need to be pre-identified), but this often leads to a highly cryptic and potentially misleading representation of the novel event, unlike topic models.

In the synthetic dataset experiments, we measure the model's performance in detecting novel events by calculating the F-scores of novel document classification. The F-score result is a straightforward and objective evaluation, but it is an underestimate of the model's true performance for two reasons. For one, we are actually interested in the detection of the injected event as a newly emerged topic in the data stream rather than correctly classifying every document that contains the injected event. The latter task is the one we evaluate, and a significantly harder task than the former (in fact, if our tweet-level F-score is non-zero, it means we have been successful in detecting the event as a novel topic, meaning we have succeeded in all cases for $T \geq 50$ other than LIÈGE-PINOCHET with the number of background events ≥ 100).

The second reason is that the model could potentially pick up other genuine novel events that occurred in the *background Tweets* that were not related to the injected novel event. Manual inspection on a sample of discovered novel topics revealed that this indeed happened, and the novel topic is often the original news event which was replaced by a TDT3 topic. As an example,

Topic ID	Topic Words
6	kim call korea north jong-il die fire pussy library jong
9	nato kosovo milosevic president force strike crisis military problem unite
13	serb albanian kosovo ethnic kill police hundred rebel home province
19	milosevic nato kosovo holbrooke president richard yugoslav official envoy force
55	kosovo nato force troops milosevic president albanian iraq serb news
72	2011 blue news kosovo maldive top white refugee stand #egypt
73	nato milosevic kosovo military war official international house tax demand
84	kosovo force security monitor mission organization milosevic europe international agreement
86	kim north jong leader die korea korean #fail news christmas

Table 10: Detected novel topics in KIM-MILOSEVIC (50 background events and $T = 100$).

we present a list of detected novel topics for KIM-MILOSEVIC with 50 background events and $T = 100$ topics in Table 10. We see that topic IDs 6 and 86 are related to Kim Jong Il's death, the original news event which was replaced by TDT3's "Holbrooke-Milosevic Meeting" topic. As the documents containing Kim's death do not constitute as part of the *gold* novel document set that have the TDT3 event, the model is penalised for classifying these Tweets as novel documents.

Admittedly, scalability of the model has not been the focus in this work. One reason is that we were initially interested in investigating the accuracy performance of topic models in detecting emerging events, leaving optimisation for future work. The second reason is that for the purposes of tracking *popular* emerging trends, we do not necessarily have to process the full collection of Tweets, as these trends occur in a significant portion of the data. Given that we have set our sights on Twitter, however, this is an obvious area to focus future attentions, given that an estimated 250 million tweets were posted per day on Twitter in 2011. If we were to apply the method to the full Twitter feed, we would use a much finer-grained time granularity and run our method over a larger number of cores than at present (our implementation is already parallelised), and are confident of being able to keep pace with this much greater data volume. Our implementation can be accessed from `http://www.csse.unimelb.edu.au/~tim/etc/online_lda.zip`.

In terms of the sensitivity of the model when scaling down to smaller numbers of documents, in our Twitter trend detection experiments conducted for London and New York, we have demonstrated that even over relatively small numbers of documents —each location has less than 60,000 tweets per day — interesting popular trends and fine-grained news events can be detected.

7 Conclusion

We have proposed a novel topic model-based approach to on-line trend analysis. On every update, we calculate the evolution of topics to detect newly emerged topics in the document collection. We first applied the methodology to a suite of synthetic datasets and demonstrated the model's strength in detecting individual documents describing novel events, and moved on to process raw Twitter data to detect trending topics. The discovered trends were promising and gave insights to the popular culture and events discussed in the Twittersphere.

Learning Compositional Semantics for Open Domain Semantic Parsing

Phong LE and Willem ZUIDEMA

University of Amsterdam, the Netherlands
{p.le,zuidema}@uva.nl

Abstract
This paper introduces a new approach to learning compositional semantics for open domain semantic parsing. Our approach is called Dependency-based Semantic Composition using Graphs (DeSCoG) and deviates from existing approaches in several ways. First, we remove the need of the lambda calculus by using a graph-based variant of Discourse Representation Structures to represent semantic building blocks and defining new combinatory operations for our graph structures. Second, we propose a probability model to approximate probability distributions over possible semantic compositions. And third, we use a variant of alignment algorithms from machine translation to learn a lexicon. On the Groningen Meaning Bank (a recently released, large-scale, domain-general, semantically annotated corpus; Basile et al. (2012)), where we preprocess sentences with an existing dependency parser, we achieve results significantly better than the baseline. On Geoquery we obtain performance comparable to semantic parsers that were developed specifically for that domain.

Title and Abstract in Vietnamese

Học Tổng hợp Ngữ nghĩa cho Phân tích Ngữ nghĩa Miền Mở

Bài báo này giới thiệu một phương pháp mới cho học tổng hợp ngữ nghĩa trong phân tích ngữ nghĩa miền mở. Phương pháp của chúng tôi được gọi là Dependency-based Semantic Composition using Graphs (DeSCoG) và khác biệt với các phương pháp có sẵn trên nhiều phương diện. Trước tiên, chúng tôi loại bỏ sự cần thiết của phép tính lambda bằng cách dùng một biến thể dựa trên đồ thị cho Discourse Representation Structure để miêu tả các khối ngữ nghĩa và định nghĩa các phép kết hợp cho những đồ thị này. Thứ hai, chúng tôi đề xuất một mô hình xác suất để xấp xỉ những phân bố xác suất trên các ngữ nghĩa tổng hợp có thể có. Và thứ ba, chúng tôi dùng một biến thể của các thuật toán gióng hàng từ dịch máy để học tập từ vựng. Thực nghiệm trên Groningen Meaning Bank (một ngữ liệu vừa được công bố, lớn, tổng quát, và đã được gán nhãn ngữ nghĩa; Basile et al. (2012)), với các câu được tiền xử lý bằng một bộ phân tích phụ thuộc có sẵn, chúng tôi đạt được kết quả tốt hơn rất nhiều so với phương pháp cơ sở. Đối với Geoquery, chúng tôi có được kết quả tương đương với các bộ phân tích ngữ nghĩa được phát triển cho chính lĩnh vực đó.

1 Introduction

Semantic parsing is the task of translating natural language sentences to formal meaning representations. The dominant approach for solving this task has been, since Montague (1970), to handcraft a semantic lexicon, using a logic to represent meanings and the lambda calculus to regulate meaning combination. Semantic parsing has until recently thus remained relatively immune to the wave of corpus-based, probabilistic approaches that have revolutionized neighboring fields, such as syntactic parsing (Petrov, 2009; Clark and Curran, 2007; Sangati and Zuidema, 2011), speech recognition (Rabiner, 1989) and machine translation (Koehn et al., 2007; Mylonakis and Sima'an, 2011).

However, an increasingly popular line of work has emerged in the last few years on using probabilistic and corpus-based methods for semantics as well. Much of this work makes use of the semantically annotated Geoquery corpus, that provides representations of queries to a geographic information system in both a natural language and a meaning representation (MR) language. For instance, the query *Which states border Arizona?* is manually translated into `answer(A,(state(A),const(B,stateid(arizona)),next_to(A,B)))`. Although the corpus is small and the domain restricted, some interesting results have been obtained in trying to learn the mapping from natural to formal language. For instance, Zettlemoyer and Collins (2005); Kwiatkowski et al. (2010, 2011) approached the problem with structural learning, Wong (2007) with machine translation, Kate and Mooney (2006) with a kernel method, and so on. Their approaches are supervised in the sense that a set of (sentence, MR) pairs is needed for training. Other work has also addressed learning with less supervision: Clarke et al. (2010); Liang et al. (2011) use the "world's response" (the answer to the query), while Goldwasser et al. (2011) even need no supervision at all.

These studies (and related ones using the CLang domain (Chen et al., 2003), where the input comes from natural language instruction) have started filling a glaring gap in statistical natural language processing. However, surveying this literature, we find some major difficulties in applying these techniques to real NLP applications in less restricted domains. First, many of the used MR languages lack expressiveness. For example, FUNQL, used in the Geoquery domain, and CLang are not designed to express tense (i.e., they make no distinction between *is*, *will be* and *has been*) or to handle possibility (e.g. *can*) nor necessity (e.g. *must*). Moreover, scalability is a big problem because of the explosion of the number of concepts as well as the number of syntactic structures in open-domain texts. For instance, in Geoquery, learning in many of the current approaches succeeds because a small number of constructions like *What is the...*, *How many states have...* and *A borders B* dominate the corpus.

Hence, the challenge of developing corpus-based, probabilistic techniques for *open-domain* semantic parsing remains unsolved. Approaches to this challenge face two major obstacles. First, sentences in open-domain texts are more complicated than those in domain-dependent texts, i.e. they are longer and contain more linguistic phenomena as well as syntactic structures. Second, large, standardized semantic corpora are not available (Bos, 2011). Wide coverage semantic parsers therefore continue to rely on hand-written rules (Bos, 2008; Allen et al., 2008), or try to use unsupervised techniques (Poon and Domingos, 2009). Alshawi et al. (2011) is based on so-called "natural logical forms" (derived directly from dependency structures) with limited applicability.

In this paper, we present an ambitious attempt to bridge the gap between hand-built approaches for open-domain semantic parsing and learning methods for domain-dependent semantic

parsing. Crucial to the success of our approach, named DeSCoG (Dependency-based Semantic Composition using Graphs), is that we make maximum use of the information provided by the syntactic structure of a sentence, and that we abandon the lambda calculus in favor of a more flexible graph-based representation. The syntactic structure comes in because we use a state-of-the-art syntactic dependency parser to drive semantic composition. There are several reasons to do that. First, dependency structures encode predicate-argument relations which are strongly related to semantics (Covington, 2001). Second, the total complexity is reduced significantly compared with parsing syntax and semantic simultaneously (Poon and Domingos, 2009). Finally, according to Ge (2010), prior knowledge of syntax is particularly helpful when sentences are long and complex.

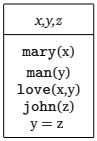
We abandon the lambda calculus, like Liang et al. (2011), but unlike many approaches (Bos, 2008; Zettlemoyer and Collins, 2005; Kwiatkowski et al., 2010; Wong, 2007; Ge and Mooney, 2009; Baral et al., 2011). Although the lambda calculus is undeniably an elegant tool for semantic composition in a bottom-up manner, it makes the learning of a lexicon difficult. This is because of the notorious λ-inverse problem, which is to find h and g such that $f = F(h, g)$ where f and F are given (Kwiatkowski et al., 2010). Zettlemoyer and Collins (2005, 2007) solved the λ-inverse problem via generating all candidates in predefined templates which correspond to categories. That solution, however, works only in domains containing sentences with simple syntactic structures such as Geoquery. To open-domain texts, because there are more than 300 frequent categories (in the WSJ corpus) (Bos, 2005), this method needs a huge effort to build a set of templates. Kwiatkowski et al. (2010) used restricted higher-order unification to carry out the λ-inverse. To adapt this method to open-domain semantic parsing, we need loosened restriction, which leads to higher complexity in learning a lexicon. Deviating from those approaches, DeSCoG represents semantics by graphs, which provide a way to flexibly break and combine components. At the same time, the formalism we use is very expressive: the graphs we obtain for complete sentences are equivalent to Discourse Representation Structure (DRS) introduced by Kamp (1981) and the formalism of choice in the hand-built Boxer system (Bos, 2008).

The paper is structured as follows. Section 2 gives a brief introduction to DRS and how to use graphs to replace the traditional box-like representations. Section 3 presents our semantic composition method, which is based on dependency structures and a probabilistic parsing model. We will describe the learning in Section 4, and finally, give experimental results on both the Groningen Meaning Bank (GMB) and Geoquery in Section 5.

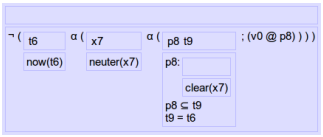
2 Meaning Representation with Semantic Graphs

2.1 Discourse Representation Structure

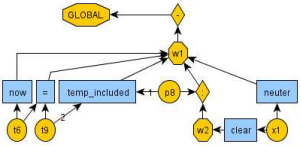
Discourse Representation Theory (DRT), which was introduced by Kamp (1981), is a theoretical framework that can handle a wide range of linguistic phenomena such as tense and anaphora, within and across sentences. It uses Discourse Representation Structures (DRS) to represent a mental representation of the hearer as the discourse unfolds (Geurts and Beaver, 2011). The traditional representation for DRS is a box-like structure which contains two components: (i) *discourse referents* (e.g. x, y, z) representing entities in the discourse, and (ii) *discourse conditions* (e.g. $\texttt{man}(x), \texttt{love}(y, x)$) representing the information about the discourse referents which is encoded in the discourse. For instance, Figure 1a shows a DRS representing the meaning of the discourse *Mary loves a man. He is John.*



(a) A sample DRS.



(b) DRS for the sentence *It is not clear .*



(c) Semantic graph for the DRS shown in Figure 1b.

Figure 1: Sample DRSs and semantic graph. Note that because our parser resolves presuppositions by local accommodation (see Section 5.1), the α-operator is treated as the $merge$-operator.

Because the pronoun *he* can only link back to the indefinite *a man*, y and z must represent the same entity. This is called *pronoun resolution*. In DRT, pronoun resolution has to satisfy the *accessibility constraint*, which says that "if y is the discourse referent introduced by a pronoun, and x is a previously introduced discourse referent, then we are only allowed to add the condition $y = x$ if x is in the universe of a DRS that is *accessible* from the DRS whose universe contains y" (Blackburn and Bos, 2000). Here, a DRS B_1 is immediately accessible from another DRS B_2 if (i) B_1 contains a condition of one of the forms: $\neg B_2$, $B_2 \vee B$, $B_2 \Rightarrow B$, for some DRS B; or (ii) $B_1 \Rightarrow B_2$ is a condition in some DRS B. B_1 is accessible from B_2 if B_1 is immediately accessible from B_2 or there is some DRS B such that B_1 is accessible from B which is immediately accessible from B_2.

Bos (2009) then developed Partial DRS which is a combination of the classic DRS, modal logic, type theory, and lambda calculus. It is used by Boxer (Bos, 2008), a state-of-the-art wide-coverage hand-built open-domain semantic parser.

2.2 Semantic Graph

Although the box-like representation captures the DRS structure very well, it does not provide us with a way to freely break and combine components. Therefore, we represent a DRS via a *semantic graph*, which is simple and directed (see Figure 1c). There are four node types corresponding to basic elements of a DRS: referent (ellipse) (e.g. x_1), predicate (rectangle) (e.g. $thing(.)$), wrapper/box (hexagon) (e.g. w_1), and operator (rhombus) (e.g. $\neg$). A global wrapper node, named `GLOBAL`, corresponds to the outermost box of a DRS. An edge is a link

- from a referent node x to a predicate node p (i.e. p has an argument x), or
- from a predicate node p to a wrapper node w (i.e. p belongs to the DRS labelled w), or
- from a wrapper node w to an operator node o (i.e. the DRS labelled w is an argument of the operator o), or
- from a referent node x to an operator node o (i.e. referent x is an argument of the operator o).

Thanks to this representation, we can break or combine components simply by removing or adding links/nodes. From this point, we will call graphs which represent meanings of words/constituents, and need to be combined with other graphs, *partial graphs*[1].

[1]A partial semantic graph should be seen as a *unsaturated formula* or a *schema*.

3 Semantic Composition

In this section we describe the components of the probabilistic, semantic parser that we will use in our model. This parser computes the best semantic graph (or DRS) for a natural language sentence, given a dependency parse of that sentence and a lexicon (which might be handcrafted, or learned, as explored in section 4).

3.1 Combinatory Operators

By abandoning the lambda calculus, we also loose its method for meaning combination. To combine partial graphs anyway, we introduce two new combinatory operators. The first (dealing with argument identity) is *binding*[2], which is to bind a referent node x with another referent node v, denoted by $x \bowtie v$. The second (dealing with the box structure in DRS) is *wrapping*, which is to link a predicate/operator node p to a wrapper node w, denoted by $p \odot w$.

Now that the lambda calculus plays no role in our new semantic representation, λ-inverse is no longer a problem. Indeed, semantic graphs provide us with maximal freedom in breaking components. Therefore, learning a semantic lexicon becomes easier. However, because it is very flexible in combining partial semantic graphs, the search space explodes. As a consequence, parsing becomes more difficult. In order to efficiently search in such a large space, we need a mechanism to bias the search. We will, in the following, give details about two key ideas: (i) partial semantic graphs are combined following the guide of given dependency structures; and (ii) some combinations are more preferable than others thanks to a probability model.

3.2 Partial Graph Combination with Dependency Structures

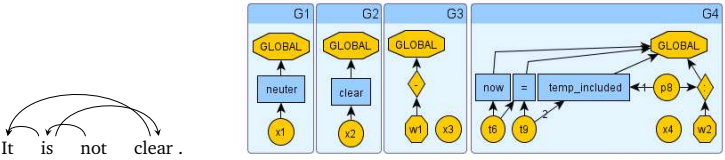
In the following, we describe how to combine partial graphs following a dependency structure, which is given by the C&C parser (Clark and Curran, 2007) (however, the model is general in the sense that it does not depend on which dependency grammar is used). Given a sentence $S = s_1 ... s_n$, a set of partial graphs $\{G^i\}$, and a dependency structure $D = \{s_i \curvearrowright s_j\}$ where $u \curvearrowright v$ means word u is a head of word v, the generative process to create a graph G consists of three steps:

1. for each word $s_i \in S$, select a partial graph G^i to represent its meaning;
2. for each $s_i \curvearrowright s_j \in D$, select a pair of referents (u, v) such that u in G^j and v in G^i to apply a binding operation to;
3. for each predicate/operator node f, select a wrapper node w to apply a wrapping operation to.

An example is given in the following. Given four partial graphs shown in Figure 2b, and a sentence with its dependency structure in Figure 2a, firstly, we assign a partial graph to each word: *It* :- $G_c^1 = G_1$, *is* :- $G_c^2 = G_4$, *not* :- $G_c^3 = G_3$, *clear* :- $G_c^4 = G_2$. Then, we bind x_1 with x_2, x_1 with x_4, x_2 with x_4, and p_8 with x_3. Finally, using the wrapper operation, we link `neuter, temp_included, =, now, :` to w_1, and `clear` to w_2. The graph in Figure 1c is what we should achieve.

It is important to note that wrapping operations should not be carried out arbitrarily. For instance, the node `clear` (Figure 1c) must not be allowed to link to the wrapper node `GLOBAL`. To stipulate that, we introduce a *wrapping constraint*: for all dependencies $s_i \curvearrowright s_j \in D$, if a

[2]It works similarly to *unification*.



(a) Dependency structure. (b) Set of partial graphs.

Figure 2: Dependency structure and set of partial graphs for the example in Section 3.2

referent node v in G^j binds with a referent node u in G^i then all the predicate/operator nodes in G^i linked from u must link to wrapper nodes which have access[3] to v. The constraint is based on the observation that in a C&C predicate-argument relation, the argument is always the one introducing referents.

Even with the dependency structure given, there are typically many choices to make among the possible partial graphs for each word, and possible binding or wrapping operations for each dependency. Computing the probabilities of all of these choices, and the most probable resulting semantic graph, is the task of the probability model.

3.3 Probability Model

The parsing task is to find the most probable semantic graph G^* such that

$$G^* = \arg\max_G Pr(G|S) = \arg\max_G \sum_D Pr(G|D,S)Pr(D|S) \quad (1)$$

where the sum is taken over all dependency derivations D for a sentence S. Similar to the model given by Ge and Mooney (2009), we assume that the dependency parse we obtain from a third party parser (here C&C) is correct. That is, we assume that the probability distribution over dependency structure derivations given a sentence S densely locates at the derivation D_S yielded by the used syntactic dependency parser, i.e. $Pr(D|S) = \delta(D = D_S)$ where $\delta(.)$ is the Kronecker delta function. As a consequence, the parsing problem becomes: given a sentence S and a dependency structure D, find the best semantic graph G^* such that $G^* = \arg\max_G Pr(G|S,D)$.

Let $G_c = \{G_c^1, ..., G_c^n\}$ be a set of assigned partial graphs, $B = \{u \bowtie v\}$ be a set of binding operations, and $W = \{f \hat{\circ}_k o\}$ be a set of in-wrapper relations, then we denote $G = (G_c, B, W)_{S,D}$, which means G is yielded by applying B, W on G_c following the dependency-structure D. We can now factorize $Pr(G|S,D)$ as follows:

$$Pr(G|S,D) = Pr(G_c, B, W|S,D) = Pr(G_c|S,D)Pr(B|G_c,S,D)Pr(W|G_c,B,S,D) \quad (2)$$

Under some independence assumptions,

$$Pr(G_c|S,D) = \prod_{i=1}^{n} Pr_l(G_c^i|s_i, POS(s_i), POS(Dep(s_i))) \quad (3)$$

$$Pr(B|G_c,S,D) = \prod_{u \bowtie v \in B} Pr_b\big(u \bowtie v|G_c(u), G_c(v), POS(s(u)), POS(s(v))\big) \quad (4)$$

[3]Because a wrapper node corresponds to a box of a DRS, the definition of *accessibility* is also applicable in this case.

where $G_c(x)$ is the partial graph containing node x and $s(x)$ is the word of which the partial graph is $G_c(x)$; $POS(.)$ is the function to get part-of-speech tags; and $Dep(s)$ is the function to get the list of the dependents of s. For the third component of Equation 2,

$$Pr(W|G_c,B,S,D) = Z \times \psi(W) \times \prod_{f\,\hat{\odot}_k o \in W} Pr_w\big(f\,\hat{\odot}_k o | G_c(f), G_c(o), POS(path(s(f), s(o)))\big) \quad (5)$$

where Z is the normalizing factor. $\psi(W)$ is the indicator function that returns 1 if W satisfies the wrapping constraint and 0 otherwise. We use the notation $f\,\hat{\odot}_k o$ for the in-wrapper relation[4] where there is a directed path from f to the k-th wrapper of the operator node o (i.e., f links to the k-th wrapper of an operator node o, or there is an operator node o' such that f links to one of o's wrappers and $o'\hat{\odot}_k o$). $f\,\hat{\odot}_0 o$ then means that there are no directed paths from f to o (e.g. in Figure 1c, `clear` $\hat{\odot}_1\langle\neg\rangle$ and `neuter` $\hat{\odot}_0\langle:\rangle$). Finally, $path(s_i, s_j)$ is the shortest path from s_i to s_j on the graph representing the dependency structure D. For instance, $path(It, not) = It \uparrow is \uparrow not$ (Fig. 2a).

Given this probability model, we can use standard techniques for finding the best semantic graph[5] G^*, given a sentence S and its dependency structure D:

$$G^* = \underset{G=(G_c,B,W)_{S,D}}{\arg\max}\ Pr(G_c|S,D)Pr(B|G_c,S,D)Pr(W|G_c,B,S,D) \quad (6)$$

Solving this optimization problem required using beam search, integer linear programming and some additional heuristics, as detailed in the appendix.

4 Learning

In this section we describe how to obtain a lexicon of partial graphs and estimate the parameters which are used in the parsing model. The learning algorithm is presented with combinations of sentences, their dependency parses and their complete semantic graphs, i.e., with a set of triples (S, D, G).

Given a sentence S and its semantic graph G, we need to split G into partial graphs corresponding to individual words. It turns out that the task is similar to the word-to-word alignment problem in machine translation. Here, English is the source language, the set of all semantic graphs is the target language, and a "word" in the target language is a connected partial graph. Hence, our problem is *word-to-graph alignment*. In Figure 3 we give a more complicated example sentence and its dependency graph (where verbs are split up in stems and tags with tense/aspect information, as explained below). In Figure 4 we give an example of an alignment with a semantic graph for this sentence .

For each triple (S, D, G), let V be the node set of G, V_F be the predicate/operator node set of G, an alignment A be a set of pairs (u, w) where $u \in V$, and $s \in S$. An alignment is feasible if all of the following constraints are satisfied

[4] In the box representation of a DRS, $f\,\hat{\odot}_k o$ means the predicate/operator f locates in the k-th box of the operator o (directly or indirectly), and $f\,\hat{\odot}_0 o$ means f does not locate in any box of o.

[5] Are the resulting DRSs valid? Although we have not provided a formal proof, we are confident they are well-formed because of the following two reasons. First, the definition of 'link' ensures that elements of a DRS (referents, predicates, boxes, etc.) are in proper relationships (e.g. it is impossible that a predicate is an argument for another predicate). Second, the wrapping constraint guarantees that the accessibility constraint is not violated. A rigorous proof of this statement is part of our future work.

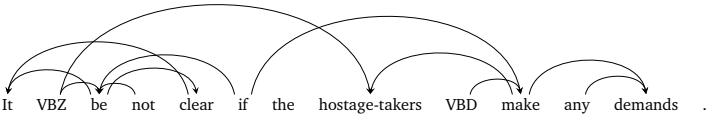


Figure 3: Dependency structure after extracting tenses out of verbs.

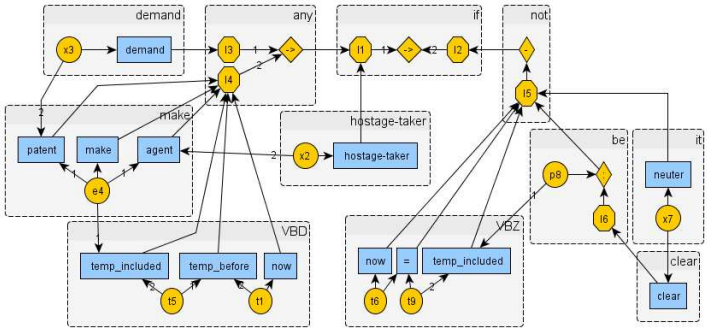

Figure 4: Semantic graph with the correct alignment for the sentence given in Figure 3.

1. for each $u \in V$, if u is a predicate or operator node, there is one and only one $s \in S$ such that $(u,s) \in A$; otherwise, for each predicate/operator node f that u links to, if $(f,s) \in A$, then $(u,s) \in A$;
2. for each $s \in S$, let V_s^A be the set of nodes associated with word s, V_s^A must be connected on G regardless of direction;
3. for each $s \curvearrowright s' \in D$, there are $u' \in V_{s'}$ and $u \in V_s$ such that u' is a predicate node. If u is a predicate node, there is a referent node x linking to both u, u'; else if u is an operator node, there is a wrapper node w linking to u such that u' links to w.

Let $\Lambda(S,D,G)$ be the set of all feasible alignments. The alignment phase is given as follows. First, a word-to-word alignment application[6] is used to estimate the probabilities $Pr(\text{node}|\text{word})$. Then, for each triple (S,D,G), the best alignment A^* is defined as[7]

$$A^* = \underset{A \in \Lambda(S,D,G)}{\arg\max}\ Pr(V_F | S = s_1 ... s_n, A) \tag{7}$$

where

$$Pr(V_F | S = s_1 ... s_n, A) \propto \prod_{s \in S} Pr(V_F \cap V_s^A | s) \propto \prod_{s \in S} \Big(Pr_n(|V_F \cap V_s^A| | s) \prod_{f \in V_F \cap V_s^A} Pr_f(f|s) \Big) \tag{8}$$

Considering solving Equation 7 as searching an A in the alignment space to minimize the objective function $g(A) = -\log\big(Pr(V_F^A | S^A, A)\big)$, we use the **A**-star algorithm with the future cost

[6] We used GIZA++ (Och and Ney, 2003) with the default parameters.

[7] Note that we use only V_F, the set of predicate and operator nodes, because the other types of nodes are determined by them.

Level	$Pr_l(G\|...)$
1	$Pr_l(G\|s, POS(s), POS(Dep(s)))$
2	$Pr_l(G\|s, POS(s))$

Level	$Pr_b(u \bowtie v\|...)$
1	$Pr_b(u \bowtie v\|G(u), G(v), POS(s(u)), POS(s(v)))$
2	$Pr_b(u \bowtie v\|G(u), G(v))$

1	$Pr_w(f \hat{\odot}_k o\|G(f), G(o), POS(path(s(o), s(v))))$
2	$Pr_w(f \hat{\odot}_k o\|G(f), G(o), POS(s(u)), POS(s(v)))$
3	$U_k(f \hat{\odot}_k o\|G(f), G(o), POS(s(u)), POS(s(v)))$

Table 1: Multilevel back-off for the parameter estimation. $U_{u,v}(u \bowtie v|G(u), G(v))$ and $U_k(f \hat{\odot}_k o|G(f), G(o), POS(s(u)), POS(s(v)))$ are respectively the uniform distributions over u, v and over k.

function $h(A) = \min_{A'}\{-\log\big(Pr(V_F \setminus V_F^A | S \setminus S^A, A')\big)\}$, where $V_F^A = \{u|\exists s, (u,s) \in A\} \cap V_F$ and $S^A = \{s|\exists u, (u,s) \in A\}$. It is worth noting that, because the future cost is smaller than the real cost, the optimal solution (if it exists) is guaranteed to be found.

When a lexicon of partial graphs is obtained, the parameters which are used in the parsing model are estimated via relative frequencies. To avoid the problem of sparse data, two techniques are used (see Jurafsky and Martin, 2009, Section 4.5 and Section 4.7): (i) Good-Turing technique, and (ii) multilevel back-off which is shown in Table 1.

Implementation The word-to-graph alignment method has a drawback: large partial graphs are not preferred because the probabilities of some nodes in a large partial graph given the best matched word tend to be small. Unfortunately, verbs with tenses have complex DRSs, which lead to large partial graphs (e.g. G_4 in Figure 2b represents the meaning of the verb *is*). To avoid this phenomenon, tense/aspect information is extracted from verbs (e.g. Figure 3).

We apply some heuristics to make the word-to-graph alignment more efficient. Operator nodes are only allowed to align to functional words (e.g. *be, will, could*), and predicate nodes related to tenses (e.g. `temp_included, temp_before`) are only allowed to align to tense words (e.g. *VBZ, VBN*). Because the **A**-star algorithm will search the whole solution space in the worst case, the alignment process spends a lot of time on difficult sentences. Therefore, sentences with lengths larger than MAX_LENGTH are ignored and the time for processing a sentence is not allowed to exceed MAX_TIME[8].

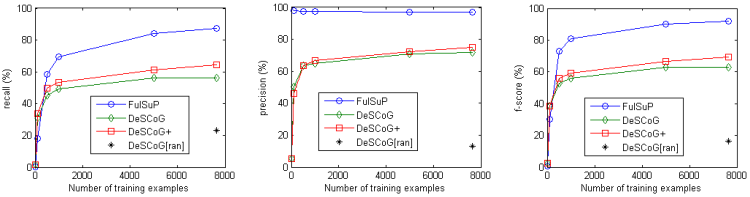
5 Experimental Results

In this section, we will show experimental results on the two corpora: Groningen Meaning Bank (GMB), an open-domain corpus, and Geoquery, a popular domain-dependent corpus.

5.1 Groningen Meaning Bank

The Groningen Meaning Bank (GMB) corpus (Basile et al., 2012) has been developed at the University of Groningen for the tasks related to deep semantic representation. The current version 1.1 contains 2000 documents with 9418 sentences from many public sources: Voice of America, fables, CIA World Factbook, and MASC Full. Each sentence is annotated with

[8] In our experiments, we set $MAX\_LENGTH = 25, MAX\_TIME = 5sec$.



(a) Recall (b) Precision (c) F-score

Figure 5: Recall, precision, and f-score curves comparing the four parsers on GMB.

a CCG parse tree with a Partial DRS at each tree node representing the meaning of the corresponding constituent. Although GMB covers many linguistic phenomena, such as anaphora and presupposition, we leave them aside. For instance, DeSCoG does not resolve anaphora whereas it resolves presuppositions by local accommodation.

Evaluation Method Our evaluation method is similar to the one introduced by Allen et al. (2008), which is based on partial credit assignment. Let G and T be semantic graphs for a gold-standard DRS and a test DRS respectively. Given an one-to-one alignment between G's nodes and T's nodes such that it results their maximum common subgraph, then

- a predicate node p in T is counted if it and all referent nodes linking to it are aligned,
- an operator node o in T is counted if it and all wrapper and referent nodes linking to it are aligned,
- count one for a predicate/operator node f in T if the wrapper node linked from f is aligned and the operator node that it links to is counted and f itself is also counted.

Intuitively, the last counting assigns credit to a component in the test DRS if its position is correct w.r.t the gold-standard DRS. Let $\Omega(G,T)$ be the number of counts, then recall $= \frac{\Omega(G,T)}{\Omega(G,G)}$, precision $= \frac{\Omega(G,T)}{\Omega(T,T)}$, and f-score $= \frac{2\Omega(G,T)}{\Omega(G,G)+\Omega(T,T)}$.

Settings We split GMB into two parts: 7642 examples in the sections from 0 to 79 for training (GMB.0-79), and the rest, 1776 examples, for testing (GMB.80-99). Because DeSCoG, to our knowledge, is the first working on this corpus, we created the following three parsers for the comparison purpose. **FulSuP** (Fully Supervised Parser) is a probabilistic semantic parser using the supervised semantic lexicon directly extracted from the GMB and some manually created semantic combinatory rules. This parser is actually a probabilistic interpretation of Boxer, the core builder of GMB. **DeSCoG+** is DeSCoG with the help from an "oracle" for the alignment process: the information about which predicate/operator nodes' labels are aligned with which words is known beforehand thanks to the semantic lexicon given by GMB. **DeSCoG[ran]** (baseline) is DeSCoG with random parameters. It is important to point out that the four parsers use different forms of supervision. FulSuP, as its name recalls, uses most supervision form; DeSCoG+ needs a set of (sentence, MRs) pairs and an oracle for training. DeSCoG and DeSCoG[ran] learn from only (S, D, G) triples.

Results Figure 5 shows the performance of DeSCoG compared to the other three parsers. The results clearly reflect the advantage of using the given semantic lexicon for training in FulSuP and DeSCoG+. The fact that FulSuP achieves the best performance (f-score 92.1% with the full

training dataset) is not surprising at all because its model is a probabilistic interpretation of the Boxer's model, which is the core builder of GMB. At the other end, DeSCoG[ran] performs remarkably poorly with an f-score of 16.3%. The result discloses the effectiveness of the parameter estimation, which helps DeSCoG gain the f-score 63.1%, which is significantly better than DeSCoG[ran].

DeSCoG+ performs better than DeSCoG. An interesting point here is that the distance between their performances is proportional to the training data size. This suggests that the alignment process of DeSCoG insufficiently exploited new structures in the added data. This suspicion is supported by the recall curve of DeSCoG: the recall is nearly unchanged after the training data size reaches 5000. DeSCoG+, on the other hand, overcomes this obstacle thanks to the help of the oracle.

Analysing the Alignment Phase

As discussed above, the quality of the alignment process strongly affects the final performance of DeSCoG. Therefore, in this section, we will look into it in some more details. First of all, because sentences longer than $MAX\_LENGTH = 25$ are ignored and the time for processing one sentence is not allowed to exceed $MAX\_TIME = 5sec$, it is clear that not all the sentences and their semantic graphs in the training dataset are successfully aligned. We found that, for the GMB.0-79, the alignment phase succeeded 5725 times, which is 74.9%.

To see when the alignment phase is wrong, let's consider an alignment result. Figure 3, 4 show the dependency structure and the semantic graph with the correct alignment for the sentence *It is not clear if the hostage-takers made any demands*. The alignment algorithm correctly aligned all of the words except *any* and *if* (Figure 6). Because $Pr(\rightarrow|any) = 0.69 > Pr(\rightarrow|if) = 0.48$, both the operator node →'s were aligned with the word *any*, and, consequently, no nodes were with the word *if*.

Theoretically, incorrect alignments could be tolerated thanks to the probability model presented in Section 3.3. For instance, if *any* and *if* do not appear together so frequently, the above fault will not have a strong effect. That is why DeSCoG+ does not perform significantly better than DeSCoG. However, the fact that the recall of DeSCoG is nearly unchanged when the training data size is over 5000 suggests that there are some structures that the alignment phase missed even when more training data were used.

5.2 Geoquery

Geoquery is a corpus which is used in the Geoquery domain, a natural language interface to a U.S geography database (Zelle and Mooney, 1996). The database contains 800 facts (e.g. names, areas, and populations), which are represented as Prolog assertions. The corpus is a collection of 880 English queries and their manually annotated MRs in a first-order Prolog language augmented with meta-predicates and Functional Query Language (FUNQL).

Although our purpose is learning open-domain semantic parsing, we found two reasons to test DeSCoG on Geoquery. First, because there are many existing semantic parsers working on this corpus, the comparison is more reliable than the previous. Second, because of many differences between Geoquery and GMB, we want to investigate the flexibility of DeSCoG. In our experiments, 10-fold cross validation was used. A test MR is correct if it and the gold-standard MR receive the same answer. Let n_c, n_D, n_P be respectively the number of correct MRs, the test

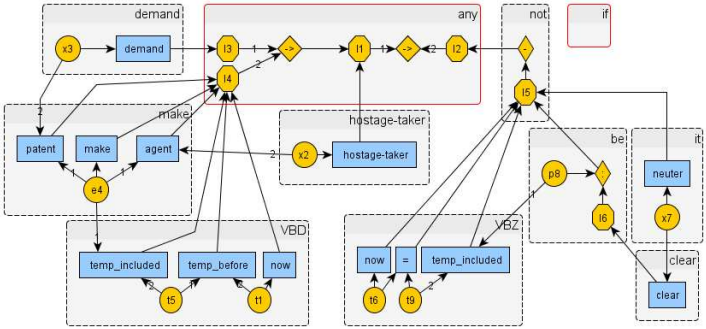


Figure 6: The alignment phase correctly aligned all the words except *any* and *if*. The correct one is given in Figure 4.

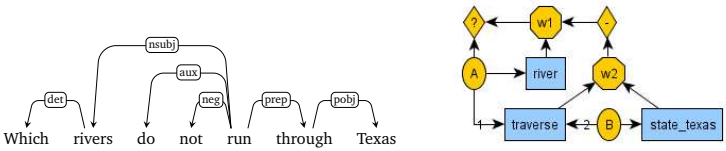

(a) Dependency structure. (b) Semantic graph.

Figure 7: Dependency structure and semantic graph for the query *which rivers do not run through Texas ?*, which has the MR
`answer(A,(river(A),not((traverse(A,B),const(B,stateid(Texas))))))`.

data size, and the number of completed MRs, then $recall = n_c/n_D$, $precision = n_c/n_P$, and $fscore = 2n_c/(n_D + n_P)$.

We made the following changes in DeSCoG. Firstly, semantic graphs are now for representing Prolog-based first-order forms. This is easily done by using operator nodes to represent metapredicates such as `answer` and `largest` (see Figure 7). Secondly, the Stanford parser[9] (De Marneffe et al., 2006) was used to syntactically parse English sentences, because it better deals with questions. Finally, the wrapping constraint was removed.

DeSCoG was compared with the following alternatives: SCISSOR (Ge and Mooney, 2005), an integrated syntactic-semantic parser; KRISP (Kate and Mooney, 2006), a SVM-based parser using string kernels; WASP (Wong and Mooney, 2006) and λ-WASP (Wong, 2007), two parsers based on synchronous grammars; Z&C05[10] (Zettlemoyer and Collins, 2005), a parser using structural learning with CCG grammars; and SYN0 (Ge and Mooney, 2009), a parser using an existing syntactic parser. Among those systems, SYN0 is the closest to DeSCoG: both of them use existing syntactic parsers and a Prolog-based first-order language as their MR languages. Table 2 shows the experimental results.

[9] http://nlp.stanford.edu/software/corenlp.shtml

[10] The results were reported on 600 training examples and 280 testing examples.

	Recall	Precision	Fscore
DeSCoG	74.89	87.40	80.66
SYN0	78.98	81.76	80.35
λWASP	86.59	91.95	89.19
Z&C05	79.29	96.25	86.95
SCISSOR	72.3	91.5	80.77
WASP	74.8	87.2	80.5
KRISP	71.7	93.3	81.1

Table 2: The results for DeSCoG and the alternatives on the Geoquery corpus.

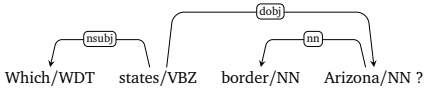

Figure 8: A sentence with its incorrect syntactic parse.

The results show that DeSCoG performs equivalently to SYN0, SCISSOR, WASP, and KRISP, but worse than λWASP and Z&C05. According to Wong (2007), SCISSOR, WASP, and KRISP perform worse than λWASP and Z&C05 because they use a different MR language, FUNQL. However, because FUNQL is variable-free, it is clear that those parsers cannot be widely used (e.g. they are not able to work on GMB). DeSCoG, on the other hand, is flexible. Although it was mainly designed for GMB (i.e. using a DRS language, the C&C parser), it achieved equal performance with many other parsers.

As mentioned above, DeSCoG and SYN0 use existing syntactic parsers and the same MR language with λWASP. So why do they perform worse than λWASP and Z&C05? Firstly, syntactic parsers are not really helpful when sentences are short. This is because sentence structures could be easily learned just from (sentence, MR) pairs in this case (Ge, 2010). Secondly, incorrect syntactic parses could lead to incorrect (or incomplete) MRs. For example, with the incorrect syntactic parse shown in Figure 8, it is very difficult to build the correct MR `answer(A,(state(B),next_to(A,B),const(B,stateid(arizona))` because one of the two words *state* and *Arizona* has to receive the meaning `next_to(A,B)`, which is very unlikely. On the other hand, parsers which learn parsing syntax and semantics simultaneously could easily overcome this problem when they recognize that the word *border* should be a head of two dependents. This is thanks to the high frequency of the appearance of the structure *A border B* in the Geoquery corpus, and that the word *border* likely matches the meaning *next_to(A,B)*.

Conclusion

This paper introduced a new learning approach, DeSCoG, mainly for open-domain semantic parsing. Our approach, on the one hand, is different from others which use lambda calculus. In those approaches, learning semantic lexicon requires huge effort because they face the λ-inverse problem. In our approach, this problem is avoided thanks to the usage of semantic graphs, which provides maximal freedom for breaking and combining MRs. In order to bias the search in a very large parse space, we used the prior knowledge of syntax encoded in dependency structures and a probability model. The former provides a skeleton for semantic composition whereas the latter tells the parser which combinations are more preferable.

On the other hand, DeSCoG has common points with some approaches. First, the idea of

flexible semantic composition is also proposed by Clarke et al. (2010); Liang et al. (2011) where lambda forms and semantic composition rules are removed. Second, the use of existing syntactic parsers in DeSCoG is inspired by Ge and Mooney (2009). Finally, UPS (Poon and Domingos, 2009), Alshawi et al. (2011), and DeSCoG use dependency structures as the prior knowledge of syntax for semantic composition.

We tested DeSCoG on the two corpora, GMB for open-domain semantic parsing and Geoquery for domain-dependent semantic parsing. DeSCoG achieved the f-score 63.1% on GMB. The fact that this f-score is significantly higher than the f-score of the random parser (16.3%) reflects that our proposed parsing model works for open-domain semantic parsing. Moreover, DeSCoG performed on Geoquery equally to many existing parsers: SYN0, SCISSOR, WASP, and KRISP.

Appendix: Search heuristics

We will describe a method for finding the best semantic graph G^* in Equation 6 given a sentence S and its dependency structure D. The problem is indeed searching within an enormous semantic graph space. The search is biased by the dependency structure D and the probability model given above. Here, we use the beam search strategy to cut off branches which could lead to solutions with low probabilities. To reduce the total complexity, we divide the search into two stages. First, the search, with the goal to maximize $Pr(G_c|S,D)Pr(B|G_c,S,D)$, will output a list of N-best (G_c,B)'s. Then, the search will look for the best W for each of those N-best (G_c,B)'s.

Stage 1 The goal of this stage is to find N-best (G_c,B)'s. The search processes one word at a time with the order: (i) from left to right, and (ii) all the dependents of the word were already processed. And, each word is processed only one time (i.e. no backtracking required). For example, given the sentence in Figure 2a, *It* is processed first, then *clear* and *is*; *not* is processed last. When processing a word (e.g. *is*), the search will considers all the candidate partial graphs for the meaning of this word, then use the binding operator to combine them with the available parses yielded after processing the prior words (*it, clear*). When there are no words left, it will remove all but N-best candidates with the highest $Pr(G_c|S,D)Pr(B|G_c,S,D)$.

Stage 2 After finding the set of N-best (G_c,B)'s, the search will look for the most probable W^* for each (G_c,B), i.e. solve $W^* = \arg\max_W Pr_w(W|G_c,B,S,D)$ where $Pr_w(W|G_c,B,S,D)$ is given by Equation 5. Because the normalizing factor Z is the same for given G_c,B, the task is to maximize the third component under the wrapping constraint, which is encoded in $\psi(W)$. It is worth noting that this is indeed a linear optimization problem where the logarithm of the third component, i.e. $\sum_{f\,\hat{\circledcirc}_k o \in W} \log Pr_w\big(f\,\hat{\circledcirc}_k o|G_c(f),G_c(o),POS(path(s(f),s(o)))\big)$, is the objective function. Therefore, we solve it by making use of Integer Linear Programming[11]. In order to calculate Z for each G_c,B, we need to take the sum over all feasible W's, which is intractable. Therefore, Z is approximated on M-best W's $Z \approxeq \big(\sum_{i=1}^{M} e^{F(W_i)}\big)^{-1}$. Together, this give us a set of triples (G_c,B,W) with their probabilities.

Evaluating different methods for automatically collecting large general corpora for Basque from the web

Igor LETURIA
ELHUYAR FUNDAZIOA, Usurbil, Basque Country (Spain)
i.leturia@elhuyar.com

ABSTRACT

In the last few years, much work has been done to build Basque corpora. But we still lack a large general corpus of a size comparable with those existing in other major languages, and much more so if we take into account the corpora lately built automatically from the web, which nowadays account for billions of word-sized corpora for English, German, Spanish, etc. As Basque is an under-resourced language, it is thus logical that we should also turn to this cheap and fast method of collecting corpora.

In this paper we present the research we have done to build a large general corpus of Basque from the web. We have tried and evaluated which of the two methods mentioned in the literature, that is, by crawling or by using search engines, best suits Basque, in terms of parameters such as speed, cost, size or quality. Our conclusion is that crawling is the one that has the potential for building the largest corpora for Basque. Using this method we have built a good quality corpus of more than 100 million words, and we expect to build a much larger one in the near future.

TITLE AND ABSTRACT IN BASQUE

Webetik euskarazko corpus orokor handiak automatikoki biltzeko metodoen ebaluazioa

Azken urteotan lan handia egin da euskarazko corpusgintzan. Baina oraindik ez dago tamainari dagokionez beste hizkuntza handiagoetakoekin konpara daitekeen corpus orokor handirik; are gehiago kontuan hartzen baditugu azkenaldian automatikoki webetik bildu diren corpusak: milaka milioi hitzetakoak daude ingelesa, alemana, gaztelania eta abarrerako. Euskara baliabide urriko hizkuntza izanik, logikoa da corpusak biltzeko metodo merke eta azkar honetara jotzea.

Artikulu honetan webetik euskarazko corpus orokor handi bat biltzeko egin dugun ikerketa aurkezten dugu. Literatura zientifikoan aipatzen diren bi metodoetatik, hau da, crawling bidez edo bilatzaileak erabiliz, euskararentzat hobekien zeinek funtzionatzen duen aztertu eta ebaluatu dugu, abiadura, kostua, tamaina edo kalitatea moduko parametroei erreparatuz. Gure ondorioa da crawling bidezkoa dela euskarazko corpus handiena eraikitzeko aukera ematen duena. Metodo hori erabiliz 100 milioi hitz baino gehiagoko corpus kalitatezko bat osatu dugu, eta etorkizun hurbilean askoz handiago bat eraikitzea espero dugu.

KEYWORDS: Basque, Corpora, Web as Corpus.

KEYWORDS IN BASQUE: euskara, corpusak, weba corpus gisa.

1 Summary in Basque

1.1 Motibazioa eta helburuak

Corpusak oso baliabide garrantzitsua dira mundu modernoan biziraun eta komunikabideetan, hezkuntzan eta abar normaltasunez erabilia izan nahi duen hizkuntza batentzat, besteren artean (baina ez bakarrik) beharrezkoak direlako hizkuntza-teknologiak garatzeko. Euskararen kasuan are gehiago, oraindik ere estandarizazio prozesuan baitago eta estatusaren normalizazioan asko baitu egiteko. Baina euskara urria da corpusetan, modu klasikoan eraikitzea garestia delako eta ez dagoelako behar adina baliabide (ekonomikoak zein giza baliabideak) berauek eraikitzeko. Besteak beste, ez du corpus orokor handirik beste hizkuntzen pareko tamainakorik.

Hala ere, azkenaldian weba gero eta gehiago erabili da hizkuntz ikerketetarako edo corpusgintzarako; izan ere, merkeagoa da, corpus handiagoak lor daitezke eta beti eguneratuta dago. Horregatik logikoaz gain ia beharrezkoa da euskararentzat webera jotzea. Azken urteetan egin dira lanak euskarazko corpus mota ezberdinak automatikoki webetik lortzeko, baina oraindik ez da corpus orokor handien gaia landu. Artikulu honetan azaltzen dira helburu horrekin dauden metodo ezberdinak probatuz egin dugun ikerketa-lana eta beronen emaitzak.

1.2 Antzeko lanak

Bi modu nagusi aipatzen dira literaturan webetik corpus orokor handiak lortzeko. Bata crawling metodoa da: URL zerrenda batetik abiatuta, orri horiek jaisten dira eta bertako esteken URLak zerrendara gehitzen dira, eta horrela errekurtsiboki egiten jarraitzen dugu. Metodo honekin egin dira WaCky (Web-as-Corpus kool ynitiative) proiektuko corpusak, milaka milioi hitzetako corpusak alemana, italiera, ingelesa eta frantseserako, eta gehiago daude bidean (Baroni et al., 2009). Bestea bilatzaileak erabiltzean datza. Hitz zerrenda batetik abiatuta, horien konbinazioak bidaltzen zaizkie bilatzaileen APIei eta itzulitako emaitzen orriak jaisten dira. Metodo hau erabiltzen du Sharoff-ek (2006) 100-200 milioi hitz inguruko corpusak osatzeko hainbat hizkuntzatarako.

Bi metodoek emaitza onak lortu badituzte ere, ez dira beraien artean konparatu, beraz galdera asko geratzen dira airean. Zein da azkarragoa? Zeinek lortzen ditu kalitate handiagoko corpusak? Lor daitezke milaka milioietako corpusak bilatzaileen bidez? Gainera, euskararentzat baliteke ezberdin funtzionatzea metodoek: batetik, euskarazko bilaketa lematizatuak egiteko erabili behar diren teknikek emaitzei eragin diezaiekete; bestetik, euskarazko webaren tamaina txikiak eragin lezake crawling-a ez hain eraginkorra izatea. Beraz, biak aztertu eta ebaluatzea beharrezkoa da.

1.3 Metodologia

1.3.1 Bilatzaileen bidezko metodoa

Bilatzaileen bidezko metodoan, Sharoff-ek (2006) 500 hitz-forma maiz eta orokorren zerrenda bat erabiltzen du. Guk XX. mendeko Euskararen Corpuseko lema maizenak erabili ditugu eta gero sorkuntza morfologiko bidezko kontsultaren hedapena aplikatu (Leturia et al., 2008b). Euskarazko emaitzak soilik lortzeko, hizkuntza iragazteko hitzen teknika baliatu dugu (Leturia et al., 2008b). Sharoff-ek 500 hitz baino gehiago ere erabil daitezkeela iradokitzen du; horren eragina frogatu nahi izan dugu, 500, 1.000, 2.000, 5.000 eta 10.000 hitzeko zerrendak erabiliz

corpus ezberdinak jaitsi eta ebaluatuta. Sharoff-ek 4 hitzeko konbinazioak bidaltzen dizkie bilatzaileen APIei eta hizkuntza txikiagoei 3; guk 1, 2, 3, 4 eta 5 hitzezko konbinazioekin egin nahi izan ditugu frogak. Sharoff-ek bilatzaileek itzulitako lehen 10 orriak jaisten ditu, guk badaezpada ere 50.

1.3.2 Crawling metodoa

WaCky proiektuan, crawling egiteko hasierako URLen zerrenda bilatzaileengandik lortzen zuten, hainbat hitzen konbinazioak bidalita; guk DMOZeko "Euskara" ataleko 1.500 URLak erabili ditugu. Haien proiektuan bezala, guk ere ataza anitz paraleloan abiarazita azkartzen dugu orrien deskarga eta webgune aniztasuna lehenesteko estrategia darabilgu.

1.4 Emaitzak

1.4.1 Bilatzaileen bidez

Bilatzaileak erabiliz, corpusik handienak 2.000 edo 5.000 hitzeko hasierako zerrendatik abiatuta lortu dira, 120-130 milioi hitz ingurukoak: lehenak webgune aniztasun handiagoa lortzen du, bigarrenak PDF gehiago (normalean arazoak ematen dituzte bihurtzean eta kalitatea ez da hain ona) eta dokumentu handiagoak (testu jarrai gehiago). Hitzen konbinazioaren luzera egokia 2 dela dirudi, berak lortzen baitu corpusik handiena (130 milioi baino gehiago) eta anitzena, PDF gutxienekin.

1.4.2 Crawling bidez

Bilatzaileen bidezko metodoekin lortu diren corpusek ez dute lortutako tamainak baino askoz gehiago handitzeko gaitasunik, ez behintzat modu produktiboan: bilatzaileei egindako lehen mila galderekin 37 milioi hitz lortzen dira bataz beste, baina egindako azken mila galderekin (12.000raino iritsi gara) 2 milioitik behera lortzen dira. Crawling bidez, aldiz, 100 milioi hitzetik gorako corpusak lortu ditugu (ia PDFrik gabe eta webgune aniztasun handienarekin) eta hazkunde erritmoak hasierakoaren erdia izaten jarraitzen du, beraz handitzen jarraitzeko potentziala du.

1.4.3 Konparazio kualitatiboa

Bi corpus klasikorekin (XX. mendeko Euskararen Corpusa eta Lexikoaren Behatokia) konparatu ditugu crawling bidez eta bilatzaile bidez lortutako web corpus bana. Bilatzaileen bidezkoa besteengandik ezberdintzen duena da testu administratibo gehiago izatea (ziurrenik erakundeen aldizkari ofizialetako PDFengatik), eta crawling bidezkoa webeko berezko generoko testu gehiago izatea. Corpus klasikoen hitz baliagarrien %90etik gora badaude web corpusetan, eta azken hauek %80 inguru hitz baliagarri berri gehiago dituzte lehenek baino.

1.5 Ondorioak

Frogatu dugu weba lehengaitzat hartuta posible dela 100 milioi hitzetik gorako corpusak osatzea bai bilatzaileen bidez bai crawling bidez, eta azken hau erabiliz ziurrenik askoz handiagoak ere osa daitezkeela. Gainera kalitatezkoak dira, corpus klasikoen hitz gehienak barne hartzen dituzte eta berri asko dauzkate. Beraz, webetik corpus orokor handiak biltzeak ekarpen handia egin diezaioke euskarazko corpusgintza eta hizkuntzalaritzari eta baita hizkuntzari orokorrean ere.

2 Motivation and objectives

A language that wants to survive in the modern world and be used normally in the media, in education, etc. needs to have language resources such as dictionaries or corpora. Besides, because language technologies are ever more present in everyday life through the web and our gadgets, it is imperative for any language with perspectives for the future to develop these language technologies; and these in turn need electronic dictionaries and corpora in order to be developed. And dictionaries (lexicographical or terminological) are nowadays produced on the basis of empirical evidence or previous use at least is studied, and these are both provided by corpora (they can even be semi-automatically extracted from corpora using NLP methods). So it is clear that corpora are a very valuable resource for many aspects of the development of a language.

In the case of the Basque language, the need for corpora is even greater, since its standardization did not start until the late 1960s and is still ongoing. But less resourced languages like Basque are not exactly rich in corpora: on the one hand, building a corpus in the classical way, i.e. out of printed texts, is normally a very costly process; on the other, the number of language experts or researchers dealing with these languages is much smaller than that of the major languages. So, the only Basque corpora that are currently available to the public are as follows:

- Orotariko Euskal Hiztegiaren Testu-Corpusa: a 6 million-word non-tagged corpus of classical literary texts produced by Euskaltzaindia, the Royal Academy of the Basque Language.
- XX. mendeko Euskararen Corpusa (http://www.euskaracorpusa.net/XXmendea): a 4.6 million-word balanced corpus produced by Euskaltzaindia; it consists mainly of twentieth century literary texts.
- Ereduzko Prosa Gaur (http://www.ehu.es/euskara-orria/euskara/ereduzkoa/): a 25.1 million-word corpus compiled by the UPV/EHU-University of the Basque Country, composed of literary and press texts regarded as "reference texts" from the years 2000 through 2006.
- Zientzia eta Teknologiaren Corpusa (http://www.ztcorpusa.net): a 8.5 million-word corpus compiled by the Elhuyar Foundation and the IXA Group of the UPV/EHU-University of the Basque Country, consisting of texts on science and technology published between 1990 and 2002 (Areta et al., 2007).
- Klasikoen Gordailua (http://klasikoak.armiarma.com/corpus.htm): a non-tagged 11.9 million-word corpus compiled by the publishing house Susa, consisting of classical texts.
- Lexikoaren Behatokia (http://lexikoarenbehatokia.euskaltzaindia.net): an 18.1 million-word corpus produced by Euskaltzaindia, the Elhuyar Foundation, the IXA Group of the University of the Basque Country and UZEI, made up of 21st century media texts.

But in recent years the web has been used increasingly for linguistic research, both via tools like WebCorp (Renouf et al., 2006) or KWiCFinder (Fletcher, 2006) that query search engines directly and show concordances, or via tools that use the Internet as a source of texts for building corpora to be used the classical way, after linguistic tagging and indexation (Baroni and Kilgarriff, 2006). As Kilgarriff and Grefenstette (2003) put it, although the use of the web as a source for building linguistic corpora has its detractors (who basically object to its lack of

representativeness and reproducibility and to the quality of its texts), this approach offers undeniable advantages, mainly that the corpora that can be obtained are much larger, that the cost of the automatic building processes is much lower and that the web is constantly up to date.

So it is not only logical but also almost unavoidable that a less resourced language like Basque should proceed as other languages have and turn to the Internet, and this is what has been done in recent years. The following are the tools or resources built by using this web-as-corpus approach:

- CorpEus (http://www.corpeus.org/): a web service to query the web live as if it were a Basque corpus, by showing KWiCs of pages in Basque (Leturia et al., 2007).
- AutoCorpEx: a tool to automatically collect specialized corpora from the web (Leturia et al., 2008a)
- Co3: a tool to obtain domain comparable corpora from the web (Leturia et al., 2009).
- PaCo2: a tool to build parallel corpora from the web (San Vicente and Manterola, 2012).

Using the last three tools, various corpora (monolingual specialized, comparable and parallel) have been built. But there is still no large general corpus in Basque with a state-of-the-art size; as we have seen, the largest Basque corpus has 25 million words, whereas, taking English as an example, the BNC was finished in 1994 and runs to 100 million words (Aston and Burnard, 1998), and the web-derived corpus ukWaC contains more than 2 billion words (Ferraresi et al., 2008). So, the main objective of the research described in this paper was to build a general Basque corpus that was as large as possible (comparable to the sizes of the corpora we have mentioned, if possible). But in order to achieve this, we have had to test the different methods mentioned in the literature for collecting large general corpora from the web to see which performed best for Basque, because the features of the language might affect the results; so the results of the evaluation of the different methods are also shown.

3 Related work

There are roughly two methods that are mentioned in the literature when it comes to building large corpora out of the web. One of them is the crawling method: starting from a list of seed URLs, the pages they point to are downloaded, and the links found in them are added to the list of URLs to do likewise with them; we apply this recursively until the list is finished or we reach a predefined endpoint. As the web is a collection of interconnected pages, starting from almost any seed list sufficiently large and applying this method, the whole public web can be downloaded. This is the method used in the WaCky project (Web-as-Corpus kool ynitiative), an initiative to build gigantic web corpora for many languages (Baroni et al., 2009), with which they have already built four corpora for four languages of around or more than 2 billion words each (and more are on the way): deWaC for German (Baroni and Kilgarriff, 2006), itWaC for Italian (Baroni and Ueyama, 2006), ukWaC for English (Ferraresi et al., 2008) and frWaC for French.

The other method relies on the use of search engines. A list of seed words is used, combinations of them are sent to the APIs of search engines and the resulting pages are downloaded, until the goal size is reached, no more combinations are left or no new pages are returned. This is the method used by Sharoff (2006) to build BNC-sized corpora (around 100-200 million words) for various languages.

Both methods report success stories. They are able to obtain corpora of the desired size and the word frequencies are comparable with those in classical corpora such as BNC. However, the two methods or the corpora obtained with them have not been compared with each other, so many questions remain in the air. Which is the fastest method? Which obtains the best quality corpora? Is it possible to obtain corpora of billions of words with the search engines method?

And even if it was clear which of the methods is the best, it does not necessarily have to be so for obtaining a corpus in Basque, due to the singularities of the language. For example, no search engine offers the possibility of restricting its results to pages that are in Basque or to perform a search taking the rich morphology of Basque into account, so some hacks have to be used when querying search engines for content in that language, which might affect the results of the corpora obtained. Or, due to the smaller size of the Basque web, the crawling method might not obtain a sufficient size because it might leave out a significant part of the Basque web if the seed URLs list is not good or large enough. So, testing and evaluating both methods (and with different parameters) for collecting a large general corpus of Basque is a necessary task.

4 Methodology

4.1 Search engine method

Sharoff (2006) uses the search engine method to build 100-200 million-word corpora for various languages. He uses a seed list of 500 words, which have to meet certain requirements: they must be frequent, they have to be general (i.e., they should not indicate a specific topic) and they must not be function words (prepositions, articles, pronouns, conjunctions, etc.).

In our case, we acted likewise. We took the list of frequent words from XX. mendeko Euskararen Corpusa (see above), and we removed the non-desired ones. We took out the pronouns and conjunctions, but there was no need to remove articles or prepositions (Basque is an agglutinative language and these are appended to the words). Topic-specific words were not removed, because there were not many of them among the first 500 (the most frequent words tend to be general).

However, we take a different approach to Sharoff's regarding lemmatization. As he points out, general search engines do not perform lemmatization, so his seed words list is formed by word forms. We use a list of lemmas and apply morphological query expansion when calling the API of the search engine. Basically, this consists of obtaining the inflections of a word by morphological generation and sending the most frequent ones within an OR operator. For example, if the lemma of a word is *etxe* ("house"), the search engine is asked for "etxe OR etxea OR etxeak OR etxeari OR etxeek OR etxearen OR…". This method has proven to be effective for obtaining from search engines a lemma-based search for Basque, and is the method usually used in services or projects that need to search for content in Basque (Leturia et al., 2008b; Leturia et al., 2009).

In order to obtain from search engines only the pages in the language of the corpus to be collected, some studies consider the need to select words that are unique to the language (Kilgarriff and Grefenstette, 2003; Ghani et al., 2003), rejecting words like "restaurant" that exist in several different languages. The above-mentioned work by Sharoff uses the language filter of search engines, except for Ukrainian (which is not covered by search engines), for which the query is complemented with a couple of very frequent function words that are not used in cognate languages. We do not reject words existing in other languages but we are not in a

position, either, to use the language filters of search engines because none of the existing search services can limit the results to pages in Basque. We apply the technique of the language-filtering words, like Sharoff for Ukrainian, by appending the most frequent words in Basque to the query ("… AND eta AND da AND ez AND ere"). As proven by Leturia et al. (2008b), this is the most effective method for obtaining results in Basque alone from search engines, although it means a loss in recall.

In the aforementioned paper, Sharoff also suggests that more than 500 words can be used. It would indeed be interesting to test the effect of the length of the seed word list in the corpus collection process and the obtained corpora; so, we tried with seed words lists of 500, 1,000, 2,000, 5,000 and 10,000 words.

In that same work, 4-word combinations are sent to the APIs, in order to get pages that contain relatively long pieces of connected text and a smaller number of noisy pages, i.e. tables or lists of links. However, he states that it is possible to relax the condition for four words in a query for languages which do not have sufficient number of Internet pages, and in fact he used 3-word combinations for Romanian. Because the Basque web may be orders of magnitude smaller than that in other languages, there is justification in seeing if there is in fact improvement with a shorter combination length; and there is no reason why the effect of longer ones should not be checked as well. That is why we also tried and evaluated 1, 2, 3, 4 and 5-word combinations.

Regarding the search engine, we used Google's API, just like Sharoff. From the results returned by the API, Sharoff downloads the first 10 pages. We decided to download the first 50, for one reason: because of the smaller size of the Basque web, many searches return no results (especially in the longer seed words lists and the longer combinations); so in order to build larger corpora while making the least possible number of queries, we downloaded more results from the productive queries.

4.2 Crawling method

The crawling method needs a list of seed URLs as a starting point. The corpora collected by the WaCky initiative (Baroni et al., 2009) obtain these seed URLs by making random queries of 2-word combinations to search engines (they make about 1,000 queries for getting around 10,000 seed URLs). In our case, we took the 1,500 URLs of the *Euskara* (meaning Basque language) section of DMOZ, the Open Directory Project. Although it is not an exhaustive list of all the websites in Basque and it is not as active and updated as it used to be, all the most important sites are undoubtedly there, and by following the links present in them recursively, we believe that it is almost certain that ultimately no site would be left out (except for island sites that have no inbound links from anywhere, but neither would these be indexed by search engines). However, this is one of the points that we wanted to test in our experiments.

The crawling is done in a multi-threaded parallel way with a breadth first strategy (prioritizing website variety above website completeness), just as in the WaCky initiative.

4.3 Common filters in both methods

The pages that are downloaded, whether by using search engines or by crawling, need to go through some cleaning and filtering if we want to build a quality corpus. Here we will describe how we implemented these steps.

Language filtering. When building a corpus, one is usually looking for texts in a language. When using search engines, the language filter is done by telling the search engine to return only results in that specific language. But when using the crawling method or, in some cases, also the search engine method (if search engines do not offer filtering by the language we want), it is up to us to do the language filtering after downloading. For this task we make use of LangId, a language identifier based on character and word trigram frequencies specialized in Basque, applied at paragraph level so that we can also extract content from bilingual documents.

Length filtering. Fletcher (2004) proved that filtering web documents by their size improved the quality of the web corpora. Those that do not reach a minimum are usually error messages from web servers or tend to have little textual content once page headers, menus, etc. are removed. On the other hand, those that are too large are not good for linguistic corpora, since they are often not representative of real language and tend to be lists, catalogues, spam and such things. We do in fact apply a length filter but, unlike most projects, it is not based on the size of the downloaded file. We reject documents the length of which after conversion to plain text is under 1,000 characters or over 100,000 characters.

Spam and porn filtering. The web is full of spam, porn and other kinds of noise. When we build a corpus out of web documents it is essential to get rid of these elements, but it is not always easy. The size filter proposed by Fletcher (2004) decreases this kind of noise but does not eliminate it completely. If we use search engines, we will most probably get less spam and porn, since they already do this filtering. But it is always desirable, and in the case of crawling methods necessary, to implement the detection of spam and porn. We do not apply any specific filter for spam and porn, because there is hardly any in Basque. People with commercial intentions target larger audiences and do not bother about minority languages spoken by communities that speak some other major language. Therefore, the language filter does the job perfectly.

Boilerplate removal. Web pages are full of "*boilerplate*", which is the linguistically uninteresting material that web server software automatically creates and which is repeated throughout every page in a website: headers, navigation menus, copyright notices, ads, etc. It is advisable to remove this boilerplate for various reasons: it makes ugly KWiCs, it distorts word frequencies and it makes the work of other filters (near-duplicate filtering, for example) more difficult. For boilerplate removal, we use Kimatu (Saralegi and Leturia, 2007), a language-independent system based on heuristics and features like tag density, punctuation signs, function words, etc. that scored second (74.3%) in the Cleaneval competition (Baroni et al., 2008).

Near-duplicate detection. The detection of exact duplicates is a straightforward task easily accomplished by hashing techniques. But much content is repeated across different websites (news from agencies in media sites, CC licensed articles in many blogs...) which are not exact duplicates, and these cannot be detected by hashing methods. The method most used for this job is Broder's algorithm (2000). We included a near-duplicate detection module based on Broder's shingling and fingerprinting algorithm.

Containment detection. It is very common for a web page containing an article with its own URL to be included in its entirety in the main page of its home newspaper or blog. Broder also implemented an algorithm for detection of already contained documents (1997). It is not as optimized as near-duplicate detection, but it is possible to use it for small- and medium-sized corpora building. In our downloading process, we included a containment detection method also based on Broder's works.

5 Evaluation

5.1 Corpora obtained by the search engine method

5.1.1 Effect of length of seed word list

As we have already stated, as a first experiment we tested and downloaded 5 different corpora using 5 different lengths of seed word list: 500, 1,000, 2,000, 5,000 and 10,000 words. In all of them, we used combinations of 3 words (as Sharoff suggested for languages with a smaller presence on the web and applied to Romanian), made 12,000 queries and downloaded the first 50 results of each query. The sizes obtained can be seen in table 1. We will now analyse various aspects of the corpora obtained.

Seed word list length	Documents	Words	Words per document	Different websites
500	49,387	81,508,628	1,650.41	4,452
1,000	83,941	105,374,227	1,255.34	4,849
2,000	83,147	119,474,991	1,436.91	4,675
5,000	52,913	129,342,982	2,444.45	4,398
10,000	25,350	85,271,975	3,363.79	3,021

TABLE 1 – Sizes of the collected corpora for each length of seed word list.

In the table we observe that the smaller the seed words list we use, the smaller the resulting corpora are, although the APIs return many more results. The reason for this is that the words in the smaller lists are more common and many pages contain them, but search engines will always be returning the same ones (the ones rated highest in their page rank) and the duplicate filters will remove them; if the words are more rare, fewer pages will contain them and they will not be repeated as much. Nevertheless, for the 10,000 list, the words are so rare that very few pages contain 3 of them and so the corpus obtained is smaller, and will probably be likewise for seed words lists above that.

For all these reasons, it can be concluded that, unlike for English or other languages, a 500-seed word list is not optimal for a language with a moderate presence on the web like Basque. Looking at the sizes, the optimal seed word list length seems to be 5,000, because that is the one that obtains the largest corpus. However, the type of documents from which the corpus has been built is something to take into account, which is shown in fig. 1. The 5,000 seed word corpus is the one containing more words from PDF documents, and PDFs are problematic: it is a visual format instead of an edition one (it does not contain the original continuous text, but rather the coordinates in the page of each line of text, word or even character), so original text extraction from them is never perfect and often very bad. PDF to text converters commit many errors when trying to rearrange the original paragraphs: two-column documents' lines are all messed up, header and footer text are repeated for every page and inserted into other paragraphs... As Fletcher (2007) points out, “PDF does not encode the logical formatting of the text (headings, paragraphs, captions etc.)” and “one problem that plagues all PDF to text converters persists: spaces are occasionally dropped or inserted between or within words”. Because of all of these, the 2,000 seed word corpus may be more appropriate (it is the one that has more words from HTMLs and second in total size), depending on our preference for size or quality.

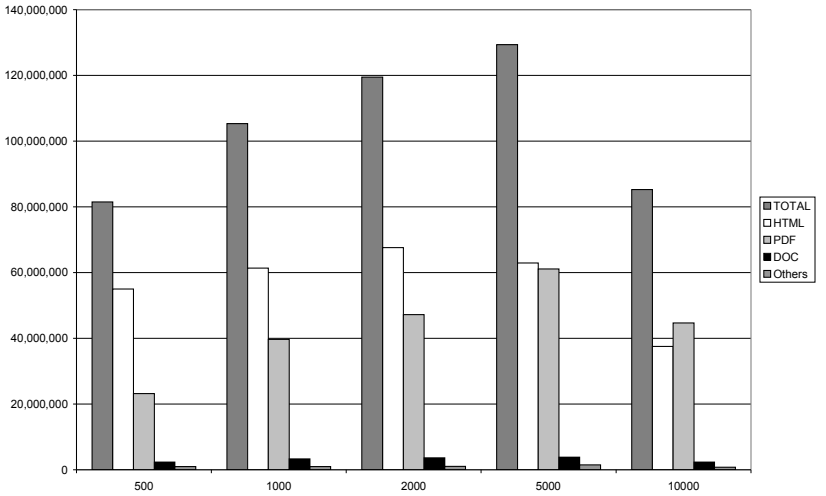

FIGURE 1 – Size in words of the corpora obtained for each seed word list length, total and by type of document.

Another clear difference in the corpora is the average size of the documents (table 1), which grows with the size of the seed word list (logically: if the words are rarer, they are more likely to be found in larger documents). Because corpora are used for linguistic research, the interesting documents for corpora are those that contain a reasonable amount of connected text (Sharoff, 2006). Although we apply the length filter in the collection process and all texts in the corpus have a minimum text, if we are interested in obtaining texts that are as long as possible, then we should opt for corpora obtained with longer seed word lists.

One more thing we have studied is the website variety of the corpora. It is usually interesting for a corpus to be from as many different sources as possible, to be able to analyse more diversity in the use of language; otherwise, style books of media, internal glossaries, etc. can lead to corpora that are too homogeneous. The number of different websites of each corpus is also shown in table 1. As can be seen there, in the last one the number of different websites falls drastically (again, it is logical if that corpus is composed of bigger documents and is smaller), but there is no significant difference among the rest.

Finally, there is one more point worth mentioning: using the search engines method, corpora do not grow continuously at a constant rate. Due to the page ranking these engines use, the same pages tend to appear over and again and are discarded by the duplicates detection, so the bigger the corpus is, the lower its growth rate gets, as the graph in fig. 2 shows. The growth rate is the number of new words obtained for each call to the search engine API, and is represented by the inclination of the curve in the graph.

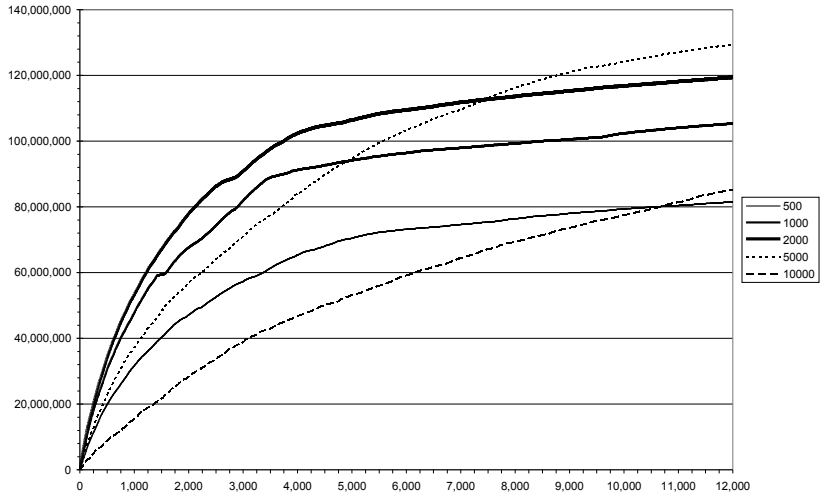

FIGURE 2 – Growth rate of the corpora obtained for each seed word list length.

So, it is not clear whether by using the search engines method we can build corpora as large as we would like to; and even if we could, it would be in a very unproductive way: while with the first 1,000 queries we obtain 37 million words on average (with a maximum 53 million words), in the last 1,000 queries we obtain less than 2 million words on average. And queries to the search engines are not an infinite resource: either they are paid services or have a maximum of calls per month.

5.1.2 Effect of length of combination sent to search engine

In the other experiment, we collected 5 corpora using 5 different search engine word combination lengths: 1, 2, 3, 4 and 5 words. For all of them, the rest of the parameters were the same: a seed word list of 2,000 words was used, 12,000 queries were made and the first 50 results of each query were downloaded. The details of the collected corpora are shown in table 2. Again, we will take a look at some features of these.

Combination length	Documents	Words	Words per document	Different websites
1	36,093	44,692,614	1,238.26	4,089
2	85,562	131,738,927	1,539.69	6,095
3	83,147	119,474,991	1,436.91	4,675
4	41,568	116,371,032	2,799.53	3,824
5	23,108	89,139,248	3,857.51	2,547

TABLE 2 – Sizes of the collected corpora for each combination length.

We can see that there is not a direct correlation between combination length and corpus size. If we send 1-word combinations of a 2,000 word seed list, there are only 2,000 different combinations, as the rest are repeated and do not return new results; therefore, we get the smallest corpus by far. With 2-word combinations we get the largest corpus, but from then on it gradually decreases again, because there will be fewer pages that have all the words. And in this case it is also the 2-word combination corpus that has the most words coming from HTML documents.

Regarding the document length, the same phenomenon as with the seed list length happens: for longer combinations, the size of the documents grows. But the website variety in this case falls for combinations longer than 2. And the dramatic fall in the growth rate also occurs in all these cases.

5.2 Corpus obtained by the crawling method

With the crawling method, and starting with the 1,500 seed URLs from the *Euskara* section of DMOZ, we have so far queued 39,163,290 links, tried to download 6,520,000 of them, successfully downloaded 3,472,166 pages (the rest were not available at the time, or had been discontinued, or gave errors) and included 168,991 out of them in the corpus. The rest were discarded because they were not in Basque (a high percentage of pages in Basque point to pages in other languages, mainly Spanish and English), or were in a format that could not be converted into text, or did not get through the filters (length, duplicate, etc.). The size in words of the downloaded corpus is 115 million. Its features can be seen in table 3.

Documents	Words	Words per document	PDFs	Different websites
168,991	114,565,240	677.94	1,276	5,060

TABLE 3 – Size of the corpora collected by crawling.

Only 1,276 documents come from PDFs, that is, only 0.75%. But the average document length is small, 678 words.

The website variety that could be obtained by the crawling method was one of our concerns. Starting from a set of seed URLs, there is a risk that they may not be enough or good enough, and that many websites are left out because they are not linked to in the initial pages or in the ones recursively linked by these. However, we can see that we have got a number of different websites larger than all but one of the search engines corpora, and compared to that single larger one it is proportionally not much smaller.

It is also interesting to take a look at the growth rate of the corpus (fig. 3). There is certainly a decrease in it, but not that pronounced: in the first million links followed, 23.3 million words were collected, whereas with the last million links we obtained 11.3 million words. It has gone down to 48.5% of the initial rate, while in the search engine corpora, this number is 5.4% on average. This proves that this method has the potential to collect a still much larger corpus.

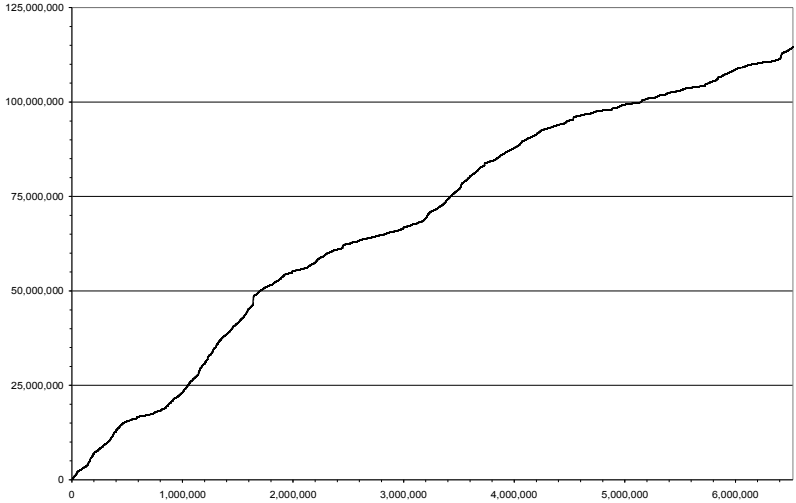

FIGURE 3 – Growth rate of the corpus obtained by the crawling method.

5.3 Qualitative analysis

In the previous subsections, the different corpora obtained were evaluated quantitatively (size, cost, etc.), but a more qualitative evaluation is necessary when corpora are involved, that is, an analysis according to linguistic criteria, because that is what corpora are used for.

5.3.1 Most characteristic words by LLR

There is no absolute method or measure to evaluate the linguistic quality of a corpus. Instead, what is usually done is to compare it with another by using the log-likelihood ratio or LLR association measure (Dunning, 1993) to identify the words that are more characteristic of one with regard to the other (Rayson and Garside, 2000); this is the method used both by Sharoff (2006) and Ferraresi et al. (2008) for evaluating the search engine method corpora and the ukWaC, respectively.

To carry out the evaluation, we chose the largest of the search engine method corpora, i.e. the one obtained with 2000 seed words and 2 combinations (we will call this corpus SE henceforth) and the crawling method corpus (CR henceforth). The number of URLs coinciding in both is only 6,815 (SE is made of 85,562 URLs and CR of 168,991).

Apart from comparing these two corpora with each other, we compared them with two reference corpora: XX. mendeko Euskararen Corpusa (a 4.6 million-word balanced corpus of twentieth century literary texts), henceforth XX, and Lexikoaren Behatokia (an 18.1 million-word corpus of 21st century media texts), henceforth LB.

Ferraresi et al. (2008) used nouns, adjectives and verbs for their analysis, but we also took adverbs and pronouns. We used the lemmas of words. Because in the case of XX we did not have access to the corpus but only to a list of lemma-frequencies and because it was lemmatized with a tagger different to the one we use, we had to discard proper nouns and numbers (the XX frequency list did not contain them) and make some adjustments (there were some deprecated lemmas that are now written in another way).

The most outstanding words of XX compared with any of the other three corpora can be put into three groups: religious words (*jaungoiko* and *jainko* "God", *eliza* "church", *apaiz* "priest", *santu* "saint", *otoitz* "prayer", etc.), pronouns (*hura* "he", *neu* and *ni* "me", *zu* and *hi* "you", *gu* "we", etc.), and words that are scarcely used any more, either because they are now usually said another way, or because they were dialectal or incorrect forms of the times before the standardization, or because they are objects that do not exist or are no longer used (*gizaldi* "century", *eroan* "to take", *ipini* "to put", *ezkero* "if", *pezeta* old currency of Spain, etc.). The prominence of words from the first and third groups is easily understood in view of the difference in temporal deixis across XX and the other three corpora. The greater presence of words from the second group is a normal phenomenon in fiction and narrative texts compared with media and web texts, as Sharoff (2006) also confirmed.

The words characteristic of LB in comparison with any of the others can be divided into two groups: adverbs of time (*atzo* "yesterday", *gaur* "today", *herenegun* "the day before yesterday", *iaz* "last year", *bihar* "tomorrow", etc.) and words from typical media sections such as sports (*talde* "team", *partida* "match", *jokatu* "to play", etc.), politics (*presidente* "president", *gobernu* "government", *nazioarte* "international", etc.), society (*atxilotu* "to arrest", *auzitegi* "court", *epaile* "judge", etc.), culture (*film* "film", *disko* "record", *kontzertu* "concert", etc.) or economy (*euro* "euro", *krisi* "crisis", *lan* "to work", etc.). Both word groups are typical of media texts.

The web corpus we collected using search engines, SE, differs from the other three in words from the administrative domain (*prozedura* "procedure", *lege* "law", *artikulu* "article", *administrazio* "administration", *eranskin* "appendix", *dekretu* "decree", etc.) or the educational domain (*hezkuntza* "education", *ikasle* "pupil", *ikastetxe* "school", *irakaskuntza* "teaching", *irakasle* "teacher", etc.). The prominence of administrative words is greater when compared with the CR corpus. The cause of this might lie in the fact that regional, provincial and local governments publish their official gazettes in PDF format; and, as we saw before, the SE corpus has a large proportion of PDFs, so these might be mostly of an administrative nature.

Finally, the words characteristic of the corpus obtained by crawling, CR, are words typical of web pages (*iruzkin* "comment", *orri* "page", *sare* "net", *erabiltzaile* "user", *web* "web", *blog* "blog", *erantzun* "to comment", *internet* "Internet", *lizentzia* "license", *software* "software", etc.) or of media websites (*albiste* "news", *argazki* "photo", *bideo* "video", *emisio* "broadcast", *kanal* "channel", *telebista* "TV", etc.), month and weekday names (*azaro* "November", *urri* "October", *igande* "Sunday", *astearte* "Tuesday", etc.) or words from the cultural domain (*dantza* "dance", *euskara* "Basque language", *kultura* "culture", *ikastaro* "course", *antzoki* "theatre", etc.). Except for the last, all the groups of words are common in web pages, so we can say that the main feature of this corpus is that it is mostly composed of genuine web pages.

5.3.2 Number of distinct and 'useful' words

Baroni et al. (2009) compared ukWaC and itWaC with reference corpora in each of those languages (the BNC and la Repubblica corpus) looking at three parameters: the number of distinct words in a corpus, the coverage of a corpus within another and the enrichment a corpus gives to another. We have done the same with the four corpora analysed in the previous subsection. We counted the lemmas of all types of words, except proper nouns and numbers (because of the reasons already explained).

Just as in the aforementioned work by Baroni et al., we show the number of distinct words in terms of absolute numbers and of words that occur at least 20 times. This frequency threshold was chosen by them as a rough way of estimating the number of 'useful' words in a corpus, following Sinclair's (2005) claim that at least 20 occurrences of a word are usually needed for an experienced lexicographer to describe its behaviour, and taking into account that low frequency words will not be of any use in NLP applications either. Although admittedly arbitrary, we also used the 'Sinclair cutoff'. The number of distinct words that each corpus has is shown in table 4.

Corpus	Total words	Words $f \geq 20$
XX	53,993	9,147
LB	36,311	12,922
SE	74,132	33,056
CR	64,424	27,238

TABLE 4 – Number of distinct words in each corpus.

As we can see, the number of total and 'useful' words is much greater in the web corpora; this is logical due to their much greater size. However, the high number of total words of the XX corpus is striking: it has almost as many words as the web corpora (which are more than 20 times larger) and much more than the LB corpus (which is almost 4 times bigger). This is due to the fact that a considerable part of the XX corpus is made up of texts from before the standardization of the Basque language and it contains many obsolete, outdated, out-of-use or non-standard words that were tagged manually but which Basque taggers do not usually recognize.

5.3.3 Coverage and enrichment

In order to prove that those 'useful' words attested in the web corpora are the sort of words linguists and lexicographers would be typically interested in, rather than, say, web-related terms of limited general interest, Baroni et al. looked at two measures of overlap, namely coverage and enrichment. The coverage of a corpus in another one is the proportion of words that are above the Sinclair cutoff in both over the total words above this threshold in the first corpus; it can be considered as a rough measure of the extent to which the first corpus is “substitutable” by the second, because it gives an idea of how many of its useful words are also present in the other. The enrichment of a corpus in another one is defined as the proportion of words that are above the Sinclair cutoff in the second corpus but below it in the first, over the total words below the threshold in the first one (to avoid noise in the form of typos or loanwords, only words with at least 10 occurrences are considered); this gives a rough idea of the number of words for which the first does not have enough information, but the second does. We have also calculated these measures, and the statistics obtained are reported in table 5.

Corpora type	Corpora	Coverage	Enrichment	Corpora	Coverage	Enrichment
Classical	XX / LB	57.14%	14.36%	LB / XX	80.71%	38.36%
Classical / Web	XX / SE	26.13%	0.48%	SE / XX	94.44%	83.67%
	XX / CR	31.43%	1.01%	CR / XX	93.59%	77.43%
	LB / SE	36.74%	0.81%	SE / LB	93.99%	83.85%
	LB / CR	44.21%	1.48%	CR / LB	93.19%	79.11%
Web	SE / CR	95.80%	56.24%	CR / SE	78.94%	9.52%

TABLE 5 – Coverage and enrichment of each corpus with regard to each of the others.

It shows that the web corpora cover high above 90% of the classical corpora with an enrichment over them of around 80%, whereas the coverage of the classical corpora over the web ones is normally below 40% and their enrichment is always below 2%; these data are similar to the ones obtained in the aforementioned research by Baroni et al. with ukWaC/BNC and itWaC/La Repubblica.

However, the comparison between the two web corpora, SE and CR, offers surprising results. Although they are of almost equal size, we have seen in the previous subsection that SE contains many more distinct and 'useful' words than CR, and the coverage and enrichment are not symmetrical: CR is almost completely covered by SE (95.80%), but in the other direction this number is only 78.94%; and SE enriches CR by 56.24%, whereas CR only contributes to SE with 9.52% of new words. It looks as if, for equal sizes, the search engine method obtains more linguistically varied corpora than the crawling method. Nevertheless, we have shown that the crawling method can collect much larger corpora, so this deficiency will supposedly be corrected if we continue crawling and enlarging the corpus.

Conclusions

We have proven that both crawling and using search engines are valid methods for obtaining BNC-sized corpora for Basque. With the search engines method, using 2,000 or 5,000 seed words we obtained the largest corpora: the former obtains greater website variety, the latter obtains more PDFs (usually problematic) and larger documents (more connected text). The optimal word-combination length to send to the APIs seems to be 2, because it obtains the largest and most varied corpus with the least number of PDFs. However, if more than 100-150 million words are needed, crawling is the way to go: we have collected a corpus of a size and website variety comparable with those obtained via search engines, with much fewer PDFs and the potential to get much bigger. This corpus is now 115 million words big, but we expect to make it much larger in the near future.

When compared with classical corpora, these web corpora differ in that the search engine ones contain more administrative texts (most probably due to the PDFs of official gazettes) and the crawling one more web-domain texts. Since almost all of the words in the classical corpora are present in the web ones, whilst they provide many new words, we can conclude that collecting large corpora from the web can make a great contribution to Basque corpus building, linguistics and the language in general.

ABSTRACT
Approximate sentence matching (ASM) is an important technique for tasks in machine translation (MT) such as example-based MT (EBMT) which influences the translation time and the quality of translation output. We investigate different approaches to find similar sentences in an example base and evaluate their efficiency (runtime), effectiveness, and the resulting quality of translation output. A comparison of approaches demonstrates that i) a sequential computation of the edit distance between an input sentence and all sentences in the example base is not feasible, even when efficient algorithms to compute the edit distance are employed; ii) in-memory data structures such as *tries* and *ternary search trees* are more efficient in terms of runtime, but are not scalable for large example bases; iii) standard IR models which only cover material similarity (e.g. term overlap), do not perform well in finding the approximate matches, due to their lack of handling word order and word positions. We propose a new retrieval model derived from language modeling (LM), named LM-ASM, to include positional and ordinal similarities in the matching process, in addition to material similarity. Our IR based retrieval experiments involve reranking the top-ranked documents based on their true edit distance score. Experimental results show that i) IR based approaches result in about 100 times faster translation; ii) LM-ASM approximates edit distance better than standard LM by about 10%; and iii) surprisingly, LM-ASM even improves MT quality by 1.52% in comparison to sequential edit distance computation.

1 Introduction

The quality of data-driven machine translation (MT) mostly depends on the size of parallel data available for training. Although statistical MT is considered as the state-of-the-art, its one limitation is that it discards the training data once the translation model and language model have been generated. This sometimes can lead to poor quality translations because translation context is limited by the value of n. In contrast, example-based MT (EBMT) usually stores the full sentence pairs in source and target data in an example base and uses translations of sentences similar to the input sentence as a template for translation. Thus, EBMT systems can often better capture long range dependencies and rich morphology. State-of-the-art MT systems comprise both statistical and example-based MT components (Dandapat et al., 2012). Typical EBMT systems (Somers, 2003; Nagao, 1984) comprise three processing stages to translate an input sentence Q with information from an example base of sentence pairs (S_i, T_i), where S_i and T_i are in source and target language, respectively: i) Matching, where sentences similar to Q are identified, and the translation template T_i with the maximum similarity between Q and S_i is used as a skeleton for the translation. ii) Alignment, where the matching parts of Q and S_i are found to identify the remaining translation gaps and translation alternatives for the mismatches are obtained from TM. iii) Combination, where the translation fragments found in the previous steps are aggregated into the final translation. The matching stage involves maximising a similarity between the input Q and all source language sentences S_i in the example base. The most widely used similarity measures in EBMT matching are based on the edit distance (ED), also known as Levenshtein distance (LD) (Levenshtein, 1966). Thus, the matching step of an EBMT system is a time-consuming process with runtime depending on the complexity of the similarity measure and the size of the example base. EBMT systems can usually only handle a moderate size example base in the matching stage. However, using a large example base is important to ensure high quality MT output. In order to make MT applicable for larger example bases while improving or maintaining its speed, we investigate different approaches to efficient approximate sentence matching: a) sequential algorithms for the computation of the similarity, where speed improvements are based on limiting the number of symbol comparisons (e.g. cut-off heuristics); b) data structures, where a traversal of the structure can be employed to compute the similarity; c) sentence indexing and retrieval, where aspects of similarity are traditionally modeled by factors based on frequencies such as *tf* and *idf*, but in the case of approximate sentence retrieval should also include word order and position.

We demonstrate that sequential (brute-force) approximate matching becomes too expensive for large example bases. Using in-memory data structures is efficient with respect to runtime, but requires much more memory. Information retrieval based on standard term weighting functions is not appropriate for finding best matches. Standard information retrieval (IR) is more efficient than sequential comparison, but not accurate enough in finding the most similar matches in top ranks. We propose a hybrid, two-stage approach. First we retrieve sentences from the example base, scoring the results based on our proposed edit distance approximating retrieval model. Secondly, we rerank the results by their true LD score. Our approach thus restricts the edist distance computation to the set of top-ranked retrieved sentences instead of the full example base. The proposed retrieval model uses positional indexing and retrieval, reflecting three aspects of similarity: how similar term positions are, how similar the word order is, and how similar the sets of terms are. The approach is shown to be fast (i.e. efficient and more scalable), accurate in terms of mean reciprocal rank (MRR) (i.e. effective in retrieving approximate matches), and can yield even better translations than the sequential approaches (i.e. results in a higher BLEU score (Papineni et al., 2002)).

The rest of this paper is organized as follows: Section 2 introduces related work; Section 3 presents

approaches to approximate sentence matching; Section 4 describes our proposed IR model; Section 5 explains our experimental setup, data and evaluation metrics; Section 6 presents and discusses the results. Section 7 concludes with an outlook on future work.

2 Related Work

Despite of a long history of research in IR and MT, there is still relatively little research on applying IR methods for MT. Two years before Levenshtein proposed the edit distance in 1966 Levenshtein (1966) and Faulk (1964) argued that three aspects of similarity should be considered for approximate sentence matching for translation: 1. positional similarity of items (e.g. words occur in the same positions), 2. ordinal similarity (e.g. words have the same order), and 3. material similarity (e.g. the sets of words are similar). He investigates different similarity metrics in different languages and demonstrates that a high sentence similarity in the source language correlates with a high similarity in the target languages. The edit distance has been widely used in diverse applications such as approximate name matching (Berghel and Roach, 1996), in the biomedical domain for the comparison of gene sequences (Yap et al., 1996), for spelling correction and dictionary search (Boytsov, 2011). and in music retrieval (Mongeau and Sankoff, 1990). Improvements of the runtime complexity of the original Levenshtein algorithm include Ukkonen's cut-off heuristics (Ukkonen, 1985b,a) and Berghel and Roach's extension of this approach. Finally, Levenshtein automata (Schulz and Mihov, 2002) have been suggested as an efficient approach to spelling correction when an upper bound for the distance is known in advance. Due to the large number of different symbols (words) and because an upper bound for the distance is not known in advance, we did not investigate Levenshtein automata for the experiments described in this paper. Alternative approaches to approximate matching include q-grams (Gravano et al., 2001) (i.e. character n-grams), variants of the longest common subsequence (Lin et al., 2011), and affine gap alignment (Needleman and Wunsch, 1970). Navarro (2001) presents an excellent survey on different approaches to approximate string matching.

The standard application of MT in IR is in Cross-language IR, where given a query in the source language, documents in a target language have to be retrieved (Di Nunzio et al., 2008). IR techniques have been applied to machine translation only recently. (Hildebrand et al., 2005) apply IR to improve the quality of the training data for a statistical MT system. They adapt the language model for translation by selecting similar sentences from a large training corpus for training data and experiment with *tf-idf* and cosine similarity and Okapi's BM25 model (Robertson et al., 1998), finding no significant difference in their performance. They conclude that adaptation of the LM is helpful in improving translation quality. Similar to the experiments described in this paper, Koehn et al. apply IR and use a combination of n-gram matching and A* pruning (Koehn and Senellart, 2010). However, they do not report individual results for the retrieval effectiveness, only optimize the speed of approximate matching, and do not report the effect of applying their matching approach to TM in detail. They achieve a processing time per query of 247ms for sentence matching in the JRC-Acquis corpus and 4.3ms in a smaller corpus with product information. Dandapat et al. (2012) investigate two methods to achieve scalable EBMT. First, they try bucketing sentences by length to limit the number of sentences in the example base that have to be compared against the input, assuming that similar sentences will have similar length. Thus, the best match is not guaranteed to be found when this heuristics is used. Their second method includes IR based on standard language modeling (LM), but individual results for the IR stage are not reported. For the retrieval experiments described in this paper, we use LM as a baseline. We investigate parameter settings and preprocessing options to obtain the best baseline for our proposed approach.

The application of edit distance for problems such as spell checking is different to its application in EBMT and TM in several aspects: 1. Typically, character sequences (i.e. strings) are considered for comparison. For our experiments, we aim at computing the similarity for sequences of symbols or tokens (i.e. words and all punctuation marks). 2. Given a large dictionary for approximate *string* matching, the distance of an input word to some word in the dictionary is usually quite low. This does not have to be the case for approximate *sentence* matching, where the size of the alphabet (the number of possible symbols) is much higher (i.e. different characters vs. different words) and the minimum edit distance can also be quite high. Thus, a general minimum edit distance threshold can not be specified in practice. 3. Providing an upper bound for the edit distance can speed up the computation considerably. For the application we consider here, no upper limit for the number of mismatches is known in advance. 4. We are interested in finding all matches with the highest similarity as opposed to finding a single close match or one best match. For the experiments described in this paper, we did not employ heuristics such as bucketing or assuming an upper bound for the edit distance to speed up processing. These methods can actually be utilized to reduce runtime for our proposed approach even more, but at the cost of the loss of accuracy.

Our proposed LM-ASM retrieval model is an extension of language modeling. An extension to language modeling, known as positional language modeling (PLM), includes a proximity heuristic rewarding a document where matched query terms occur close to each other (Lv and Zhai, 2009). The PLM favours documents where the query terms appear in the same order as that in the query. In PLM, relative term positions are modelled via their term context. In constract, our proposed retrieval model for approximate sentence matching takes into account the absolute term positions.

3 Approaches for Approximate Sentence Matching

Approximate sentence matching (ASM) is the problem of finding the sentences with the highest similarity to a given inpuit sentence in a collection of sentences. The matching stage of EBMT can be considered as an instance of ASM. It identifies sentence pairs (S_i, T_i) from the example base where S_i closely matches with the input sentence Q. The EBMT system considers the translation T_i where Q has maximum similarity to the source sentence S_i to build a skeleton for translation of the input. From the perspective of IR, we are trying to find sentences (documents) in the example base (document collection) which have a high similarity (document score) with the input sentence (query). The results are then used in the alignment and recombination stage of EBMT to produce a translation. The set of sentences with the highest Levenshtein score (LS), i.e. the highest fuzzy match score, is computed by a sequential approach and corresponds to the set of relevant documents. Relevance assessment for IR is typically based on manual assessment of pooled results, whereas in the experiments described in this paper, the relevant (correct) results are determined based on a sequential computation of fuzzy match scores. We introduce similarity metrics between sequences Q and D with length $|Q|$ and $|D|$, where i and j denote an index in a sequence and Q_i and D_j denote the ith and jth symbol in sequence Q and D.

3.1 Sequential Search

Levenshtein Distance Algorithms ($\mathbf{LD}_{WF}$ and $\mathbf{LD}_{BR}$). The Levenshtein distance or edit distance is typically employed in EBMT to find the closest matching sentence in the example base. The edit distance for two sequences Q and D is defined as the minimum number of edits, i.e. symbol insertions, deletions and substitutions, needed to transform Q into D (Levenshtein, 1966). The sequential computation of the distance can be computationally expensive, because the Levenshtein algorithm has a runtime complexity of $O(|Q|$ x $|D|)$, which has to be calculated for every sentence

in the example base. The straightforward solution to compute the edit distance is via dynamic programming, where a $|Q|$ x $|D|$ matrix is filled following a recursive schema (Wagner and Fischer, 1974). For all approaches based on computing the exact LD, we use the normalized Levenshtein similarity score (fuzzy match score), which is computed as

$$LS(q, d) = 1 - LD(Q, D)/\max(|Q|, |D|) \quad (1)$$

Several improvements have been proposed to improve runtime complexity. Ukkonen's Enhancend Dynamic Programming Approximation algorithm (Ukkonen, 1985b) for computing edit distance has the worst case complexity $O(|Q|$ x $B)$, where B is an upper bound of the edit distance. The improvement results from the fact that $distance(i, j)$ values are non-decreasing along any given diagonal. Only those $distance(i, j)$ values p for which i is the highest numbered row on which p occurs on diagonal k for a given threshold k have to be computed. The modified Berghel-Roach algorithm (Berghel and Roach, 1996) is an extension of Ukkonen's cut-off heuristic. It achieves 42% speed-up compared to Ukkonen's approach for name matching and is 79% faster than the Wagner-Fischer algorithm. We employ the Berghel-Roach algorithm (LD_{BR}) to investigate speed-up by an algorithm with lower runtime complexity. As a baseline for runtime, we compute the edit distance based on the Wagner-Fischer algorithm (LD_{WF}).

Longest Common Subsequence (LCS). Our experiments to improve MT with IR methods are based on the assumption that the sentence with the minimum edit distance in the source language is a good template for its translation. This assumption is widely accepted and has been validated for translation memory (TM) (Sikes, 2007). We compare our experimental results for the edit distance with corresponding results for the longest common subsequence (LCS) (Gusfield, 1997). The LCS is the longest shared subsequence of – not necessarily consecutive – symbols in two sequences. The corresponding score is computed by replacing the edit distance LD in Equation 1 with the LCS and calculating the scores by iterating over all examples in the example base.

3.2 Data Structures

Efficient data structures have been proposed for fast approximate lookup operations in dictionaries (e.g. for spelling correction), but to the best of our knowledge, the following approaches have not been investigated for ASM, i.e. for computing the edit distance for sequences of words. In fact, the existing implementations consider only characters as symbols, while our implementation abstracts from that view and allows any type of symbol as the basic element of a sequence.

Tries (TR). A trie is an ordered tree data structure that can be used to store key-value pairs where the keys are sequences of symbols (Gusfield, 1997). Each node in a trie stores a single symbol of the corresponding sequence and a node represents the prefix of the key on the path of the root up to that node. All the children of a node have a common prefix of the sequence associated with that node, and the root represents the empty sequence. Values are associated with nodes corresponding to the end of a sequence, i.e. leaf nodes and some inner nodes. The main idea to efficiently compute the edit distance with tries is to compute only the part of the distance matrix up to the length of the current prefix, so that redundant computations are avoided for sequences sharing the same prefix. For our experiments, we regard sentences comprised of tokens as sequences of symbols and store the corresponding document ID (i.e. sentence ID) as a value.

Ternary search trees (TST). Ternary search trees (Bentley and Sedgewick, 1997) are tree structures where each node has three children. Similar to hash tables, ternary search trees can be em-

ployed as an associative structure to store key-value pairs (here: pairs of sentence and document ID). Each node of a ternary search tree stores a single symbol for comparison with a symbol of a search key, and pointers to three children which determine which subtree to search next, based on the result of a comparison, i.e. lower, equal or higher lexicographical order. As for tries, only part of the edit distance matrix – a single row – is computed at a given node.

BK-trees (BKT). Burkhard and Keller (1973) proposed BK-trees for efficient file searching. A BK-tree is a metric tree adapted to discrete metric spaces, defined by a distance metric $D(x, y)$. A BK-tree can be formed as follows. An arbitrary element a is selected as the root node. The root node may have zero or more subtrees. The kth subtree is recursively built of all elements y such that $D(x, y) = k$. As BK-trees support distance metrics, and not similarities, we directly employ the edit distance as a metric. To improve runtime, we use a distance threshold of 2, i.e. subtrees exceeding the threshold distance are not visited. This setting was obtained empirically and chosen to yield the best results in terms of effectiveness and efficiency. Lower values result in finding fewer correct results, higher values more than double the runtime because more nodes have to be visited. Note that this cutoff heuristic results in lower runtime but also lower effectiveness.

3.3 Information Retrieval Approaches

The problem with brute force, sequential computation is that it involves a linear search for the closest matching sentence by computing edit distance between the given query and each sentence in the example base. The time complexity is thus $O(N)$, N being the number of sentences in the collection, which clearly makes the brute-force approach infeasible for large collections. In-memory data structures could be much faster in LD computation, but have high space complexity, i.e. require a huge memory and are thus not scalable for very large collections.

Standard IR models. Information retrieval (IR) is concerned with finding relevant documents from a document collection, given a query (Manning et al., 2008). IR involves computing document scores for a given query by aggregating scores from the local importance of a term in a document (e.g. the term frequency, *tf*) and a global importance factor of the term in the document collection (e.g. the inverse document frequency, *idf*). Generally speaking, a retrieval model aims to compute the similarity between a document and a query. As a simplification, queries and documents can be defined as vectors over the vocabulary term space, so that the similarity can be computed as a dot product between query and document term vector, i.e. $sim(d, q) = \sum_{i=1}^{|V|} d_i q_i$. In standard IR, similarity features such as the word position in the query or a document are typically ignored. Features such as word ordering are modeled implicitly when indexing word n-grams.

IR makes use of *inverted list* structures which are a combination of in-memory data structures and file structures. The list of documents where a term occurs, namely the *postings list* for a term is loaded into memory from files hashed by the term identifier. This combination results in very fast retrieval and also makes retrieval scalable to very large collections. The inverted list data structure is suitable for computing the query-document similarity, because document vector term weights i.e. the d_i values are read from the postings list of the ith query term, and accumulated over all query terms to calculate the final similarity. The computational complexity of the similarity is thus $O(\sum_{i=1}^{n} s_i)$, where n is the number of query terms and s_i is the size of the postings list for the ith query term. In practise, n is a small constant and $s_i << N$, where N is the number of document in the collection. Hence the method is very fast.

Although the inverted list structure of IR looks promising, it should not be directly applied to

the ASM problem because of basic differences: In standard IR, documents are much longer than queries, compared to ASM, where documents and queries have similar length. Preprocessing techniques such as removing stopwords and eliminating punctuation, and applying a stemmer are common for IR and reduce the index size and the retrieval time, because highly frequent terms such as stopwords are excluded from the inverted lists.[1] In ASM, keeping all terms (i.e. words and punctuation) is important for exact matching of symbols and to retain the syntactic sentence structure for translation. Relative and absolute term positions are usually ignored in standard IR (except for phrase search, which partially models relative term position). In ASM, it might be important to implicitly retain word order as a similarity factor by matching n-grams.

The LD computation for ASM cannot directly be performed, i.e. it is not possible to compute the exact edit distance between a document and a given query within an IR application. One thus has to strive for designing a similarity function which produces rankings as close as possible to the ranking as computed by the LD computation. However, this proves difficult because standard IR similarity scores work on the principle of material similarity, i.e. a document is potentially ranked higher if it contains a higher number of query terms. For each ith query term match, the contributing factor of $d_i q_i > 0$ is added to the document score. However, material similarity alone may not be a good approximation for ranking based on LD.

Towards better sentence similarity metric for LD approximation. Three measures of similarity are crucial for ASM, namely the positional, ordinal and material similarity (Faulk, 1964). A direct application of standard IR methods for ASM can only estimate the last one, i.e. the material similarity. In addition to material similarity, it is required to consider the following, particularly for finding closest edit distance sentences for EBMT (Somers, 2003). Firstly, a sentence from the example base with a partial exact match of words (identical surface forms of words) in the query sentence is helpful because the longer the matched portion, the higher the likelihood is of generating a target translation of good quality. Secondly, identical term positions between Q and D indicate structural similarity, which is helpful in inferring the inherent reordering between D and the translation. Thirdly, similarity in length between Q and D requires substitution operations between mismatched portions during the *recombination* stage of EBMT. This is advantageous over insertion, since the positions in the translation of D to substitute are exactly known during recombination. To the best of our knowledge, a retrieval model incorporating aspects of material, ordinal, and positional similarity has not yet been proposed for ASM.

4 ASM Retrieval Model

The objective of ASM is to estimate the edit distance ranking as accurately as possible without computation of the actual distances. Let Q be a query sentence and D a sentence for which we need to estimate its edit distance from Q.

Language modeling (LM) is a state-of-the-art retrieval model (Ponte and Croft, 1998), where a document D is scored by the posterior probability of generating the given query Q, i.e. $P(D|Q)$ (Hiemstra, 2000). This in turn is estimated at indexing time from the prior probability $P(Q|D)$ using the assumption that the query terms can be generated independently from a document D by a linear combination of two events of either generating a query term q from D (i.e. the *tf* component) with probability λ, or generating it from the collection (i.e. the *idf* component) with probability $(1 - \lambda)$, as shown in Equation 2 ($cf(q)$ and cs denote the collection frequency of term q and the

[1] Note that while we aim at reducing runtime, we still include stopwords and punctuation for indexing in our main experiments, which is contrary to a standard IR setup.

collection size respectively). Equation 2 does not take into account the relative (or even absolute) positions of documents and query terms.

$$P(D|Q) \propto P(D)P(Q|D) = P(D) \prod_{q \in Q} P(q|D) = P(D) \prod_{q \in Q} \lambda \frac{tf(q,D)}{|D|} + (1-\lambda)\frac{cf(q)}{cs} \quad (2)$$

We propose an extension of the LM retrieval model for ASM, which we call LM-ASM. In contrast to standard LM, the probability of generating the query Q from a document D in case of LM-ASM has two components: i) $P_{len}(Q|D)$, which denotes how close is the length of Q to the length of D; and ii) $P_{pos}(Q|D)$, which is representative of how likely it is for a query term to belong to the same absolute position where it occurs in D. The first likelihood component minimizes the likely number of insertions and deletions while transforming D to Q and is given by Equation 3. Note that this likelihood function decreases with an increase in the absolute difference of the lengths of D and Q, attaining a maximum for $|D| = |Q|$.

$$P_{len}(Q|D) = \min(|Q|, |D|) / \max(|Q|, |D|) \quad (3)$$

To model the generation of a query term in its absolute position from the corresponding absolute position of that term in a document D, we use the following notation. Let $pos(q, D)$ be the set of absolute positions of a term q in a document D. In contrast to standard LM, for ASM, we also need to consider the current position of a query term. Let q_i be the query term at position i. Thus, even if the same query term q occurs in multiple positions in a query, we compute $P_{pos}(q_i|D)$ for all positions i where q occurs.

$$P_{pos}(q_i|D) = 1 \,/ \min_{j \in pos(q_i, D)} (|j - i| + 1) \quad (4)$$

In Equation 4, $|j - i|$ denotes the absolute value of the minimum difference of term positions. The final probability of $P(Q|D)$ is thus given by multiplying the two components $P_{len}(.)$ and $P_{pos}(.)$ of Equations 3 and 4 into Equation 5.

$$P(Q|D) = P_{len}(Q|D)P_{pos}(Q|D) = \frac{\min(|Q|, |D|)}{\max(|Q|, |D|)} \prod_{i=1}^{|Q|} \Big(\frac{1}{\min\limits_{j \in pos(q_i, D)} |j - i| + 1} \Big) \quad (5)$$

Analogous to LM, in order to avoid underflow for multiplications of small numbers, we implement the positional score with the log transform (omitted for brevity). A closer look at Equation 5 reveals that for every matching query term in a document D, we include the reciprocal of the absolute differences of the term positions in the score. The higher this difference, the lower is the similarity component being aggregated. In case a query term does not occur in D, nothing is added to the score. We propose to use this approach for approximate sentence retrieval and call it LM-ASM.

5 Experimental Setup

Data. We conduct experiments to report the accuracy of our EBMT approach for English-Turkish (EN-TR) and English-French (EN-FR) translation tasks. In order to compare the translation performance of our approaches, we use the EBMT system described in (Dandapat et al., 2012), which follows the framework in (Nagao, 1984) as a baseline. We do not combine our EBMT approach with an SMT system, as we focus on effectiveness and efficiency evaluation of IR for ASM to improve the EBMT component. For further details, we refer the reader to (Dandapat et al., 2012).

Name	Domain	Language pair	Example base	Avg. sentence length	Test data
IWSLT 09	Travel	EN-TR	19,972 sentences	9.5 words	414 sentences
EMEA	Medicine	EN-FR	250,806 sentences	18.8 words	10,000 sentences

Table 1: Statistics on the two evaluation data sets.

The two data sets used for all our experiments represent two language pairs with parallel data of different size and type. Statistics for the data sets, IWSLT 09[2] and European Medicines Agency[3] (EMEA), are shown in Table 1. The original EMEA corpus comprises approximately 1M sentences, including many duplicates. We discard duplicates and consider only sentences with unique translation equivalents. Note that, to the best of our knowledge, efficient solutions for ASM for EBMT that scale up to millions of sentences have not been reported in the literature.

Evaluation Objectives. Our experiments focus on different research questions: *Which approach is the most efficient and scales up to large example bases for EBMT?* To investigate this question, we conduct experiments using different algorithms and data structures for EBMT matching as described in Section 3 and 4 and compare them with our proposed two stage approach based on IR methods and reranking IR results.

Which approach has the highest accuracy when a trade-off between efficiency and effectiveness becomes necessary? Naturally, sequential computation will yield the highest accuracy (e.g. MRR) of results. However, when using IR methods, we expect a drop in effectiveness because the edit distance similarity is only approximated by the scoring method. Related to this question is the aspect of preprocessing (word matching), e.g. *Should stopwords or punctuation be removed or should a stemmer be applied?* We expect that stopwords and punctuation are actually important for ASM and that stemming would decrease retrieval effectiveness. We perform experiments using different preprocessing methods and indexing word-level n-grams.

Which approach leads to the highest translation quality? With the sequential computation, we will find all and only exact approximate matches, i.e. all sentences with the exact maximum edit distance score LS. Using IR, potentially only a subset of all "relevant" sentences[4] will be identified. A related question is *How many documents should be retrieved in the IR stage?* One objective in ASM is to restrict the number of retrieved documents to a small number, e.g. 10 or 20, since it is more efficient to retrieve a small number of sentences; and it is more efficient to rerank a small set of sentences by the true LS (e.g. by computing $LS(Q, D)$ for the top-ranked results). For example, retrieving 100 or more documents in the retrieval step could result in higher runtime, because the set of retrieved documents has to be reranked again. We try to determine the number of documents needing to be retrieved empirically to achieve this trade-off, i.e. achieve a satisfactory MT performance without sacrificing computation speed.

Evaluation Metrics. The experiments described in this paper aim at maintaining or improving three aspects of performance for large example bases: *efficiency*, *effectiveness*, and *translation quality*, described as follows. 1. *Efficiency:* A lower runtime implies that larger example bases can be used and the MT system becomes more scalable. We report the time for reading and indexing the documents in seconds (IT), computation time (CT), and the average time per sentence

[2] http://mastarpj.nict.go.jp/IWSLT2009/2009/12/downloads.html
[3] http://opus.lingfil.uu.se/EMEA.php
[4] Relevant in this context means the best translation template in the target language.

(AT), exlcuding indexing time. 2. *Effectiveness:* As some similarity scores and the proposed retrieval approach approximate the edit distance instead of actually computing it, the accuracy of finding correct matches with minimum LD (more specifically: with maximum LS) is measured. We employ IR metrics such as mean average precision (MAP) and the mean reciprocal rank (MRR) (Voorhees, 1999). The significance of MRR is that the closer the MRR is to 1, the fewer documents need to be reranked using their true edit distances. We also report the number of queries in the test set with a reciprocal rank (RR) of 1 (i.e. the top ranked document is relevant) and with $|RR > 0|$, i.e. the result set contains at least one relevant result. A reciprocal rank of 1 means that a correct result is already at rank 1, and $RR > 0$ implies that there is at least one correct result contained in the set of retrieved results. In addition, we report the number of retrieved documents (#ret) and the number of relevant documents retrieved, i.e. *recall* (#rel_ret). Achieving a high recall enables an additional level of processing to choose a particular sentence for the EBMT matching phase among a set of candidate sentences with equal LS values with respect to the input sentence. Since developing an efficient tie-breaking heuristic is outside the scope of this paper and we are not aware of any such existing work, we simply resolve ties by choosing the sentence with minimum identifier for all our experiments. However, we include recall and MAP as evaluation metrics to justify the relative usefulness of a system under the presence of a tie-breaking mechanism. 3. *Translation quality:* Finally, we compute how good the final translation output is, based on the standard MT evaluation score BLEU (Papineni et al., 2002).

Relevance Judgements. Since the objective is to approximate edit distance scores, the target documents (relevant documents) are those with the maximum LS scores with respect to the query. The "relevance judgements" are thus obtained from computing the sentence pairs in the example base with maximum LS score (see Equation 1) for a query, presuming that all sentences with the minimum distance (or highest sentence similarity) are correct or relevant. This can lead to a high number of relevant results for queries which have many exact or near-matches in the data. For the EN-TR data, there are 4.74 relevant results per query on average; queries in the EN-FR data have 16.38 relevant results per query on average. To resolve these ties for EBMT, the highest scoring document with the lowest document ID is selected for subsequent translation stages.

Test System. The test system is a standard PC with a 3.16 GHz Core 2 Duo CPU and 8 GB RAM. The retrieval engine is SMART[5], which was modified to support positional indexing and language modeling. In the postings list of every term, we store the document ID for each document the term appears in and the absolute position of that term in that particular document. The EBMT system is an implementation of the translation by analogy approach described in (Nagao, 1984).

6 Experimental Results

Effect of Preprocessing. ASM is different from standard IR. Therefore, we explore how to optimize the IR settings for the ASM problem. We have argued that standard IR preprocessing such as stopword removal and stemming may not be suitable for ASM. Table 2 shows the results for different IR approaches. In this section, we are only interested in the retrieval effectiveness which is measured in terms of how close the retrieved set is with respect to the reference set of minimum edit distance sentences from the training set for each test sentence. Results are obtained by retrieving 50 sentences. The results in Table 2 can be interpreted as follows. Simple retrieval methods such as raw term frequency (*tf*) or *tf-idf* do not perform well for ASM. In contrast to standard IR, stopword removal and stemming decrease performance. The number of retrieved documents (#ret) is also

Table 2: IR results on EN-TR data for retrieval of 50 documents per query. Parameter settings include stopword removal (SR), stemming (ST), and the use of n-grams.

lower compared to the runs where neither stopword removal nor stemming is performed, because some query sentences comprise of only stopwords e.g. "I am sorry". Stemming also degrades retrieval performance. So the the question *'Should stopwords or punctuation be removed or should a stemmer be applied?'* can be answered with no. In our experiments, all forms of preprocessing degrade performance.

We employ LM as the baseline for our retrieval experiments. In order to obtain the best LM baseline, we conducted experiments with varying values for the λ parameter in the interval $[0, 1]$. Selecting $\lambda = 0.99$ yields the highest MAP (0.593). This explains that *idf* is not important for ASM. Normalized *tf* (i.e. $tf(t, D)/|D|$) suffices to approximate LS (see Equation 2).

Our proposed method LM-ASM produces significantly better results both in terms of MAP and MRR as compared to LM[6]. LM-ASM, unlike LM, takes into consideration the term position differences between document words and the given query words, thus better estimating the number of edit operations and hence the edit distance. Note that LM-ASM does not rely on collection statistics such as *idf*.

We also experimented with bigrams ($n = 2$) on the best IR settings for the unigrams i.e. without stopword removal and stemming. The results are shown in the last two rows of Table 2. It can be seen that the use of bigrams yields significant improvement in MRR (0.733 vs. 0.699) at the cost of an insignificant decrease in MAP. The reason for the improvement can be attributed to the better estimation of the word order and term overlap achieved by bigrams. The use of higher order n-grams ($n \geq 3$) did not further significantly improve results.

Comparison of Approaches. Results for our experiments are shown in Table 3 and 4. Numeric indices in the run name indicate the number of documents retrieved per query. The improvement of the LM-ASM approach with bigram indexing over the baseline MT as obtained by brute-force sequential computation, is statistically significant with a reliability of 97%, for the EN-TR dataset, as seen by comparing the BLEU score of LD_{WF} (21.71) with that of LM-ASM-2_{50} (22.08)[7].

Results on the English-Turkish data set are shown in Table 3. We conduct selected experiments on

[6] A '*' denotes a significantly better result of LM or LM-ASM over its counterpart with the same experimental settings.
[7] This improvement is statistically significant as measured by the paired-bootstrap resampling(Koehn, 2004).

the English-French data set (see Table 4) to investigate scalability and efficiency of the approaches on a larger example base. Additional IR experiments with the BM25 retrieval model (Robertson et al., 1998) were based on indexing all word n-grams up to 5-grams (e.g. unigrams and bigrams for $n = 2$) and retrieving 50 results per query. For the EN-TR data, 1160 relevant results were retrieved when indexing unigrams. For other n-grams, 1348-1356 relevant results are retrieved, thus showing an considerable increase, but not much change for higher values of n. Other performance metrics show similar behaviour: higher performance but little variance for values of $n \geq 2$ compared to unigrams. We briefly revisit the unanswered questions raised in Section 5.

Which approach is the most efficient and scales up to large example bases for EBMT? A sequential approach to compute the edit distance between an input sentence and all source language sentences in the example base is not feasible, because it requires too much run-time (columns CT and AT in Table 3). The sequential brute force approach has the lowest efficiency, but can be improved by either using a metric that can be computed faster, such as LCS, or more efficient data structures such as TR and TST. Interestingly, LCS is a good approximation of the edit distance (as can be seen from the MT scores in the table) and requires a similar run time compared to LD_{BR}. Sequential approaches do not scale up well when using large example bases, even when efficient implementations of the Levenshtein algorithm are used (see Table 4). The use of data structures such as ternary search trees and tries is more efficient, but requires that the structures are kept in memory. Thus, these approaches have higher memory requirements. IR approaches are the most efficient, even

Name	Efficiency (runtime)			IR effectiveness						MT

Table 4: Experimental results on EN-FR data set.

when a reranking phase based on sequential computation of LS is included.

From the results in Table 4, we observe that when the sequential computation or the efficient data structures are used, the translation quality is high, but at the cost of a runtime of 1.4 seconds in the best case (TST) and 10.6 seconds in the worst case (LD_{WF}). This makes a close-to real-time translation nearly impossible. The use of IR yields a much better runtime, but performance depends on how many documents are retrieved in the initial stage. Note for all of these top-ranked documents, the true edit distance has to be computed to facilitate result reranking. Runtime experiments with the Moses[8] decoder took 0.34s for EN-TR and 1.86s for EN-FR on average per sentence, i.e. a $5\times$ increase in the runtime for a $10\times$ larger dataset. In contrast, our proposed IR approach scales up better (0.010 to 0.015).

Which approach has the highest accuracy when a trade-off between efficiency and effectiveness becomes necessary? The best exact approach to compute the edit distance is the ternary search tree (see columns MRR), which however suffers from higher memory requirements because the data structure has to be kept in memory. As expected, standard IR approaches such as *tf-idf* do not perform well in finding approximate matches, due to missing constraints for the search (e.g. word ordering and word position). Additional reranking of results by the normalized similarity score (based on LD_{WF}) ensures that correct matches are at top ranks (see columns $|\mathrm{RR} = 1|$ and $|\mathrm{RR} > 0|$). The combination of IR followed by a reranking stage is efficient and effective and leads to a high translation quality (see columns AT, MRR, and BLEU in Tables 3 and 4).

Standard LM performs better than *tf-idf*, but does not take into account word positions. Positional ranking in LM-ASM manages to rank the sentences candidates with a high precision and takes into account word positions and word order. It consistently outperforms standard LM in terms of MAP, MRR, and recall (see Table 3), at a moderate cost of additional runtime per query.

Which approach leads to the highest translation quality? Sequential computation of the edit distance based scores yields the highest effectiveness and MT scores, together with all other approaches aiming at finding the exact results with minimum edit distance, i.e. TR and TST.

Surprisingly, we found that the MT scores for our proposed approach with bigram indexing are ac-

[8] http://www.statmt.org/moses/

tually higher than the scores for the sequential computation. To explain why our proposed approach to ASM achieves a higher BLEU score than experiments based on sequential LD computation, we examined some sentences in detail. It can be argued that choosing the minimum edit distance sentence globally from the example base may not necessarily lead to the best translation. For the English input sentence *"where can i buy accessories"* (TR: *nereden aksesuar alabilirim*), the most similar sentence retrieved by sequential LD computation from the full example base is *"where can i buy plates"* (TR: *tabak almak istiyorumi*). Since ties in LD are resolved by taking the sentence with minimum document identifier, the IR method LM-ASM-2_{50} retrieves a different sentence – with the same LS – namely *"where can i buy stockings"* (TR: *nereden çorap satın alabilirim*). The target language sentence parallel to the source sentence candidate found by LD_{WF} compared to *"tabak almak istiyorumi"* does not have a single word common to the reference translation (TR: *nereden aksesuar alabilirim*), whereas the sentence retrieved by LM-ASM-2_{50} has two words in common. The translation template is thus better for the latter which is also reflected in a higher overlap of the final translation output (TR: *nereden aksesuarı satın alabilirim*) with the reference output thus resulting in a higher BLEU score for LM-ASM-2.

How many documents should be retrieved in the IR stage? The results in Table 3 and 4 show that there is a trade-off between speed and quality of translation when using IR: A very fast translation can be achieved by simply retrieving a single sentence, thus completely eliminating the need for a reranking stage, but this requires a high MRR of the initial retrieval. Retrieving more documents results in a higher translation score because for more sentences the best approximate match is found. However this also results in a higher processing time per sentence, because the edit distance has to be computed for more sentences. In practice, this implies that the user of an EBMT system can control whether he is more interested in a high-quality or in a fast translation.

Thus, it proves important to choose source-side sentences with care. Edit distance can be a used as a first filter to choose a set of candidate sentences. A second stage is required to carefully break the ties to ensure selection of the best source side sentence with an equivalent target language sentence *close* to the reference translation.

7 Conclusions

IR can benefit in solving problems beyond the search for information. In this paper, we have described how the adaptation of an information retrieval model to fit specific requirements of approximate retrieval can help to make EBMT more scalable, efficient, and even produce better translations. To solve the problem of approximate sentence matching, we proposed and evaluated LM-ASM, a novel IR model which incorporates three aspects of similarity, namely positional, ordinal, and material similarity. Our approach demonstrates the general usefulness of IR for other tasks. The evaluation covers three aspects: IR metrics, metrics of the problem domain (e.g. BLEU score), and non-functional requirements (e.g. the runtime). We found that our proposed approach for ASM, LM-ASM, outperforms sequential computation of scores and in-memory data structures in terms of runtime, while losing almost none of the translation quality.

As part of future work, we plan to investigate alternatives for generating the relevance assessments based on the BLEU score obtained when using a potentially relevant sentence as translation template. This could lead to similarity metrics and IR models that better approximate the MT quality.

ABSTRACT
There are many abbreviation and non-standard tokens in SMS and Twitter messages. Normalizing these non-standard tokens will ease natural language processing modules for these domains. Recently, character-level machine translation (MT) and sequence labeling methods have been used for this normalization task, and demonstrated competitive performance. In this paper, we propose an approach to segment words into blocks of characters according to their phonetic symbols, and apply MT and sequence labeling models on such block-level. We also propose to combine these methods, as well as with other existing methods, in order to leverage their different strengths. Our experiments show our proposed approach achieved high precision and broad coverage.

TITLE AND ABSTRACT IN CHINESE

使用字符块模型和系统合成提高文字纠错率

在手机短信和Twitter消息中存在许多缩写和非规范的单词。纠正这些非规范的单词会给后续的自然语言处理模型带来便利。近年来，基于字符层面的机器翻译方法和序列标注方法被广泛应用到这个任务中，并且大大提高了纠错率。本文介绍了一种根据单词发音来切割单词的方法，然后把上述的两种模型利用在切割后的字符块层面进行纠错尝试。另外，我们还尝试了将现有的方法和提出的方法进行各种合成以期利用各自的优点来提高最终的效果。最后我们的实验表明我们的方法在对非规范词的纠错召回率和准确率上都有了明显的提高。

1 Introduction

There has been a rapid increase in social text in the last few years, including the mobile phone text messages (SMS), comments from the social media websites such as Facebook and Twitter, and real-time communication platforms like MSN and Gtalk. For example, by July 2012[1], Twitter has more than 500 million users, and more than 340 million new tweets are sent everyday. This trend attracts a lot of research in order to mine valuable information and knowledge from this data. Unfortunately, traditional NLP tools sometimes perform poorly when processing this kind of text. One of reasons is that social text is very informal, and contains many misspelled words, abbreviations and many other non-standard tokens. There are different efforts to develop robust language processing techniques for this domain. One is to develop NLP tools that are designed specially for tweets or SMS. For example, the system in (Ritter et al., 2011) reduced the errors of POS tagging by 41% compared with Stanford POS Tagger, and by 22% in parsing tweets compared with OpenNLP chunker tool. Another way is to perform some preprocessing on the original informal text, such as normalization, such that the resulting text is easier for the subsequent modules. The task of normalization is to automatically convert the non-standard tokens into corresponding standard words. Intuitively this will ease subsequent language processing modules in this domain. For example, if '2mr' is converted to 'tomorrow', a text-to-speech system will know how to pronounce it, a POS tagger can label it correctly, and an information extraction system can identify it as a time expression.

Non-standard tokens are formed in different ways in social text, and because of different reasons, including factors such as length limitation, individual's writing style, need to convey emotional or other information. A lot of research has been conducted for text normalization. Some are designed to handle one type of non-standard words, such as deletion (e.g., 'abt' for 'about') (Pennell and Liu, 2010); some can deal with different kinds of non-standard tokens (Liu et al., 2011). Various modeling approaches have been explored for this problem. In particular, a character-level MT method (Pennell and Liu, 2011) and sequence labeling approach (Pennell and Liu, 2010) were used recently and showed good performance. Their essential thought is to make alignment between characters in non-standard tokens and standard words, and predict the probability of the candidate standard words given the non-standard tokens.

In this paper, we propose to use character blocks for alignment, rather than single characters, but adopt the same framework as the above character based methods. Since some characters appear together frequently (e.g., 'ght', 'tion', and 'ure'), we expect that keeping such combinations in the alignment is better than splitting into individual characters in improving system precision (yielding fewer candidates but more accurate). To generate the character blocks, we resort to the word's phonetic symbol and some common pronunciation rules. This results in much better alignment for the MT and sequence labeling methods. In addition, we use two other normalization methods: spell checker (Damerau, 1964) and character-level two-step MT model (Li and Liu, 2012). We further propose to combine these different systems to take advantage of each individual system's strength. For example, the spell checking model is good at correcting simple errors such as 'talkin' (meaning 'talking'), 'freind' (meaning 'friend'), and 'tgether' (meaning 'together'); character-level two-step MT is designed to process the non-standard tokens generated by phoneme similarity like 'ate' (meaning 'eight' in certain context); character blocks level MT and sequence labeling complement in improving the precision on transferring non-standard tokens that have high grapheme similarity with possible standard

[1] http://en.wikipedia.org/wiki/Twitter

words. Results on one public test set show that our proposed individual systems and combined systems perform better than prior work.

2 Related Work

Text normalization has been well studied in text-to-speech field. See (Sproat et al., 2001) for a good report of this problem. Recently, much research has been done on this problem for social text domain, which has many abbreviations or non-standard tokens. A simple approach for normalization would be applying traditional spell checking model, which is usually based on edit distance (Damerau, 1964; Levenshtein, 1966). This method works well for non-standard tokens that are generated by a few simple operations such as substitution, insertion, and deletion of letters of the standard words. However, it cannot handle words such as 'ate' (meaning 'eight'), where non-standard tokens are created based on the phoneme similarity with the standard words, or 'bday' (meaning 'birthday'), which involves too many operations.

Another popular and successful line of work in normalization adopts a noisy channel model. For a non-standard token A, this method finds the most possible standard word S based on Bayes rule: $argmaxP(S|A) = argmaxp(A|S)*p(S)$. Different methods have been used to compute p(A|S). (Pennell and Liu, 2010) used a CRF sequence modeling approach for deletion-based abbreviation. (Liu et al., 2011) further extended this work – they also used CRF framework, but considered more types of nonstandard words without explicit pre-categorization for non-standard tokens. They also used a set of automatically collected training data. (Liu et al., 2012) continued their work by adopting visual prime approach to improve the coverage of candidate list. (Xue et al., 2011) modeled p(A|S) by computing the grapheme and phoneme similarity and then combined those results with context channel and acronym channel.

Some research also utilized the noisy channel model at sentence level. For informal text T and its possible standard form S, using a noisy channel model: $argmaxP(S|T) = argmaxP(T|S)P(S)$, where P(S) is a normal word-based language model, and P(T|S) is an error model. (Choudhury et al., 2007) used hidden Markov model to simulate SMS messages generation, considering the non-standard tokens in input sentence as emission state in HMM and labeling results are possible candidates. (Cook and Stevenson, 2009) extended the work by adding several more subsystems in the error model according to the most common non-standard tokens' formation process. (Wong and Xia, 2008) used the noisy channel model to handle the normalization of Chinese chat language based on a specific property of Chinese language – the similarity of two Chinese characters is measured based on the initial (shengmu) and final (yunmu) pinyin.

Machine translation is another commonly chosen method for text normalization. (Aw et al., 2006) treated SMS as another language, then machine translation techniques are used to translate this 'foreign language' to regular English. (Contractor et al., 2010) used an MT model as well but the focus of his work is to generate an unsupervised method to clean noisy text in this domain. (Pennell and Liu, 2011) firstly introduced an MT method at the character-level for normalization. In fact, this is another way to compute the word-level $p(A|S)$ mentioned before. (Li and Liu, 2012) extended this character-level MT by leveraging phonetic symbol, translating nonstandard words to phones first, and then phones to standard words. They called it character-level two-step MT and showed better overall coverage of candidates than the one-step MT. (Kobus et al., 2008) tackled normalization through an ASR-like system based on the fact that text messages can be represented by phonetic symbols. They decoded SMS message through a nondeterministic phonemic transduction.

For the normalization task for sentences (or messages), a system needs to first identify words that need to be normalized. This is typically done by simply checking whether a word is in a given dictionary. (Han and Baldwin, 2011) conducted a pilot study on determining whether an out-of-vocabulary (OOV) word is a non-standard token that needs normalization or it is just a well formed OOV word. Then for those ill-formed OOV words, they used grapheme and phoneme level similarity to generate candidate words.

Most of the above systems are specially designed to tackle certain aspects of the normalization task. Some focus on improving precision and some aim for a broad coverage. For example, character-level MT from (Pennell and Liu, 2011) achieved top-1 precision of 60.39% on the SMS test set from (Choudhury et al., 2007), and the sequence labeling model from (Liu et al., 2011) improved it to 62.05%, but they have limitations on the candidate coverage (the top-10 precision in (Pennell and Liu, 2011) is around 75%). In addition, (Pennell and Liu, 2010) can only handle the abbreviations. The character-level two-step MT model from (Li and Liu, 2012) improved the top-10 coverage to over 80% on the same data, however, its top-1 precision is not much better than previous work. The visual prime approach from (Liu et al., 2012) improves the overall coverage to around 94%, but the online computation is very time consuming since for a non-standard token T, the system needs to compute the visual prime value between T and all the words S that start with the same character as T. In this paper, we propose an enhanced MT and sequence labeling model, which are built at the character-block level. Furthermore, we combine multiple systems. The performance on a public test set shows our system yields better precision and recall/coverage. Compared to the visual prime approach (Liu et al., 2012), our system also has lower computational cost. To the best of our knowledge, we are the first to use word segmentation to obtain phonetically meaningful character blocks in the normalization task, and also first to combine MT and sequence labeling models.

3 Normalization System

For a non-standard token, we use four different subsystems to normalize it. Each system generates a list of candidate standard words. We then use heuristic rules to re-rank the candidates to form a final candidate list. The four subsystems are developed based on previous work, however, one key contribution of ours in this study is that we propose to segment words into several blocks based on the word's pronunciation and use these blocks as the units in the machine translation or sequence labeling approaches. This helps yield better alignment for model training. In this section, we first describe our four normalization subsystems in details, and then the combination rules.

3.1 Character-Block Level MT

3.1.1 Character-level Machine Translation

This method was first used in (Pennell and Liu, 2011). Similar to machine translation for a word sequence (i.e., a sentence), character-level machine translation translates the character sequence as seen in a non-standard token to another character sequence of a proper word. Formally, for a non-standard token $A = a_1a_2a_3...a_n$, the task is to find the most likely standard word $S = s_1s_2s_3...s_m$, where a_i and s_i are the characters in the words. A statistical machine translation method is used for this task:

$$\hat{S} = argmaxP(S|A) = argmaxP(A|S)P(S) = argmaxP(a_1a_2a_3...a_n|s_1s_2s_3...s_m)P(s_1s_2s_3...s_m) \quad (1)$$

where $P(a_1a_2a_3...a_n|s_1s_2s_3...s_m)$ is from a character-level translation model, and $P(s_1s_2s_3...s_m)$ is from a character-level language model. The translation model is trained using a parallel corpus containing pairs of non-standard tokens and standard words, and the character n-gram language model can be trained using an English dictionary. During testing, the translation module generates hypotheses of character sequences for a given non-standard token. An English dictionary can be used to remove candidates that are not in the dictionary and preserve N-best candidates.

3.1.2 Character-block Level Machine Translation

When using the character-level MT normalization method as described above, we find some character alignments between the non-standard tokens and standard words are not correct. Fig 1(a) shows such an incorrect example. The second 'e' in 'yesterday' is aligned to 's' in the non-standard token, rather than to 'null' (i.e., character deletion). This wrong alignment will affect translation model training and subsequently the decoding process. For this example, if 'er' in 'yesterday' can be viewed as a block or segment, it can be easily aligned to 'r' in the non-standard token 'ystrdy'. This can be achieved using pronunciation information – 'er' together is pronounced as 'ɚ' in the above example. Therefore, we propose to segment an English word according to its phonetic symbol or pronunciation, and then use these segments as units in the MT system. For the example of 'yesterday', when considering its pronunciation, it is segmented as 'y e s t er d ay'.

In our experiment, we collected about 60 most common pairs of character-blocks and their corresponding phonetic symbols, and use them for segmentation. Some example pairs are shown in Table 1. Once we perform this new segmentation, the normalization procedure is similar to the character-based one described earlier, except that now the units in the MT system are characters or character blocks. Fig 1 (b) shows the translation alignment when using the character blocks. During testing, the MT system generates sequences of characters or character blocks. Again, we remove the spaces and only keep a word candidate if it is in the dictionary.

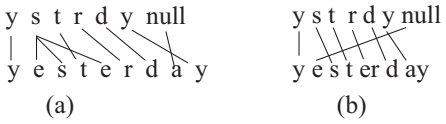

Figure 1: Alignment of 'ystrdy' and 'yesterday' using Character-level MT (a) and Character-block level MT (b)

3.2 Character-Block Level Sequence Labeling

3.2.1 Character-level Sequence Labeling

In (Pennell and Liu, 2010), a CRF sequence modeling approach was used for normalizing deletion-based abbreviation. Given a pair of standard word *W* and its abbreviation *A*, every character in *W* is labeled as 'Y' if it appears in *A*, otherwise 'N'. Fig 2 (a) presents a training instance. A sequence labeling model can be trained using characters as instances, each of which is represented by some features (e.g., character n-grams, position, phonetic information). Next, this model is applied to all the dictionary words. N-best labeling results (i.e., possible abbrevi-

Size of block	Block	Phonetic symbol
2	ea	eɪ,iə,iæ,i
	oo	u,ʊ,ʌ,oʊɑ,oʊə
	ch	k,ʧ
3	ear	ɛər,ɪər,ɜr
	oar	ɔr
	ght	t
4	tion	ʃən
	cial	ʃəl
	sure	ʃər, ʃɜr, ʒər

Table 1: Example pairs of character blocks and corresponding phonetic symbols.

ations) are generated for each word. This forms a lookup table – an abbreviation is associated with all the words that can possibly generate this abbreviation. During testing, for a given abbreviation A, if it is an entry in the lookup table, all of its candidate words will be returned, each with a score $P(A|W) * P(W)$, where $P(A|W)$ is based on the sequence labeling model, and $P(W)$ is from a word-based unigram LM. The best candidate can be obtained from this ranked list. Note if the test abbreviation is not an entry of the lookup table, it means this model fails to normalize this abbreviation token.

(Liu et al., 2011) extended the above model by relaxing the limitation that it only tackles the abbreviation tokens. Rather than labeling 'Y' or 'N' for every character in standard words, they give each character the following 4 types of label: (1) one of the 0-9 digits; (2) one of the 26 characters; (3) null character '_', and (4) letter combination (they used 5 common combinations, such as 'wh', 'ck', and 'ey'). Therefore this system can handle other types of non-standard tokens, such as substitution. An automatic letter level alignment method was used to assign every character in the standard word with a proper label in the non-standard token. Fig 2 (b) presents such a training instance.

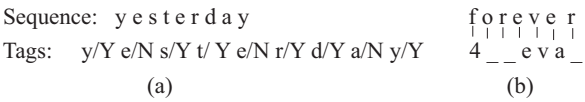

Figure 2: Training examples in sequence labeling models: (a) used in (Pennell and Liu, 2010) and (b) used in (Liu et al., 2011).

3.2.2 Character-Block Level Sequence Labeling

In the above sequence labeling approach, characters are used as instances in the CRF model (although the labels include other symbols or a few letter combination in (Liu et al., 2011)). Similar to the character-based MT method, this can introduce some problems in the alignment. As Fig 2 (b) shows, in the pair of 'forever' and '4eva', letter 'o' and 'r' are aligned to the empty character. Intuitively it is better to align the whole letter chunk 'for' with '4' (actually this is similar to the phrase table in the MT method). Therefore in the sequence labeling model, we

also propose to segment a word into character-blocks rather than single characters, in order to avoid this kind of improper alignments.

Given a training pair (S,T), where T is a non-standard token, and S is the corresponding standard word. First, S is segmented into a sequence of character-blocks and characters, in the same way as in Section 3.1. Then we align it with the characters in non-standard tokens based on the longest common sequence algorithm. At last, we use similar rules as in (Liu et al., 2011) to process the remaining characters between the aligned characters. The only difference is that in non-standard tokens we do not have predefined frequent letter combinations to help decide whether to group a character or character-block with the previous or the following chunk. We put them together with the previous chunk if they have no characters or character-blocks to align in the standard word.

After assigning proper labels for every character and character-block in the standard word, we extract the following features:

- Character-blocks n-gram: c_{-1}, c_0, c_1, $c_{-2}c_{-1}$, $c_{-1}c_0$, c_0c_1, c_1c_2, $c_{-3}c_{-2}c_{-1}$, $c_{-2}c_{-1}c_{-0}$, $c_{-1}c_0c_1$, $c_0c_1c_2$, $c_1c_2c_3$. These are the same as those used (Liu et al., 2011), except that c_i can be character blocks in our work.

- Phonetic features: p_{-1}, p_0, p_1, $p_{-2}p_{-1}$, $p_{-1}p_0$, p_0p_1, p_1p_2, where p_i is the phone corresponding to character or character block c_i. In segmenting words into character-blocks by using phonetic symbols, we notice that for some words the resulting number of blocks is the same as the number of phones. In this case, it is straightforward to align the two sequences (one to one mapping). Otherwise, for the words in the training set, we manually align the two sequences in order to derive the phonetic featuers.

- Syllable features: The website http://www.dict.cn provides syllabification information. We use their syllable segments to assign feature 'B', 'I', and 'L' label for every character-block or character. 'B' means this character or character-block is at the beginning of a syllable, 'I' means inside of a syllable, and 'L' means at the end position of a syllable.

- Word boundary feature: We distinguish the first, last, and inside characters and character-blocks by this feature.

Table 2 shows an example training instance with its features.

Character-block level word	for	e	v	er
Phonetic symbols	fɔr	e	v	ər
Syllable boundary	B	B	I	L
Word boundary	B	I	I	L
Label	4	e	v	a

Table 2: Example of an instance with features in character-block level sequence labeling system.

After training the character-block level CRF model, similar to the previous character-level sequence labeling methods, we apply it to the standard words in the dictionary to create the reverse look-up table, and use it to retrieve candidate words for non-standard tokens during

testing. One thing we need to point it out is that for the words that have different number of character segments and phonetic symbols, we do not include them when building the look up table (since generating high quality phonetic features needs human intervention, which is time consuming).

(Pennell and Liu, 2011),

3.3 Character-level Two-step MT

Li and Liu (2012) introduced a character-level two-step MT method for normalization. Instead of directly translating the character sequence, it first translates the non-standard tokens to possible phonetic sequences, and then to proper words. The purpose of this design is to tackle some difficult cases. For example, for the non-standard word 'rit', it is not easy for the single translation model to convert it to 'right' if there are not enough samples containing 'ght' and 't' in the training pairs. In this case, we can first translate 'rit' to possible phonetic sequences such as 'rait' or 'rIt', and then convert them back to in-vocabulary words. The two steps can both be implemented using machine translation.

In re-implementing this system, we use a different rule to rerank the the candidates compared to that used in (Li and Liu, 2012). For the phonetic sequence generated in the first stage using this method, some can be converted to proper words directly by a simple lookup in the dictionary that consists of word along with their pronunciation (we call these candidates List 1); others have to go through the second-stage translation module to generate possible word candidates (we call these List 2). Our reranking procedure uses a set of heuristic rules to update the probabilities for the candidates in List 2 depending on a candidate's positions in the two lists. For example, one rule is that, if a candidate ranks between 3 and 10 in List 2, and ranks above position 5 in List 1, we change its posterior probability to the same as that of the first candidate's in List 2. Another rule is that, if a candidate ranks between 20 and 40 in List 2 and ranks above position 5 in List 1, we change its posterior probability to the same as that of the 20th candidate in List 2. The essence of this set of rules is to change some candidates' positions to 1, 2, 3, 10 or 20 (we measure the top-N performance for these numbers of candidates). Finally for those candidates with the same posterior probabilities because of the above re-ranking process, we re-rank them again by their longest common sequence with the non-standard tokens.

3.4 Spell Checker

The last normalization subsystem we use is the Jazzy Spell Checker,[2] which is based on edit distance and integrates a phonetic matching algorithm as well.

3.5 System Combination

The above four methods have different strength: Spell checker is very good at correcting simple misspelled words that are formed by a few operations of deletion, insertion or substitution. MT and sequence labeling models have advantages in dealing with more complicated non-standard tokens, regardless of the types. The two-step MT model is designed to tackle the cases when the non-standard tokens have similar pronunciation with the correct answer, but are rather

[2]Jazzy: The java open source spell checker. http://jazzy.sourceforge.net

different on character surface (e.g., 'lrg' and 'large'). In general, the character-block level MT normalization system performs well (as shown later in the experiments).

In order to utilize the advantages of different systems, we propose to combine hypotheses from different systems to obtain the final result. To better evaluate the contributions of these subsystems in the combined system, we examine the combination of different systems:

- Comb1 (two systems): Character-block level MT system + Character-level two-step MT system
- Comb2 (two systems): Character-block level MT system + Character-block level sequence labeling system
- Comb3 (three systems): Character-block level MT system + Character-level two-step MT system + Jazzy Spell Checker
- Comb4 (three systems): Character-block level MT system + Character-block level sequence labeling system + Jazzy Spell Checker
- Comb5 (three systems): Character-block level MT system + Character-level two-step MT system + Character-block level sequence labeling system
- Comb6 (four systems): Character-block level MT system + Character-level two-step MT system + Character-block level sequence labeling system + Jazzy Spell Checker

Since the scores from different systems are in different range and vary greatly, we develop rules to combine them. The combination rules used for these systems are:

- Comb1 and Comb2: These involve two subsystems. The essence of combination rules is to re-rank. The steps we used are:
  (i) create an empty final candidate list;
  (ii) find the common candidates from the two candidate lists (i.e., intersection of the two sets). Since we notice that candidates below position 20 are often not very accurate or not useful for future use (e.g., sentence level normalization/decoding), we decide to obtain the intersection from the top 10 candidates of the two systems' result lists.
  (iii) put elements from the intersection set into the final candidate list, reversely rank them according to the sum of their positions in the two original lists (the smaller, the better). If there is a tie, we re-rank again according to their longest common sequence with the non-standard tokens (the higher, the better).
  (iv) after dealing with the elements in the intersection set, we add the remaining candidates from the two systems into the final list – the first remaining candidate from the character-block level MT system, then the first one from the other system's list, then the second ones from both lists, and so on, until one list is empty and we put all the rest candidates into the final candidate list.
- Comb3 and Comb4: These involve three subsystems and one is Jazzy Spell Checker. We only use the first candidate of the Jazzy spell checker. The combination rule is, if these three subsystems or any of the two subsystems have the same first candidate, select it as the first candidate in the final list, then ignore the Jazzy Spell Checker's result and combine the rest two candidate lists as above. Otherwise, ignore Jazzy Spell Checker's results and just combine the two subsystems as described above for Comb1 and Comb2.

- Comb5: This has three complicated subsystems (not including Jazzy spell checker). The essence of the combination rule is similar to the one used for two subsystems, but here we will consider the intersection of the three systems' top 10 results first, and then three intersection sets from any two subsystems' results. We use similar position information to rank candidates in these common sets. After this step, we first add the remaining candidates from the top 30 results from the sequence labeling system, then the top 30 from character-block lever MT, and at last those from character-level two-step MT.
- Comb6: This includes all the 4 subsystems. If the first candidate of all the systems are the same, or the first candidate of any three sub-systems are the same, choose it as the first candidate in the final list, then ignore the Jazzy Spell Checker's result and combine the rest three candidate lists as above. Otherwise, ignore Jazzy Spell Checker's results and combine the rest three system as Comb5.

Note if any one individual system's result list is empty, the condition is reduced to the combination of fewer individual systems. In addition, no duplicate candidates are included in the final candidate list.

4 Experiments

4.1 Experiment Setup

We use the following data sets. Data set 4 is first used as the training set and the other three as test sets. To evaluate the impact of training size, we use data sets 3 and 4 for training, and evaluate the models on data sets 1 and 2.

- Data 1: 303 pairs of non-standard tokens and standard words collected from SMS in 2007, used in (Choudhury et al., 2007).
- Data 2: 558 pairs of non-standard tokens and standard words collected from 549 tweets in 2010 by (Han and Baldwin, 2011).
- Data 3: 3,998 pairs of non-standard tokens and standard words collected from 6160 tweets between 2009 and 2010 by (Liu et al., 2011). We made another pass of this data set and corrected some annotation.
- Data 4: 2,028 unique pairs of non-standard tokens and standard words, collected from 4,660 Twitter messages, selected from the Edinburgh Twitter Data set collected in Aug 2009 by (Pennell and Liu, 2011).

The dictionary we used is obtained from http://ciba.iciba.com/, which includes 75,262 English word entries and corresponding phonetic symbols (IPA symbols). This is used in various modules in the normalization systems. We segment the English words into character-blocks and use them in both the character-block level MT and character-block sequence labeling model. As described earlier, in order to extract phonetic features for character-block sequence labeling model, we only use the words that have the same number of character-block segments and phones. Therefore, the number of the final standard words used to create the lookup table is 10,105. We choose 10,000-best output in CRF sequence labeling testing. This resulted in about 48,995K non-standard token entries in the lookup table, and the average number of standard words for an entry is about 8. We use CRF++ toolkit for our sequence labeling model.

For the two-step MT system, the training data for the first step is the parallel pairs containing non-standard tokens and their pronunciations (this is the pronunciation for the corresponding normalized words). We obtain this by replacing the standard words in the training set with their phonetic symbols. For the second stage, the training pairs are all the dictionary words and their phonetic symbols.

We train a 5-gram character language model from the Edinburgh Twitter corpus for both character-block level MT model and the second step of the two-step MT method. A phone-based language model is built from the IPAs in the dictionary, and used for the first step translation model in the two-step MT method. SRILM toolkit (Stolcke, 2002) is used to build these language models. We use Moses (Koehn et al., 2007) for all of our experiments. Giza++ (Och and Ney, 2003) is used for automatic word alignment for the three MT systems. We use 8 iterations by IBM model 1, 6 iterations by HMM model, and 6 iterations by IBM model 3 in the alignment. The final score from the translation model is a combination of the four sub-models: phrase translation, language model, reordering model, and the word length penalty weight.

In this study, we only focus on the word-level normalization in all of our experiments. A word-based unigram language model is combined with the normalization score when calculating the final score for a candidate for every individual system except the Jazzy Spell Checker system.

4.2 Experiment Result and Discussion

Tables 3, 4, and 5 present results on test data set 1, 2 and 3, using data set 4 as the training set. Similar to previous work, we evaluate n-best performance (n equals to 1, 3, 10 and 20), and also the candidate coverage (how many test cases' correct answers can be obtained in the final list regardless of its positions). We also include in the table the average number of candidates in the final list to make the coverage result more meaningful. Results in the tables are shown for individual systems and the combined systems, as well as those from previous work.

Among the individual systems, we notice that for data set 1 and 2, character-block level MT system's top one precision outperforms other individual systems, and character-level two-step MT has advantage on the top-n coverage (n from 3) compared with other systems. Character-block level sequence labeling usually has a lower top-1 precision than the two MT models, but its top-20 precision is not much poorer than others (sometimes it is even better). Character-block level sequence labeling can successfully normalize non-standard tokens such as 'gf', 'prof', and 'pro' (to 'girlfriend', 'professor', and 'problem' or 'probably'). However, these cases are very hard for the MT systems to tackle with. MT systems often fail to find correct candidates or sometimes offer no results for these cases. Jazzy spell checker has the worst performance on these two test sets compared to other three systems. In addition, because of its limited number of candidates, its top-n coverage is much lower than others.

The patterns on data set 3 are different. It indicates this data set has different characteristics than the other two. On data set 3, the sequence labeling method performs the best, although its absolute performance is similar to that on the other two data sets. Test data set 3 includes many test cases that the MT system is not good at tackling, such as those examples given above. Because of the poor performance of the MT systems on this data set, there is not much performance difference between them and the Jazzy spell checker.

For all the data sets, we can see that generally the sequence labeling method generates more candidates than others. This is partly because when creating the lookup table, we generated

a large number (10,000) of possible variations for a standard word in the dictionary in order achieve high coverage. Jazzy spell checker has limited number of candidate words, which explains its lower coverage than other methods, even though sometimes it can achieve competitive performance in the top-1 accuracy (e.g., on data set 3). Comparing the character-level MT and character-block level MT, we can see that our proposed method generates fewer number of candidates, but with better accuracy. This will be very beneficial when rescoring these candidates in sentence-level decoding/normalization.

Regarding the combination results, we can see that in general the combined system performs better than the individual systems. Comparing results for comb1 and comb3, and comb2 and comb4, we can see that after adding Jazzy Spell Checker's candidate, the top1 precision has some improvement, but the top-n coverage has no change. This is because we only use the first candidate from the spell checker. It also shows that Jazzy spell checker has some advantages in dealing with some cases and that adding it can yield performance gain. Comparing comb4 and comb6 (the latter includes Jazzy spell checker), we can see that for data set 2, comb4 has better top-1 performance, but not the top-n coverage, whereas on data set 1 and 3, comb6 performs better. We think this might be explained by the relative performance of the character-level two-step MT system. On data set 1 and 3, the character-level two-step MT has better top-n performance (n from 3) than the character-block MT. However, it is different for data set 2. Another important reason for the mixed results for these combined systems is the heuristic rules we use in system combination. We believe better ways of combination can improve performance and make the systems more robust.

Comparing our system performance with other previously reported results, we can see that on data set 1 (which is the most widely used data in previous studies), our system performs the best. On data set 2 and 3, out results are slightly worse than (Liu et al., 2012). One important reason is the training data size – ours is much smaller. However, our system uses fewer candidates and is more efficient than (Liu et al., 2012), which considers all the English words with the same initial character. For the size of the English dictionary we use, which consists of 75,262 words, the average number of candidates would be about 2,894, much higher than the candidates we have in our systems.

For the character-block sequence labeling system, we also performed some manual correction to fix some bad alignment between the character blocks and their phonetic symbol. Results for this modified sequence labeling system and using it in the combination with others are shown at the end of the tables (marked up **). We can see that there is consistent improvement after doing manual correction for the alignment, suggesting the alignment quality is important for model training. This is consistent with the finding that using character blocks outperforms character-based models, since the former has better alignment quality.

Since three of the normalization systems are statistical models, we evaluate the effect of the training data size on the system performance. In this experiment, we also include data set 3 in the labeled training data. We randomly chose some training pairs from it and combine with data set 4, creating training data with 3,000, 4,000 and 5,480 unique pairs respectively (5,480 pairs is the union of data set 3 and 4). Fig 3(a) shows the learning curve evaluated on data set 1 and 2 using these 4 training sizes. This is the result using the combined system 6 involving manual correction. As expected, the performance improves as the training data becomes larger. The pattern suggests that adding more training data may yield further gain. Note that for data set 2, when the training data is 5,480 pairs, it can achieve top one precision of 75.8%, which is

higher than the state-of-the-art result. We also plot the learning curves for individual systems along with the combined system in Fig 3(b). This is for data set 2. Similar trends are observed for data set 1. It is clear that the combined system outperforms all the individual systems. We can see that the performance of the character-block level MT improves steadily as the training data grows. In contrast, the training size effect on the character-level two-step MT is rather small. This suggests that the two-step MT may not need a large training set, and at the same time this method also has limits and it is hard to make further improvement. Finally for the character-block level sequence labeling, we notice a jump in its performance when training data grows from 4k to 5.48k, which may imply that the added new instances in the last trail are a better match with the test set, and there is still potential for performance gain. More annotated data is needed for a better understanding of the properties of these statistical models.

5 Conclusion and Future Work

In this paper we presented a character-block level MT and sequence labeling method for normalization in social text, and proposed various ways to combine these two novel methods with two other approaches: character-level two-step MT and Jazzy Spell checker. Experiments on several data sets show our methods perform competitively. In particular, on a widely used public test set containing 303 non-standard tokens (Choudhury et al., 2007), our system yields higher 1-best accuracy (74.6%) and better coverage (94.6%) than previous work. Results demonstrate that our proposed character blocks help generate better alignment in the MT and sequence labeling methods, which further improves normalization performance. We believe that our approach is general and applicable to many languages. The idea of aligning standard and non-standard word tokens is not language specific, and we expect it works for other languages, especially for Western European languages that are similar to English in terms of the way of forming non-standard words. Even for languages such as Chinese, there is previous work (Yang et al., 2009) that uses the CRF sequence labeling method for abbreviation detection. In our future work, we plan to first design more robust combination rules to combine different systems (e.g., weighted combination or reranking). Second we will perform sentence level normalization where word n-gram language models will be incorporated to re-rank the candidates.

ABSTRACT

Update summarization is a new challenge which combines salience ranking with novelty detection. Previous researches usually convert novelty detection to the problem of redundancy removal or salience re-ranking, and seldom explore the birth, splitting, merging and death of aspects for a given topic. In this paper, we borrow the idea of evolutionary clustering and propose a three-level HDP model named h-uHDP, which reveals the diversity and commonality between aspects discovered from two different epochs (i.e. epoch history and epoch update). Specifically, we strengthen modeling the sentence level in the h-uHDP model to adapt to the sentence extraction based framework. Automatic and manual evaluations on TAC data demonstrate the effectiveness of our update summarization algorithm, especially from the novelty criterion.

Proceedings of COLING 2012: Technical Papers, pages 1603–1618,
COLING 2012, Mumbai, December 2012.

1 Introduction

Update summarization aims to generate a short and concise summary for the latest updating topic-related documents (hereafter *update documents* for short), under the assumption that the user has already read the earlier historical documents (*history documents* for short) about the same topic. Recently, there have been many attempts to explore different approaches to generate update summaries. The predominant approaches are mainly built upon the sentence extraction framework.

Update summarization for an evolving topic differs from previous generic summarization for a static topic in that the latter aims to acquire the salient information in one topic, while the former cares for both the salience and the novelty of information. By developing traditional summarization techniques, massive efforts on update summarization have been made to dig out new information (Boudin et al., 2008; Fisher and Boark, 2008; Wan, 2007; Li et al., 2008; Du et al., 2010; Li et al., 2012). The typical examples include the scaled Maximal Marginal Relevance (MMR) algorithm which excludes those sentences similar to the history documents, and some extensions of TextRank such as TimedTextRank (Wan, 2007), PNR^2 (Li et al., 2008), MRSP (Du et al., 2010) which re-rank the salience scores of sentences by employing various kinds of reinforcement between sentences. One problem with these approaches is that they tend to regard update summarization more as a redundancy removal problem than a novelty detection problem. Another problem is that these approaches are mainly based on the computation of lexical similarities between sentences and fail to consider higher level information to avoid semantic redundancy in update summarization.

To solve these two problems, we borrow the techniques of evolutionary clustering which focuses on detecting the dynamics of a given topic. Normally, one topic is described from various specific aspects [1], accompanied with the background information running the whole topic (Chemudugunta et al., 2007; Li et al., 2010). For example, the topic "Quebec independence" may involve the specific aspects including "leader in independence movement", "referendum", "related efforts in independence movement" and so on, while "Quebec" and "independence" are seen as the general background information. The evolving dynamics of a topic is mainly embodied in the birth, splitting, merging and death of the specific aspects (Ren et al., 2008). Then, the commonality and diversity between history documents and update documents can be easily summarized from the aspect level and update summarization is not limited to lexical redundancy removal. Recently, hierarchical Dirichlet process (HDP) (Teh et al., 2006) has been widely used to model the aspects in evolutionary clustering. HDP does not need to predefine the number of clusters, and can be easily and naturally extended to multiple correlated corpora for detecting aspects (Ren et al., 2008; Xu et al., 2008; Zhang et al., 2010; Gao et al., 2011). These distinct advantages make it suitable to update summarization. However, to our best knowledge, no previous work has explored HDP for update summarization.

Aiming at the task of update summarization, in this paper, we develop a novel three-level (i.e. corpus, document set, and document levels) HDP model, called h-uHDP model, which extends the standard HDP to the scenario of two related document sets in different epochs (namely history epoch and update epoch). In h-uHDP, the diversity and connections of aspects between two epochs are naturally modeled: two epochs may share some common aspects; further, some aspects may become outdated while some become popular or some new may appear over time, causing the number of aspects and aspect structures to change at different epochs.

[1] Aspect in this article is usually called *cluster* in evolutionary clustering.

Under the framework of extractive summarization, it is important to acquire the relationship between sentences and aspects for sentence selection. However, in most existing HDP models, the sentence level is disregarded and we cannot directly get the aspect distribution of sentences. Inspired by the progress made in Latent Dirichlet Allocation (LDA) models (Chemudugunta et al., 2007; Li et al., 2010; Delort and Alfonseca, 2012), we newly add the sentence level between the word level and document level in the h-uHDP model. Since neighboring sentences in one document usually talk about one same aspect, we assume that the aspect assignment of each sentence is not conditionally independently. With such assumption, the aspect of each sentence is determined by the aspect distribution of both the document and its neighboring sentences. Our h-uHDP model is capable of mapping multiple levels of information into the latent aspect space.

The rest of this paper is organized as follows. Section 2 discusses the related work on update summarization and evolutionary clustering. Section 3 briefly introduces Dirichlet Process (DP) and Hierarchical Dirichlet Process (HDP). Section 4 presents our proposed aspect model h-uHDP and its inference algorithm. Section 5 addresses the algorithm of update summarization. Section 6 shows the experimental results. Finally, Section 7 concludes the paper.

2 Related work

In this section, we review the related work on update summarization and evolutionary clustering.

2.1 Update summarization

In generic summarization[2], numerous techniques have been developed to measure the salience of sentences and remove the redundancy in summaries, such as the well-known Maximal Marginal Relevance (MMR) (Carbonell and Goldstein, 1998), TextRank (Mihalcea and Tarau, 2004) et al. Some initial work on update summarization inherited the idea of salience ranking in generic summarization and extended the available algorithms to selecting sentences from the newly-coming documents. Boudin et al. (2008) proposed a sentence scoring algorithm derived from MMR and preferred to select those sentences dissimilar to previously read sentences. Fisher and Roark (2008) used a supervised perceptron and simple filtering rules to get the salient sentences for the update documents. Gillick et al. (2008) formulated sentence selection as the problem of integer linear programming and aimed to select a set of sentences that maximize the sum of weights of n-grams covered by the sentences. Adapting the ILP of Gillick et al.(2008), CLASSY by Conroy et al.(2009) seeked to find the sentences that maximize the total approximate oracle scores. Wang and Li (2010) employed an incremental hierarchical clustering algorithm COBWEB to re-organize sentence clusters immediately after new documents/sentences arrive and the most representative sentences for the updated clusters were selected. The graph-based algorithm – TextRank (Mihalcea and Tarau, 2004) has more extensions for update summarization. TimedTextRank by Wan (2007) introduced the time decaying ratio for weighting sentence reinforcement, PNR^2 by Li et al. (2008) added the negative reinforcement between sentences, and MRSP by Du et al. (2010) turned the historical sentences into sink points which are limited their reinforcement with other sentences. Through reinforcement propagation, the salience of sentences in the update documents is influenced by history documents to assure that those sentences with less redundancy with history documents appear in the update summaries. However, they mainly start from the lexical level and cannot explain explicitly what the novel information is.

There are also a few attempts to explore semantic information in update summarization. Steinberger and Jezek (2009) proposed the Iterative Residual Rescaling (IRR) algorithm which

[2] In this paper, generic summarization refers to the non-update summarization.

maps the documents to a set of latent semantic aspects[3]. Then sentences containing novel and significant aspects are then selected for the summary. Inspired by Latent Dirichlet Allocation (LDA) (Blei et al., 2003), Delort and Alfonseca (2012) proposed the DualSum algorithm which designs a nonparametric Bayesian approach to generate four kinds of aspects respectively for background, document, common and novel information. Though these researches have achieved some preliminary findings on exploring semantic information in update summarization, they still cannot present a unified framework to reveal the dynamics of a given topic.

2.2 Evolutional clustering and HDP

Evolutionary clustering is a relatively new research for topic detection, which aims to preserve the smoothness of clustering results over time, while fitting the data of each epoch. The work by Chakrabarti et al. (2006) was probably considered as the first to address the problem of evolutionary clustering. They proposed a general framework of evolutionary clustering and extended two classical clustering algorithms to the evolutionary setting: (1) k-means clustering, and (2) agglomerative hierarchical clustering. Later, Chi et al. (2008) presented two frameworks by incorporating temporal smoothness constraint and applied them on spectral clustering algorithm. While the researches on extending classic clustering algorithms have advanced the literature of evolutionary clustering, they have a very restrictive assumption: the number of clusters over time stays the same. It is clear that this assumption is obviously violated in many real applications.

Recently, HDP has been widely used in evolutionary clustering due to its capability of learning number of clusters automatically and sharing mixture components across different corpora. In HDP, each corpus is modeled by an infinite Dirichlet Process (DP) mixture model, and the infinite set of mixture clusters is shared among all corpora. Sethuraman (1994) gave a stick-breaking constructive definition of DP for arbitrarily measurable base space, which is very useful to model the weight of mixture components in the mixture model. Blackwell and MacQueen (1973) explained DP using the Polya urn scheme, as the predictive distribution of an event is proportional to the frequency of the existing events or to a concentration parameter for an unpresented event. The Polya urn scheme is closely related to the Chinese Restaurant Process (CRP) metaphor, which is applied on HDP demonstrating the 'clustering property' as the 'distribution on partition'. In addition, HDP can also be seen as an LDA-based model, which can automatically and naturally infer the number of clusters from data (Teh et al., 2006). Base on HDP, some algorithms of evolutionary clustering are proposed by incorporating time dependencies, such as DPChain, HDP-EVO, HDP-HMM, dynamic HDP and EvoHDP et al. (Xu et al., 2008; Xu et al., 2008; Ren et al., 2008; Zhang et al., 2010; Gao et al., 2011).

3 DP and HDP

In this section, we briefly introduce Dirichlet Process (DP) and Hierarchical Dirichlet Process (HDP).

A DP can be considered as a distribution of probability measure G. Suppose a finite partition $(T_1,\ldots,T_K)$ in the measure space Θ and a probability distribution G_0 on Θ, we write $G \sim DP(\alpha, G_0)$ if $(G(T_1),\ldots,G(T_K)) \sim Dir(\alpha G_0(T_1),\ldots,\alpha G_0(T_K))$, where α is a positive concentration parameter and G_0 is called a base measure. Sethuraman (1994) showed that a measure G drawn from a DP is discrete by the stick-breaking construction:

[3] aspect is called as topic in the original paper of (Steinberger and Jezek, 2009).

$$\beta_k \sim Beta(1,\alpha),\quad \pi_k = \beta_k \prod_{l=1}^{k-1}(1-\beta_l) = \beta_k(1-\sum_{l=1}^{k-1}\pi_l),\quad \{\phi_k\}_{k=1}^{\infty} \sim G_0,\quad G = \sum_{k=1}^{\infty}\pi_k \delta_{\phi_k} \tag{1}$$

where δ_{ϕ_k} is a probability measure concentrated at ϕ_k. It is important to note that the sequence $\boldsymbol{\pi} = (\pi_k)_{k=1}^{\infty}$ constructed by Eq. (1) satisfies $\sum_{k=1}^{\infty}\pi_k = 1$ with probability 1. For convenience, we write $\boldsymbol{\pi}$~GEM(α)[4] if $\boldsymbol{\pi}$ is a random probability measure defined by Eq. (1). After observing the draws $\theta_1, \theta_2, ..., \theta_{n-1}$ from *G*, the posterior of *G* still satisfies the *DP* distribution:

$$G \mid \theta_1, \theta_2, ..., \theta_{n-1} \sim DP(\alpha + n - 1, \frac{m_k \delta_{\phi_k} + \alpha G_0}{\alpha + n - 1}) \tag{2}$$

where m_k denotes the number of draws taking the value ϕ_k.

A HDP defines a distribution over a set of DPs. In HDP, a global measure G_0 is distributed as a DP with concentration parameter γ and base measure *H*. Then a set of measures $\{G_j\}_{j=1}^{J}$ is drawn independently from a DP with base measure G_0. Such a process is described as:

$$G_0 \sim DP(\gamma, H), \qquad G_j \mid \alpha_0, G_0 \sim DP(\alpha_0, G_0) \tag{3}$$

For each *j*, let $\{\theta_{ji}\}_{i=1}^{n_j}$ be independent and identically distributed (i.i.d.) random variables drawn from G_j. n_j observations $\{x_{ji}\}_{i=1}^{n_j}$ are drawn from the mixture model:

$$\theta_{ji} \sim G_j, \qquad x_{ji} \sim F(x \mid \theta_{ji}) \tag{4}$$

where $F(x|\theta_{ji})$ denotes the distribution of generating x_{ji}. Equations (3) and (4) complete the definition of a HDP mixture model, whose graphical representation is shown in Figure 1(a).

According to Eq. (1), the stick-breaking construction of HDP can be represented as:

$$\boldsymbol{\beta} = (\beta_k)_{k=1}^{\infty} \sim GEM(\gamma),\quad G_0 = \sum_{k=1}^{\infty}\beta_k \delta_{\phi_k},\quad \boldsymbol{\pi_j} = (\pi_{jk})_{k=1}^{\infty} \sim \mathrm{DP}(\alpha_0, \boldsymbol{\beta}),\quad G_j = \sum_{k=1}^{\infty}\pi_{jk}\delta_{\phi_k} \tag{5}$$

and the corresponding graphical model is shown in Fig. 1(b). We can see that HDP can readily be extended to as many levels as are deemed useful. That is, we can obtain a hierarchy of DPs, where the draw from the DP at a given node serves as a base measure for its children (Teh, 2006).

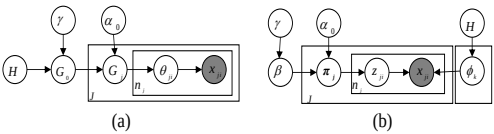

FIGURE 1 – Graphical representation for HDP. (a) original representation. (b) stick-breaking construction

4 h-uHDP model

This section clarifies why and how we propose our improved HDP model (named history-update HDP, *h-uHDP* for short) for the task of update summarization.

In update summarization, a given topic is composed of two document sets (*docset* for short) varying two epochs, namely *history* and *update* epoch. To precisely observe the dynamics of the aspects in one topic, we need to model the aspects over three levels: topic corpus, *docset* at each

[4] GEM stands for Griffiths, Engen, and McCloskey (Teh et al. 2006)

epoch, and document. In such case, we extend the standard HDP to a three level HDP: a set of common aspects on the top level of the hierarchy explicitly address the issue of aspect correspondence between two epochs; the second level is for the aspects at each different epoch, which are considered as the subset of the top level aspects; and the third level is designed for the aspects of each document; the relationship among these three levels of aspects can be obtained through statistical inference. Thus, h-uHDP can naturally model the diversity and connections of aspects between two epochs.

First of all, we introduce some notations in our real data setting of update summarization. We use J^H and J^U to denote the number of documents in the *history* and *update* epochs respectively. For the convenience of description, we use the symbol e in the superscript to denote U or H. Each docset is denoted as $D^e = \{D_j^e\}_{j=1}^{J^e}$ where document D_j^e has N_j^e sentences $\{s_{j,i}^e\}_{i=1}^{N_j^e}$ and the i^{th} sentence in D_j^e has $N_{j,i}^e$ observed word samples $\{x_{j,i,n}^e\}_{n=1}^{N_{j,i}^e}$.

4.1 Model

Our h-uHDP model is an extension of a three-level HDP model which naturally incorporates the levels of corpus, docset and document as shown in Fig. 2. Specifically, we design a two-level HDP respectively for each docset, and these two HDPs share an overall base measure G which is drawn from $DP(\varepsilon,G_0)$ and serves as the overall component bookkeeping for both epochs. We use G^H to denote the global measure for the *history* epoch and call it the *history* global measure. Similarly, G^U is called the *update* global measure. Then, the local measures for each document are denoted as $\{G_j^e\}_{j=1}^{J^e}$, which are drawn from the *history* or *update* global measures. That is, $G_j^e \sim DP(\alpha^e, G^e)$ given $e \in \{H, U\}$.

Then, we introduce the sentence level into the HDP model where each sentence is assigned to one aspect with the consideration of both its neighboring sentences and words contained by this sentence. We use $\theta_{j,i}^e$ to denote the aspect assignment of the i^{th} sentence in D_j^e. There is also a binomial distribution $y \sim binomial(\rho)$, which controls for each sentence how often we encounter a background word, or an aspect word. ρ has a beta prior with parameter β: $\rho \sim beta(\beta)$.

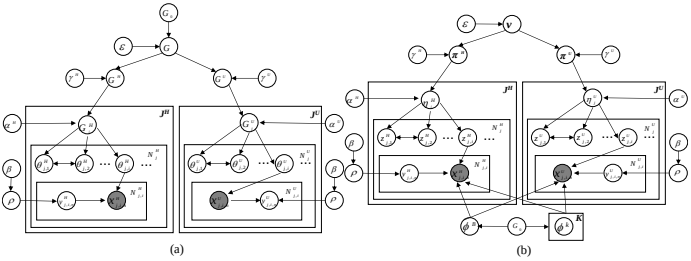

FIGURE 2 –Graphical representation for h-uHDP. (a) original representation. (b) stick-breaking construction

Fig. 2(a) illustrates the graphical representation of h-uHDP model. The generation process of our h-uHDP model is as follows:

1. Draw an overall base measure $G \sim DP(\varepsilon, G_0)$, which denotes the overall aspect distribution for all documents at two epochs.

2. For $e \in \{H, U\}$:

   2.1 Draw the global measure G^e according to the overall measure G. G^e serves as the base measure for each docset. That is, $G^e \sim DP(\gamma^e, G)$.

   2.2 Draw the local measures $\{G_j^e\}_{j=1}^{J^e}$. Each G_j^e for document D_j^e is drawn from the corresponding global measure G^e: $G_j^e \sim DP(\alpha^e, G^e)$.

   2.3 Draw the aspect for sentence $s_{j,i}^e$ according to G_j^e and the aspect assignment of neighboring sentences: $\theta_{j,i}^e \sim g(\theta \mid G_j^e, \boldsymbol{\theta}_{j,-i}^e)$

   2.4 Sample the words $\{x_{j,i,n}^e\}_{n=1}^{N_{j,i}^e}$: $y_{j,i,n}^e \sim binomial(\rho)$, $x_{j,i,n}^e \sim f(x \mid \theta_{j,i}^e, y_{j,i,n}^e)$ where $f(x \mid \theta_{j,i}^e, y_{j,i,n}^e)$ is a distribution parameterized by $\theta_{j,i}^e$ and $y_{j,i,n}^e$.

We can see that the extended three-level HDP model h-uHDP, in fact, considers five levels for a given topic, including word, sentence, document, docset, and corpus. At the same time, aspect assignment dependency between sentences is naturally incorporated in the model.

Next, we will provide the stick-breaking perspective and a Gibbs sampler for model inference.

4.2 The stick-breaking construction

According to the stick-breaking construction of DP, the overall base measure G can be expressed with the following form:

$$G = \sum_{k=1}^{\infty} v_k \delta_{\phi_k}, \quad \boldsymbol{v} \sim GEM(\varepsilon) \tag{6}$$

Then, according to Eq. (5), we can also get the global and local measures with the form as:

$$G^e = \sum_{k=1}^{\infty} \pi_k^e \delta_{\phi_k}, \quad \boldsymbol{\pi}^e \sim DP(\gamma^e, v) \tag{7}$$

and

$$G_j^e = \sum_{k=1}^{\infty} \eta_{jk}^e \delta_{\phi_k}, \ \boldsymbol{\eta}_j^e \sim DP(\alpha^e, \boldsymbol{\pi}^e) \tag{8}$$

As with the standard HDP, we get the stick-breaking construction for h-uHDP, illustrated in Figure 2(b).

Next, we focus on the modeling of the sentence level. $z_{j,i}^e$ is used to indicate the aspect assignment of sentence $s_{j,i}^e$ and the formula of assigning aspect k to $z_{j,i}^e$ is as follows:

$$p(z_{j,i}^e = k \mid \boldsymbol{\phi}, \boldsymbol{z}_{-j,i}^e) \propto f_k(s_{j,i}^e) g(z_{j,i}^e = k \mid \boldsymbol{z}_{-j,i}^e) \tag{9}$$

$$\text{and} \quad g(z_{j,i}^e = k \mid \boldsymbol{z}_{-j,i}^e) = \frac{1}{|N_j^e - 1|} \sum_{d \in [1, N_j^e] - \{i\}} \exp\left\{ \frac{\sigma \cdot \delta(k, z_{j,d}^e)}{|d - i|} \right\} \tag{10}$$

In Formula (9), $f_k(s_{j,i}^e)$ denotes the probability of generating sentence $s_{j,i}^e$ given aspect k and the function $g(\bullet)$ reflects the influence from the neighboring sentences. We use the symbol '-' to denote the exclusion of current sentence or word, and $\boldsymbol{z}_{-j,i}$ means the aspect assignment of all sentences in D_j^e excluding the current sentence. $\delta(k, z_{j,d}^e)$ equals 1 if the aspect assignment of the d^{th} sentence in D_j^e is k, 0 otherwise. The parameter σ (named as *sentence influence factor*) is used to tune the influence from neighboring sentences. Eq. (10) shows that the longer the distance from one sentence to the current sentence, the less the influence that sentence has on the aspect assignment of the current sentence. $y_{j,i,n}^e$ is the indicator variable of word $x_{j,i,n}^e$ and controlled by a binomial distribution with beta prior β. If $y_{j,i,n}^e = 0$, $x_{j,i,n}^e$ is a background word.

If $y^e_{j,i,n} = 1$, $x^e_{j,i,n}$ is an aspect word.

4.3 Inference

For model inference, we use a straightforward Gibbs sampler based on the Chinese Restaurant Franchise (CRF) and the stick-breaking construction. Thus, we begin with an analog of the CRF process for h-uHDP: a document D^e_j corresponds to a *restaurant*, and a sentence $s^e_{j,i}$ corresponds to a customer. Different from the standard HDP, one customer in our model is seen as a family which includes a few persons. Here, we assume that the persons in one family usually have the same preference for one dish at one table except some persons shown no preference for any food. The general *background dish* is assigned to the persons having no preference and a specific dish k is assigned to those persons having preference. The global menu of dishes is denoted by K+1 i.i.d. random variables $\phi_B, \phi_1, \ldots, \phi_K$ distributed according to G_0. We also introduce variables, ψ^e_{jt}, to represent the dish served at table t in restaurant j. To denote the associations among $\theta^e_{j,i}$, ψ^e_{jt} and ϕ_k, we let t^e_{ji} be the index of ψ^e_{jt} associated with $\theta^e_{j,i}$, and let k^e_{jt} be the index of ϕ_k associated with ψ^e_{jt}. In the CRF metaphor, customer $s^e_{j,i}$ sits at table t^e_{ji} while table t in restaurant D^e_j serves dish k^e_{jt}.

We also need a notation for counts. Specifically, we need to record the counts of families, persons and tables. Marginal counts are represented with dots in the subscript. $n^e_{jt\bullet}$ represents the number of families in restaurant j at table t in the corresponding epoch, and $n^e_{j\bullet k}$ represents the number of families in restaurant j eating dish k in the corresponding epoch. The notation m^e_{jk} denotes the number of tables in restaurant j serving dish k in one epoch, $m^e_{j\bullet}$ denotes the number of tables in restaurant j in one epoch, $m^e_{\bullet k}$ denotes the number of tables serving dish k in one epoch, and $m^e_{\bullet\bullet}$ denotes the total number of tables in each epoch. The notation above with removing the superscript represents the corresponding counts in both epochs. For example, $n_{\bullet\bullet k}$ is the total number of customers assigned to aspect k in both epochs and $m_{\bullet k}$ denotes the total number of tables serving dish k in both epochs.

In our implementation, we first sample the index variables t^e_{ji} and k^e_{jt}. Then the $\theta^e_{j,i}$ and ψ^e_{jt} can be reconstructed from their index variables and ϕ_k, which makes the MCMC sampling more efficient (Blei et al., 2006).

Sampling ***t****.* Due to the space limit, we would just show the sampling formula without derivation. The likelihood due to $s^e_{j,i}$ given $t^e_{ji} = t$ for some previously t is $f^{-s^e_{j,i}}_{k^e_{jt}}(s^e_{j,i})$. The likelihood of generating $s^e_{j,i}$ given $t^e_{ji} = t^{new}$ can be calculated by integrating out the possible values of $k_{jt^{new}}$. K^e denotes the set of aspects assigned in current epoch. The prior probability that t^e_{ji} takes on a previously used t is calculated according to $g(z^e_{j,i} \mid \mathbf{z}^e_{\mathbf{-j,i}})$, $f^{-s_{ji}}_{k_{jt}}(s^e_{j,i})$ and $n^e_{jt\bullet}$, whereas the probability that it takes on a new value (i.e. $t^{new} = m^e_{j\bullet} + 1$) is proportional to α^e. Then, the conditional distribution of t^e_{ji} given the rest of the variables is:

$$p(t^e_{ji} = t \mid \mathbf{t}_{-ji}, \mathbf{k}) \propto \begin{cases} g(z^e_{j,i} = k \mid \mathbf{z}^e_{\mathbf{-j,i}}) n^e_{jt\bullet} f^{-s_{ji}}_{k_{jt}}(s^e_{j,i}) & \textbf{\textit{if } } t \textbf{\textit{ previously used}} \\ \alpha^e P(s^e_{j,i} \mid \mathbf{t}_{-ji}, t^e_{ji} = t^{new}, \mathbf{k}) & \textbf{\textit{if }} t = t^{new} \end{cases} \tag{11}$$

and
$$P(s^e_{j,i} \mid \boldsymbol{t}_{-ji}, t_{ji} = t^{new}, \boldsymbol{k}) = \sum_{k \in K^e} g(z^e_{j,i} = k \mid \boldsymbol{z}^e_{-j,i})\left(\frac{m^e_{\bullet k}}{m^e_{\bullet\bullet} + \gamma^e} + \frac{\gamma^e}{m^e_{\bullet\bullet} + \gamma^e} \cdot \frac{m_{\bullet k}}{m_{\bullet\bullet} + \varepsilon}\right) f_k^{-s^e_{j,i}}(s^e_{j,i}) + \sum_{k \in K^{\{H,U\}} - K^e} \frac{\gamma^e}{m^e_{\bullet\bullet} + \gamma^e} \cdot \frac{m_{\bullet k}}{m_{\bullet\bullet} + \varepsilon} f_k^{-s^e_{j,i}}(s^e_{j,i}) + \frac{\gamma^e}{m^e_{\bullet\bullet} + \gamma^e} \cdot \frac{\varepsilon}{m_{\bullet\bullet} + \varepsilon} f_{k^{new}}^{-s_{j,i}}(s^e_{j,i}) \tag{12}$$

where $m^e_{\bullet\bullet}$ denotes the total number of tables in epoch *e* and $K^{\{H,U\}}$ means the set of the aspects available in the two epochs.

According to the distribution $y^e_{j,i,n} \sim binomial(\rho)$ and $\rho \sim beta(\beta)$, we can get the conditional probability of generating sentence $s^e_{j,i}$ given a specified aspect *k*:

$$f_k^{-s^e_{j,i}}(s^e_{j,i}) = \begin{cases} \dfrac{\Gamma(n_{\bullet\bullet k} + V\beta)}{\Gamma(n_{\bullet\bullet k} + \sum_k A^{(k)}_{(s^e_{j,i})} + V\beta)} \prod_{\substack{x^e_{j,i,n} = x^e_{j,i} \\ y^e_{j,i,n} = 1}} \dfrac{\Gamma(E^{(k)}_{(x^e_{j,i,n})} + E^{(s^e_{j,i})}_{(x^e_{j,i,n})} + \beta)}{\Gamma(E^{(k)}_{(x^e_{j,i,n})} + \beta)} & \text{if } k \text{ previously used} \\ \dfrac{\Gamma(V\beta)}{\Gamma(\sum_k A^{(k)}_{(s^e_{j,i})} + V\beta)} \prod_{\substack{x^e_{j,i,n} = x^e_{j,i} \\ y^e_{j,i,n} = 1}} \dfrac{\Gamma(E^{(s^e_{j,i})}_{(x^e_{j,i,n})} + \beta)}{\Gamma(\beta)} & k = k^{new} \end{cases} \tag{13}$$

$A^{(k)}_{(s^e_{j,i})}$ denotes the number of words that belong to aspect *k* in sentence $s^e_{j,i}$. It is obvious that background words do not influence the aspect assignment of sentences. $n_{\bullet\bullet k}$ is the total number of words assigned to aspect *k* in both epochs. *V* represents the size of vocabulary. $E^{(k)}_{(x^e_{j,i,n})}$ denotes the total number of times that word $x^e_{j,i,n}$ belongs to topic *k* in both docsets, and $E^{(s^e_{j,i})}_{(x^e_{j,i,n})}$ denotes the number of times that word $x^e_{j,i,n}$ exists in $s^e_{j,i}$.

If the sampled value of t^e_{ji} is t^{new}, then we can sample $k^e_{jt^{new}}$ according to (12):

$$p(k^e_{jt^{new}} = k \mid \boldsymbol{t}, \boldsymbol{k}^e_{-jt^{new}}) \propto \begin{cases} g(z^e_{j,i} = k \mid \boldsymbol{z}^e_{-j,i})\left(\dfrac{m^e_{\bullet k}}{m^e_{\bullet\bullet} + \gamma^e} + \dfrac{\gamma^e}{m^e_{\bullet\bullet} + \gamma^e} \cdot \dfrac{m_{\bullet k}}{m_{\bullet\bullet} + \varepsilon}\right) f_k^{-s^e_{j,i}}(s^e_{j,i}) & \textbf{if } k \in K^e \\ \dfrac{\gamma^e}{m^e_{\bullet\bullet} + \gamma^e} \cdot \dfrac{m_{\bullet k}}{m_{\bullet\bullet} + \varepsilon} f_k^{-s^e_{j,i}}(s^e_{j,i}) & \textbf{if } k \in K - K^e \\ \dfrac{\gamma^e}{m^e_{\bullet\bullet} + \gamma^e} \dfrac{\varepsilon}{m_{\bullet\bullet} + \varepsilon} f_{k^{new}}^{-s^e_{j,i}}(s^e_{j,i}) & \textbf{if } k = k^{new} \end{cases} \tag{14}$$

All the counts above except $A^{(k)}_{(s^e_{j,i})}$ and $E^{(s^e_{j,i})}_{(x^e_{j,i,n})}$ exclude the current sentence.

Sampling $\boldsymbol{k}$. Because the process of sampling $\boldsymbol{t}$ actually changes the component member of tables, we continue to sample k^e_{jt} for each table. The conditional probability $p(k^e_{jt} = k \mid \boldsymbol{t}, \boldsymbol{k}_{-jt})$ can be calculated similar to Eq. (14) and it is noted that a set of customers (not one custom) at table *t* should be considered.

Sampling $\boldsymbol{y}$. $y^e_{j,i,n}$ determines whether $x^e_{j,i,n}$ is a background word or an aspect word. If $y^e_{j,i,n} = 0$, $x^e_{j,i,n}$ is a background word, otherwise assigned to aspect *k*. we sample $y^e_{j,i,n}$ as:

$$p(y^e_{j,i,n} \mid z^e_{j,i} = k, \boldsymbol{y}_{-i,j,n}) = \begin{cases} \dfrac{C_{(0)} + \beta}{C_{(\bullet)} + 2\beta} \cdot \dfrac{C^{(x^e_{j,i,n})}_{(0)} + \lambda}{C_{(0)} + V\lambda} & \textbf{if } y^e_{j,i,n} = 0 \\ \dfrac{C_{(1)} + \beta}{C_{(\bullet)} + 2\beta} \cdot \dfrac{C^{(x^e_{j,i,n})}_{(k)} + \lambda}{C^{(k)}_{(1)} + V\lambda} & \textbf{if } y^e_{j,i,n} = 1 \end{cases} \tag{15}$$

where $C_{(\bullet)}$ denotes the total number of words in both docsets, $C_{(0)}$ denotes the total number of background words, $C_{(1)}$ denotes the total number of aspect words, and $C^{(k)}_{(1)}$ denotes the total

number of words that are assigned to aspect k. $C_{(0)}^{(x_{j,i,n}^e)}$ represents the number of times that word $x_{j,i,n}^e$ is assigned to background word and $C_{(k)}^{(x_{j,i,n}^e)}$ represents the total number of times that word $x_{j,i,n}^e$ is assigned to aspect k. The base measure G_0 was set a symmetric Dirichlet distribution with parameters λ (e.g. 0.5).

Based on Equations (11), (12) and (14), the aspect assignment probability of each sentence can be calculated as:

$$p(s_{j,i}^e = k \mid \boldsymbol{k}_{-ji}^e) \propto \begin{cases} g(z_{j,i}^e = k \mid \boldsymbol{z}_{-j,i}^e) n_{j\bullet k}^e f_k^{-s_{j,i}^e}(s_{j,i}^e) + \alpha^e g(z_{j,i}^e = k \mid \boldsymbol{z}_{j,i}^e) & \\ \times \left(\frac{m_{\bullet k}^e}{m_{\bullet\bullet}^e + \gamma^e} + \frac{\gamma^e}{m_{\bullet\bullet}^e + \gamma^e} \frac{m_{\bullet k}}{m_{\bullet\bullet} + \varepsilon}\right) f_k^{-s_{j,i}^e}(s_{j,i}^e) & \text{if } k \in K^e \\ \alpha^e \frac{\gamma^e}{m_{\bullet\bullet}^e + \gamma^e} \frac{m_{\bullet k}}{m_{\bullet\bullet} + \varepsilon} f_k^{-s_{j,i}^e}(s_{j,i}^e) & \text{if } k \in K^{(H,U)} - K^e \\ \alpha^e \frac{\gamma^e}{m_{\bullet\bullet}^e + \gamma^e} \frac{\varepsilon}{m_{\bullet\bullet} + \varepsilon} f_{k^{new}}^{-s_{j,i}^e}(s_{j,i}^e) & \text{if } k = k^{new} \end{cases} \tag{16}$$

As for the concentration parameters of h-uHDP, i.e., ε , α^e and γ^e, we sample them from a vague gamma prior which is set to be $Ga(10.0, 1.0)$. The sampling method is the same as that in (Teh et al., 2006).

5 Update Summarization with h-uHDP model

The task of update summarization aims to produce an update summary for the documents in the *update* epoch, assuming that users already read earlier documents in the *history* epoch. That is, we need to boost sentences in *update* epoch that can bring out important and novel information. On one hand, the generated summary should extract the main content in D^U, and on the other hand, the summary should avoid mentioning too much old information in D^H. To care for these two points, we propose a sentence selection strategy based on Kullback-Leibler (KL) divergence, which has been widely used in extractive summarization (Haghighi and Vanderwende, 2009; Mason and Charniak, 2011; Delort and Alfonseca, 2012).

Given the *history* sentence set S^H and the *update* sentence set S^U, we propose a function to score a set of sentences *Sum* which is a subset S^U.

$$Score(Sum) = KL(p_{S^H} \mid\mid p_{Sum}) - \kappa KL(p_{S^U} \mid\mid p_{Sum}) \tag{17}$$

In the equation, the first term means the prize on the divergence from epoch *history* and the second term represents the penalty on the divergence from epoch *update*. The parameter κ (called as *epoch balance factor*) is used to tune the weights of two KL distances. p_{Sum} is the empirical aspect distribution of the candidate summary *Sum*. p_{S^H} and p_{S^U} respectively denote the aspect distribution of S^H and S^U. $KL(p_{S^e} \mid\mid p_{Sum})$ $(e \in \{H, U\})$ represents the KL divergence given by $\sum_{k=1}^{K} p(S^e \mid k) \log \frac{p(S^e \mid k)}{p(Sum \mid k)}$. $p(\cdot \mid k)$ represents the probability distribution of a set of sentences on a specific aspect k, and is calculated based on the aspect assignment probability of each sentence which can be obtained according to Eq. (16).

$$p(S^e \mid k) = \frac{1}{\sum_j N_j^e} \sum_{s \in S^e} p(s = k), \quad p(Sum \mid k) = \frac{1}{\mid Sum \mid} \sum_{s \in Sum} p(s = k) \tag{18}$$

Generally, an optimum update summary should have the aspect distribution which approximates to p_{S^U} as possible and keep far away from the distribution p_{S^H}. Let Sum^* denote the optimum update summary. We can get Sum^* that maximizes the scoring function.

$$Sum^* = \underset{Sum \subseteq S^U \,\&\&\, words(Sum) \le L}{\arg\max} Score(Sum) \tag{19}$$

Since the problem of finding the subset of sentences from a collection that maximize the scoring function is NP-complete, a greedy algorithm is applied by adding sentences one by one. We use *Y* to denote the sentence set which contains the selected summary sentences. The algorithm first initializes *Y* to ϕ and *X* to S^U. During each iteration, we select from *X* one sentence (i.e. s_m) which makes $Score(s_m \cup Y)$ have the highest score. To avoid aspect redundancy in the summary, we also adopt the MMR strategy in the process of sentence selection. That is, for each s_m, we compute the semantic similarity between s_m and each sentence s_t in set *Y* as follows:

$$\cos\_sem(s_m, s_t) = \frac{\sum_k p(s_m \mid k) \cdot p(s_t \mid k)}{\sqrt{\sum_{k=1}^{K} p^2(s_m \mid k)} \cdot \sqrt{\sum_{k=1}^{K} p^2(s_t \mid k)}} \tag{20}$$

6 Experiments

In our experiments, we use four years of TAC (2008-2011) data, which contain 44-48 topics per year. For each topic, two docsets (named docset *H* and *U*) are given to respectively describe the *history* epoch and the *Update* epoch. Table 1 illustrates the number of topics, averaged number of documents per docset, and averaged number of sentences per docset for each year's data.

TAC	**2008**		**2009**		**2010**		**2011**	
Topics #	48		44		46		44	
docset	***H***	***U***	***H***	***U***	***H***	***U***	***H***	***U***
Avg Doc # per docset	10	10	10	10	10	10	10	10
Avg Sen # per docset	236.5	222.4	253.5	228.3	238.6	230.2	208.9	210.5

TABLE 1 – Experiment data (TAC 2008 - 2011).

As for the automatic evaluation of summarization, we still use the widely used ROUGE (Recall-Oriented Understudy for Gisting Evaluation) (Lin and Hovy, 2003) measures, including ROUGE-1, ROUGE-2, and ROUGE-SU4[5] and their corresponding 95% confidential intervals. In order to obtain a more comprehensive measure of summary quality, we also conduct manual evaluation on TAC 2011 dataset with the reference to (Haghighi and Vanderwende, 2009; Celikyilmaz and Hakkani-Tur, 2011; Delort and Alfonseca, 2011).

6.1 Parameter tuning

To get the final update summary using the h-uHDPSum algorithm, we still need to determine two parameters: sentence influence factor σ in Eq. (10) and epoch balance factor κ in Eq. (17). The combination of the two factors makes it hard to find a global optimized solution. So we apply a

[5]Jackknife scoring for ROUGE is used in order to compare with the human summaries.

gradient search strategy. At first, the epoch balance factor κ is fixed to a given value. Then the performance using different values of σ is evaluated. After that, we fix σ with the value which has achieved the best performance, and conduct experiments to find an appropriate value for κ. TAC 2008 and 2009 datasets are used as training data to tune these two parameters.

Firstly, κ is set to the value of 1, i.e. the prize on the divergence from epoch *history* is as important as the penalty on the divergence from epoch *update*. Reviewing Eq. (10), we can see that, the aspect assignment of one sentence is mainly determined by its neighboring sentences when σ is set a large value, whereas the influence from other sentences is not considered at all when σ is set 0. In the first place, we experiment the h-uHDPsum algorithm by setting σ in the range from 0 to 10 with interval of 1. The ROUGE scores drop sharply when σ is set a value larger than 2.0. Next, σ is set in the range from 0.0 to 2.0 with interval of 1.0. Fig. 4 presents the ROUGE-2 and ROUGE-SU4 evaluation results of h-uHDPSum, with regard to different values of σ. We find that the ROUGE scores reach their peak at around 1.0 and drop afterwords. The experimental results conform to our expectation and verify that the h-uHDP model is reasonable by considering the influence among sentences.

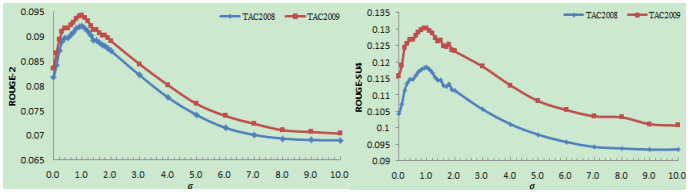

FIGURE 4 – Tuning parameter σ when κ is set to 1.

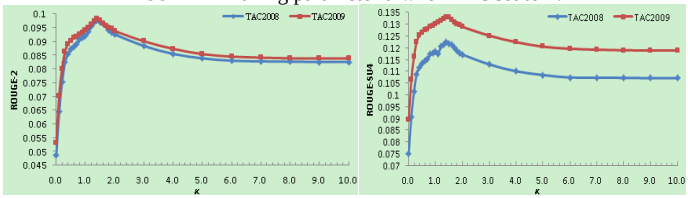

FIGURE 5 – Tuning parameter κ when σ is set to 1.

Next, we fix the sentence influence factor σ at 1.0 and tune the parameter κ. From Eq. (17), we can see that κ is used to balance the prize for the divergence from *history* epoch and penalty on the divergence from the update epoch. When κ is set as the value of 0, the scoring of sentences is only determined by docset *H*. That is, a sentence is likely to be selected into summary, only when it has a large divergence of aspect distribution from docset *H*. When κ is set a larger value, penalty on the divergence from docset *U* is more considered. Similar to the process of tuning σ, the performance using different values of κ ranging from 0 to 10 with interval of 1 is evaluated. We find that the peak performance of κ should be located in the range of [0.0, 2.0]. Thus, we conduct experiments to find an appropriate value for κ in the range from 0.0 to 2.0 with interval of 0.1. Fig. 5 shows the performance of h-uHDPSum with respect to κ. Performance gets better as κ increases from 0 to 1.4, and then declines gently until κ arrives at 3.0. Afterwards, the curve becomes smooth and means that the summarization algorithm is mainly up to docset *U* to decide which sentences to select. Parameters σ and κ are respectively set as 1.0 and 1.4 in the h-uHDPSum algorithm.

6.2 Comparison with other approaches

In this subsection, we compare our h-uHDPSum algorithm with several baseline methods on TAC 2010 and TAC 2011 datasets. One kind of baseline methods consists of the top three performing systems (denoted as SysRank 1st, 2nd and 3rd) on update summarization tasks according to the ROUGE-2 metric on TAC2010 and TAC2011. From Table 3, we can see that our approach obviously outperformed the top three participating systems both on TAC2010 and TAC2011, with respect to the ROUGE-2 and ROUGE-SU4 scores along with the corresponding 95% confidence intervals.

TABLE 2 – Performance Comparison on TAC2010 and TAC2011.

To illustrate the effectiveness of our aspect modeling technique, we provide five other baseline systems which adopt different aspect modeling techniques. The systems *h-uHDPSum-noBG* and *2LevHDPSum* can be seen the simplified versions of *h-uHDPSum*. *h-uHDPSum-noBG* is the same as *h-uHDPSum* except that the general background information is not considered, whereas *2LevHDPSum* is a two-level (i.e. document level and sentence level) HDP model where the docset level is removed. At the same time, we implement one standard HDP model for comparison. As shown in Table 2, *h-uHDPSum* is better than both *h-uHDPSum-noBG*, *2LevHDPSum* and *HDPSum*, which verifies that the identification of background words or the introduction of the docset level can promote the performance of update summarization. Even without consideration of the background information, we can see the *h-uHDPSum-noBG* approach can be comparable to the best participating system of TAC evaluations. In addition, to compare with another popular modeling technique - Latent Dirichlet Allocation (LDA), we design a two-level LDA-based system *2LevLDASum* and a standard LDA-based system *LDASum*. Both *2LevLDASum* and *2LevHDPSum* are similar as possible beyond the distinction that *2LevLDASum* assume a fixed finite number of aspects[6] while *2LevHDPSum* does not. We can see that *2LevHDPSum* is better than *2LevLDASum* and *HDPSum* better than *LDASum* in performance. This can be easily explained, novel aspects can be automatically detected and the aspect number is determined naturally in HDP-based models. In contrast, how to determine the aspect number in the LDA-based models is still an open problem. This is also the reason why we select HDP as the foundation of our aspect modeling technique.

6.3 Manual evaluation

In order to obtain a more accurate measure of summary quality, manual evaluation is required. In this section, we compare our *h-uHDPSum* approach with *2LevLDASum* and the best participating

[6] In our experiments, the aspect number is set as 10, 20, 30 and 40 respectively and we select the best performed result with the aspect number as 20.

system (*Peer 43*). Similar to the manual evaluation in TAC, human assessors assign a score to each summary with respect to each of the following four criteria: 1) Overall responsiveness (overall performance in terms of content and fluency), 2) Focus (containing less irrelevant details), 3) Novelty (containing novel information beyond docset *H*), 4) Non-redundancy (repeating less the same information). The score is an integer between 1 (very poor) and 5 (very good). We randomly select 28 topics from TAC 2011 data and assign each topic to three different assessors[7]. In Table 3, the left four columns report the average scores of each criterion for the three systems. The experimental results indicate that *h-uHDPSum* is significantly better than both *Peer 43* and *2LevLDASum* (based on paired t-test with p-value < 0.01).

Simultaneously, a fairly standard approach for manual evaluation is conducted through pairwise comparison (Haghighi and Vanderwende, 2009; Celikyilmaz and Hakkani-Tur, 2011). According to the rating scores, each pair of summaries is judged which one is better under each criterion. If two summaries have the same score, they are judged a tie (of the equal quality). We record the times of 'winning' (having a higher score) and tie for each system. In Table 3, the right six columns show the evaluation results in frequencies respectively for *h-uHDPSum* vs. *Peer 43*, and *h-uHDPSum* vs. *2LevLDASum*. The experimental results also indicate that *h-uHDPSum* is significantly better than both *Peer 43* and *2LevLDASum*. We also observe that the winning times of *h-uHDPSum* under the novelty criterion is much more than those under the other criteria. This indicates that our approach can exhibit a clear advantage of promoting the novelty performance in update summaries.

				h-uHDPSum vs. *Peer 43*			*h-uHDPSum* vs. *2LevLDASum*

TABLE 3 – Results of manual evaluation on TAC2011.

Conclusion

In this paper, we propose a novel approach based on a three-level HDP model h-uHDP for update summarization. The h-uHDP model can detect the birth, splitting, merging and death of specific aspects and the general background information for a given topic. Under the sentence extraction based framework of summarization, we especially strengthen modeling the sentence level in h-uHDP, where the aspect assignment of each sentence is influenced by its neighboring sentences. Based on h-uHDP, we propose a sentence selection strategy adopting KL divergence, which cares for both salience and novelty of sentences. Automatic and manual evaluations on TAC data illustrate that our approach obviously outperforms the state-of-the-art approaches.

ABSTRACT

Current Chinese event extraction systems suffer much from the low recall due to unknown triggers. To resolve this problem, this paper firstly introduces morphological structures to better represent the compositional semantics inside Chinese triggers and then proposes a mechanism to automatically identify the head morpheme (either verb or noun) as the governing sememe of a trigger. Finally, it proposes a mechanism of combining the morphological structures and sememes of Chinese words to infer unknown triggers to improve the recall of the Chinese event extraction system. Evaluation on the ACE 2005 Chinese corpus justifies the effectiveness of our approach over a state-of-the-art system.

形态结构和义原在中文事件抽取中的应用

由于存在大量未知的触发词，当前的中文事件抽取系统受限于它的低召回率。为了解决这个问题，本文首先引入形态结构来更好地表示隐含在中文触发词内部的组合语义，然后提出了一个自动识别触发词中作为支配义原的核心词素（动词或名词）的机制。最后，本文提出了一个结合了中文词语的形态结构和义原去推测未知触发词的方法，用于提高中文事件抽取系统的召回率。在ACE 2005中文语料上的实验验证了我们方法的性能超越了目前最好的中文事件抽取系统。

KEYWORDS: Chinese event extraction; Morphological structure; Governing sememe; Trigger identification; Head morpheme.
Keywords in L2: 中文事件抽取; 形态结构; 支配语义; 触发词识别; 核心语素

1 Introduction

As a compromise to natural language understanding, Information Extraction (IE) aims to extract structured information (e.g., entities, relations and events) from a text. Event extraction, a classic subtask in IE, is to recognize event trigger mentions of a predefined event type and their participants and attributes. While most studies in the literature focus on English event extraction, there are few successful stories concerning Chinese event extraction due to the special characteristics and challenges in Chinese language. Even with ground truth entities, times and values, the performance of most Chinese event extraction systems is much lower than that of English ones.

For Chinese event extraction, unknown triggers (a trigger in the test set doesn't occur in the training set and otherwise, a known trigger.) and word segmentation errors are two major reasons for the low performance, particularly the recall. The statistics on the ACE 2005 Chinese and English corpora (Li et al., 2012) shows that these two cases cover almost 30% of Chinese trigger mentions while this figure reduces to only about 9% in English. Besides, given the same number of event mentions, there are about 30% more different triggers in Chinese than those in English. This amplifies the problem. Therefore, trigger identification becomes a key to the success of Chinese event extraction.

Currently, there mainly exist two major mechanisms to solve this problem. The first one is to expand the triggers using predefined or automatically-clustered synsets, a common mechanism widely used in various NLP applications. The problem with this mechanism is that it fails to consider the sense shifting of a word in difficult contexts and thus may introduce too many pseudo triggers and harm the precision. This largely limits the contribution of this mechanism (Chen and Ji, 2009b; Ji, 2009; Qin et al. 2010). For example, as a trigger of the *Start-position* event, "担任" has more than five senses (e.g., serve as, bear, engage, do, etc.) and only one of them (serve as) can trigger a *Start-position* event. Take following two sentences as samples:

*(E1) 我们将**承担**所有本公司的费用。 (We will bear all the expenses for our company.)*

*(E2) 他将在IBM**从事**科学研究工作。 (He will engage in scientific research in IBM.)*

Although "承担" (bear) and "从事" (engage) are two synonyms of "担任", they do not trigger the *Start-position* event but any other events.

The second one is to expand the triggers using the compositional semantics inside Chinese words. The intuition is that if a Chinese word contains more than one character, and its meaning can be often inferred from the meanings of its component characters (Yuan, 1998). For example, Li et al. (2012) infer the semantics of a verb (most triggers in Chinese events are verbs) from its basic single-character verb (BV) and significantly improve the F1-measure, largely due to the dramatic increase in the recall. The problem with Li et al. (2012) is that they extract all single-character verbs contained in triggers as BVs (e.g., "担" (undertake, verb) and "任" (serve as, verb) are treated as two BVs for "担任" (serve as)). Therefore, pseudo triggers are much introduced. This severely harms the precision. Take the following sentence as a sample:

*(E3) 所有的公司员工**信任**他们的董事长。（All employees **trust** their chairman.）*

Although "信任" (trust) and "担任" have the same BV ("任") and the same verb structure (*verb+BV*), "信任"(trust) does not trigger the *Start-position* event but any other events.

Further analysis indicates that above two mechanisms are quite complementary. For example, we can find out that if we introduce the semantic similarity into the compositional semantics, "信任"(trust) in (E3) will not be expanded as a trigger for the *Start-position* event because of its different sense from "担任"(serve as), while if we introduce the compositional semantics into the semantic similarity, "从事"(engage) in (E2) will be filtered out from the trigger list of the *Start-position* event since it doesn't have the same BV as "担任" (serve as). However, a more refined mechanism is required to filter out "承担"(bear) in (E1).

In this paper, we first introduce the more general morphological structures in Chinese triggers, in place of verb structures in Li et al. (2102), to better represent the compositional semantics inside Chinese words and then propose a mechanism to automatically identify the head morpheme (either verb or noun) as the governing sememe of a trigger based on its morphological structure. The intuition behind is that the head morpheme can better represent the semantics of a Chinese word than the combination of all its component BVs. Finally, we propose a mechanism of combining the morphological structures and sememes of Chinese words to infer unknown triggers. Evaluation on the ACE 2005 Chinese corpus justifies the appropriateness of our approach.

To better understand the Chinese event extraction task as defined in ACE evaluations, where an event is defined as a specific occurrence involving participants, we list some ACE terminologies:

- **Event mention**: a phrase or sentence within which an event is described;
- **Trigger**: the main word that most clearly expresses the occurrence of an event, so recognizing an event can be recast as identifying a corresponding trigger;
- **Trigger mention:** a reference to a trigger.
- **Trigger type/Event type**: the type of an event;
- **Argument**: the entity mentions involved in an event;
- **Argument role**: the relation of an argument to an event where it participates.

In particular, the event extraction task is divided into four components:

- **Trigger identification**: to distinguish true trigger mentions from pseudo trigger mentions;
- **Event type determination**: to classify trigger mentions by event types;
- **Argument identification**: to distinguish true arguments from pseudo arguments;
- **Argument role determination**: to classify arguments by argument roles.

The rest of this paper is organized as follows. Section 2 overviews the related work. Section 3 describes various morphological structures in Chinese words and proposes a mechanism for determining the morphological structure and head morpheme in a Chinese trigger. Section 4 proposes an algorithm to infer unknown triggers on their morphological structures and sememes. Section 5 presents the experimental results. Finally, we conclude the paper with future work.

2 Related work

In the literature, most of existing studies on event extraction concern English and can be classified into either pattern-based (e.g., Riloff, 1996; Yangarber et al., 2000; Stevenson and Greenwood, 2005; Shinyama and Sekine, 2006; Patwardhan and Riloff, 2007; Chambers and

Jurafsky, 2011) or classifier-based (e.g., Grishman et al., 2005; Ahn, 2006; Hardy et al., 2006; Maslennikov and Chua, 2007; Ji and Grishman, 2008; Patwardhan and Riloff, 2009; Liao and Grishman, 2010; & 2011; Hong et al., 2011; Lu and Roth, 2012; Llorens et al., 2012). In particular, while earlier studies focus on sentence-level extraction, later ones turn to employ global information.

Compared with tremendous work on English event extraction, there are only a few studies on Chinese event extraction with focus on either feature engineering or trigger expansion, under the same framework as English event extraction.

On feature engineering, Tan et al. (2008) first employ a local feature selection method to ensure the performance of trigger classification and then apply multiple levels of patterns to improve the coverage in argument classification. Fu et al. (2010) apply a feature weighting scheme to re-weight various features for trigger identification and event type determination. Chen and Ji (2009b) apply various kinds of lexical, syntactic and semantic features to address the special issues in Chinese. Li et al. (2012) extend Chen and Ji (2009b) with more refined features and additional dependency and semantic role features.

On trigger expansion, Chen and Ji (2009a) propose a bootstrapping framework to exploit extra information captured by an English event extraction system. Ji (2009) first extracts some cross-lingual predicate clusters using bilingual parallel corpora and a cross-lingual information extraction system, and then employs the derived clusters to expand the triggers. Qin et al. (2010) employ a semantic dictionary "TongYiCi Ciling (expanded version)" to expand triggers for Chinese event type determination. Li et al. (2012) propose an inference mechanism to infer new triggers by employing the verb structures to explore the compositional semantics inside Chinese triggers (verbs only) and achieve the state-of-the-art performance of 67.4% in F1-measure on the ACE 2005 Chinese corpus, ignoring the post-processing – discourse consistency.

3 Morphological structures and head morphemes inside Chinese triggers

In this section, we introduce various morphological structures to better represent the compositional semantics inside Chinese triggers and then propose two mechanisms to identify the morphological structures and the head morpheme in Chinese triggers respectively.

3.1 Compositional semantics and morphological structures in Chinese words

Both in English and Chinese languages, a word is composed of one or more characters. However, a component character in English is just the basic unit to form a word instead of a semantic unit. In comparison, almost all Chinese characters have their own meanings and are called morpheme (or single-morpheme word), the minimal meaningful unit in Chinese language. If a Chinese word contains more than one character, its meaning can be often interpreted in terms of its composite characters/morphemes. This more fine-grained semantics are the compositional semantics inside Chinese words namely. Actually, it is also a normal way to understand a new Chinese word in everyday life for a Chinese native speaker.

Without doubt, a general method to represent the compositional semantics inside Chinese words is to systematically explore the morphological structures in Chinese words since it is the nature of compound words. Morphological structures in Chinese words are the word-building process to form the morphemes into words and are formulated by three major processes: compounding, affixation, and conversion. Compounding is a process, by which two or more morphemes are composed together to form a compound word. Affixation is a morphological process to add

grammatical or lexical information to a base form. By the conversion process, a word is changed from one part-of-speech (POS) into another without the addition or deletion of any morphemes. Compounding is the most productive way to compose a Chinese word while affixation is the most popular way to construct an English word. Affixation also is used widely in Chinese, but its prefix or suffix doesn't have the meaning and can be always omitted (e.g., "老虎" (tiger) and "虎" (tiger) have the same meaning.). As for conversion, it's really not a way to construct a word and just represents the fact that some words have more than one tense.

3.2 Morphological structures in Chinese triggers

Since almost all triggers in Chinese events are verbs and nouns, we focus on the morphological structures of Chinese verbs and nouns. Actually, statistics on the ACE 2005 Chinese corpus shows that 95% of triggers are either verbs or verbal nouns and just nearly 5% are pure nouns (e.g., "公开信" (open letter), "大会" (plenary session)). In ACE 2005 English corpus, there are some adjectives triggering an event of special type. However, no adjective acts as a trigger in the ACE 2005 Chinese corpus for the special characteristics in Chinese language. Besides, almost 95% of triggers in the training set just contain one or two morphemes, so this paper only considers the one-morpheme and two-morpheme triggers of verbs and nouns.

There are two type words in Chinese triggers: single-morpheme words and compound words. Single-morpheme word just contains one morpheme. Sometimes, a single-morpheme word maybe is composed by more than one character, such as the transliterated word. But it doesn't occur in Chinese triggers and we disregard them in this paper. So there is only one morphological structure concerning a single-morpheme trigger:

Single-Morpheme Structure: Single-morpheme trigger whose POS is a verb or a noun (e.g., "死" (die), "去" (go), "信" (letter), etc.).

Compounding is the most productive way to compose a Chinese trigger. In this paper we define five types (similar to (Chang, 1995)) of the morphological structures in Chinese triggers based on the relations between their morphemes.

Coordinative Structure: The two morphemes of a trigger play coordinative role. For example, "合" (combine) and "并" (merge) are coordinative in trigger "合并" (merge).

Modifier-Head Structure: The modified morpheme follows the modifying one in a trigger. For example, "婚" (marry) is modified by "新" (new) in trigger " 新婚" (newly-married).

Subject-Predicate Structure: One morpheme is the subject and the other one tells something about the subject. This structure is like a subject-predicate sentence condensed in a trigger. For example, "身" (body) is a subject of predicate "亡" (die) in trigger "身亡" (die).

Predicate-Object Structure: The first morpheme (predicate) governs the second one (object) in a trigger. For example, "业" (business) serves as the object of predicate "开" (start) in trigger "开业" (start business).

Predicate-Complement Structure: The first morpheme is a predicate and the second one interprets the first one from different aspects (e.g., direction, result and tense) in a trigger. For example, morpheme"入" (into) expresses the direction of action "进" (go) in trigger "进入" (go into).

3.3 Determining the morphological structure in a Chinese trigger

A general method to determine the morphological structures in Chinese triggers is to first annotate some instances manually and then train a classifier. Alternatively, a simple way is employed in this paper to determine the morphological structures in Chinese triggers via their POS structures, due to our finding that the morphological structures in Chinese triggers can be inferred from their POS structures. Following are the inference rules employed in this paper for different morphological structures:

Single-Morpheme Structure: For a single-morpheme trigger whose POS is a noun or a verb, its morphological structure is *Single-Morpheme*. The statistics on the training set shows that this inference rule covers almost 100% of cases given correct POSs.

Predicate-Complement Structure: If the POS structure of a trigger is (*verb + preposition*) or *(verb + auxiliary*), its morphological structure is *Predicate-Complement*. The statistics on the training set shows that this inference rule covers almost 100% of cases given correct POSs.

Predicate-Object Structure: If the POS structure of a trigger is (*verb + noun)*, its morphological structure is *Predicate-Object*. The statistics on the training set shows that this inference rule covers almost 100% of cases given correct POSs.

Coordinative Structure: If the POS structure of a trigger is (*verb + verb*) (e.g., "捐/VV 赠/VV" (donate), "购/VV 买/VV" (buy), etc.), its morphological structure is *Coordinative*. The statistics on the training set shows that this inference rule covers almost 98% of cases given correct POSs. The only exception to this inference rule is that it ignores those triggers whose POS structure is (*noun + noun*), This happens in Chinese triggers, though seldom. In such cases, i.e. if the POS structure of a trigger is (*noun + noun*), its morphological structure can be either *Modifier-Head* or *Coordinative* (e.g., "婚/NN 姻/NN" (marriage)).

Modifier-Head Structure: The morphological structure of a trigger is *Modifier-Head*, *if* its POS structure is one of following four structures: 1) (*adjective + verb*); 2) (*adjective + noun*); 3) (*noun + noun*); 4) (*noun + verb*). The statistics on the training set shows that this inference rule covers almost 96% of cases given correct POSs. The only exceptions to this inference rule are that if the POS structure of a trigger is (*noun + noun*) or (*noun + verb*), its morphological structure can also be *Coordinative* or *Subject-Predicate*, respectively.

Subject-Predicate Structure: Our exploration on the ACE 2005 Chinese corpus shows that only one trigger (i.e. "身亡" (die)) has the *Subject-Predicate* structure. Therefore, we ignore this structure.

Structure	% Trigger mentions
Single-Morpheme	19.1
Coordinative	46.3
Modifier-Head	13.3
Predicate-Object	11.4
Predicate-Complement	8.7
Words (length>=3)	1.2

TABLE 1 – Distribution of different morphological structures in Chinese trigger mentions

To obtain the POS structures of Chinese triggers, we split all triggers into characters and employ a Chinese POS tool – ICTCLAS to tag their POSs. Table 1 shows the distribution of the morphological structures in Chinese triggers in the training set, extracted using above inference rules. Random manual evaluation of 1000 instances shows that our inference rules achieve the accuracy of more than 91% given automatically-tagged POSs.

3.4 Identifying head morpheme in Chinese triggers

Normally, almost all Chinese verbs or nouns contain one morpheme as the governing semantic element, called Head Morpheme (HM), to construct a word and the semantics of such a word thus can be inferred from its HM. Since the semantics of a Chinese trigger can be often inferred from its HM, it's natural to infer unknown triggers via HMs. For example, given verb "死" (die) as HM in trigger "烧死" (burn to death, trigger of the *Die* event) whose morphological structure is *Coordinative*, it is reasonable to infer "砸死" (crush to death), "炸死" (burst to death), "闷死" (stifle to death) to be triggers of the same event, due to their same HM and morphological structure as "烧死".

Li et al. (2012) regards all single-character verbs contained in triggers as BVs and use them to infer unknown triggers. It may introduce many pseudo triggers into candidates and harm the precision for that loose constraint. For example, the morphological structure of "烧死" is *Coordinative*, and "烧" (burn) and "死" (die) are two single-morpheme verbs in it. Following Li's inference rule, all words including BV "烧" or "死" are regarded as triggers if their verb structures are (*BV* + *verb*) or (*verb* + *BV*). Hence, some pseudo triggers, such as "烧烤" (barbecue), "烧焊" (weld), "烧制" (fire), etc., would be expanded to be triggers.

Besides, a noun may be a HM to infer new triggers. For example, given "信" (letter) as the HM in trigger "私信"(private letter, trigger of *Phone-Write* event) whose morphological structure is *Modifier-Head*. It's correctly to infer those words (e.g., "贺信" (congratulatory letter), "密信" (secret letter), etc.) with the HM "信" (letter) and the morphological structure *Modifier-Head*, as triggers.

Therefore, how to identify the HM in a Chinese trigger becomes the key to infer unknown triggers. Table 2 shows our automatic mechanism to identify HM, where *LM(w)* and *RM(w)* are used to obtain the left and right morphemes from one-morpheme or two-morphemes word *w* respectively.

Structure	Inferences to select HM
Single-morpheme	*tr*
Coordinative	LM(*tr*): **if** SSIM*(tr,* LM*(tr))* > *α* RM(*tr*): **if** SSIM*(tr,* RM*(tr))* > *α*
Modifier-Head	RM(*tr*)
Predicate-Object	RM(*tr*)
Predicate-Complement	LM(*tr*)

TABLE 2 – Inferences on different morphological structures to extract HMs

For a trigger whose morphological structure is *Single-morpheme*, *Predicate-Complement* or *Modifier-Head*, it's easy to identify its HM from the relationship between its two morphemes. If the structure of a trigger is *Predicate-Object*, we select the noun (object) as HM because it better represents the semantics of the trigger than the predicate, i.e. the governing semantic element

always comes from the object. However, without additional information, it's hard to select HM from a trigger whose morphological structure is *Coordinative*. For example, given the trigger "访问" (visit) whose morphological structure is *Coordinative*, its two component morphemes, "访" (visit) and "问" (ask), have their own semantics respectively. Fortunately, we can find out that morpheme "访" (visit) has the same meaning as trigger "访问" (visit). So an effective way to identify HM in a trigger with the *Coordinative* structure is via the semantic similarity (SemSim).

In this paper, we employ HowNet[1] (Dong and Dong, 2006) to obtain the semantics of Chinese words. Similar to Wordnet in English, HowNet is a structured Chinese lexical semantic resource. In HowNet, sememe is a basic semantic unit and represents the meaning of a word. In total, about 2200 sememes are used to define 95000 Chinese words. In this paper, the governing sememe is introduced to recognize HMs from those triggers with the *Coordinative* structure. That is, if a morpheme represents the governing sememe, it is recognized as HM of that trigger. Following Liu and Li (2002), function *SemSim(x, y)* is used to calculate the semantic similarity between the sememes of the trigger *x* and its morpheme *y* as follow:

$$SemSim(x, y) = \frac{\phi}{Dis(x, y) + \phi} \tag{1}$$

where *Dis(x,y)* is the distance between the sememe of *x* and *y* in HowNet's sememe hierarchical architecture, and ϕ is an adjustable parameter and assigned 0.75 following Liu and Li (2002).

4 Inferring unknown triggers on HMs and sememes

To better represent the compositional semantics inside Chinese words and filter out more pseudo triggers, we introduce the morphological structures and sememes of Chinese words to infer unknown triggers. The methodology is shown as follows: 1) following the principle of compositional semantics, we extract these one-morpheme or two-morpheme words in the test set as candidates when they contain at least one HM and their POS are nouns or verbs; 2) according to the morphological structure of each candidate word, we applied different inferences to choose unknown triggers. We implement an algorithm to determine whether a candidate is an unknown trigger and the input and output are shown as follows:

Input: *HMs* $\leftarrow$ the set of all HMs extracting from the training set

$$candidates \leftarrow \{w \mid \begin{array}{l}(LM(w) \in HMs \vee (RM(w) \in HMs) \\ \wedge (POS(w) = noun \vee POS(w) = verb)\} \\ \wedge MPRO(MORPH(w), HM(w)) \geq 0\end{array}$$

$$triggerwords \leftarrow \phi$$

Output: *triggerwords* : the set of unknown triggers accepted by our algorithm

POS(w) and *HM(w)* are applied to get the POS of word *w* and obtain the HM in word *w* respectively. *MPRO(ms, hm)* is defined to compute the conditional probability of a trigger when it contains a HM *hm* and its morphological structure is *ms*. *MORPH(w)* is used to get the morphological structure of word *w*.

For each candidate word *w* in *candidates*, we apply following inferences to distinguish the true unknown triggers from the pseudo ones according to the morphological structure and sememe.

[1] http://www.keenage.com

Single-Morpheme: These expanding single-morpheme words are those HMs in two-morpheme triggers. So we apply a simple constraint to determine whether or not it's an unknown trigger:

$$\underset{m_i \in S}{MAX}(SemSim(w, m_i)) = 1 \tag{2}$$

where S is the set of triggers in the training set which contain word w. If the maximum score of the semantic similarity between these triggers and word w is equal to 1, we accept it.

Predicate-Complement: The first morpheme is usually a verb, so the sememe of word w always is similar to the sememe of its first morpheme. The constraint for *Predicate-Complement* structure is:

$$LM(w) \in S_{sm} \cup S_{pc} \tag{3}$$

where S_{sm} is the set of triggers in the training set whose structures are *Single-morpheme* while S_{pc} is the set of left morphemes of triggers in the training set whose structures are *Predicate-Complement*.

Predicate-Object: for a word w whose morphological structure is *Predicate-Object*, we regard it as the unknown trigger following two conditions to constrain its two morphemes:

$$RM(w) \in HMs \tag{4}$$

$$\underset{m_i \in SW}{MAX}(SemSim(LM(w), m_i)) \geq \beta \tag{5}$$

where SW is the set of predicates in the similar triggers[2] of word w. For example, if there are two triggers "离职" (resign) and "辞职" (resign), and their HMs are "职" (job) too. For a candidate "免职" (resign), its morphological structure is as same as the above two and its HM also is "职" (job). We call them similar triggers and calculate the similarities between "免"(dismiss) and the predicates ("离" (leave), "辞" (dismiss)) in its similar triggers in the training set.

Modifier-Head: The first morpheme of word w modifies the second one, so that the semantics of word w comes from its second morpheme. We apply following rules based on POS consistency and semantic similarity.

$$RM(w) \in HMs \tag{6}$$

$$POS(LM(w)) \in \{POS(l) \mid COM(l,b) \in S_{mh} \wedge b \in HMs\} \tag{7}$$

$$\underset{m_i \in S}{MAX}(SemSim(w, m_i)) = 1 \tag{8}$$

where S_{mh} is the set of triggers in the training set whose structures are *Modifier-Head* and *COM(l,b)* is to combine morpheme l and b to be a two-morpheme word. Otherwise, S is the set of those triggers which contain word w.

Coordinative: Since the two composite morphemes of word w are homogeneous and its semantics is flexible and maybe comes from the combination of its two morphemes or one of its morpheme. We calculate the average score of the similarities to infer trigger of this type:

[2] Similar triggers are those triggers with the same morphological structure and the same BM in the training set.

$$\frac{\sum_{co \in \{w, LM(w), RM(w)\}} \underset{m_i \in SC}{MAX}(SemSim(co, m_i))}{3} > \lambda \quad (9)$$

where

$$SC \in \{s | MORPH(s) = MORPH(w) \wedge (LM(w) \in HMs \wedge LM(s) = LM(w) \vee RM(w) \in HMs \wedge RM(w) = RM(s))\} \quad (10)$$

where *SC* is the set of triggers in the training set with following two constraints: 1) their morphological structures are *Coordinative*; 2) their left/right morphemes and the left/right morpheme of word *w* are the same HM.

5 Experimentation and discussion

In this section, we evaluate our mechanism of combining the morphological structures and sememes of Chinese words in inferring unknown triggers and report the experimental results on trigger identification and its application to overall Chinese event extraction.

5.1 Experimental setting and baseline

We use a state-of-the-art Chinese event extraction system (Li et al., 2012) as one of our baselines which consists of four typical components (trigger identification, event type determination, argument identification and argument role determination) in a pipeline way. During testing, each word in the test set is first scanned for instances of known triggers from the training set and then scanned by employing the compositional semantics inside Chinese triggers to infer instances of unknown triggers. When an instance is found, the trigger identifier is applied to distinguish those true trigger mentions from pseudo ones. If true, the event type determiner is then applied to recognize its event type. For any entity mention in a sentence which is identified as an event, the argument identifier is employed to assign its possible arguments afterwards. Finally, the argument role determiner is introduced to assign a role to each argument.

Besides, we adopt the same experimental setting as Li et al. (2012). The ACE 2005 Chinese corpus (only the training data is available) is used in all our experiments. The corpus contains 633 Chinese documents annotated with 8 predefined event types and 33 predefined event subtypes[3]. We randomly select 567 documents as the training set and the remaining 66 documents as the test set. Besides, we reserve 33 documents in the training set as the development set and follow the setting of ACE diagnostic tasks and use the ground truth entities, times and values for our training and testing. As for evaluation, we also follow the standards as defined in Li et al (2012):

- A trigger is **correctly** identified if its position in the document matches a reference trigger;
- An event type is **correctly** determined if the trigger's event type and position in the document match a reference trigger;
- An argument is **correctly** identified if its involved event type and position in the document match any of the reference argument mentions;
- An argument role is **correctly** determined if its involved event type, position in the document, and role match any of the reference argument mentions.

[3] Similar to previous studies, we treat these subtypes simply as 33 separate event types and do not consider the hierarchical structure among them.

Finally, all the sentences in the corpus are divided into words using a word segmentation tool (ICTCLAS) with all entities annotated in the corpus kept. Besides, we use Berkeley Parser and Stanford Parser to create the constituent and dependency parse trees. We use N-gram features and employ the ME model[4] to train individual component classifiers.

5.2 Results on identifying HMs and unknown triggers

As the key to infer unknown triggers, Table 3 shows the performance of HM identification. For evaluation, the HMs of all the known triggers in the ACE 2005 Chinese corpus are manually labeled by three annotators and we accept those morphemes as HMs when at least two annotators agree on them. The thresholds α is fine-tuned to 0.85 using the development set. Compared to Li et al. (2012), our approach can improve the F1-measure by 6.9%, largely due to the dramatic increase in Precision of 15.8%. Li et al. (2012) extracted all single-character verbs as BVs, so their Recall is higher than that of ours. Otherwise, we extract 30 single-morpheme nouns as HMs and 73% of them occur in the gold set while this number in Li et al. (2012) is 0.

System	#BV/HMs	P(%)	R(%)	F1
Li et al. (2012)	361	64.3	88.5	74.5
Ours	266	80.1	82.1	81.4

TABLE 3– Performance of the HM identification (#Gold: 262)

We apply the mechanism of combining the morphological structures and sememes of Chinese words (CMS) to infer unknown triggers. The thresholds β and λ are fine-tuned to 0.7 using the development set. Following Li et al. (2012), we also apply the non-trigger filtering rule in our system and just filter out those candidates which occur as pseudo triggers more than 5 times in the training set. So we obtain a candidate set of words including known triggers in the training set and those unknown triggers identified by our mechanism. Manual inspection shows that 62 words are inferred as unknown triggers, among which 69.4% are true triggers.

To verify the effectiveness of our mechanism, we extract those trigger mentions from the test set when they are instances of known triggers from the training set or unknown triggers extracted by CMS. Table 4 shows the results of our CMS and two baseline systems in inferring unknown trigger mentions. Here, Baseline-1 (Chen and Ji (2009b)) just extracts those trigger mentions occurring in the training data while Baseline-2 (Li, et al., 2012) infers unknown trigger mentions based on the compositional semantics and verb structures of Chinese words.

System	#True trigger mentions	#Pseudo trigger mentions
Baseline-1	266	629
Baseline-2	302	444
CMS	326	508
Gold	367	-

Table 4 – Impact of combining the morphological structure and sememe of Chinese words in inferring unknown triggers

Compared with Baseline-1 and Baseline-2, our mechanism recovers 16.3% (60) and 6.5% (24) of true trigger mentions respectively. This improvement mainly comes from two factors. The first one is that we introduce those nouns to be HMs and almost 20% of the true unknown triggers

[4] http://mallet.cs.umass.edu/

(e.g., “失**业**” (lose one’s job), “出**境**” (leave the country)) are extracted. The second one is that our mechanism filters out more pseudo trigger mentions due to the contribution of combining the morphological structures and sememes of Chinese words. For example, Baseline-2 will infer “**调**频” (frequency adjustment) “妨**害**” (impair) to be triggers due to “调” (adjust) and “害” (harm) are BVs and their syntactic structures are (*BV+noun*) and (*verb+BV*) respectively. On the contrary, our mechanism will filter out “**调**频” since its structure is *Modifier-Head* and the head morpheme “频” (frequency) doesn’t appear in HMs while “妨**害**” will also be ignored because its sememe is not similar to any known triggers with the same HM “害” (harm). It justifies the effectiveness of our mechanism to combine the morphological structures and sememes of Chinese words in recovering true triggers.

Otherwise, some triggers in the training set are seldom used as trigger mentions. We also applied above mechanism to filter out those triggers. Table 4 shows that almost 28% of pseudo trigger mentions is filtered out, so the number of pseudo trigger mentions is reduced to 508.

5.3 Results on trigger identification and overall Chinese event extraction

There are too many pseudo trigger mentions showed in Table 4 by using our mechanism to infer unknown triggers and extract trigger mentions from the test set, so we introduce a ME-based trigger identifier to distinguish the true trigger mentions from the pseudo ones as previous works.

Table 5 shows the contribution of our mechanism to trigger identification on the held-out test set. Compared to Baseline-1, our approach can dramatically improve the F1-measure by 10.0%, with a big gain of 17.8% in Recall and a small loss of 1.8% in Precision. It further proves the effectiveness of the compositional semantics in inferring Chinese unknown triggers. Compared to the state-of-the-art system *(*Baseline-2), our approach also enhances F1-measure by 4.1%, largely due to a dramatic increase of 7.7% in Recall. It also justifies that the morphological structures of Chinese words are more effective than the verb structures when they are employed to infer unknown triggers. Besides, these results also show that introducing sememes of Chinese words into our mechanism is a helpful way to filter out those pseudo triggers.

We also employ the mechanism of discourse consistency (Li et al., 2012) to improve the Precision and our results show that our approach achieves 79.4%, 69.2% and 73.9% in F1-measure, Precision and Recall respectively and it outperforms Li et al. (2012) by 3.4% and 5.7% in F1-measure and Recall, with a small loss of 0.1% in Precision.

System	Trigger identification		
	P(%)	R(%)	F1
Baseline-1	75.2	52.0	61.5
Baseline-2 (Li et al. (2012))	73.5	62.1	67.4
CMS	73.4	**69.8**	71.5
Baseline-2+ Discourse consistency	79.3	63.5	70.5
CMS + Discourse consistency	**79.4**	69.2	**73.9**

Table 5 – Contribution to Chinese trigger identification

Table 6 shows the contribution of trigger identification to overall event extraction on the held-out test set. Compared to Baseline-2, we can find that our approach can improve the F1-measure for event type determination by 4.0%, argument identification by 3.3% and argument role determination (i.e. overall event extraction) by 2.9%, largely due to the dramatic increase in

Recall of 7.4%, 6.1% and 5.6%. These results also ensure the importance of trigger identification in Chinese event extraction.

System	Event type determination			Argument identification			Argument role determination		
	P(%)	R(%)	F1	P(%)	R(%)	F1	P(%)	R(%)	F1
Baseline-1	70.3	49.0	57.8	58.4	42.7	49.3	55.2	38.6	45.4
Baseline-2	70.2	59.1	64.2	58.0	48.9	53.0	54.7	44.5	49.1
CMS	**69.9**	**66.5**	**68.2**	**57.6**	**55.0**	**56.3**	**54.1**	**50.1**	**52.0**

Table 6 – Contribution to Overall Chinese event extraction

5.4 Discussion

Through manual inspection, we find that many remaining errors are related to three aspects. The first one is that almost 4.7% of trigger mentions in the test set doesn't have a morpheme appeared in the set of HMs. For example, there are so many ways to hurt a human to express an *injure* event and just a few of triggers or its HMs occurred in the training set. The second one comes from the errors in POS tagging in the verb structures of triggers and constituent parse tree. Almost all errors in determining morphological structures are come form those wrong POSs, especially those single-morpheme triggers, with the wrong POS in the parse tree will be ignored in inferring unknown triggers. The last one is the low quality of the annotated event corpus and many event mentions are missed. Those un-annotated true mentions would make the classifier confuse to distinguish true event mentions from pseudo ones. We look into those pseudo trigger mentions which are classified as true ones by the ME classifier and find out almost 20% of them maybe are true ones by our knowledge.

In order to evaluate the effect of the training set size on the performance, we modify the proportion of the training set to the test set from 9:1 to 1:9. Fig. 2 shows the percentages of true trigger mentions extracted by our baseline and our CMS. From Figure 1, we can find out that our mechanism can extract much more true trigger mentions than that of the baseline, especially for a smaller training set. When the proportion of the training set to the test set is set to 1:9, our mechanism can extract 67.5% of true trigger mentions while the figure drops to 43.3% in our baseline. This justifies that our mechanism can be well applied to minimally-supervised event extraction.

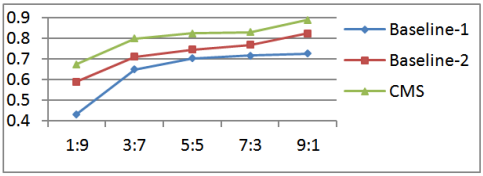

FIGURE 1 – The percentages of extracting true trigger mentions on different proportions of the training set to the test set

Compared to Li et al. (2012), There are three contributions in our work: 1) we use the morphological structure to better represent the compositional semantics inside Chinese triggers; 2) we introduce a mechanism to identify HMs in triggers automatically and those HMs can be verbs or nouns; 3) we propose a mechanism of combining the morphological structures and sememes of

Chinese words to extract unknown triggers. The results show that our mechanism outperforms the state-of-the-art system.

Conclusion

To address the special characteristics of Chinese event extraction and extract more true trigger mentions, this paper presents a novel approach to Chinese trigger identification which combines the morphological structures and sememes of Chinese words to infer unknown triggers. The experimental results show that our approach can significantly improve the performance of the Chinese event extraction system, especially Chinese trigger identification in Recall. In future work, we will focus on how to apply the mechanism of compositional semantics to unsupervised or minimally supervised event extraction system and improve their performance.

ABSTRACT

Currently, Chinese event extraction systems suffer much from the low quality of annotated event corpora and the high ratio of pseudo trigger mentions to true ones. To resolve these two issues, this paper proposes a joint model of trigger identification and event type determination. Besides, several trigger filtering schemas are introduced to filter out those pseudo trigger mentions as many as possible. Evaluation on the ACE 2005 Chinese corpus justifies the effectiveness of our approach over a strong baseline.

一个应用于中文事件抽取的事件触发词识别和类型判别联合模型

当前，有2个问题困扰着中文事件抽取系统：低质量的事件标记语料库和假事件触发词相对于真事件触发词的高比例。为了解决以上2个问题，本文提出了一个结合事件触发词识别和事件类型判别的联合模型。另外，几个触发词过滤模式同样被引入本系统用于过滤掉尽可能多的假触发词实例。在ACE2005中文语料上的测试结果表明，本文的方法和基准系统相比具有更高的性能。

1 Introduction

Information extraction (IE) is a task of extracting structured information (e.g. entities, relations and events) from the text. As a critical part of IE, event extraction is to identify trigger mentions of a predefined event type, and their participants and attributes. It can be typically divided into four components: trigger identification, event type determination, argument identification and argument role determination. Due to the central role of the contained events in a text, it is critical to mine their semantics in order to understand a text. Unfortunately, event extraction has been proven its performance is still very low.

In the literature, most studies focus on English event extraction and have achieved certain success (e.g., Grishman et al., 2005; Ahn, 2006; Patwardhan and Riloff, 2009; Hong et al., 2011; Lu and Roth, 2012; Llorens et al., 2012). However, there are few successful stories regarding Chinese event extraction due to the special characteristics in Chinese trigger identification. Besides unknown triggers[1] and word segmentation errors (Li et al., 2012), the low quality of annotated corpora and the high ratio of pseudo trigger mentions to true ones are also blamed for the low performance of Chinese event extraction.

To examine the low quality of annotated corpora in Chinese event extraction, we take the ACE (Automatic Content Extraction) 2005 Chinese corpus (with 8 types and 33 subtypes of events), one of the most popular corpora in event extraction, as an example. In particular, we randomly select 33 documents from the training set and ask two human annotators to manually tag event mentions and their types following the definition of the ACE 2005 corpus. Here, human annotator 1 is a first year postgraduate student with no background in Chinese event extraction while human annotator 2 is a third year postgraduate student working on Chinese event extraction. Table 1 justifies the difficulty of Chinese event extraction, particularly for trigger identification and event type determination, even for a well-educated human being. As shown in Table 1, the IAA (Inter-Annotator Agreement) on both trigger identification and event type determination is well below 50%. Even so, it is not surprising since the IAA on trigger identification on the ACE 2005 English corpus is only about 40% (Ji and Grishman, 2008).

Performance / Human	Trigger identification			Event type determination		
	P%	R%	F1	P%	R%	F1
annotator1 (blind)	63.3	62.9	63.1	61.7	59.5	60.6
annotator2 (familiar)	72.6	74.3	73.4	69.1	70.2	69.6
Inter-Annotator Agreement	45.8	42.9	44.3	45.3	42.5	43.8

TABLE 1 – Low quality of human annotation in the ACE 2005 Chinese corpus

Detailed analysis shows that one major reason for the low quality of human annotation is due to the difficulty of following the specified annotation guidelines, as mentioned in Ji and Grishman (2008). To better justify this issue, we randomly select 20 triggers and extract all the sentences which contain those triggers from the training set. Our exploration shows that although almost all the annotated trigger mentions are true ones, ensuring the reliability of the annotated trigger mentions, many true trigger mentions, e.g., those with exactly the same constituent or dependency structure as annotated ones, are not annotated, accounting for about 10% of trigger mentions. Table 2 shows the statistics.

[1] A trigger word/phrase occurring in the training data is called a known trigger and otherwise, an unknown trigger.

#Triggers	#Sentences	#Annotated trigger mentions	#un-annotated trigger mentions
20	452	198	23

TABLE 2 – Statistics of annotated vs. un-annotated trigger mentions in the ACE 2005 Chinese corpus

Take following two sentences as examples:

*(E1) 3 名抗议者在**冲突**中受伤。(Annotated trigger mention)*

*(Three protestors were injured in the **conflict**.)*

*(E2) 双方各有数人在**冲突**中受伤。(Un-annotated trigger mention)*

*(Several people from both sides were injured in the **conflict**.)*

Although the two examples are similar, "冲突" (conflict) in example (E1) is annotated as a trigger mention of the *Conflict* event while the one in example (E2) is not annotated. With the extreme example of "战争" (war), as the trigger of the *Conflict* event, among 11 trigger mentions concerned with "朝鲜战争" (Korean war) and "海湾战争" (gulf war), four of them are annotated as *Conflict* event while the others are ignored. Those un-annotated true trigger mentions would make the classifier difficult to distinguish true trigger mentions from pseudo ones.

For the high ratio of pseudo trigger mentions to true ones, Table 3 shows top 5 imbalanced triggers from the training set of the ACE 2005 Chinese corpus and justifies the difficulty for a classifier to identify a true trigger mention, especially for those of a particular event type, which appears only a few times in the training set.

Trigger[2]	#True trigger mentions	#Pseudo trigger mentions
投资 (invest)	1	67
建设 (set up)	1	66
取得 (obtain)	1	52
发 (provide)	1	36
给 (give)	2	64

TABLE 3 – Top 5 triggers with the highest ratios of pseudo trigger mentions to true ones in the ACE 2005 Chinese corpus

Recently, Li et al. (2012) justified that trigger identification was most critical for the performance of Chinese event extraction. In this paper, we also focus on trigger identification and its impact on overall Chinese event extraction.

In order to address the above-mentioned two critical issues in Chinese event extraction, this paper proposes a joint model of trigger identification and event type determination to improve the performance of trigger identification and overall Chinese event extraction. Besides, several trigger filtering schemas are introduced to filter out those pseudo trigger mentions as many as possible.

The rest of this paper is organized as follows. Section 2 overviews the related work. Section 3

[2] Most Chinese words have more than one sense. Here, we just give the one when it acts as a trigger.

describes the joint model of trigger identification and event type determination. Section 4 introduces those trigger filtering schemas. Section 5 evaluates our approach and shows its effectiveness over a strong baseline. Section 6 concludes the paper with future work.

2 Related work

To better understand the Chinese event extraction task as defined in ACE, where an event is defined as a specific occurrence involving participants, we list some ACE terminologies:

Event mention: a phrase or sentence within which an event is described, including a trigger and its arguments.

Trigger: the main word which most clearly expresses the occurrence of an event, so recognizing an event can be recast as identifying a corresponding trigger.

Trigger mention: a reference to a trigger word.

Trigger type/Event type: the type of an event.

Argument: the entity mentions involved in an event.

Argument role: the relation of an argument to an event where it participates.

In the literature, almost all the existing studies on event extraction are concerned with English. While earlier studies focus on sentence-level extraction (Grishman et al., 2005; Ahn, 2006; Hardy et al., 2006), later ones turn to employ high-level information, such as document (Maslennikov and Chua, 2007; Finkel et al., 2005; Patwardhan and Riloff, 2009), cross-document (Ji and Grishman, 2008), cross-event (Gupta and Ji, 2009; Liao and Grishman, 2010) and cross-entity (Hong et al., 2011) information.

2.1 Chinese event extraction

Compared with tremendous efforts in English event extraction, there are only a few studies on Chinese event extraction.

Some studies focused on feature selection. Tan et al. (2008) used a local feature selection method to ensure the performance of trigger classification and applied multiple levels of patterns to improve their coverage in argument classification. Fu et al. (2010) applied a feature weighting algorithm to re-weight various features extracted for trigger identification and event type determination. Chen and Ji (2009b) applied various kinds of lexical, syntactic and semantic features to address the special issues in Chinese. They also constructed a global errata table to record the inconsistency in the training set and used it to correct the inconsistency in the test set.

The other studies focused on automatic expansion of event triggers to improve the recall. Chen and Ji (2009a) proposed a bootstrapping framework, which exploited extra information captured by an English event extraction system. Ji (2009) first extracts some cross-lingual predicate clusters using bilingual parallel corpora and a cross-lingual information extraction system, and then employs the derived clusters to expand the triggers. Qin et al. (2010) described a method to expand the event triggers for Chinese event type determination based on a Chinese semantic dictionary "TongYiCi CiLin (expansion version)". Li et al. (2012) proposed a novel inference mechanism to infer new trigger words by employing compositional semantics inside Chinese triggers. Their system achieved the state-of-the-art performance of 67.4 units in F1-measure on the ACE 2005 Chinese corpus, ignoring the post-processing – discourse consistency.

2.2 Joint modeling

While a pipeline model may suffer from the errors propagated from upstream tasks, a joint model can benefit from the close interaction between two or more tasks: it not only allows the uncertainty about one task to be carried forward to next ones but also allows useful information from one task to be carried backward to previous ones. Recently, joint modeling has been widely attempted in various NLP tasks, such as joint named entity recognition and syntactic parsing (Finkel and Manning, 2009), joint syntactic parsing and semantic role labeling (Li et al., 2010), joint anaphoricity and coreference determination (Denis and Baldridge, 2007; Iida and Poesio, 2011).

In the event extraction task, only a few studies are concerned with joint modeling, mostly in the bio-molecular domain. Riedel et al. (2009) used Markov Logic as a general purpose framework for jointly modeling the complete bio-molecular event structure for a given sentence. Poon and Vanderwende (2010) also adopted Markov Logic for bio-molecular event extraction in jointly predicting events and their arguments. Riedel and McCallum (2011) presented three joint models for bio-molecular event extraction. While the first model jointly predicts triggers and their arguments and the second model enforces additional constraints that ensure the consistency between events in hierarchical regulation structures, the third model integrates the first one and the second one in explicitly capturing the interaction of various arguments in the same event. Do et al. (2012) constructed a timeline of events mentioned in a given text which proposed a joint inference module that enforced global coherency constraints on the final outputs of the two pairwise classifiers, one between event mentions and time intervals, and one between event mentions themselves.

Our joint model is inspired by both Roth and Yih (2004) on joint named entity recognition and relation extraction and Denis and Baldridge (2007) on joint anaphoricity determination and coreference resolution. However, as far as we know, there are no successful models for jointly solving Chinese trigger identification and event type determination.

2.3 Trigger filtering

With the high ratio of pseudo trigger mentions to true ones, it is natural to filter out those unlikely trigger mentions in a preprocessing step. Basically, the general purpose for instance filtering is to reduce the class distribution imbalance by discarding harmful or superfluous instances.

In the literature, instance filtering has been widely employed in various NLP tasks. As for event extraction, there are also a few relevant studies. Patwardhan and Riloff (2009) first applied a self-trained relevant sentence classifier to identify relevant regions and split all candidate sentences into two sets: relevant and irrelevant sentences. Then, they used a pattern-based classifier to recognize events from those relevant sentences and a SVM-based classifier to recognize events from those irrelevant sentences. Landeghem et al. (2009) provided a negative-instances filter to check whether the length of the sub-sentence spanned by a candidate event does not exceed a certain value. Landeghem et al. (2010) further designed a false-positive filter using specific categories of relations to serve as negative indicators in Bio-NLP. Liao and Grishman (2010) applied a pseudo co-testing algorithm based on various criteria, such as informativeness, representativeness and diversity of the sentence, to filter out those pseudo samples to reduce annotation labour in event corpus annotation.

3 Joint modeling of trigger identification and event type determination

In this section, an ILP (Integer Logic Programming) -based inference framework is proposed to jointly model trigger identification and event type determination in reducing the influence of un-annotated true trigger mentions in the ACE 2005 Chinese corpus. Besides, a CRF (Conditional Random Field) model is applied as a supplement to the ME model to capture local sequential information around a trigger mention in trigger identification.

3.1 Joint inference of trigger identification and event type determination

As mentioned in Section 1, many true trigger mentions in the ACE 2005 Chinese corpus are not annotated. When training a classifier to identify trigger mentions, these un-annotated true trigger mentions in the training set will be extracted as negative samples. This will make the trigger identifier wrongly classify many true trigger mentions as pseudo ones, resulting in low recall in trigger identification. On the contrary, without the interference of these un-annotated true trigger mentions, the event type determiner has the higher probability of recognizing these annotated true trigger mentions as some kinds of events. This indicates the necessity and potential of jointly modeling for trigger identification and event type determination.

Besides, although the ME (Maximum-Entropy) model has been widely used in various subtasks of event extraction and achieved certain success in capturing the global information around a trigger mention, our experimentation shows that it suffers from low precision in trigger identification. To overcome this problem, a CRF model is introduced in trigger identification to capture the local sequential information. Our preliminary experimentation shows that the CRF model is much complementary to the ME model in trigger identification.

In our joint model, an ILP-based inference framework is introduced to integrate two trigger identifiers and one event type determiner. Figure 1 shows the ILP-based inference framework, which integrates a CRF-based trigger identifier (CRF_I) with an ME-based trigger identifier (ME_I) and an ME-based event type determiner (ME_D). The features used by ME_D and ME_I are as same as Li et al. (2012).

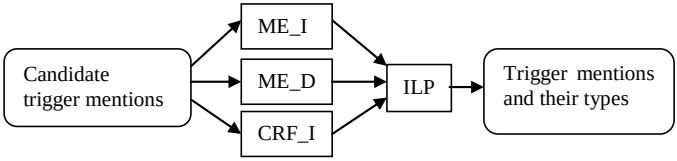

FIGURE 1 – Joint modeling of trigger identification and event type determination

ILP is a mathematical method for constraint-based inference to find the optimal values for a set of variables that minimize an objective loss function in satisfying a certain number of constraints. In the literature, ILP has been widely used in various NLP tasks (e.g., Roth and Yih, 2004; Barzilay and Lapata, 2006; Iida and Poesio, 2011; Do et al., 2012) in combining multiple classifiers, where the traditional pipeline architecture is not appropriate.

We assume $p_{ME\_I}(EVENT|Tr_{i,j})$ is the probability of ME_I identifying a trigger mention as a true one, where $Tr_{i,j}$ is the *jth* mention of the *ith* trigger word in a discourse, and $p_{ME\_d}(R_k\ |Tr_{i,j})$ *is* the probability of ME_D determining a trigger mention as an event of type R_k. Like Roth and Yih (2004), we define following assignment costs:

$$c^{I}_{<i,j>} = -\log(p_{ME\_I}(EVENT \mid Tr_{i,j})) \quad (1)$$

$$\bar{c}^{I}_{<i,j>} = -\log(1 - p_{ME\_I}(EVENT \mid Tr_{i,j})) \quad (2)$$

$$c^{D}_{<i,j>} = -\log(p_{ME\_D}(R_k \mid Tr_{i,j})) \quad (3)$$

$$\bar{c}^{D}_{<i,j,k>} = -\log(1 - p_{ME\_D}(R_k \mid Tr_{i,j})) \quad (4)$$

where $c^{I}_{<i,j>}$ is the cost of $Tr_{i,j}$ as an event trigger mention while $\bar{c}^{I}_{<i,j>}$ is the cost of $Tr_{i,j}$ not as an event trigger mention; $c^{D}_{<i,j>}$ is the cost of $Tr_{i,j}$ as an event trigger mention of type R_k while $\bar{c}^{D}_{<i,j,k>}$ is the cost of $Tr_{i,j}$ not as an event trigger mention of type R_k.

Besides, we use indicator variable $x_{<i,j>}$ that is set to 1 if $Tr_{i,j}$ is an event mention, and 0 otherwise. Similar to $x_{<i,j>}$, we use another indicator variable $y_{<i,j,k>}$ that is set to 1 if $Tr_{i,j}$ is an event mention of type R_k, and 0 otherwise. Finally, the objective function of the ILP-based inference framework can be represented as follows, where D is the set of trigger words in a discourse and M_i is the set of all mentions with the same *ith* trigger word,

$$\begin{aligned} \min \sum_{i \in D} \sum_{j \in M_i} (c^{I}_{<i,j>} x_{<i,j>} + \bar{c}^{I}_{<i,j>} (1 - x_{<i,j>}) \\ + \sum_{i \in D} \sum_{j \in M_i} \sum_{1 \le k \le 33} c^{D}_{<i,j,k>} y_{<i,j,k>} + \bar{c}^{D}_{<i,j,k>} (1 - y_{<i,j,k>}) \end{aligned} \quad (5)$$

Subject to

$$x_{<i,j>} \in \{0,1\} \qquad \forall i \in D \wedge j \in M_i \quad (6)$$

$$y_{<i,j,k>} \in \{0,1\} \qquad \forall i \in D \wedge j \in M_i \wedge 1 \le k \le 33 \quad (7)$$

To enforce consistency, we add further constraints:

(C1) Event type constraint: if a trigger mention $Tr_{i,j}$ belongs to event type R_k, it must be a true trigger mention.

$$x_{<i,j>} \ge y_{<i,j,k>} \qquad \forall i \in D \wedge j \in M_i \wedge 1 \le k \le 33 \quad (8)$$

(C2) True trigger mention constraint: if a mention $Tr_{i,j}$ is a true trigger mention, it must belong to only one event type R_k.

$$x_{<i,j>} = \sum_{1 \le k \le 33} y_{<i,j,k>} \qquad \forall i \in D \wedge j \in M_i \quad (9)$$

(C3) Discourse consistency: all trigger mentions which have the same trigger word must have the same event type in a discourse, or all of them aren't true trigger mentions.

$$x_{<i,j>} = x_{<i,l>} \qquad \forall i \in D \wedge j, l \in M_i \quad (10)$$

As a discourse-driven language, the syntax of Chinese is not as strict as English and very often we need to count on the discourse-level information to understand the meaning of a Chinese sentence. As for an event, a trigger may appear many times in a discourse and a trigger is considered discourse-consistent when all its appearances have the same event type. The statistics on the training sets of both the ACE 2005 Chinese and English corpora shows that within a discourse, there is a strong consistency in both Chinese and English between trigger mentions: if one instance of a word is a trigger, all the other instances in the same discourse will be a trigger

of the same event type with a very high probability (> 90% in Chinese).

(C4) Different event types for trigger mentions in a clause: Different trigger mentions in a clause must have different event types.

$$y_{<i,j,k>} + y_{<r,t,k>} < 2 \quad \forall Tr_{i,j} \in cl_a \wedge Tr_{r,t} \in cl_a \wedge i,r \in D \wedge j \in M_i \wedge t \in M_r \wedge 1 \le k \le 33 \wedge Tr_{i,j} \neq Tr_{r,t} \quad (11)$$

where cl_a is the set of words in clause a.

For example, trigger mentions "暴力" (violence, *Conflict* event) and "冲突" (conflict, *Conflict* event) may occur together to form a phrase "暴力冲突" and we should identify them as one *Conflict* event instead of two.

(C5) Cross-event constraint: Those events with high probability of co-occurring in a discourse must have same indicator values (event or non-event).

$$y_{<i,j,k>} = y_{<r,t,k'>} \quad \forall i,r \in D \wedge j \in M_i \wedge t \in M_r \wedge <k,k'> \in O \wedge 1 \le k \le 33 \wedge 1 \le k' \le 33 \quad (12)$$

where O is the set of event type pairs with high probability of co-occurring[3] in the training set.

As mentioned in Liao et al. (2010), there are strong correlations among event types in a document. We also find out that some events have a high probability of co-occurring in a discourse. For examples, if there is a *Die* event in a discourse, there is more than 70% probability that an *Attack* event also appears in the same discourse.

3.2 CRF-based trigger identification

CRF is a conditional sequence model which represents the probability of a hidden state sequence given some observations. It is a popular and efficient machine learning technique for supervised sequence labeling and has been applied to many NLP tasks.

We choose CRF due to its ability of capturing the local information around a trigger mention. For this purpose, we build a separate character-based trigger identifier and use the CRF model to label each character with a tag indicating whether it is out of a given trigger (O), the beginning of the trigger (B) or a part of the trigger except the beginning one (I). In this way, our CRF-based trigger identifier performs sequential labeling by assigning each character one of the three tags and a character assigned with tag B is concatenated with following characters with tag I to form a trigger. For example, example (E1) can be labelled as follows and ***冲突*** is identified as a trigger.

*(E3) 3/O 名/O 抗/O 议/O 者/O 在/O **冲/B 突/I** 中/O 受/O伤/O 。/O*

To achieve high precision as much as possible, we just use the character itself and characters around it as features. For each character c_i, assuming its 5-windows characters are c_{i-2} c_{i-1} c_i c_{i+1} c_{i+2}, our CRF-based trigger identifier adopts following features: c_{i-2}, c_{i-1}, c_i, c_{i+1}, c_{i+2}, $c_{i-1}c_i$, c_ic_{i+1}, $c_{i-2}c_{i-1}c_i$, $c_{i-1}c_ic_{i+1}$, $c_ic_{i+1}c_{i+2}$.

Our preliminary experimentation shows that the CRF model achieves high precision and is much complementary to the ME model in trigger identification. In this paper, the CRF-based trigger identifier is included into the ILP-based inference framework by introducing one more constraint.

(C6) CRF trigger constraint: due to high precision of the CRF model, we include a simple inference rule in our joint model:

[3] The threshold of the probability of the event type pair is fine-tuned to 0.70 using the development set.

$$x_{<i,j>} = 1 \quad \text{if the CRF model identifies } Tr_{i,j} \text{ as an event} \tag{13}$$

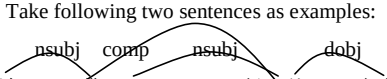
4 Trigger filtering

In this section, we firstly introduce two trigger filtering mechanisms: dependency-based inference mechanism and divide-and-conquer mechanism, to remove pseudo trigger mentions. Then we provide another trigger filtering mechanism by employing both local and global discrimination to filter out those un-annotated true trigger mentions.

4.1 Dependency-based inference mechanism

Some single-character trigger words are very ambiguous, e.g. with more than one senses and POSs (part of speeches), and it is hard to tell their true trigger mentions from their pseudo ones. For example, "到" (come) has 246 mentions (not including those words containing "到") corresponding to 6 senses and 3 POSs, and only 84 of them are true trigger mentions. In this paper, according to the total number of senses and POSs, we select 32 top ambiguous single-character words, such as "到", "往", "并", and employ a dependency-based inference mechanism to filter out their occurrences as pseudo trigger mentions.

In a sentence, there normally exists strong structural dependency between a trigger and its arguments. Take following two sentences as examples:



(E4) 朱婉清/PER 带 儿子/PER 已经 到 了 纽约/GPE。

(Zhu Wanqing has arrived New York with her son.)

(E5) 我/PER 找 不 到 工作。

(I can't find a job.)

(E4) is a positive example where "到" (arrive) is a trigger mention of the *Movement* event and there is a strong structural dependency between the trigger and its arguments, while example (E5) is a negative example where "到" is not a *Movement* event and there is no obvious dependency between the trigger and subject "我" (I).

In this paper, we adopt Markov Logic Network (MLN) to determine whether a single-character word is a trigger mention or not. For this purpose, we construct two inference formulas based on the dependency and POS information as follows, similar to Poon and Vanderwende (2010):

$$Token(i,+w) \wedge Pos(i, +o) \Rightarrow Event(i)$$

$$Token(j,+w) \wedge Dep(i, j, +r) \Rightarrow Event(i)$$

where

Token(i,w): whether token *i* has word *w*;

Pos(i, o): whether token *i* has POS *o*;

Dep(i, j, r): whether there is a dependency edge from *i* to *j* with relation *r* or relation path *r* (e.g., ccomp->nsubj, pp->pobj);

Event (i): whether token *i* is an event trigger mention.

Here, notation "+" signifies that the MLN contains an instance of the formula, with a separate weight, which is learnt from the training set. In particular, the open-source *Alchemy* package[4] is employed for learning and inference. Like Pooh and Vanderwende (2010), we use the Stochastic Gradient Descent (SGD) to learn weights and introduce MC-SAT, a slice sampling Markov chain Monte Carlo algorithm, to make the inference. To obtain a final assignment, we set the query atoms with probability no less than 0.3 (fine-tuned to maximize F1 on the development set) to true and the rest to false, in order to keep true trigger mentions.

4.2 Divide-and-conquer mechanism

Trigger mentions with high ratios of pseudo trigger mentions to true ones are treated differently from those with low ratios, using a threshold θ[5]. For the former, two patterns are applied to filter those high-unlikely trigger mentions as follows, while for the later, we adopt a ME classifier to filter out pseudo trigger mentions as many as possible.

(P1) <entity type of subject> <trigger[6]*>*

(P2) <trigger> <entity type of direct/indirect object>

where the subject and object must be the arguments of that event.

4.3 Local and global discrimination

Like the representativeness of an event, the *discrimination* considers the distributional similarity of a pseudo trigger mention against those true trigger mentions. If a pseudo trigger mention is similar to one of those true trigger mentions, it should be filtered out from the set of pseudo trigger mentions due to its low *discrimination*; otherwise, it should be kept in the set of pseudo trigger mentions due to its high *discrimination*. For an un-annotated true trigger mention which is extracted as a pseudo trigger mention, it tends to have the large distributional similarity with those true trigger mentions and should be filtered from the set of pseudo trigger mentions due to its low discrimination.

Normally, the distribution of events of a particular type is not balanced. For example, in the ACE 2005 Chinese corpus, *Movement* events occur most frequently in the training set with 701 times and occupy 22.0% of all event occurrences, while for the 10 least frequently-occurring event types (e.g. *Execute*, *Delare-Bankruptcy*, *Divorce*, etc.), each of them only occupies less than 1%.

To well address the above phenomenon, this paper introduces two types of discrimination, local discrimination *local_d* and global discrimination *global_d*, to filter out those un-annotated true trigger mentions and reduce their negative impact on trigger identification.

On the one hand, the local discrimination measures the similarity between a particular pseudo trigger mention and all of true trigger mentions with the same trigger word (shorted as STMs). In our case, each trigger mention is represented as a vector of features and the cosine similarity is applied to measure the similarity between a pseudo trigger mention and each STM.

If the pseudo trigger mention is similar to one STM, their similarity will be high. Instead of calculating the average similarity, we calculate the maximum similarity to identify whether the pseudo trigger mention should be filtered out:

[4] http://alchemy.cs.washington.edu/

[5] Threshold θ is fine-tuned to 3, using the development set.

[6] We just extract those trigger mentions with POS verb.

$$local\_d(\vec{p}) = \underset{i \le i \le n}{Max}(sim(\vec{p}, \vec{m_i})) \quad (14)$$

where n is the number of STMs for the pseudo trigger mention p and $sim(\vec{p}, \vec{m_i})$ is the cosine similarity between p and its STM m_i.

On the other hand, the global discrimination comes from the probability of a pseudo trigger mention belonging to the set of true trigger mentions in the training set. While the local discrimination measures the distance between a pseudo trigger mention and those STMs, the global discrimination calculates the distance between a pseudo trigger mention and all the true trigger mentions. In this paper, we use the probability from the event type determiner to calculate the global discrimination:

$$global\_d(\vec{p}) = \underset{1 \le i \le m}{Max}(p(R_i \mid \vec{p})) \quad (15)$$

where m is the number of event types, R_i is the type of a particular event and $p(R_i \mid \vec{p})$ is the probability from the event type determiner.

Given local and global discrimination, the final *discrimination* is calculated via linear interpolation.

$$\text{discrimination}(\vec{p}) = 1 - (\alpha * global\_d(\vec{p}) + (1-\alpha) * local\_d(\vec{p})) \quad (16)$$

where coefficient α ($0 \le \alpha \le 1$) is fine-tuned to 0.75 on the development set and all trigger mentions whose discrimination values are lower than 0.1 are filtered out.

5 Experimentation and discussion

In this section, we evaluate our trigger filtering mechanisms and joint model in Chinese trigger identification and its application to overall Chinese event extraction.

5.1 Experimental setting

For fair comparison, we use the state-of-the-art Chinese event extraction system, as described in Li et al. (2012), as our baseline[7], which consists of four typical components, trigger identification, event type determination, argument identification and argument role determination, and works in a pipeline way. During testing, each word in the test set is first scanned for instances of known triggers from the training set and then scanned by employing the compositional semantics inside Chinese triggers to infer instances of unknown triggers. When an instance is found, the trigger identifier is applied to distinguish those true trigger mentions from pseudo ones. If true, the event type determiner is then applied to recognize its event type. For any entity mention in a sentence which is identified as an event, the argument identifier is employed to assign its possible arguments afterwards. Finally, the argument role determiner is introduced to assign a role to each argument.

Besides, we adopt the same experimental setting as Li et al. (2012) and all the evaluations are done on the ACE 2005 Chinese corpus (only the training data is available), which contains 633 Chinese documents annotated with 8 predefined event types and 33 predefined event subtypes. Similar to previous studies, we treat these subtypes simply as 33 separate event types and do not

[7] To simplify the experiments, the baseline only contains compositional semantics in Li et al. (2012).

consider the hierarchical structure among them. Particularly, we randomly select 567 documents as the training set and the remaining 66 documents as the test set. Besides, we reserve 33 documents in the training set as the development set and follow the setting of ACE diagnostic tasks and use the ground truth entities, times and values for our training and testing. As for evaluation, we also follow the standards as defined in Li et al (2012):

- A trigger is **correctly** identified if its position in the document matches a reference trigger;
- An event type is **correctly** determined if the trigger's event type and position in the document match a reference trigger;
- An argument is **correctly** identified if its involved event type and position in the document match any of the reference argument mentions;
- An argument role is **correctly** determined if its involved event type, position in the document, and role match any of the reference argument mentions.

Finally, all the sentences in the corpus are divided into words using a Chinese word segmentation tool (ICTCLAS[8]) with all entities annotated in the corpus kept. Besides, we use Berkeley Parser[9] and Stanford Parser[10] to create the constituent and dependency parse trees and employ the ME model[11] to train individual component classifiers.

5.2 Trigger filtering

Table 4 shows the impact of the three trigger filtering mechanisms in Chinese event extraction on the held-out test set. From Table 4, we can find out that our trigger filtering mechanisms enhance the F1-measures of trigger identification, event type determination, argument identification and argument role determination by 2.5, 2.7, 2.6 and 2.3 units, respectively. It justifies the effectiveness of our trigger filtering mechanisms in addressing the low quality of the ACE 2005 Chinese corpus.

Performance / System	Trigger identification			Event type determination			Argument identification			Argument role determination		
	P%	R%	F1	P%	R%	F1	P%	R%	F1	P%	R%	F1
Baseline	73.5	62.1	67.4	70.2	59.1	64.2	58.0	48.9	53.0	54.7	44.5	49.1
+DepInference	75.4	61.9	68.0	71.9	59.1	64.9	59.8	48.9	53.8	56.1	44.5	49.6
+D&C	**76.7**	62.9	69.2	**73.1**	59.9	65.6	**60.7**	49.7	54.7	**57.2**	45.4	50.6
+L&G	75.0	**65.4**	**69.9**	71.6	**62.7**	**66.9**	59.5	**52.1**	**55.6**	56.1	**47.5**	**51.4**

TABLE 4 – Contribution of trigger filtering to Chinese event extraction (incremental)

Detailed analysis shows that

- The dependency-based inference (**DepInference**) filters out 8.5% of candidate trigger mentions and 98.8% of them are pseudo ones. As a result, Table 4 shows that this inference improves the precision by 1.9 units for trigger identification with only a slight loss of 0.2 units in the recall. Given the fact that only 20% trigger mentions are single-character words

[8] http://ictclas.org/
[9] http://code.google.com/p/berkeleyparser/
[10] http://nlp.stanford.edu/software/lex-parser.shtml
[11] http://mallet.cs.umass.edu/

and some of them can be distinguished by the trigger identifier, this justifies the effectiveness of the dependency-based inference in filtering out those pseudo single-character trigger mentions.

- While the divide-and-conquer mechanism **(D&C)** filters out 20.3% of candidate trigger mentions, it is surprising that less than 6% of filtered trigger mentions are true ones. As a result, the divide-and-conquer mechanism much improves the F1-measure, precision and recall by 1.3, 1.0 and 1.2 units respectively. Our exploration also shows that our two simple patterns can recover almost 40% of the filtered true trigger mentions.
- The local and global discrimination (**L&D**) improves the recall by 2.5 units with a loss of 1.7 units in precision. When coefficient α is fine-tuned to 0.75 and the threshold of $\text{discrimination}(\vec{p})$ is fine-tuned to 0.1, 5.8% of pseudo trigger mentions are filtered out, in which almost 80% of them are un-annotated true trigger mentions.

5.3 Joint modeling

Table 5 shows the contribution of both Trigger Filtering (**TF**) and Joint Modeling (**JM**) of trigger identification and event type determination to overall Chinese event extraction on the held-out test set. Table 5 indicates that our approach can improve the F1-measures of trigger identification, event type determination, argument identification and argument role determination (i.e. overall event extraction) by 5.7, 6.0, 5.1 and 4.8 units, respectively, largely due to the dramatic increase in recall of 9.8, 9.8, 8.3 and 7.1 units respectively.

Performance / System	Trigger identification			Event type determination			Argument identification			Argument role determination		
	P%	R%	F1	P%	R%	F1	P%	R%	F1	P%	R%	F1
CRF	**83.7**	43.3	57.1

Table 5 – Contribution of joint modeling to Chinese event extraction

Table 5 also shows that

- For trigger identification, the ILP-based joint model (w/o CRF) improves the F1-measure by 3.1 units due to a big gain of 6.0 units in recall and a small loss of 0.4 units in precision. This result indicates that event type determination can much help trigger identification to improve its performance. This justifies the effectiveness of our ILP-based joint model. As for the loss in precision, it's not surprising that more pseudo trigger mentions tend to be wrongly recognized as true ones since our goal of various constraints in the ILP-based joint model is to identify those true trigger mentions as many as possible.
- Further inclusion of the CRF model as a constraint in the joint model improves the F1-measure of trigger identification by 4.1 units due to a big gain of 7.9 units in recall and a small loss of 0.5 units in precision. Our experimentation also shows that the CRF model is much complementary to the ME model in trigger identification with a high precision of 83.7

units and a low recall of 43.3 units, and the new constraint helps bring back 1.9% of true trigger mentions.

- We also apply the postprocessing mechanism of discourse consistency in Li et al. (2012) to both the baseline and our approach, and their improvement of F1-measues in trigger identification are 3.1 units and 2.4 units respectively. The reason for the loss of our approach is that our three trigger filtering mechanisms reduce the probability of the consistency in a discourse for those filtered pseudo trigger mentions.
- Finally, our trigger filtering schema and joint modeling of trigger identification and event type determination together significantly improve the recall for all of four components in Chinese event extraction with a decent gain in precision.

5.4 Discussion

From Table 5, we can also find out that the performance gaps between trigger identification and event type determination are rather small in all settings (2.9~3.2 units in F1-measures). The fact is that, even if we just assign the type with the highest prior probability to all true trigger mentions, the accuracy can still reach more than 90%. This indicates the importance of trigger identification in overall Chinese event extraction.

Normally in a pipeline system, the improvement in event type determination is always lower than that in trigger identification due to the pipeline nature (i.e. propagated errors from the upstream processes). However, Table 5 shows that our improvement in F1-measure for event type determination is higher than that for trigger identification. This is due to joint modeling of these two components in well capturing the interaction between them.

Conclusion

In order to address the special characteristics of Chinese event extraction, this paper presents a joint model to better integrate trigger identification and event type determination. Besides, several trigger filtering mechanisms are proposed to reduce the influence of those un-annotated true trigger mentions in the corpus as many as possible. The experimental results show that our approach can significantly improve the performance of Chinese trigger identification and overall Chinese event extraction.

Besides those un-annotated true trigger mentions, which much encumber the performance of trigger identification and overall event extraction, we find that 9.7% of the pseudo trigger mentions in the ACE 2005 Chinese corpus are actually true ones. Therefore, a natural extension of this work is to explore some effective methods to recover those pseudo-annotated true trigger mentions. Moreover, encouraged by the success of the ILP-based joint model, we will further explore more on this joint model and more effective joint models to event extraction.

ABSTRACT

Current character-based approaches are not robust for cross domain Chinese word segmentation. In this paper, we alleviate this problem by deriving a novel enhanced character-based generative model with a new abstract aggregate candidate-feature, which indicates if the given candidate prefers the corresponding position-tag of the longest dictionary matching word. Since the distribution of the proposed feature is invariant across domains, our model thus possesses better generalization ability. Open tests on CIPS-SIGHAN-2010 show that the enhanced generative model achieves robust cross-domain performance for various OOV coverage rates and obtains the best performance on three out of four domains. The enhanced generative model is then further integrated with a discriminative model which also utilizes dictionary information. This integrated model is shown to be either superior or comparable to all other models reported in the literature on every domain of this task.

KEYWORDS : Chinese Word Segmentation, Cross-Domain, Robust Feature, Utilize Dictionary

Proceedings of COLING 2012: Technical Papers, pages 1653–1670,
COLING 2012, Mumbai, December 2012.

1 Introduction

As words are the basic units for text analysis, Chinese word segmentation (CWS) is critical for many Chinese NLP tasks such as parsing. However, current state-of-the-art character-based approaches fail to give robust performance for cross-domain tests (Gao and Vogel, 2010; Huang et al., 2010; Jiang and Dong, 2010; Wang et al., 2012, Sun et al., 2012), despite their acceptable performance for in-domain tests. For example, with the same PKU-News training corpus, the best system in SIGHAN-2005 (Emerson, 2005) achieved a high in-domain performance (96.9% in F-score) in open[1] tests, while the best cross-domain performance for the medicine domain only achieved 93.8%[2] in CIPS-SIGHAN-2010 (Zhao and Liu, 2010) open tests.

Their poor performances result not only from the fact that out-domains have higher out-of-vocabulary (OOV) rates (please refer Table 1 in Section 3.1), but also from the fact that various domains frequently possess different tag distributions for the same character, especially for those out-domain OOV words (which are also technical terms most of times). For example, "酸" (acid) is a typical suffix of medical terms, such as "尿酸" (uric acid) and "氨基酸" (amino acid), and is frequently tagged as "E" in the medicine domain. However, it is usually a single-character word which means 'sour' in general text, and should be tagged as "S". As a result, those surface features (such as character n-grams) adopted in the approaches mentioned above have more difficulty in identifying the correct position-tag, which is a member of {**B**eginning, **M**iddle, **E**nd, **S**ingleton}(Xue, 2003), of a character within an OOV word in this case. Since many technical OOV words appear in the out-domain text, the performance thus degrades sharply. For instance, when we test the main stream character-based discriminative approach for medicine domain in CIPS-SIGHAN-2010 contest, 27.7% of the wrong segmented words are OOV terms.

On the other hand, unlike surface features, the distribution of the proposed abstract feature, which checks if the given candidate prefers the corresponding position-tag of the longest dictionary matching word, is almost invariant across different domains. Enhanced discriminative approaches (Low et al., 2005; Zhao et al., 2010) which adopt this abstract feature thus show better generalization capability in our cross-domain tests.

To adopt the above matching-longest-word feature, a dictionary is required. It is well known that the domain dictionary provides direct and reliable hints for deciding the position-tags of characters within a covered OOV word. Furthermore, unlike named entity, technical terms of a specific domain usually can be considerably covered by a domain dictionary. Since domain dictionaries are frequently available for NLP related projects (e.g., technical manual translation), they can thus provide big help in real applications.

However, the above dictionary related feature utilized in discriminative approaches (Low et al., 2005; Zhao et al., 2010) cannot be directly adopted by a generative model[3]. Therefore, we propose a new tag-matching-status feature for checking if the selected position-tag matches the longest dictionary-matching-word, and derive a novel enhanced character-based generative model. The proposed feature not only induces an additional probabilistic factor but also possesses richer information in comparison with the one adopted in previous works.

[1] Unlike close test, the open test can use any language resource, not restricted to training data only.
[2] 93.8% only corresponds to 23.7% sentence accuracy rate (average 23.3 words per sentence in the medicine corpus), evaluated from its associated 94.0% recall-rate, while 96.9% corresponds to 46.9% sentence accuracy.
[3] It is required by the integrated approach given at Section 4.2.

Several factors that might affect the performance of the new model are studied in this paper: including the context information, the OOV coverage rate of the dictionary, and the weight of the new factor in the model. We evaluated our final system on the CIPS-SIGHAN-2010 Bakeoff data. The obtained results not only convincingly demonstrate the effectiveness of the proposed model for cross-domain CWS, but also achieve the best performance on 3 out of 4 domains in the open test. Afterwards, the proposed enhanced generative model is integrated with another enhanced discriminative model (Low et al., 2005) to further improve the performance, and achieves the best performance on all the tested corpora.

The remainder of this paper is organized as: Section 2 discusses how to incorporate dictionary information and section 3 describes the proposed models. Empirical results and error analysis are presented in section 4 and 5. Section 6 reviews the related work.

2 Dictionary related features

2.1 Word-ID or Word-Matching-Indicator?

Given a dictionary, there are two kinds of features that can be utilized: word-ID, which are binary features that fire only when the word matches one specific word entry, and Word-Matching-Indicator (e.g. TM defined in Section 2.3), which checks the relationship between the assigned position tag of the current character and the dictionary words within local context. Since the statistics of OOV words can never be learnt from the training corpus, the approaches that adopt word-ID as features (Zhang and Clark, 2007; Sun, 2010; Zhang and Clark, 2011) cannot really utilize the information of the OOV words kept in the dictionary. On the contrary, the word-matching-indicator is applicable for both IV and OOV words kept in the dictionary. This feature thus provides valuable information for those OOV words covered by the dictionary. Therefore, based on the positions of those dictionary matching words, two dictionary-related features (i.e., Dictionary Coverage Status and Tag Matching Status, to be specified later) are proposed in this paper, and they will be incorporated into the character-based generative model.

2.2 Dictionary Coverage Status

Let c_i be the i-th character in a given sentence. To check whether there are ambiguities with those dictionary matching words at c_i (and what kind of ambiguities it has), we propose the Dictionary Coverage Status feature, which is a member of {No-Dictionary-Word, No-Ambiguity, Crossed-Ambiguity[4], Included-Ambiguity, Mixed-Ambiguity} that are defined below. This status depends only on the given sentence and the dictionary, and is irrelevant to the position tag assigned to the character. Let D be the given dictionary which only contains multi-character words, and $c_{[i:j]}$ denotes the string from c_i to c_j (including c_j), then the conditions for "Included-Ambiguity" and "Crossed-Ambiguity" are defined below.

(A) Conditions for Included-Ambiguity (IA):

(1) Both c_i and c_{i+1} will be assigned "IA" if they meet the following condition (Figure 1(a)):

$$\exists j,l>0,k\geq j:\{c_{[i-j:i]},c_{[i-k:i+l]}\}\subseteq D;$$

(2) Both c_{i-1} and c_i will be assigned "IA" if they meet the following condition (Figure 1(b)):

$$\exists j,k>0,l\geq j:\{c_{[i:i+j]},c_{[i-k:i+l]}\}\subseteq D.$$

[4] Please note that ambiguity status is traditionally defined on words, but ours is defined on characters.

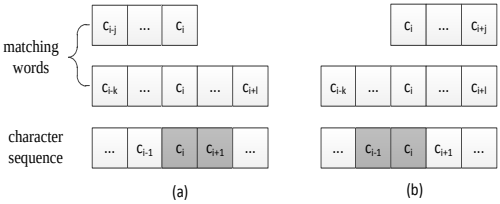

FIGURE 1 – Cases for Included-Ambiguous characters (marked in grey)

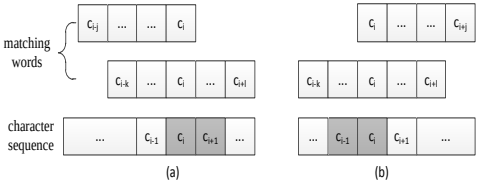

FIGURE 2 – Cases for Crossed-Ambiguous characters (marked in grey)

(B) Conditions for Crossed-Ambiguity (CA):

(1) Both c_i and c_{i+1} will be assigned "CA" if they meet the following condition (see Figure 2(a)):

$$\exists j,l > 0, 0 \le k < j : \{c_{[i-j:i]}, c_{[i-k:i+l]}\} \subseteq D ;$$

(2) Both c_{i-1} and c_i will be assigned "CA" if they meet the following condition (Figure 2(b)):

$$\exists j,k > 0, 0 \le l < j : \{c_{[i:i+j]}, c_{[i-k:i+l]}\} \subseteq D .$$

Then Dictionary Coverage Status at c_i (denoted by DC_i) can be decided as follows:

$$DC_i = \begin{cases} \text{No-Dictionary-Word, if no matching word is found;} \\ \text{Included-Ambiguity, if only (A) is satisfied;} \\ \text{Crossed-Ambiguity, if only (B) is satisfied;} \\ \text{Mixed-Ambiguity, if both (A) and (B) are satisfied;} \\ \text{No-Ambiguity, otherwise.} \end{cases}$$

The above definition implicitly implies that a character which possesses the same position-tag for all associated dictionary matching words will be assigned "No-Ambiguity".

For example, given a character sequence "大学生物" (university biology) and a set of dictionary-matching-words {"大学" (university), "大学生" (undergraduate)}, for characters '学' and "生", condition (A.1) is satisfied , but condition (B) is not; therefore, DC_2 and DC_3 should be set to "Included-Ambiguity". On the other hand, if the dictionary-matching-words are {"大学生", "生物" (biology)}, then condition (B.1) is satisfied, but condition (A) is not; DC_2 and DC_3 thus

should be set to "Crossed-Ambiguity". However, if we have all the three matching words {"大学", "大学生", "生物"}, then both condition (A.1) and condition (B.1) are satisfied; therefore, DC_2 and DC_3 should be set to "Mixed-Ambiguity" in this case. Furthermore, if the matching words are {"大学", "生物"}, then DC_2 and DC_3 would be "No-Ambiguity". Last, DC_1 and DC_4 are always "No-Ambiguity" for all above three different cases.

2.3 Tag Matching Status

To indicate the relationship between the tag assigned to c_i and those dictionary matching words which cover c_i, we introduce the Tag Matching Status feature (the abstract aggregate candidate-feature, and is abbreviated as **TM** from now on), which is a member of {Following-Longest-Word, Only-Following-Shorter-Word, Not-Following-Any-Word, Inapplicable} that are defined below. Denote the set of dictionary matching words that begin with c_i as $D_B = \{c_{[i:j]} \mid c_{[i:j]} \in D\}$, the set of dictionary matching words that enclose c_i as $D_M = \{c_{[j:k]} \mid c_{[j:k]} \in D, j < i < k\}$, and the set of dictionary matching words that end with c_i as $D_E = \{c_{[j:i]} \mid c_{[j:i]} \in D\}$. If c_i is tagged as t_i, then TM_i can be decided as follows:

(1) If $D_B \bigcup D_M \bigcup D_E = \varnothing$, which indicates that this character is not covered by any dictionary word, then TM_i is set to "Inapplicable".

(2) If $D_{t_i} = \varnothing$, and $D_B \bigcup D_M \bigcup D_E \neq \varnothing$ (where D_{t_i} is the set of dictionary matching words corresponding to t_i; for example, D_{t_i} will be D_B, if $t_i = B$. Please note that $D_S = \varnothing$, since the adopted dictionary only contains multi-character words), which indicates that the assigned tag does not follow any dictionary matching word, then TM_i is set to "Not-Following-Any-Word";

(3) If $\forall w \in (D_B \bigcup D_M \bigcup D_E), \exists w' \in D_{t_i} : \mathrm{len}(w') \geq \mathrm{len}(w)$, then TM_i is set to "Following-Longest-Word". It indicates that the assigned tag matches the corresponding position-tag of the longest dictionary matching word at that character;

(4) Otherwise, TM_i is set to "Only-Following-Shorter-Word". It indicates that the assigned tag does not match the corresponding position-tag of the longest dictionary matching word at that character, but matches that of some shorter words.

For example, when we consider the second character '学' in the sequence "大学生" and assume that the dictionary matching words are {"大学", "大学生"}: if the tag assigned to '学' is "M", then TM_2 will be "Following-Longest-Word"; if it is "E", then TM_2 will be "Only-Following-Shorter-Word"; if it is "B" or "S", TM_2 would be "Not-Following-Any-Word". Therefore, this candidate-feature is associated with each candidate of the position-tag. However, if no dictionary word covers this character, then TM_2 will be set to "Inapplicable" regardless of which tag is assigned to '学' (i.e., we do not want to disturb the original model in this case).

3 Proposed models

3.1 Enhanced generative model

Wang et al. (2009) proposed a character-based generative model for CWS, which is able to handle the dependency of character-bigrams within words and thus give a good balance for the performance of IV words and OOV words. Their approach adopts the character-tag-pair trigram model, and obtains the desired position-tag sequence $\tilde{t}_1^n$ as follows:

$$\bar{t}_1^n \equiv \arg\max_{t_1^n} \prod_{i=1}^{n} P([c,t]_i \mid [c,t]_{i-2}^{i-1}) \quad (1)$$

where $[c,t]_1^n$ is the associated character-tag-pair sequence for the given character sequence c_1^n.

To alleviate the data sparseness problem, we pre-convert the given character string into its corresponding unit string before segmentation, where the unit denotes a FN-String (which is a string mixed with foreign/Arabic/selected-punctuations [5] characters, such as "HTML5", "www.google.com", etc.), a CN-String (which is a string of **C**hinese **N**umbers consisting of Chinese digit-characters such as "六五七七二" (65772), etc.), or a single Chinese character. Therefore, a unit is either a Chinese character or a foreign/numerical expression as defined above, and is represented by either a Chinese-Character-ID or a Meta-Type-ID (i.e., FN-type or CN-type) in the model.

After the character string has been pre-converted into the unit string, we incorporate the dictionary related features proposed in Section 2 into the generative model and re-formulate it as follows:

$$\begin{aligned} \bar{t}_1^n &\equiv \arg\max_{t_1^n} P(t_1^n, TM_1^n \mid u_1^n, DW_1^n) \\ &= \arg\max_{t_1^n} \left[\frac{P([u,t,TM]_1^n \mid DW_1^n)}{P(u_1^n \mid DW_1^n)} \right] \\ &= \arg\max_{t_1^n} P([u,t,TM]_1^n \mid DW_1^n) \end{aligned} \quad (2)$$

where DW_i denotes the set of dictionary words that cover u_i (i-th unit). $P([u,t,TM]_1^n \mid DW_1^n)$ is then approximated by $\prod_{i=1}^{n} P([u,t,TM]_i \mid [u,t,TM]_{i-2}^{i-1}, DW_i)$ and its associated factor is further derived as follows:

$$\begin{aligned} & P([u,t,TM]_i \mid [u,t,TM]_{i-2}^{i-1}, DW_i) \\ &= P(TM_i \mid [u,t]_{i-2}^{i}, TM_{i-2}^{i-1}, DW_i) \times P([u,t]_i \mid [u,t,TM]_{i-2}^{i-1}, DW_i) \\ &\approx P(TM_i \mid MWL_i, DC_i, u_{i-2}^{i}) \times P([u,t]_i \mid [u,t]_{i-2}^{i-1}) \end{aligned} \quad (3)$$

where MWL_i denotes the Maximum Word Length of the words that cover u_i, DC_i (Dictionary Coverage Status) and TM_i (Tag Matching Status) are defined at Section 2.2 and Section 2.3, respectively. The first term $P(TM_i \mid MWL_i, DC_i, u_{i-2}^{i})$ is the tag matching factor, which is mainly introduced to give guidance in the case that the second term $P([u,t]_i \mid [u,t]_{i-2}^{i-1})$ (the original generative model) cannot give reliable prediction when the associated character-tag bigram is unseen in the training corpus.

Equation (3) weighs the tag matching factor and the character-tag trigram factor equally. However, it is reasonable to expect that they should be weighted differently according to their contribution. We thus combine these two factors via log-linear interpolation, which is shown as follows:

[5] Selected punctuations include those members from {'+', '-', '*', '/', '.', '%', '@'}.

$$\begin{aligned}\text{Score}(t_i) = \alpha \times \log P([u,t]_i \mid [u,t]_{i-2}^{i-1}) \\ + (1-\alpha) \log P(TM_i \mid MWL_i, DC_i, u_{i-2}^{i})\end{aligned} \quad (4)$$

Where α is the weighting coefficient to be decided from the development set, and $0 < \alpha < 1.0$.

3.2 Enhanced integrated model

To incorporate the dictionary information into the discriminative approach, Low et al. (2005) added two additional features (which are features (d) and (e) in the following list) to the widely adopted primitive templates described in (Ng and Low, 2004), and used them to enhance the original discriminative model (Xue, 2003):

(a) C_n $(n = -2, -1, 0, 1, 2)$; (d) MWL_0, t'_0;
(b) $C_n C_{n+1}$ $(n = -2, -1, 0, 1)$; (e) $C_n t'_0$ $(n = -1, 0, 1)$.
(c) $C_{-1} C_1$;

Let W denote the longest dictionary word that covers c_0, then MWL_0 denotes the length of W, and t'_0 denotes the corresponding tag of c_0 in W.

Since the enhanced generative model cannot utilize the features from future context, which is a common drawback of generative approaches (Wang et al., 2010), following the approach of (Wang et al., 2011), we further integrate the enhanced generative model with the above enhanced discriminative model via log-linear interpolation, shown as follows:

$$\begin{aligned}\text{Score}(t_i) = \beta \times [\alpha \times \log P([u,t]_i \mid [u,t]_{i-2}^{i-1}) \\ + (1-\alpha) \log P(TM_i \mid MWL_i, DC_i, u_{i-2}^{i})] \\ + (1-\beta) \times \log(P(t_i \mid u_{i-2}^{i+2}, MWL_i, t'_i)\end{aligned} \quad (5)$$

Where α and β are two weighting coefficients to be decided from the development set, and $0 < \alpha, \beta < 1.0$.

4 Experiments

All experiments are conducted on the corpora provided by SIGHAN-2005 (Emerson, 2005) and CIPS-SIGHAN-2010[6] (Zhao and Liu, 2010). Both the in-domain test and cross-domain tests are trained on PKU-News[7] from CIPS-SIGHAN-2010. The PKU-News testing corpus of SIGHAN-2005 is adopted for in-domain test, while the corpora of CIPS-SIGHAN-2010 are used for cross-domain tests. There are four different domains: Literature (denoted as **Lit.**), Computer (**Cmp.**), Medicine (**Med.**) and Finance (**Fin.**). To obtain the weights of different factors in Equations (4) and (5), we randomly selected 1% from the original training corpus as the development set, and

[6] CIPS-SIGHAN-2010 is the first cross-domain Chinese Word Segmentation (CWS) bake-off competition which involves 18 systems. To our knowledge, this data-set is the most well-known and widely adopted (also publically available) one for cross-domain CWS test.
[7] The PKU-News training data of CIPS-SIGHAN-2010 is the same with the PKU training data of SIGHAN-2005.

regard the remaining part as the new training set. The updated corpora statistics are shown at TABLE 1.

TABLE 1 – Corpus statistics for CIPS-SIGHAN-2010

Besides, the SRI Language Modelling Toolkit (SRILM)[8] (Stolcke, 2002) is used to train $P([u,t]_i | [u,t]_{i-2}^{i-1})$ with the modified Kneser-Ney smoothing method (Chen and Goodman, 1996). Also, the Factored Language Model in SRILM is adopted to train $P_{BF}(TM_i | MWL_i, DC_i, u_{i-2}^i)$, and $P_{BF}(TM_i | MWL_i, DC_i, u_{i-2}^i)$ sequentially back-off to $P_{GT}(TM_i | MWL_i, DC_i)$, where the subscripts "BF" and "GT" denote back-off and Good-Turing estimations, respectively. For the discriminative approach, the ME Package[9] provided by Zhang Le is adopted for training. Last, all adjustable weights are first selected only based on the development set. Those obtained optimal values are then fixed and applied to the testing-set.

4.1 Enhanced generative model

4.1.1 Effect of having character context

It is observed that tag matching status is less reliable when there are several dictionary matching words for the given character. Therefore, the character context is introduced to help disambiguate them. To show the influence of character context information, we test two different enhanced generative models. The first one adopts the factor $P(TM_i | MWL_i, DC_i)$ (denoted as G1), and the second one adopts the factor $P(TM_i | MWL_i, DC_i, u_{i-2}^i)$ (denoted as G2; with character context). In addition, the performance of the original generative model (denoted as B for baseline) is also shown for comparison. The dictionary adopted here contains all the training words and the testing words excluding the named entities (which are usually not covered by domain dictionaries).

TABLE 2 shows that character context effectively improves the performance for four out of five domains in F-score (except the Computer domain), which mainly resultes from the inconsistent segmentation criteria between the News training set and the computer testing set. For example, 18.3% of "就是" (just like) occurrences are segmented as a single word, and 81.7% of them are segmented into two single-character words "就" (just) and "是" (be) under similar context in the training set. However, this string is always treated as a single word in the Computer testing set. When the context is not considered, G1 prefers the longer word and gives correct answer for all the occurrences in the Computer corpus. While the context is considered, G2 will prefer to follow those occurrences in the training set and thus give wrong result most of the time.

TABLE 3 –Tagging error rates for seen/unseen cases in the testing-set

Overall, G2 outperforms B and G1 by 2.6% and 0.3%, respectively. This phenomenon can be explained by classifying the tagging errors into two groups according to whether the associated character-tag bigram is seen or not in the training set. TABLE 3 shows that the original character-tag trigram factor (i.e., B) works well when the bigram is seen, but it performs poorly when this bigram is unseen. On the other hand, G1 (without context) mainly boosts the performance for unseen cases. However, G2 (with context) also boosts the performance for seen cases. Therefore, it will not let the newly added tag-matching factor contaminate the original trigram model when associated character-tag bigrams are seen. The above observations hold for both development-set and testing-set. G2 is thus adopted for the enhanced generative model and integrated model.

4.1.2 Effect of dictionary coverage rate

Since no dictionary can cover all OOV words for real applications, we would like to know how this enhanced generative model performs under different dictionary coverage rates. We extract two dictionaries: the first one (D1) includes all the training words; and the second one (D2) contains all the OOV words in the testing set (excluding named entities). TABLE 4 gives the results for various combinations of D1 and D2 with $\alpha = 0.5$, where the first row "None" denotes that no dictionary (even D1) is adopted; also, the last column "OA" gives the overall performance of various domains (except News).

It can be seen that the improvements with the dictionary information from the training set are not obvious (None vs. D1). The reason is that the original character-tag trigram model already handles IV words well enough and the information of IV words seems redundant to this model. However, when the dictionary starts to cover OOV words, the performance rises sharply according to the OOV coverage rate. Anyway, the enhanced model always outperforms the original model even when the dictionary only covers a few OOV words.

TABLE 5 – F-score versus different OOV coverage rates for the word-based trigram model

Nonetheless, not every model possesses the robustness for varying dictionary coverage rate. For example, the corresponding result of the word-based generative trigram model[10], given at TABLE 5, shows that it is quite fragile in comparison with our model. In this model, all words kept in the dictionary are used to construct the word lattice in the decoding process. Those OOV words will be treated as unseen events and given a very low score. However, it can be seen that although the results with full dictionary are satisfactory, the performance drops dramatically while the OOV coverage rate decreases. This indicates that this model is quite sensitive to those OOV words, due to its incapability of identifying OOV words beyond the dictionary. This model is thus not useful for real applications, as it is impossible to know the corresponding dictionary coverage rate in the testing set in advance. Therefore, checking the robustness of dictionary-based models for different dictionary coverage rates is important in selecting an appropriate model.

4.1.3 Effect of varying weights

The F-scores of the enhanced generative model versus various α values (the weight of $P([u,t]_i \mid [u,t]_{i-2}^{i-1})$ in Equation (4) are evaluated on the development set, and are shown in FIGURE 3. It can be seen that all the curves are flat near their peaks, which indicates that this enhanced model is not sensitive to which α value is picked. Besides, although the performance decreases when the OOV coverage rate drops, the α locations of peaks for various curves are almost the same (all around $\alpha = 0.4$). This indicates that the best α value is not sensitive to the OOV coverage rate.

[10] This well-known model adopts the form : $WSeq = \arg\max \prod_{i=1}^{m} P(w_i \mid w_{i-2}^{i-1})$ (Wang et al., 2012).

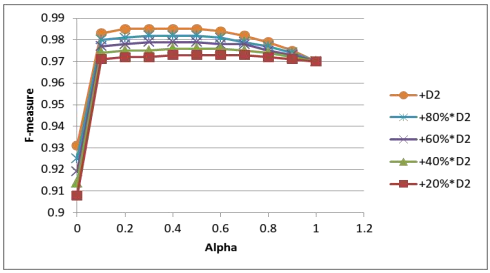

FIGURE 3 – F-score of the enhanced generative model versus various weights α on the development set

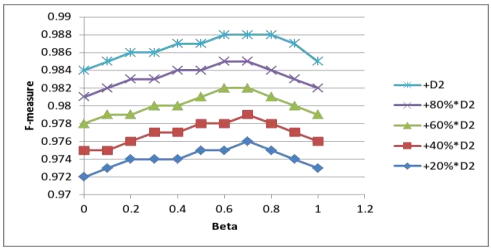

FIGURE 4 –F-score of the enhanced integrated model versus various weights β on the development set

4.2 Enhanced integrated model

Since the original generative model and the discriminative model are found to complement each other (Wang et al., 2011), it is expected that the enhanced generative model and the enhanced discriminative model (Low et al., 2005), which is re-implemented, should also complement each other. This inference is supported by the statistics that these two approaches share only 31.9% of their errors in the literature domain (similarly in other domains). Therefore, integrating these two models is expected to achieve a better result too. For the enhanced integrated model, we fix the weight α of $P([u,t]_i \mid [u,t]_{i-2}^{i-1})$ to be 0.4 (according to section 4.1.3). Afterwards, we adjust the weight of the enhanced generative model and the enhanced discriminative approach on the same development set. FIGURE 4 gives F-scores with different dictionaries versus various β values. The β locations of peaks for various curves are also almost the same (all around β =0.7) for various dictionary coverage rates. This indicates that the β weight is not sensitive to the OOV coverage rate. This figure also shows that the peak of the integrated model is robust for different dictionary coverage rates.

Last, to fairly compare different models in a more realistic condition, Table 6 shows the results of the enhanced discriminative model (denoted by ED) and the integrated model (denoted by EI) with an external dictionary (which roughly corresponds to 65% D2 coverage rate in TABLE 4, and is specified in the next section). Note that our ED result (0.968) is a little bit different from that

reported in (Low et al., 2005), which gives 0.965 F-score with a smaller dictionary that is a part of ours (see the next section). It can be seen that our enhanced integrated model achieves the best results on all five corpora.

TABLE 6 - F-scores on the testing sets. SBest: best results from SIGHAN 2005 (News) and CIPS-SIGHAN 2010 (other domains). Boldface indicates the best result.

4.3 Comparison with other state-of-the-art systems

To provide publically accessible dictionaries for open comparison, we combine a general dictionary downloaded from the Internet[11] and another technical dictionary extracted from Wiki[12] as our external dictionary. The first general dictionary is also adopted by (Low et al., 2005). For simplicity, we adopted the same dictionary (the union of above two dictionaries) for all five different domains. This external dictionary includes 458,165 words in total which roughly corresponds to 65% D2 coverage rate in TABLE 4. Since the external dictionary is expected to be collected by the user in real applications, dictionary words should be consistent with his/her own segmentation criterion. Therefore, to give true evaluation for reflecting the real situation, words in the dictionary are first transformed into their corresponding ones according to the same criteria adopted in various given corpora. For example, "免疫系统" (immune system) is converted into "免疫" (immune) and "系统" (system) according to the gold criterion adopted in CIPS-SIGHAN-2010.

The results of the enhanced generative model (denoted by EG) with the external dictionary and the SIGHAN best results in each domain are also given in TABLE 6. They are summarized as follows: Low et al. (2005) added the dictionary information to the discriminative approach and adopted additional corpora. They achieved the best result (0.969 F-score) on PKU News corpus in the open test of SIGHAN-2005. On the other hand, Huang et al. (2010) adopted HMM and some rules to post-process the output of the CRF discriminative approach. They achieved the best in the Literature domain in CIPS-SIGAHN-2010. Last, (Gao and Vogel, 2010) combined several classifiers with a large margin classifier and won the best on other three remaining domains. It shows our enhanced generative model achieves the best results on three out of four cross-domains, and our enhanced integrated model outperforms all the systems reported in the literature.

To further check if the difference between various models listed in Table 6 is really statistically significant, we adopt the bootstrapping technique (Koehn, 2004; Zhang et al., 2004) to conduct the significant tests. We follow the work of (Wang et al., 2010) and take the re-sampling size to be 2,000. 95% confidence interval is adopted in our tests. TABLE 7 shows that our enhanced generative model is superior to the enhanced discriminative model in overall comparison on those four cross-domains. Furthermore, the enhanced integrated model is either superior or comparable to all other models.

5 Error analysis and discussion

Following the work of (Sun, 2010), we get the upper bound of our enhanced generative model (EG) and enhanced integrated model (EI) by regarding each factor as an independent model, which is shown in TABLE 8. Compared with the results in TABLE 6, we can find that there is still a large room to further improve our proposed models.

Model	News	Lit.	Cmp.	Med.	Fin.
EG	0.984	0.973	0.971	0.968	0.978
EI	0.986	0.976	0.973	0.970	0.980

TABLE 8 - F-score upper bound for EG and EI models

Furthermore, we collect and analyse the remaining errors generated by the enhanced integrated model on the Medicine corpus, which contains a large number of technical terms and is most far away from the upper bound. It is found that 66.6% (out of 1,385) of error words are related to OOV (not seen in the training-set). Among those 922 OOV errors, 758 (82.2%) of them are not covered by the dictionary and 401 (52.9%) out of 758 are technical terms. Therefore, it again confirms how important a dictionary is. Also, 88 (21.9%) of those uncovered terms are with prefix/suffix. For example, "造影术" (radiography) is an OOV word with suffix "术" (technique), while the word "造影" (radiograph) is contained in the dictionary. However, it is wrongly split into "造影" and "术", since the longest word in the dictionary is preferred. This problem will be our future work.

6 Related work

The word-based generative model (Gao et al., 2003; Zhang et al., 2003) is a classical approach for CWS. However, this approach needs an additional module to recognize OOV words. Therefore, the character-based discriminative model (Xue, 2003; Low et al., 2005; Zhang et al., 2006; Jiang et al., 2008; Zhao et al., 2010) has become the main stream due to its capability in handling OOV words.

However, the character-based discriminative model cannot give satisfactory performance for IV words. Wang et al. (2010) thus proposed a generative model to fix this problem. Afterwards, they

further proposed an integrated model to integrate generative and discriminative approaches, as these two approaches complement each other.

On the other hand, dictionary information has been utilized in the discriminative approach in the previous works of (Low et al., 2005; Zhao et al., 2010). However, they focus on improving the in-domain word segmentation accuracy, while we investigate how the domain invariant feature (based on dictionary information) helps for cross-domain tasks. Besides, the effect of varying OOV words coverage rates is studied in this paper for the first time.

In addition to dictionary feature, Zhao and Kit (2007; 2008), Sun and Xu (2011) too, also adopted the accessor variety feature to gain better generalization ability. Since this feature can be extracted from unlabelled corpora, it is suitable to be adopted for domain adaptation. Again, all their works focus on in-domain performance. Other works that focus on in-domain performance also include (Zhang and Clark, 2007), (Fu et al., 2008), (Jiang et al., 2008), (Lin, 2009), (Xiong et al., 2009), and (Zhang and Clark, 2011).

Last, (Ben-David et al., 2007) pointed out that a good feature representation for domain adaptation should minimize the difference between its distributions in source and target domains. The proposed abstract feature is also inspired by their conclusion.

Our approach differs from those previous works in several ways. First, we do not simply add the dictionary matching information as an additional feature under the Maximum Entropy framework. In contrast, we derive a new generative model with dictionary information starting from the problem formulation, and solve the problem in a principled way. Second, the robustness of the proposed model for varying dictionary coverage rate is first studied and checked in this paper. As explained in Section 4.1.2, this issue is important for selecting a model for real applications.

7 Conclusion

Current character-based approaches are not robust for cross domain Chinese word segmentation, because those surface features adopted in the model frequently possess different tag distributions for the same character in various domains. This paper thus proposes a new abstract aggregate candidate-feature, which indicates if the assigned tag follows the corresponding position-tag of the longest dictionary matching word. With this novel domain invariant feature, we then derive an enhanced generative model for cross-domain CWS to solve the problem in a principled way. Experiments show that the proposed approach is robust for various OOV coverage rates and outperforms the best system in three out of five corpora.

The proposed model is further integrated with an enhanced discriminative approach because they complement each other. With the help of a publically accessible external dictionary, experiments on the SIGHAN-2005 and CIPS-SIGHAN-2010 show that our integrated approach outperforms all the systems in open test and achieves the best F-score in each corpus across five different specified domains.

Code-switch Language Model with Inversion Constraints for Mixed Language Speech Recognition

Ying Li, Pascale Fung

ABSTRACT
We propose a first ever code-switch language model for mixed language speech recognition that incorporates syntactic constraints by a code-switch boundary prediction model, a code-switch translation model, and a reconstruction model. A WFST-based decoder then recognizes speech by combining an acoustic model, a pronunciation model and the code-switch language model in an integrated approach. Our proposed approach avoids making early decisions on code-switch boundaries and is therefore more robust than previous approaches. Our proposed system using the code-switch language model outperforms a baseline of interpolated language models by a statistically significant 0.91% on a mixed language lecture speech corpus, and 1.25% on a mixed language lunch conversation corpus. Our method also outperforms a language model that permits code-switch at all word boundaries by a statistically significant 1.35% on the lecture speech corpus and 1.69% on the lunch conversation corpus.

KEYWORDS: Code-switch, mixed language, language modeling.

Proceedings of COLING 2012: Technical Papers, pages 1671–1680,
COLING 2012, Mumbai, December 2012.

1 Introduction

Multilingual people often code-switch (CS) — mixing two languages in the same sentence (intra-sentential code-switch) or between sentences (inter-sentential code-switch). For inter-sentential switches, many researchers use two language models to decode separate sentences (Fugen et al., 2003). However, a sentence that contains two languages poses a more formidable challenge to speech recognition systems, as the same sentence would contain words or phrases belonging to two or more grammatical systems or subsystems (Gumperz, 1982). It is challenging to predict where in the sentence the speaker switches to another language and back, if at all. Some researchers (Lee et al., 2009) use the transcription of the code-switch speech to train a domain-dependent language model. This approach is limited by the small amount of code-switch data available for training.

Code-switch should be distinguished from loanword, which is a word borrowed from one language and incorporated into another language to become part of the lexicon. Code-switch speech is where the speaker actually tries to speak another language in its own grammar. In code-switch, the matrix language is the 'principal' language, where the 'embedded' language is the second language(C. and C., 1993; Coulmas, 1998).

There are two main approaches to recognizing code-switch mixed language speech. One is to detect the boundaries at which the speaker code-switches, then identify the language in the speech segments between the boundaries, and decode the speech segments using the acoustic and language models in the corresponding language(Chan et al., 2005; Shia et al., 2004; Lyu and Lyu, 2008; Vu et al., 2012). For text only code-switch language, Solorio and Liu (2008) used Naive Bayes and Value Feature Interval to classify the hypothesis code-switch points by F-measure and the naturalness rating.

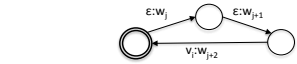
However, this approach requires multiple passes of boundary detection, language identification and speech recognition. The boundaries and language identity of each speech segment are irreversibly determined by the previews pass. Moreover, the speech segment of the embedded language tends to be very short. This poses challenges to the state-of-the-art language identification approaches.

A more holistic way to decode code-switch speech is by using a set of universal acoustic models for both matrix and embedded languages and a language model that permits code-switch (while predicting with probability where CS might occur) and which does not require an early decision of the code-switch points.

There are many methods proposed to build universal acoustic models for both the matrix and embedded languages that range from mapping the pronunciation dictionary to phonetic set combination and acoustic model merging (Imseng et al., 2011; Li et al., 2011; Bhuvanagiri and Kopparapu, 2010; Zhang et al., 2008). In this paper, we focus on code-switch language modeling.

A common approach is to build a code-switch language model from the language models of the matrix and embedded languages, trained separately from monolingual texts and combined together with linear interpolation (Bhuvanagiri and Kopparapu, 2010; Li et al., 2011; Imseng et al., 2011). This approach does not assume any syntactic constraint.

One can also use hand written grammar to constrain the code-switch point, such as in Zhang et al., 2008 or a bilingual dictionary to map the statistical n-grams in one language to the other, such as in Cao et al., 2010. Yeh et al., 2010 used a class-based n-gram language model based on



A portion of the code-switch boundary prediction model

A portion of the code-switch translation model

A portion of the code-switch reconstruction model

Figure 1: Weighted finite state transducers of the code-switch language model

perplexity and part-of-speech tag features. Tsai et al., 2010 proposed to use part-of-speech tags and to use Hakka-Chinese bilingual word mapping in the language model. The code-switch points are deterministic.

Linguists who study mixed language speech have discovered a typical constraint when speakers switch from one language to another in a sentence(Woolford, 1983; Mahootian, 1993; MacSwan, 1999). They found that code-switch can only occur in positions where "*the order of any two sentence elements, one before and one after the switch, is not excluded in either language*"(Poplack and Sankoff, 1980). This constraint, known as the “equivalence constraint" in linguistics, corresponds to an inversion constraint in statistical machine translation.

In this paper, we propose for the first time to incorporate this syntactic inversion constraint to a statistical code-switch language model. Our CS language model is composed of a CS boundary prediction model, a CS translation model, and a reconstruction model. The prediction model learns from word aligned parallel sentences to give the permissible CS points. The translation model is obtained by logit regression and incorporates syntactic inversion constraints. A *maximum a posterior* framework employs weighted finite state transducers in the process of final decoding, integrating a bilingual acoustic model, a code-switch language model, and a monolingual language model in the matrix language.

The structure of the paper is as follows: Section 2 presents the code-switch language model. The framework of decoding via the weighted finite state transducers is described in Section 3. Section 4 describes the results of the experiments. Section 5 draws the conclusion.

2 Code-switch language modeling

Given a speech utterance, S, with N_S frames, the automatic speech translation system converts S into a word sequence, W_1^M, where M is the total number of words. There are four components in the system, the language model, $P(W_1^M)$; the acoustic models, $P(S_1^{N_S}|W_1^M)$; the pronunciation dictionary; and the decoder.

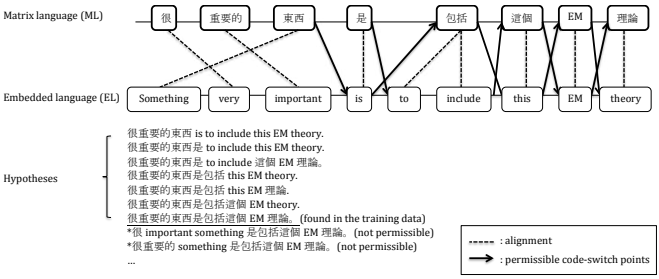


Figure 2: An example of permissible code-switch points

It is difficult to obtain mixed language text data which can be used for training the language model. Instead of directly calculating the probabilities, we use a monolingual language model in the matrix languagetogether with the CS language model.

$$P(W_1^M) = \sum_{w_1^m} P(w_1^m)P(W_1^M|w_1^m) \cong \max_{w_1^m} P(w_1^m)P(W_1^M|w_1^m) \quad (1)$$

where W_1^M is in mixed language, and w_1^m is in the matrix language. The code-switch language model can be modeled as

$$P(W_1^M|w_1^m) \cong \max_{v_1^n, u_1^n, W_1^M} \{P(v_1^n, n|w_1^m) \cdot P(u_1^n|v_1^n, w_1^m) \cdot P(W_1^M|u_1^n, v_1^n, w_1^m)\} \quad (2)$$

where $P(v_1^n, n|w_1^m)$ is the code-switch boundary prediction model, $P(u_1^n|v_1^n, w_1^m)$ is the code-switch translation model, and $P(W_1^M|u_1^n, v_1^n, w_1^m)$ is the reconstruction model. We assume that w_1^m is a word sequence in the matrix language; the words are segmented into phrases, v_1^n; and u_1^n is a phrase sequence in mixed language.

2.1 Code-switch boundary prediction model

According to the equivalence constraint suggested by linguists(Poplack and Sankoff, 1980), the code cannot occur at the points where the order of the words are inverted between the matrix language and the embedded language. An example of a Mandarin-English mixed language sentence is shown in Figure 2. Code-switch is not allowed between the first three words with syntactic inversion.

Word-aligned parallel sentences in the matrix and the embedded languages are used to constrain at which point code-switch is allowed. We propose to generate bilingual training data as follows:

1) Translate words of the mixed language sentences in the embedded language into the matrix language using a statistical machine translation system;

2) Translate the monolingual sentences from 1) into the embedded language by a statistical machine translation system with inversion transduction grammar constraint (Wu, 1997; Wu and Fung, 2005) to obtain monolingual sentences in the embedded language;

3) Align the pairs of monolingual sentences in the matrix and embedded languages from 1) and 2). In theory, we can generate as many bilingual sentence pairs as possible.

The code-switch boundary prediction model trains the probabilities of a sequence of words segmented into a sequence of phrases from the aligned parallel sentences. A phrase is a word or a concatenation of words in which there exists one or more inversions of an aligned parallel sentence pair in the matrix language and the embedded language.

$$P(v_1^n, n|w_1^m) = \frac{1}{Z_n} \prod_{i=1}^{n} P(v_i) \tag{3}$$

where $P(v_i)$ can be approximated by the relative frequency of the i-th phrase.
$Z_n = \sum_{v_1^n} \prod_{k=1}^{m} P(v_i)$ such that $\sum_{v_1^n} P(v_1^n, n|w_1^m) = 1$.

2.2 Code-switch translation model

Given the permissible code-switch points by the above model, the code-switch translation model is the actual probability of code-switch at these points. We assume that the code-switch translation probability, $P(u_1^i|v_1^i)$, depends on the previous phrase, v_{i-1}.

The code-switch translation probability distribution is specified by probabilities $\pi(\mathbf{x})$ of code-switch and $(1-\pi(\mathbf{x}))$ of not code-switch. $\mathbf{x}$ is an n-tuple containing the conditional probability $P(e|w)$ of code-switch from a word, w, in the matrix language to a word, e, in the embedded language, and reordering probability $\prod_{j=1}^{k} P(r_j|j,k,l)$ of a phrase in the matrix language of length k and a phrase in the embedded language of length m, where r_j denotes that the j-th ML word is aligned to the r_j-th EL word, phrase translation probability $Pr(u|v)$ from a phrase, v, in the matrix language to a phrase, u, in the embedded language and phrase penalty $Pen(v)$. These probabilities are trained from word-aligned bilingual sentences.

The code-switch translation probability is neither linear nor exponential; it changes dramatically near the CS threshold. Thus we propose to use a logit regression model to describe the code-switch translation probability

$$\text{logit}[\pi(\mathbf{x})] = \log(\frac{\pi(\mathbf{x})}{1-\pi(\mathbf{x})}) = \alpha + \sum \beta_j x_j \tag{4}$$

where β_j refers to the effect of the j-th item in the n-tuple $\mathbf{x}$ on the logit of the code-switch translation probabilities, controlling the other items of the n-tuple $\mathbf{x}$. The code-switch translation probability

$$\pi(\mathbf{x}) = \frac{\exp(\alpha + \sum \beta_j x_j)}{1 + \exp(\alpha + \sum \beta_j x_j)} \tag{5}$$

$$P(u_i|v_1^i) = \begin{cases} 1 - \pi(\mathbf{x_{i-1}^i}) & u_i = v_i \\ \pi(\mathbf{x_{i-1}^i}) & otherwise \end{cases} \tag{6}$$

where $\mathbf{x_{i-1}^i}$is the n-tuple of the word alignment probabilities, reordering probability and the phrase penalty.

2.3 Code-switch reconstruction model

The code-switch reconstruction model assigns probabilities to a sequence of mixed language words, W_1^M, given the constraint that the words agree with u_1^n, v_1^n, n, w_1^m

$$P(W_1^M|u_1^n, v_1^n, n, w_1^m) = \prod_{i=1}^{n} P(W_{S_i}^{E_i}|u_i) \tag{7}$$

$$P(W_{S_i}^{E_i}|u_i) = \begin{cases} \frac{1}{Z_i} \prod_{j=S_i}^{E_i} q(W_j) & W_{S_i}^{E_i} = u_i \\ 0 & otherwise \end{cases} \tag{8}$$

$p(W_j)$ is the frequency of occurrences of word W_j obtained from the bilingual sentences. $W_{S_i}^{E_i} = u_i$ indicates that the word sequence $W_{S_i}^{E_i}$ is exactly the same as the phrase u_i, S_i is the start of phrase u_i, and E_i is the end of phrase u_i. $Z_i = \sum_{u_1^n} \prod_{j=S_i}^{E_i} p(W_j)$ is set so that the probabilities sum to unity over possible values of u_i.

3 Decoding via weighted finite state transducers

The decoding of mixed language speech can be considered as searching the weighted finite state network. Suppose S denotes a speech utterance with N_S feature vectors, the recognition result $\hat{W}_1^M$ can be found as

$$\hat{W}_1^M = \arg\max_{W_1^M} P(W_1^M|S_1^{N_S}) \tag{9}$$

By Bayesian rule, the $\hat{W}_1^M$ is in

$$\{\hat{v}_1^n, \hat{u}_1^n, \hat{W}_1^M\} = \arg\max_{v_1^n, u_1^n, W_1^M} P(S_1^{N_S}|W_1^M) P(w_1^m) P(v_1^n, n|w_1^m) P(u_1^n|v_1^n, w_1^m) P(W_1^M|u_1^n, v_1^n, w_1^m) \tag{10}$$

while the possible code-switches are specified by $\hat{v}_1^n$ and $\hat{u}_1^n$.

The acoustic models $P(S_1^{N_S}|W_1^M)$, the pronunciation dictionary, the matrix language model $P(w_1^m)$, the code-switch boundary prediction model $P(v_1^n, n|w_1^m)$, the code-switch translation model $P(u_1^n|v_1^n, w_1^m)$ and the reconstruction model $P(W_1^M|u_1^n, v_1^n, w_1^m)$ are implemented as weighted finite state transducers and composed into a search network.

A lattice of the hypothesis speech recognition result is generated. When each token in the lattice transits from the end of one word to the start of the next word, a word insertion penalty is added. The insertion penalties of Chinese words and English words are separately trained from the development data. Lattice rescoring is proposed to adjust the word penalty of recognition results.

4 Experimental setup

This section briefly describes the data resources and feature analysis that were used for all the experiments used to evaluate the presented approach in the paper.

The acoustic features used in our experiments consist of 39 components (13MFCC,13ΔMFCC,13$\Delta\Delta$MFCC using subtraction of the cepstral mean), which are

analyzed at a 10msec frame rate with a 25msec window size. The acoustic models used throughout our paper are state-clustered crossword tri-phone HMMs with 16 Gaussian mixture output densities per state. The phone set consists of 21 standard Mandarin initials, 37 toneless Mandarin finals, 6 zero initials and 6 English extended phones. The pronunciation dictionary is obtained by modified dictionaries in the matrix and embedded languages using the phone set. The acoustic models are adapted to the speakers using maximum likelihood linear regression. The WFST decoder is used for decoding.

4.1 Corpora

We evaluate our proposed method on two mixed language speech corpora of different speaking styles, namely a lecture speech corpus and a lunch conversation corpus. The audio data is sampled at 16kHz.

About 20 hours of lecture speech of a digital speech processing course recorded at National Taiwan University are separated into three sets. Eighteen hours of the speech is used for adaptation of the acoustic models, and 0.9 hours of the speech is used as a development set. The testing set contains one hour of 1037 utterances. The lecture is given in Mandarin by a single speaker with 16% embedded English words.

The lunch conversation speech was recorded at the Hong Kong University of Science and Technology from a single speaker. The speech is highly spontaneous and the topics are wide ranging. The total length of the conversations is 163 minutes and 127 minutes are used to adapt acoustic models. The development set contains 26 minutes of the speech. Ten minutes of the speech is used for testing. There are 14762 Chinese words and 4280 English words. The percentage of the embedded English words is 22%.

250,000 sentences from digital speech processing conference papers, power point slides and web data are used for language model training and parallel sentence generation for the lecture speech recognition task(LM data 1). 250,000 sentences of the Gale conversational speech transcription are used for language model training and parallel sentence generation for the lunch conversion speech recognition(LM data 2).

4.2 Langauge models

The baseline language model (Model_IP) for the lecture speech recognition is an interpolation of the language model trained from LM data 1 and the language model trained on the transcriptions of the mixed language lecture speech. Another baseline model (Model_IP) of the lunch conversations is trained from LM data 2 and interpolated with the language model trained from the transcriptions of the mixed language conversations.

Our proposed language model (Model_CS) is constructed from combining the monolingual language model, the code-switch boundary prediction model, the code-switch translation model and the reconstruction model.

5 Experimental Results

Table 1 shows the word or character error rates of experiments on the mixed language lecture speech. The baseline interpolated language model reduces the overall word error rate by 0.49%. However, it degrades the recognition results of English phrases. Our proposed method outperforms the interpolated language model by 0.45% (Mandarin CER), 1.86% (English WER)

and 0.89% (overall).

Table 1: *Word/character error rate (%) of the lecture speech*

	Mandarin (ML)	English (EL)	Overall
Allow code-switch any where	35.16	43.54	36.55
Interpolated LM	34.35	44.36	36.09
Proposed method	**33.90**	**41.68**	**35.2**

The results of experiments on the mixed language lunch conversation speech are shown in Table 2. The baseline interpolated language model gives a 0.8% character error rate reduction on the Mandarin phrases and a 0.44% overall word error rate reduction, but degrades the performance on the English phrases. On the other hand, our proposed CS language model reduces the character error rate of Mandarin phrases by 0.41%, the word error rate of English phrases by 1.98% and overall word error rate by 1.25%. All the character error rate and word error rate reductions are statistically significant at 99%.

Table 2: *Word/character error rate (%) of the lunch conversations*

	Mandarin (ML)	English (EL)	Overall
Allow code-switch any where	47.20	49.14	47.63
Interpolated LM	46.40	49.98	47.19
Proposed method	**45.99**	**48.01**	**45.94**

Conclusions

In this paper, we propose a first ever statistical language model of code-switch speech that incorporates syntactic inversion constraints that have been found in that kind of speech. Our language model is composed of a code-switch prediction model, a translation model and a reconstruction model. A WFST-based decoder integrates this code-switch language model with an acoustic model and a monolingual language model in the matrix language for the final decoding. We tested our system on two tasks in mixed language lecture speech recognition, with 16% English words in Chinese sentences; and in mixed language lunch conversation, with 22% English words in Chinese sentences. Our system reduces word error rate in a baseline of the interpolated language model by 0.91% in the first task, and by 1.25% in the second task. Our model also outperforms another baseline, that of allowing code-switch at all points by 1.35% in the first task, and by 1.69% in the second task. All results are statistically significant. In addition, our method reduces error rates for both the matrix language and the embedded language.

ABSTRACT
Recent study shows that parsing accuracy can be largely improved by the joint optimization of part-of-speech (POS) tagging and dependency parsing. However, the POS tagging task does not benefit much from the joint framework. We argue that the fundamental reason behind is because the POS features are overwhelmed by the syntactic features during the joint optimization, and the joint models only prefer such POS tags that are favourable solely from the parsing viewpoint. To solve this issue, we propose a separately passive-aggressive learning algorithm (SPA), which is designed to separately update the POS features weights and the syntactic feature weights under the joint optimization framework. The proposed SPA is able to take advantage of previous joint optimization strategies to significantly improve the parsing accuracy, but also overcome their shortages to significantly boost the tagging accuracy by effectively solving the syntax-insensitive POS ambiguity issues. Experiments on the Chinese Penn Treebank 5.1 (CTB5) and the English Penn Treebank (PTB) demonstrate the effectiveness of our proposed methodology and empirically verify our observations as discussed above. We achieve the best tagging and parsing accuracies on both datasets, 94.60% in tagging accuracy and 81.67% in parsing accuracy on CTB5, and 97.62% and 93.52% on PTB.

1 Introduction

Given an input sentence of n words, denoted by $\mathbf{x} = w_1...w_n$, part-of-speech (POS) tagging aims to find an optimal tag sequence $\mathbf{t} = t_1...t_n$, where $t_i \in \mathcal{T}$ $(1 \leq i \leq n)$ and $\mathcal{T}$ is a predefined tag set. POS tags are designed to represent word classes so that words of the same POS tag play a similar role in syntactic structures. The size of $\mathcal{T}$ is usually much less than the vocabulary size. Typically, POS tagging is treated as a sequence labeling problem, and has been previously addressed by machine learning algorithms, such as maximum-entropy (Ratnaparkhi, 1996), conditional random fields (CRF) (Lafferty et al., 2001) and perceptron (Collins, 2002). Figure 1 gives an example sentence from Penn Chinese Treebank 5.1 (CTB5). The lowest three rows present the n-best POS tags for each word, produced by a state-of-the-art CRF model. Looking at the 1-best POS tags, we can see that the CRF model makes four errors, i.e. de/DEC→DEG, ouwen/NR→NN, xiaoli/VV→NN, and liwupudui/NR→NN. In fact, (DEC,DEG) and (NN,VV) ambiguities, which usually require long-distance syntactic knowledge to resolve, are very difficult for the sequential labeling models.

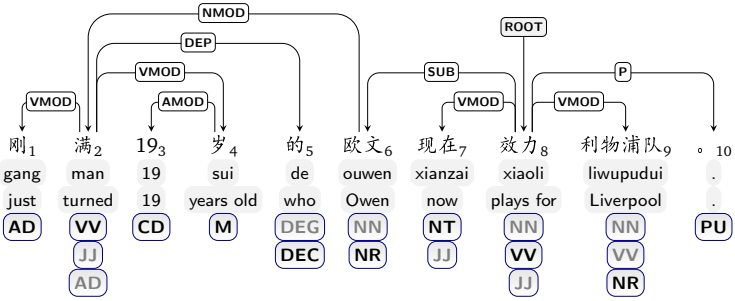

Figure 1: An example from CTB5. The Pinyin transcriptions and English translations are presented in the two rows below the Chinese sentence. We prune out the implausible POS tags according to the marginal probabilities (see Section 4.1) and list the top three candidate POS tags in the lowest three rows (incorrect POS tags in grey color and correct ones in black color).

Dependency Parsing maps a natural language sentence into a structural dependency tree conforming to a predefined dependency grammar, as depicted in Figure 1. A dependency tree is denoted by $\mathbf{d} = \{(h, m, l) : 1 \leq h \leq n, 1 \leq m \leq n, l \in \mathcal{L}\}$, where (h, m, l) means a dependency from the *head word* (also called *father*) w_h to the *modifier* (also called *child* or *dependent*) w_m with a dependency label l, and $\mathcal{L}$ is the label set. Dependency labels are used to indicate the syntactic or semantic relation between the two words. For instance, the dependency (8, 6, SUB) in Figure 1 means ouwen is the *subject* of xiaoli.

Data-driven dependency parsing models make heavy use of POS tags to compose supporting features, since it leads to severe data sparseness problem if only lexical features are used. However, POS tagging errors significantly degrade the parsing accuracy by about 6% (see Table 4 where, for example, due to the error of xiaoli/VV→NN, our pipelined parsing model fails to recognize xiaoli as the predicate of the sentence and returns a fully unreasonable structure).

Recently, there has been increasing interest in joint modeling of Chinese POS tagging and

dependency parsing (Li et al., 2011; Hatori et al., 2011; Bohnet and Nivre, 2012), motivated by the intuition that the two individual tasks should help each other. Their work demonstrates that the joint models can substantially boost the parsing accuracy. In contrast, the tagging subtask does not benefit much from the joint framework. (Li et al., 2011) show that the graph-based joint models lead to large decrease in the tagging accuracy, whereas (Hatori et al., 2011) and (Bohnet and Nivre, 2012) find small gains in the tagging accuracy with transition-based joint models (see Table 4). This is contradictory to the intuition that better syntactic structure should help POS disambiguation. The detailed error analysis in (Li et al., 2011) show that their joint models are helpful in resolving syntax-sensitive POS ambiguities like {VV,NN} and {DEC,DEG}, but become very weak in disambiguating {NN,NR} and {NN,JJ} which usually play similar roles in syntactic trees.

We believe that one possible reason is that the graph-based joint models of (Li et al., 2011) is dominated by the syntactic features. Looking deeper into their joint models, we find that on average, the score corresponding to the POS features only is $1/50$ of the score of the syntactic features in a returned joint result. In other words, the POS features have little impact on determining the best joint result. Therefore, the joint models prefer such POS tags that are more helpful and discriminative solely from the parsing viewpoint.

To address this issue, this paper proposes a variant of the passive-aggressive (PA) online training algorithm (Crammer et al., 2003), which we name as *separately passive-aggressive algorithm (SPA)*. SPA separately updates the POS feature weights and the syntactic feature weights and naturally raises the weights of the POS features under the joint optimization framework. As a result, SPA can make better use of the discriminative power of the POS features in resolving the syntax-insensitive POS ambiguities, leading to a large tagging accuracy improvement. On the other hand, the improved tagging accuracy can further help parsing. Specifically, we make the following contributions.

- We propose a separately passive-aggressive training algorithm for joint POS tagging and dependency parsing. Empirically, we compare SPA with averaged perceptron (AP) and PA from the perspective of the model score, showing that SPA is more suitable for the joint models. Experimental results demonstrate that SPA outperforms AP and PA in both the tagging and parsing accuracies. More importantly, SPA significantly improve both the tagging and parsing accuracies over the pipelined baselines.
- We present the first feature-rich graph-based joint model for POS tagging and labeled dependency parsing. We conduct experiments on two versions of CTB5 and achieve the best tagging and parsing accuracies on both datasets. Especially, our joint model trained with SPA achieves a tagging accuracy of 94.7%, largely outperforming the 93.9% of the baseline CRF model.
- We also conduct experiments on PTB to find out the effect of joint modeling on English. Thanks to relatively richer morphologies, English POS tagging achieves much higher accuracy than Chinese (97% vs. 94%). Therefore, English dependency parsing suffers less error propagation problem than Chinese. Nevertheless, we still find significant gains from the joint model. The tagging accuracy and the parsing accuracy increase by about 0.5% and 0.4% respectively. Our joint model achieves the best tagging and parsing accuracies on this dataset as well.
- We present the first work that conducts extensive studies on the effect of labeled dependency parsing. We find that dependency labels consistently improve the unlabeled parsing accuracy. Especially, the unlabeled attachment score (UAS) can be boosted by

0.6-0.7% on the two Chinese datasets.

2 Related work

This work is most closely related to (Li et al., 2011) who present the first work on joint models for Chinese POS tagging and unlabeled dependency parsing. Similar to us, their joint models are based on graph-based dependency parsing. They find that the joint models largely outperform the pipeline models in the parsing accuracy but lead to substantial tagging accuracy drop. Compared with their work, we propose a better training algorithm for the joint models that can improve both tagging and parsing accuracies. In addition, our joint model adopts richer features and handles labeled dependency parsing.

(Hatori et al., 2011) propose the first transition-based joint model for Chinese POS tagging and unlabeled dependency parsing and gain large improvement in the parsing accuracy. However, their joint models only slightly improve the tagging accuracy over a sequential tagging model. (Bohnet and Nivre, 2012) propose a transition-based joint model which can handle labeled non-projective dependency parsing. They conduct experiments on a variety of languages including Chinese, English, Czech, and German. Similarly, their joint model largely improves the parsing accuracy but only slightly increases the tagging accuracy. Differently, we are the first work on joint POS tagging and dependency parsing that achieves large improvement in the tagging accuracy.

(Smith and Eisner, 2008) apply loopy belief propagation (LBP) to dependency parsing and points out that LBP can naturally represent POS tags as latent variables so that the POS tags can be inferred jointly with the parse. (Lee et al., 2011) extend the LBP based approach of (Smith and Eisner, 2008) and study joint morphological disambiguation and dependency parsing for morphologically-rich languages including Latin, Czech, Ancient Greek, and Hungarian. For these languages, morphological analysis requires the disambiguation of POS tags, gender, case, etc. They show that the joint model can well capture the interaction between morphology and syntax and achieve gains on both subtasks. (Rush et al., 2010) propose dual decomposition (DD) for integrating different NLP subtasks at the test phase. They experiment with two cases, one integrating a phrase-structure parser and a dependency parser, and the other integrating a phrase-structure parser and a POS tagger. Both cases show that DD can help the individual subtasks. (Auli and Lopez, 2011) conduct an extensive comparison of LBP and DD for joint CCG supertagging and parsing. They show that LBP and DD achieves similar parsing accuracy improvement but has largely different convergence characteristics. Moreover, their work focuses on integrating two separately-trained sub-models, and they find that training the integrated model on LBP leads to large improvement drops compared with separately-trained models.

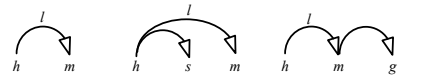
3 Pipeline POS tagging and dependency parsing

The pipeline method treats POS tagging and dependency parsing as two cascaded problems. First, an optimal POS tag sequence $\hat{\mathbf{t}}$ is determined.

$$\hat{\mathbf{t}} = \arg\max_{\mathbf{t}} \mathrm{Score}_{\mathrm{pos}}(\mathbf{x}, \mathbf{t}) \tag{1}$$

Then, an optimal dependency tree $\hat{\mathbf{d}}$ is determined based on $\mathbf{x}$ and $\hat{\mathbf{t}}$.

$$\hat{\mathbf{d}} = \arg\max_{\mathbf{d}} \mathrm{Score}_{\mathrm{syn}}(\mathbf{x}, \hat{\mathbf{t}}, \mathbf{d}) \tag{2}$$



(a) *single dependency* (b) *adjacent sibling* (c) *outermost grandchild*

Figure 2: Three types of scoring subtrees used in our parsing and joint models.

Feature category	Atomic features incorporated
Dependency features $\mathbf{f}_{\text{dep}}(\mathbf{x},\mathbf{t},h,m,l)$	$l, w_h, w_m, t_h, t_m, t_{h\pm1}, t_{m\pm1}, t_b, dir(h,m), dist(h,m)$
Sibling features $\mathbf{f}_{\text{sib}}(\mathbf{x},\mathbf{t},h,m,l,s)$	$l, w_h, w_s, w_m, t_h, t_m, t_s, t_{h\pm1}, t_{m\pm1}, t_{s\pm1}, dir(h,m), dist(h,m)$
Grandchild features $\mathbf{f}_{\text{grd}}(\mathbf{x},\mathbf{t},h,m,l,g)$	$l, w_h, w_m, w_g, t_h, t_m, t_g, t_{h\pm1}, t_{m\pm1}, t_{g\pm1}, dir(h,m), dir(m,g)$

Table 1: Brief illustration of the syntactic features. b is an index between h and m. $dir(i,j)$ and $dist(i,j)$ denote the direction and distance of the dependency (i,j). Please refer to Table 4 of (Bohnet, 2010) for the complete feature list.

CRF-based POS tagging. We adopt the first-order CRF to build our baseline POS tagger. As a conditional log-linear probabilistic model, CRF defines the probability of a tag sequence as

$$\begin{aligned} P(\mathbf{t}|\mathbf{x}) &= \exp(\texttt{Score}_{\text{pos}}(\mathbf{x},\mathbf{t}))/\sum_{\mathbf{t}'}\exp(\texttt{Score}_{\text{pos}}(\mathbf{x},\mathbf{t}')) \\ \texttt{Score}_{\text{pos}}(\mathbf{x},\mathbf{t}) &= \mathbf{w}_{\text{pos}}\cdot\mathbf{f}_{\text{pos}}(\mathbf{x},\mathbf{t}) = \sum_{1\le i\le n}\mathbf{w}_{\text{pu}}\cdot\mathbf{f}_{\text{pu}}(\mathbf{x},t_i) + \mathbf{w}_{\text{pb}}\cdot\mathbf{f}_{\text{pb}}(\mathbf{x},t_{i-1},t_i) \end{aligned} \tag{3}$$

where $\mathbf{f}_{\text{pos/pu/pb}}(.)$ refers to the feature vectors and $\mathbf{w}_{\text{pos/pu/pb}}$ is the corresponding weight vectors. We call $\mathbf{f}_{\text{pu}}(\mathbf{x},t_i)$ the *POS unigram features*, and $\mathbf{f}_{\text{pb}}(\mathbf{x},t_{i-1},t_i)$ the *POS bigram features*. For Chinese, we adopt the features proposed by (Zhang and Clark, 2008a). They use Chinese characters contained in a word to compose rich features, which turns out to be helpful for low-frequency words. For English, we adopt the features of (Ratnaparkhi, 1996) which exploit suffixes and prefixes to improve tagging performance over rare words.

Second-order graph-based dependency parsing. The graph-based approach views dependency parsing as finding a highest scoring tree in a directed graph (McDonald et al., 2005; Carreras, 2007; Koo and Collins, 2010). We adopt the second-order model of (Carreras, 2007) since previous studies show that it leads to best parsing accuracy on a variety of languages (Koo and Collins, 2010; Bohnet, 2010). The score of a dependency tree is factored into scores of the three kinds of subtrees in Figure 2.

$$\begin{aligned} \texttt{Score}_{\text{syn}}(\mathbf{x},\mathbf{t},\mathbf{d}) &= \mathbf{w}_{\text{syn}}\cdot\mathbf{f}_{\text{syn}}(\mathbf{x},\mathbf{t},\mathbf{d}) \\ &= \sum_{\{(h,m,l)\}\subseteq\mathbf{d}}\mathbf{w}_{\text{dep}}\cdot\mathbf{f}_{\text{dep}}(\mathbf{x},\mathbf{t},h,m,l) \\ &+ \sum_{\{(h,m,l),(h,s)\}\subseteq\mathbf{d}}\mathbf{w}_{\text{sib}}\cdot\mathbf{f}_{\text{sib}}(\mathbf{x},\mathbf{t},h,m,l,s) \\ &+ \sum_{\{(h,m,l),(m,g)\}\subseteq\mathbf{d}}\mathbf{w}_{\text{grd}}\cdot\mathbf{f}_{\text{grd}}(\mathbf{x},\mathbf{t},h,m,l,g) \end{aligned} \tag{4}$$

For syntactic features, we adopt those of (Bohnet, 2010) which include three categories corresponding to the three types of scoring subtrees. We summarize the atomic features used in

each feature category in Table 1. For unlabeled parsing and joint models, the label l is omitted. Compared with the syntactic features used in (Li et al., 2011), this feature set explores more context POS tags including $t_{s\pm1}, t_{g\pm1}$. In addition, for Chinese, we use the last character of each word as its lemma, and duplicate each word-related feature by replacing words with lemmas (Che et al., 2012). Experiments on CTB5 show that these lemma-related features can improve our baseline parsing models by 0.3-0.4% in UAS. For English, we use coarse-grained POS tags to duplicate all the feature that depend on POS tags (Koo and Collins, 2010), resulting in a 0.4% UAS gain on PTB.

4 Joint POS tagging and dependency parsing

In the joint framework, we aim to simultaneously solve the two problems.

$$(\hat{\mathbf{t}}, \hat{\mathbf{d}}) = \arg\max_{\mathbf{t},\mathbf{d}} \text{Score}_{\text{joint}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) \tag{5}$$

The score of a tagged dependency tree is the combination of the POS score and the syntactic score that are previously defined in the pipeline models.

$$\begin{aligned} \text{Score}_{\text{joint}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) &= \text{Score}_{\text{pos}}(\mathbf{x}, \mathbf{t}) + \text{Score}_{\text{syn}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) \\ &= \mathbf{w}_{\text{pos}} \cdot \mathbf{f}_{\text{pos}}(\mathbf{x}, \mathbf{t}) + \mathbf{w}_{\text{syn}} \cdot \mathbf{f}_{\text{syn}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) \\ &= \mathbf{w}_{\text{pos}\oplus\text{syn}} \cdot \mathbf{f}_{\text{pos}\oplus\text{syn}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) = \mathbf{w}_{\text{joint}} \cdot \mathbf{f}_{\text{joint}}(\mathbf{x}, \mathbf{t}, \mathbf{d}) \end{aligned} \tag{6}$$

where $\oplus$ denotes vector concatenation. Note that our joint model incorporates the same POS and syntactic features with the pipeline models. Under the joint model, the weights of POS and syntactic features, denoted by $\mathbf{w}_{\text{pos}\oplus\text{syn}}$ or $\mathbf{w}_{\text{joint}}$, are simultaneously learned. Therefore, they can interact with each other to determine an optimal joint result.

4.1 Decoding

Similar to (Li et al., 2011), we extend the parsing algorithm of (Carreras, 2007) using the idea of (Eisner, 2000) and propose a dynamic programming (DP) based decoding algorithm for our joint model. Figure 3 illustrates the basic DP structures and operations. The key idea is to augment the basic DP structures in the parsing algorithm (namely *spans*) with a few POS tags. A span means a partially built structure spanning a sub-sentence. For example, the left-side span in Figure 3(a), which is called an *incomplete span* and is denoted by $I_{(h,m,l)(t_h,t_m)}$, represents a partial tree spanning $w_h...w_m$ with w_h being tagged as t_h and w_m as t_m. The left-side span in Figure 3(b) is a complete span and is denoted by $C^{(e)(t_e)}_{(h,m)(t_h,t_m)}$.

The decoding algorithm works in a bottom-up fashion and combines two smaller spans into a larger one at each step. During combination, the newly-introduced features are incorporated and the score of the span is computed accordingly. For example, the operation in Figure 3(a) introduces five feature sets, i.e. $\mathbf{f}_{\text{dep}}(\mathbf{x}, t_h, t_m, h, m, l)$, $\mathbf{f}_{\text{sib}}(\mathbf{x}, t_h, t_m, t_s, h, m, l, s)$, $\mathbf{f}_{\text{grd}}(\mathbf{x}, t_h, t_m, t_g, h, m, l, g)$, $\mathbf{f}_{\text{pu}}(\mathbf{x}, t_m)$, and $\mathbf{f}_{\text{pb}}(\mathbf{x}, t_r, t_{r+1})$. And the operation in Figure 3(b) introduces one feature set $\mathbf{f}_{\text{grd}}(\mathbf{x}, t_h, t_m, t_g, h, m, l, g)$.[1] Note that in the above syntactic feature functions, several context POS tags are not encoded in the DP structures and therefore are not provided in the parameter lists, including $t_{h\pm1}, t_{m\pm1}, t_b, t_{s\pm1}, t_{g\pm1}$. For those, we use the most

[1] (Li et al., 2011) adopt a complex strategy to incorporate the POS features in their joint decoding algorithm. The way illustrated here is much easier and its correctness can be easily proved.

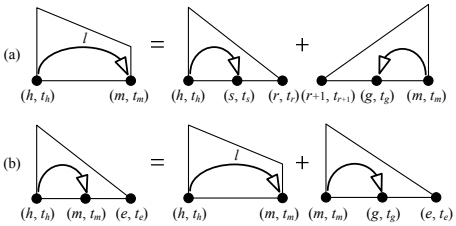


Figure 3: An illustration of the dynamic programming based decoding algorithm for our joint model. We omit the creation of right-headed spans for brevity.

likely POS tags provided by the baseline CRF tagging model following (Li et al., 2011). They find that this approximation substantially improves the efficiency of their joint models without accuracy loss. The time complexity of the algorithm is $O(|\mathscr{L}|n^4q^5)$, and the space complexity is $O(|\mathscr{L}|n^2q^2 + n^3q^3)$ where q is the tag number of each word ($\leq |\mathscr{T}|$).

POS tag pruning. Since the time complexity is high in terms of q, we follow (Li et al., 2011) and prune out the lower-probability POS tags for each word based on their marginal probabilities provided by our baseline CRF model. After pruning, each word has 1.4 candidate POS tags on average and the oracle tagging accuracy is 99.27% on CTB5. On PTB, each word has 1.2 candidate POS tags and the oracle is 99.71%.

Dependency pruning. The parsing time grows quickly with n. Therefore, we train a CRF-based first-order dependency parser to eliminate the unlikely dependencies following (Charniak and Johnson, 2005; Petrov and Klein, 2007; Koo and Collins, 2010). After pruning, 31.3% of the dependencies are left and the oracle dependency accuracy (UAS) is 99.77% on CTB5. On PTB, 28.9% of the dependencies are retained and the oracle UAS is 99.91%.

5 A separately passive-aggressive training algorithm

Online training has proven successful in several structured classification problems such as POS tagging (Collins, 2002) and parsing (McDonald et al., 2005; Zhang and Clark, 2011). Algorithm 1 shows the generic framework of online training when applied to our joint task. Online training iteratively traverses the entire training dataset and use one instance to update the feature weights at each time. First, the best result for the instance is found based on the current feature weights (line 6). Then, the feature weights are updated by comparing the best result and the gold-standard reference (line 7).

According to the update criterion, three different online training algorithms are widely used in parsing community, i.e. *averaged perceptron (AP)* (Collins, 2002), *passive-aggressive algorithm (PA)* (Crammer et al., 2003), and *margin infused relaxed algorithm (MIRA)* (Crammer and Singer, 2001). Previous work mostly adopts AP to train their joint models (Li et al., 2011; Hatori et al., 2011; Bohnet and Nivre, 2012). We compare AP and PA for our joint models and find similar accuracy in both tagging and parsing. Then we propose a variant of PA named as separately passive-aggressive algorithm (SPA) to improve the tagging accuracy. For the sake of conciseness, we do not make comparison with MIRA, since our preliminary results show that MIRA achieves similar performance to AP and PA.

Algorithm 1 Generic online training for joint POS tagging and dependency parsing

1. **Input:** Training Data $\mathbb{D} = \{(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{d}^{(j)})\}_{j=1}^{N}$
2. **Output:** $\mathbf{w}_{\text{joint}}$ $(\equiv \mathbf{w}_{\text{pos}\oplus\text{syn}})$
3. **Initialization:** $\mathbf{w}_{\text{joint}}^{(0)} = \mathbf{0}; \mathbf{v} = \mathbf{0}; k = 0$
4. **for** $i = 1$ **to** I **do** // *iterations*
5. **for** $j = 1$ **to** N **do** // *traverse the samples*
6. $(\hat{\mathbf{t}}, \hat{\mathbf{d}}) = \arg\max_{\mathbf{t},\mathbf{d}} \mathbf{w}_{\text{joint}}^{(k)} \cdot \mathbf{f}_{\text{joint}}(\mathbf{x}^{(j)}, \mathbf{t}, \mathbf{d})$ // *decode based on current feature weights.*
7. $\mathbf{w}_{\text{joint}}^{(k+1)} = \text{update } \mathbf{w}_{\text{joint}}^{(k)} \text{ with } (\mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \hat{\mathbf{t}}, \mathbf{d}^{(j)}, \hat{\mathbf{d}})$ // *update weights according to some criterion.*
8. $\mathbf{v} = \mathbf{v} + \mathbf{w}_{\text{joint}}^{(k+1)}$
9. $k = k + 1$
10. **end for**
11. **end for**
12. $\mathbf{w}_{\text{joint}} = \mathbf{v}/(I \times N)$ // *average the weights*

All algorithms adopt the update direction of the distance between the reference feature vector $\mathbf{f}_{\text{joint}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{d}^{(j)})$ and the feature vector of the best result $\mathbf{f}_{\text{joint}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}, \hat{\mathbf{d}})$. However, different strategies are adopted to determine the update step. AP uses a constant update step of 1.

$$\texttt{AP}\left\{\mathbf{w}_{\text{joint}}^{(k+1)} = \mathbf{w}_{\text{joint}}^{(k)} + \mathbf{f}_{\text{joint}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{d}^{(j)}) - \mathbf{f}_{\text{joint}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}, \hat{\mathbf{d}})\right. \tag{7}$$

PA computes the update step τ_{joint} by considering the loss of the best result, the score distance, and the feature vector distance.

$$\texttt{PA}\left\{\begin{array}{l}\tau_{\text{joint}} = \dfrac{\text{Score}_{\text{joint}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}, \hat{\mathbf{d}}) - \text{Score}_{\text{joint}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{d}^{(j)}) + \rho_{\text{pos}}(\mathbf{t}^{(j)}, \hat{\mathbf{t}}) + \rho_{\text{syn}}(\mathbf{d}^{(j)}, \hat{\mathbf{d}})}{\|\mathbf{f}_{\text{joint}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{d}^{(j)}) - \mathbf{f}_{\text{joint}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}, \hat{\mathbf{d}})\|^2} \\ \mathbf{w}_{\text{joint}}^{(k+1)} = \mathbf{w}_{\text{joint}}^{(k)} + \tau_{\text{joint}}(\mathbf{f}_{\text{joint}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{d}^{(j)}) - \mathbf{f}_{\text{joint}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}, \hat{\mathbf{d}}))\end{array}\right. \tag{8}$$

where $\rho_{\text{pos}}(\mathbf{t}^{(j)}, \hat{\mathbf{t}})$ is the incorrect POS tag number in $\hat{\mathbf{t}}$ according to $\mathbf{t}^{(j)}$, and $\rho_{\text{syn}}(\mathbf{d}^{(j)}, \hat{\mathbf{d}})$ is the dependency error number in $\hat{\mathbf{d}}$ according to $\mathbf{d}^{(j)}$. Following (Johansson and Nugues, 2008), $\rho_{\text{syn}}(\mathbf{d}^{(j)}, \hat{\mathbf{d}})$ increases by 1 for an incorrect dependency and by 0.5 for a correct dependency with a wrong label. Theoretically, Eq. 8 computes the smallest update that makes the correct hypothesis outscores the returned highest-scoring hypothesis by the overall error.

We can see that AP and PA use the same update step for the POS features $\mathbf{f}_{\text{pos}}(.)$ and syntactic features $\mathbf{f}_{\text{syn}}(.)$. Therefore, the weights of the POS features and the syntactic features are of the same scale after training is completed. We argue that this is problematic since the number of the syntactic features are much larger than the number of the POS features. We find that in $\mathbf{f}_{\text{joint}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}, \hat{\mathbf{d}})$, $\mathbf{f}_{\text{syn}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}, \hat{\mathbf{d}})$ contains more than 3,000 non-zero features, whereas $\mathbf{f}_{\text{pos}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}})$ only has less than 200 non-zero features on average. As a result, the model is dominated by the syntactic features and the POS features would play a very limited role in determining the best joint result. Actually, we find that the POS features contribute a very small part to the score of the best joint results when trained with AP or PA (see Figure 5).

After several empirical trials, we find that we can raise the score contributed by the POS features by increasing the update step of the POS features. Furthermore, we find that we can elegantly achieve this goal by slightly modifying the update formulas of PA. We name the proposed training algorithm as the *separately passive-aggressive algorithm (SPA)*. SPA separately

computes two update steps for the POS features and the syntactic features.

$$\text{SPA}\begin{cases} \tau_{\text{pos}} = \dfrac{\text{Score}_{\text{pos}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}) - \text{Score}_{\text{pos}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}) + \rho_{\text{pos}}(\mathbf{t}^{(j)}, \hat{\mathbf{t}})}{\|\mathbf{f}_{\text{pos}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}) - \mathbf{f}_{\text{pos}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}})\|^2} \\ \tau_{\text{syn}} = \dfrac{\text{Score}_{\text{syn}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}, \hat{\mathbf{d}}) - \text{Score}_{\text{syn}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{d}^{(j)}) + \rho_{\text{syn}}(\mathbf{d}^{(j)}, \hat{\mathbf{d}})}{\|\mathbf{f}_{\text{syn}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{d}^{(j)}) - \mathbf{f}_{\text{syn}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}, \hat{\mathbf{d}})\|^2} \\ \mathbf{w}_{\text{pos}}^{(k+1)} = \mathbf{w}_{\text{pos}}^{(k)} + \tau_{\text{pos}}(\mathbf{f}_{\text{pos}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}) - \mathbf{f}_{\text{pos}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}})) \\ \mathbf{w}_{\text{syn}}^{(k+1)} = \mathbf{w}_{\text{syn}}^{(k)} + \tau_{\text{syn}}(\mathbf{f}_{\text{syn}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{d}^{(j)}) - \mathbf{f}_{\text{syn}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}, \hat{\mathbf{d}})) \end{cases} \quad (9)$$

Analogous to PA, Eq. 9 separately finds the smallest update to the POS feature weights that makes the POS score of the correct hypothesis higher than the POS score of the returned highest-scoring hypothesis by the POS error, and the smallest update to the syntactic feature weights that makes the syntactic score of the correct hypothesis higher than the syntactic score of the returned highest-scoring one by the syntactic error. Note that Eq. 9 sometimes leads to negative τ_{pos} or τ_{syn}, because the correct hypothesis already has a POS or syntactic subscore larger than the 1-best one but the deficiency is entirely confined to the other subscore. However, such cases are rare. We just set the update step to zero when it is negative.

Since $\mathbf{f}_{\text{pos}}(.)$ contains much less non-zero features than $\mathbf{f}_{\text{syn}}(.)$, $\|\mathbf{f}_{\text{pos}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}) - \mathbf{f}_{\text{pos}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}})\|^2$ is much smaller than $\|\mathbf{f}_{\text{syn}}(\mathbf{x}^{(j)}, \mathbf{t}^{(j)}, \mathbf{d}^{(j)}) - \mathbf{f}_{\text{syn}}(\mathbf{x}^{(j)}, \hat{\mathbf{t}}, \hat{\mathbf{d}})\|^2$. Therefore, τ_{pos} is much larger than τ_{syn}. Our experiments show that τ_{pos} is about 10 times larger than τ_{syn} on average. This means that the POS features are updated in much larger step than the syntactic features. As a result, the POS features play a more important role in the joint models. We find that the POS score becomes much closer to the syntactic score in the best joint results (see Figure 5).

As discussed in Section 1, (Li et al., 2011) find that their joint models trained with AP are good at resolving syntax-sensitive POS ambiguities like {VV,NN}, whereas their baseline sequential POS tagging model does well in disambiguating the syntax-insensitive ones like {NN,NR}. We believe that it is because the discriminative power of the POS features in resolving such syntax-insensitive POS ambiguities are suppressed in the joint models when trained with AP or PA. Compared with AP and PA, SPA raises the weight of the POS features and can better utilize the disambiguation power of both the POS and syntactic features, leading to large tagging accuracy boost. On the other hand, better tagging results can further help parsing.

6 Experiments

Data. We conduct experiments on CTB5 (Xue et al., 2005). Following the standard practice, we adopt the data split of (Duan et al., 2007; Zhang and Clark, 2008b; Huang and Sagae, 2010) and adopt Penn2Malt[2] for constituent-to-dependency conversion with the head-finding rules of (Zhang and Clark, 2008b).

We also evaluate our models on another version of CTB5 used in (Bohnet and Nivre, 2012) to compare with their joint model. We thank Bernd Bohnet for sharing their dataset. We refer to their dataset as CTB5-Bohnet. We carefully compare CTB5 with CTB5-Bohnet and find that except for the mismatch of about 30 sentence, the datasets differ in both dependency structures and dependency labels. After discussions with Bernd Bohnet, we find out that they adopt Yue Zhang's constituent-to-dependency conversion tool[3] whereas we use Penn2Malt for

[2] http://w3.msi.vxu.se/~nivre/research/Penn2Malt.html
[3] http://sourceforge.net/projects/zpar/files/0.3/

Corpus	Train	Dev	Test
CTB5	16,091	803	1,910
CTB5-Bohnet	16,069	803	1,905
PTB	39,832	1,346	2,416

Table 2: Data used in this work (in sentence number).

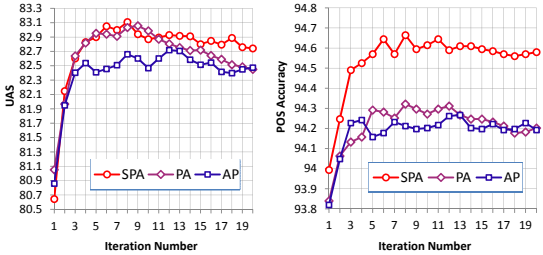

Figure 4: Training curves of UAS and POS tagging accuracy of the unlabeled joint model using SPA/PA/AP on the CTB5 development dataset.

CTB5, although the head-finding rules are the same.

For English, we adopt PTB (sec 02-21 for training, sec 24 for development, sec 23 for test) and convert the original bracketed structures into dependencies using Penn2Malt with its default head-finding rules. Table 2 summarizes the data sets used in the present work.

Evaluation metrics. We use the standard *POS tagging accuracy (POS)* to evaluate POS tagging. For dependency parsing, we use *unlabeled attachment score (UAS)* and *labeled attachment score (LAS)* (all excluding punctuation) (Hajič et al., 2009).

6.1 Experiments on CTB5

6.1.1 Comparison of the three training algorithms

The curves in Figure 4 show the performance of the unlabeled joint model on the development dataset using SPA/PA/AP after each iteration during training. We can see that the PA outperforms AP in both UAS and tagging accuracy. SPA achieves a slightly higher peak UAS than PA, and substantially outperforms both PA and AP in tagging accuracy. In addition, Figure 4 empirically indicates that SPA can converge as fast as AP and PA. We leave the theoretic proof of the convergence of SPA in the future work.

To better understand the reason behind the improvement in tagging accuracy, we try to analyze the two-part model scores, i.e. the POS score $\mathsf{Score}_{\mathrm{pos}}(.)$ and the syntactic score $\mathsf{Score}_{\mathrm{syn}}(.)$. After each iteration, we parse the development dataset using the current weights, and then compute and average each part of the model score. Figure 5 shows the results. For PA and AP, the scale of the POS score is about 1/50 ($10^{1.7} = 50$) of the syntactic score, which means the POS features play an insignificant role in determining the joint result. Obviously, SPA can raise the weight of the POS features, as the POS score is about 1/8 ($10^{0.9} = 8$) of the syntactic score.

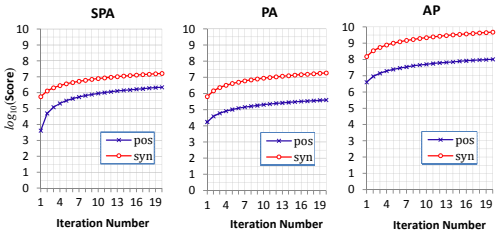

Figure 5: Model score analysis on the CTB5 development dataset. "pos" and "syn" refer to $\text{Score}_{\text{pos}}(.)$ and $\text{Score}_{\text{syn}}(.)$ (see Eq. 6).

	UAS	POS
SPA	81.21	94.51
PA	80.98	94.18
AP	80.94	94.17
pipeline	80.22	93.88

Table 3: Performance of three training algorithms on the CTB5 test dataset.

As a result, the POS features can make more contributions, and the discriminative power of the syntactic features in resolving the syntax-sensitive ambiguities and the power of the POS features in the syntax-insensitive POS ambiguities can be better balanced. We believe this is the reason behind the improvement in tagging accuracy.

Table 3 reports the results of our unlabeled joint model trained with SPA/PA/AP on the CTB5 test dataset. We adopt the parameters which lead to the best parsing accuracy on the development dataset as shown in Figure 4. We also present the performance of our pipelined unlabeled parsing model trained with PA. Different to (Li et al., 2011), our joint models trained with AP or PA both outperform our baseline POS tagging model by about 0.3%. We believe that this may be due to the richer syntactic features incorporated in our joint models. Moreover, SPA can outperform both PA and AP in tagging accuracy by more than 0.3%, which is an error reduction of 5%. Meanwhile, SPA also improves UAS by about 0.2% since better tagging results help parsing. This again demonstrates the effectiveness of the proposed SPA.

6.1.2 Main results

Table 4 shows the final results on the CTB5 test set. Three sets of results are presented. For "gold POS" and "pipeline", we train the parsing models with PA. For "joint" models, we adopt SPA. For each case, we train our models with two different settings, one labeled and one unlabeled, to study the effect of dependency labels. We can see that we achieve best results on all three cases. Specifically, a few interesting conclusions can be drawn.

- Labeling the dependencies during parsing improves UAS by 0.6%/0.5% in the pipeline and joint cases and by 0.2% when using gold-standard POS tags. Dependency labels also slightly help POS tagging in the joint case.
- Compared with the pipeline models, the joint models with SPA can largely improve POS

	Models	LAS	UAS	POS

tagging accuracy by 0.6-0.7%, which is an error reduction of 10%.

- Our joint models largely outperforms their pipeline counterparts by 0.9-1.0% in UAS and 1.2% in LAS.

6.1.3 Analysis

Figure 6 compares different models on a number of high-frequency POS error patterns. An error pattern X→Y means that the focus word, whose true tag is X, is assigned a tag Y. We thank the authors of (Li et al., 2011) for sharing their results. The joint model of (Li et al., 2011) reduces errors for syntax-sensitive ambiguities such as {(DEC,DEG} and {NN,VV}, but largely increases errors for syntax-insensitive ambiguities like {NN,NR}, {NN,JJ}, and {VV,VA}, which can explain its low tagging accuracy. Compared with (Li et al., 2011), our joint model trained with SPA does much better in resolving the syntax-insensitive ambiguities and achieves similar performance to the baseline CRF-based tagging model on those patterns. In summary, we can conclude that our joint model trained with SPA performs similarly to the baseline CRF-

Models		LAS	UAS	POS

based tagging model on the syntax-insensitive ambiguities and meanwhile similarly to the joint model of (Li et al., 2011) on the syntax-sensitive ambiguities. This demonstrates that SPA can better balance the discriminative power of both the POS and syntactic features.

6.2 Experiments on CTB5-Bohnet

We conduct experiments on CTB5-Bohnet to make comparison with the recent results of (Bohnet and Nivre, 2012). Table 5 presents the results. We can see that our pipeline and joint models largely outperform those of (Bohnet and Nivre, 2012). Moreover, the parsing accuracies on this dataset are much higher than those on CTB5 due to the different conversion strategy. We will study the reasons in the future work. Again, we find that labeled parsing can largely improve UAS.

6.3 Experiments on PTB

To find out the effect of the joint models on English, we conduct experiments on PTB. Table 6 shows the results. Several state-of-the-art results are also presented. The pipeline models on English suffer from less error propagation problem than that on Chinese, as the POS tag-

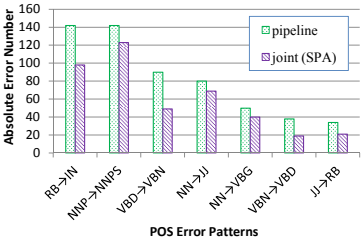

Figure 7: Statistics for different POS error patterns on the PTB test dataset.

ging accuracy on English is much higher (97% vs. 94%). However, we still find that our joint models can obtain a 0.3-0.4% gain in UAS, a 0.4% gain in LAS, and a 0.5% gain in tagging accuracy. Similar to the findings on the Chinese datasets, we demonstrate that labeled parsing can boost UAS by 0.3-0.4% on English. Our labeled joint model outperforms the one of (Bohnet and Nivre, 2012) by 0.1% in UAS and 0.3% in tagging accuracy. Actually, our labeled joint model achieves the best parsing and tagging accuracy on PTB.

We compare the POS tagging results of the unlabeled joint model and the baseline tagging model. Figure 7 shows a few high-frequency error patterns. We can see that the joint model can help resolve a variety of POS ambiguities. For example, the error number of RB→IN (adverbs wrongly tagged as prepositions or subordinating conjunctions) are reduced from 142 to 98, which is a 31% error reduction. Also, the ambiguous pair {VBD, VBN} (verbs of past tense, verbs of past participle) are much better disambiguated by the joint model.

Conclusions

This paper presents a separately passive-aggressive training algorithm (SPA) for joint POS tagging and labeled dependency parsing models. We show that SPA can more properly learn the feature weights than the averaged perceptron (AP) and the passive aggressive algorithm (PA) and can better balance the discriminative power of the POS feature in resolving the syntax-insensitive POS ambiguities and the power of the syntactic features in resolving the syntax-sensitive ambiguities, leading to large tagging accuracy improvement. On the other hand, better POS tagging can further help parsing.

For future work, we are interested in studying SPA from the theoretic perspective and try to provide more insights and justifications of its effectiveness in training the joint models. Besides, although this paper focuses on graph-based joint models, we believe that SPA can also be applied to transition-based joint models (Hatori et al., 2011; Bohnet and Nivre, 2012).

Acknowledgements

We thank Meishan Zhang, for suggesting the easier way to incorporate the POS features during joint decoding, and the anonymous reviewers, for their valuable comments which lead to better understanding of the proposed SPA. Abstract

We study the multi-tweet summarization task, which aims to find representative tweets from a given set of tweets. Multi-tweet summarization allows people to quickly grasp the essential meaning of a large number of tweets. It can also be used as a pre-processing component for information extraction tasks on tweets. The challenge of this task lies in computing a tweet's salience score with little information in a single tweet. We propose a graph-based multi-tweet summarization system that incorporates social network features, which make up for the information shortage in a tweet. Another distinguished feature of our system is that tweet readability and user diversity are considered. We evaluate our system on a manually annotated dataset, and show that our system outperforms the state-of-the-art baseline. We further evaluate our method in a real scenario of summarization of Twitter search results and demonstrate its effectiveness.

Title and Abstract in another language (Chinese)

基于图模型和社会关系特征的推特消息摘要方法

本文考察多推特消息摘要任务。其目的是帮助用户快速了解大量推特消息的基本意思，或在信息抽取前对推特消息做预处理。 该任务的主要挑战是：单条推特消息往往不能提供足够的信息来计算它的显著度。本文提出基于图模型的方法，考虑社会关系网相关的特征、可读性及用户的多样性来克服单条推特消息的不足。 在人工标注的数据集以及推特搜索上，该方法均展示了其有效性。

1 Introduction

Twitter[1] is a microblogging and social networking service with a huge number of users and is continuously growing at a tremendous rate. Tweets, short messages shared through Twitter with less than 140 characters, have become an important repository of real-time information. However, it is often inefficient for people to consume a large number of tweets, owing to the noise prone nature of tweets[2]. We propose the task of multi-tweet summarization to overcome this obstacle: eliminating redundancy and noise while keeping the essential information for a given set of tweets. As an illustrative example, consider the following tweets, returned from Twitter search related to the query "obama":

- "@morrowchris: Christmas card from the Obama's :) http://pic.twitter.com/F3VU52io" thts special.
- Christmas card from the Obama's :) http://pic.twitter.com/7xqBQdBV
- RT @liberalease: RT if you like President Obama better than ALL OF GOP COMBINED. / That was easy :)
- Obama did it! The war is OFFICIALLY OVER! #WelcomeHomeTroops! :)
- obama really brought the troops home :)

The first and the second tweet are almost the same; the third tweet is a private conversation, thus not meaningful for the general audience; and the last two talk about similar things. After summarization, the expected outputs are as follows, which keep the main information with noises removed.

- Christmas card from the Obama's :) http://pic.twitter.com/7xqBQdBV
- obama really brought the troops home :)

We advocate that multi-tweet summarization can play a critical role for many tweet related studies, which have attracted increasing research interests in recent days, such as named entity recognition (NER) and sentiment analysis (SA) for tweets. One common issue of these tasks is the scalability challenge, which means they are required to process a huge number of tweets each day. Summarization system is then an ideal pre-processing component in the sense that it helps to reduce the number of tweets for processing without much lose of information.

Multi-document summarization has been well studied, and a couple of systems have been developed. We test LexRank (Erkan and Radev, 2004), a state-of-the-art summarization system and find a sharp drop of ROUGE-2, from 0.3894 on news to 0.2871 on tweets. This can be largely attributed to the short and noise prone nature of tweets, which causes a single tweet to be insufficient to provide reliable information to compute its salience score. We develop a graph-based summarization system that aggregates social signals, i.e., re-tweeted times and follower numbers to handle this challenge. More specifically, the translation probability from one tweet to the other depends on both the similarity between the two tweets and the social network features associated with the second tweet. This largely differentiates our system from existing studies, such as the work of Sharifi et al. (2010), which uses only tweet-level content features (e.g., keywords) to select representative sentences.

[1] http://www.twitter.com

[2] Noise in tweets means ill-formed words or sentences in tweets.

Besides utilizing social signals, our system has two additional features. Firstly, the readability feature is introduced to the graph model to reduce the chance of tweets hard to read to appear in the summarization. Several factors are considered while computing a tweet's readability, including: 1) The number of out-of-vocabulary (OOV) words; 2) the number of words; and 3) the number of abnormal symbols, e.g., "!,,),(,*". Secondly, while selecting representative tweets using an alternative of the Maximal Marginal Relevance (MMR) (Goldstein et al., 1999) algorithm, our system penalizes tweets which are selected from a same twitter account, to achieve diversity among users.

We collect 100 sets of tweets, each of which is related to a trending topic. For each set of tweets, we manually select representative tweets as the summarization, forming the gold-standard dataset. We show that our system compares favorably to the LexRank (Erkan and Radev, 2004) baseline in terms of ROUGE-1 and ROUGE-2. We also show the positive effects of considering social signals, readability and user diversity, respectively. To understand how well our method performs in a real scenario, we apply our system to summarize Twitter search results, and consistently observe an improvement of user's satisfaction of Twitter search in a serials of user studies. It is worth mentioning that our proposed summarization system can be easily adapted to other social contents that are short and noisy but with rich social evidences, e.g., Facebook updates or short messages shared through Facebook.

Contributions of this work are summarized as follows.

1. We propose a graph-based multi-tweets summarization system that leverages social network features, readability and user diversity for selecting representative tweets.
2. We evaluate our system on a human annotated dataset and show our system outperforms the baseline. We conduct extensive user studies and show our system considerably improves user's satisfaction of Twitter search.

The rest of this paper is organized as follows. Section 2 introduces related work. Section 3 defines the task. Section 4 describes the baseline. Section 5 details our method and Section 6 evaluates our method. Section 7 demonstrates the application of the proposed method to the Twitter search. Finally, Section 8 concludes with a discussion of future work.

2 Related Work

Two categories of research are highly related to our work: multi-document summarization and recent studies of tweets.

2.1 Multi-document Summarization

Abstraction and selection are two strategies employed for multi-document summarization. The former involves information fusion (Barzilay et al., 1999; Xie et al., 2008), sentence compression (Knight and Marcu, 2002), and reformulation (Barzilay et al., 2001; Saggion, 2011); while the latter requires computing salience scores of some units (e.g., sentences, paragraphs) and extracting those with highest scores with redundancy removed. NewsBlaster[3] and our method are examples of abstraction and selection based methods, respectively. We choose the selection strategy because it is relatively simpler, e.g., not requiring

[3]http://newsblaster.cs.columbia.edu

language generation to produce a grammatical and coherent summary, and better suites the scenario of tweet summarization. Note that our method considers each tweet as the unit for summarization, which often cannot provide reliable information to compute the salience. This is one main difference between our system and the existing studies.

Existing selection-based methods can be divided into four categories: cluster based (Hardy et al., 2002), centroid based (Radev, 2004), graph based (Erkan and Radev, 2004; Mani and Bloedorn, 1999), and machine learning based (Neto et al., 2002). Cluster-based methods first separate a document set into several groups, each representing a sub-topic. Then representative sentences are selected from each group, and finally those sentences are put together as the summarization of the whole document set. Centroid-based methods compute the center of a document set, and then use the similarity between the sentence and the center as the sentence salience score. Graph-based methods construct a graph, where a vertex denotes a sentence and the weight of an edge represents the similarity between the two sentences connected by the edge. Then, similar to PageRank (Page et al., 1998), a Markov Random Walk is performed on the graph to compute the salience score of every sentence. Machine learning based methods model the summarization process as a classification problem: Whether or not a sentence should be selected as summary sentences. A proper classifier, e.g., a Naive Bayes classifier, is learnt statistically from the training data. There are methods between those categories. For example, Wan and Yang (2008) consider cluster level information, i.e., the importance of the cluster and the relevance of sentence to the cluster, for computing sentence salience score. Motivated by LexRank (Erkan and Radev, 2004), we adopt graph based methods. Differently, our system incorporates rich social network features and considers readability to compute salience score of every tweet.

Most existing studies focus on formal texts such as news. However, exceptions exist. For instance, Qazvinian and Radev (2010, 2008) study the problem of summarizing a scientific paper. They propose a clustering approach where communities in the citation summary's lexical network are formed and sentences are extracted from separate clusters. Sharifi et al. (2010) use the Phrase Reinforcement algorithm to generate one-line summary for a collection of tweets related to a topic. Though our method is also designed for tweets, there are several significant differences. Firstly, our method does not assume that the input tweets are about a topic. Secondly, our method selects representative tweets by exploiting social network features, readability and keywords. In contrast, Sharifi et al. (2010) find the most commonly used phrases that encompass the topic phrase.

The maximal marginal relevance (MMR) measure (Goldstein et al., 1999) is widely used in summarization to simultaneously rewards relevant sentences and penalizes redundant ones by considering a linear combination of two similarity measures. We adopt an alternative implementation of MMR, which greedily selects the next most salient tweet whose similarity to any previously selected tweet is less than a threshold and that the number of tweets from the same account is also below a threshold.

2.2 Research on Tweets

Recently we have witnessed growing research interests in tweets. For example, Kwak et al. (2010) first study the topological characteristics of Twitter and its power as a new medium for information sharing; various studies are carried out on how Twitter is used by leg-

islators, particularly by members of the United States Congress (Golbeck et al., 2010), by city police departments in large U.S. cities (Heverin and Zach, 2010), and by scholars (Priem and Costello, 2010); Jansen et al. (2009) report research results investigating microblogging as a form of electronic word-of-mouth for sharing consumer opinions concerning brands; Heverin and Zach (2010) give insights into why particular events resonate with the population. All the above studies indicate the critical role of tweets as a dynamic information source.

There is another line of studies aiming to help people to efficiently access tweets. For instance, Finin et al. (2010) annotate named entities in tweets by exploiting Amazon's Mechanical Turk service[4] and CrowdFlower[5]; Liu et al. (2011) propose to combine a K-Nearest Neighbors (KNN) classifier with a linear Conditional Random Fields (CRF) model under a semi-supervised learning framework to recognize named entities in tweets; Liu et al. (2010) conduct a pilot study of Semantic Role Labeling on tweets; Sankaranarayanan et al. (2009) extract breaking news from tweets to build a news processing system, called TwitterStand; Duan et al. (2010) give an empirical study on learning to rank of tweets; Weng et al. (2010) propose TwitterRank, an extension of the PageRank algorithm to identify influential twitter accounts; O'Connor et al. (2010) present TweetMotif which groups tweets by frequent significant terms; Inouye and Kalita (2011) compare several tweet summarization algorithms that use text features like TFIDF to compute the similarity between any two tweet; Sharifi et al. (2010) exploit the Phrase Reinforcement Algorithm to find the most commonly used phrases that encompass the given topic phrase, based on which salient sentences are selected; and most recently, Efron (2011) offers a comprehensive introduction to the problems encountered by researchers and developers of Information Retrieval (IR) systems in microblog settings. Our work develops this line of research, with its focus on summarizing multiple tweets using a novel summarization system which considers social network related information, such as re-tweeted times and follower numbers, and partially addresses some of the research challenges discussed by Efron (2011).

3 Task Description

A tweet is a short text message containing no more than 140 characters. Here is an example: "mycraftingworld: #Win Microsoft Office 2010 Home and Student *2Winners* #Contest from @office and @momtobedby8 #Giveaway http://bit.ly/bCsLOr ends 11/14", where "mycraftingworld" is the name of the user who published this tweet. Words beginning with the "#" character, like ""#Win", "#Contest" and "#Giveaway", are hash tags, usually indicating the topics of the tweet; words starting with "@", like "@office" and "@momtobedby8", represent user names, and "http://bit.ly/bCsLOr" is a shortened link.

Given a collection of tweets, our task is to output a subset of no more than M representative tweets that best preserve important information in the original set. The number of input tweets varies from hundreds, e.g., for tweets related to a given query or user, to tens of millions, e.g., for tweets in a given time range. M is a systematic parameter whose value is set according to Formula 1, where α is set to 0.05 and n is the input size. In this study, we limit our attention to English tweets only, though our method is almost language

[4]https://www.mturk.com/mturk/
[5]http://crowdflower.com/

independent[6].

$$M = \lceil \alpha \cdot n \rceil \quad (1)$$

An example of tweet summarization is given below. The input collection is:

- Finally got Windows 8 on my laptop as a primary OS. Sort of my way of welcoming the new holidays :)
- I Just Got Windows 8 . Whoooo ! :)
- ...
- Windows 8 Picture Passwords: Smudging Your Finger for Security interesting alternative...it's not a replacement :)
- Windows 8 will have picture password sign in http://is.gd/JoXYHx

Suppose $M = 2$, the generated summarization is:

- I Just Got Windows 8 . Whoooo ! :)
- Windows 8 will have picture password sign in http://is.gd/JoXYHx

From this example, it can be seen that selection based multi-tweet summarization allows users to quickly grasp the essential information conveyed in the input tweets, which are prone to noise and rich in redundancy. This is exactly the main motivations of this study.

4 The Baseline

We choose an adapted LexRank as the baseline, considering that LexRank outperforms both centroid-based methods and other systems participating in Document Understanding Conferences (DUC) in most of the cases, and proves quite insensitive to the noise in the data. Note that the one-line summarization system (Sharifi et al., 2010), which requires a given topic and focuses on the selection of key phrases most related to the topic, works on a setting different from ours.

In general, LexRank is a graph-based method for computing relative importance of textual units. Erkan and Radev (2004) use it to compute the sentence importance based on the concept of eigenvector centrality in a graph representation of sentences. They use a connectivity matrix based on intra-sentence cosine similarity as the adjacency matrix of the graph representation of sentences. We adapt LexRank to compute the importance of tweets.

Algorithm 1 shows the framework of the baseline. The input tweets are denoted by ts and the outputted summarization are denoted by ret.

We first call the function $repr$ to represent each tweet t into bag-of-words vector $\vec{t}$, with the usual TFIDF weighting schema as defined in Formula 2, where tf is the occurrence times of the term in the tweet, N is the total number of the tweets for summarization, df is the number of tweets that contain that term. To extract words from tweets, some preprocessing is conducted. Firstly, stop words are removed. Stop words are mainly from a set of frequently-used words[7]. We also extract the top 200 most frequent words from about

[6]For example, to summarize Chinese tweets, the main effort involves an additional pre-processing: to run Chinese work breaker to get words.

[7]http://www.textfixer.com/resources/common-english-words.txt

Algorithm 1 Framework of the baseline.

Require: A collection of tweets: ts.

1: Initialize the set of tweet vectors ts_v:$ts_v = \emptyset$.
2: **for all** tweet $t \in ts$ **do**
3: Get a feature vector $\vec{t}$:$\vec{t} = repr(t)$.
4: Add $\vec{t}$ to ts_v:$ts_v = ts_v \cup \{\vec{t}\}$.
5: **end for**
6: Construct the graph:$gr = graph(ts_v)$.
7: Compute salience scores:$sc = scores(gr)$.
8: Select tweets :$ret = select(sc, ts)$.
9: **return** ret.

10 million tweets, from which another 54 words are manually selected as stop words. Secondly, tweet metadata (e.g., links, account names and hash tags) is extracted using regular expressions and then normalized. Links and account names are replaced by LINK and ACCOUNT, respectively, while hash tags are treated as common keywords. Finally, a simple dictionary-lookup based normalization procedure is conducted, using a pre-compiled list including incorrect/correct word pairs, e.g., "loooove"/"love", to correct common ill-formed words.

$$\text{TFIDF} = tf \times ln(\frac{N}{df}) \tag{2}$$

Then we call the function $graph$ to construct a graph, denoted by $G =< V, E >$, where V stands for the set of vertexes and E represents the set of edges. Firstly, a vertex is introduced for each tweet. Secondly, for each tweet pair, if their similarity is non-zero, an unidirectional edge connecting the corresponding vertices is added. The edge weight is defined in Formula 3, where i denotes the i^{th} vertex, corresponding to tweet $\vec{t}_i$. We enforce $\text{sim}(\vec{t}, \vec{t}) = 0$ to avoid self-transition. Following Formula 3, the transition probability from the i^{th} vertex to the j^{th} vertex can be defined by Formula 5. It is worth noting that $p(i, j)$ is usually not equal to $p(j, i)$ because of the different normalization factor in the denominator.

$$w(i, j) = \text{sim}(\vec{t}_i, \vec{t}_j) \tag{3}$$

$$\text{sim}(\vec{t}_i, \vec{t}_j) = \frac{\vec{t}_i \cdot \vec{t}_j}{|\vec{t}_i| \cdot |\vec{t}_j|} \tag{4}$$

$$p(i, j) = \begin{cases} \dfrac{w(i, j)}{\sum_{j'} w(i, j')}, if \sum\limits_{j'} w(i, j') \neq 0 \\ 0, otherwise \end{cases} \tag{5}$$

Next we call the function $scores$ to compute the salience score for each tweet according to Formula 6, where s_i is the salience score of the i^{th} vertex, λ is the damping factor, and V is

the number of tweets for summarization.

$$s_i = \lambda \cdot \sum_{j \neq i} s_j \cdot p(j,i) + (1-\lambda) \cdot 1/|V| \tag{6}$$

We can consider the above process as a Markov chain, which takes tweets as states and the transition matrix T is defined in Formula 7, where E is the identity matrix. Since T is irreducible, it is guaranteed that the salience scores can be obtained by the principal eigenvector of the transition matrix T.

$$T = \lambda \cdot P + (1-\lambda)/|V| \cdot E \tag{7}$$

For implementation, the initial salience scores of all tweets are set to 1 and the iteration algorithm in Formula 6 is used to compute the new scores. Usually the convergence of the iteration algorithm is achieved when the difference between the scores computed at two successive iterations for any tweet goes below a given threshold δ.

Finally, we run the function $select$, an alternative implementation of the MMR algorithm, to select at most M tweets as the summarization. Whether a tweet is selected as a representative depends on two factors: its salience score and its similarity to the already selected tweets. Specifically, a tweet is chosen if it is the candidate with the greatest salience score and its similarity to any selected tweet is below a threshold ϵ [8]. No matter whether the most salient candidate is chosen or not, it will be removed from the candidate set. This selection process repeats until M tweets are chosen or the candidate set is empty. Details are illustrated in Algorithm 2.

Algorithm 2 Representative tweet selection.

Require: maximum number of tweets allowed: M.
Require: Scored tweets: $\{(\vec{t}, score)\}$.

Initialize the set of selected tweets sel:$sel = \emptyset$.
Initialize the set of candidates cd: $cd = \{(\vec{t}, score)\}$.
while $|sel| < M$ and $|cd| \neq 0$ **do**
    Select the most salient t^*:$t^* = \arg\max_{t \in cd} t.score$.
    Remove t^* from cd:$cd = cd - \{t^*\}$.
    if $\forall s \in sel, sim(s.\vec{t}, t^*.\vec{t}) < \epsilon$ **then**
        Select t^*:$sel = sel \cup \{t^*\}$.
    end if
end while
return sel.

5 Our System

The baseline has several limitations. Firstly, only terms are used to compute a tweet's salience score. Because a tweet is short and often noisy, the computed importance score is often not reliable. For example, consider the following two tweets:

[8] We treat δ and ϵ as systematic parameters, whose value are experimentally determined on the development dataset.

- is Obama planning to spend the 17 days in Hawaii? #vacation#
- Obama Christmas shopping for his family, already in Hawaii for vaca

They have similar meanings but low cosine similarity, largely caused by the “vaca" in the second tweet , which is actually an abnormal abbreviation of “vacation" in the first tweet. Secondly, tweets are selected only according to their salience scores, despite how hard they can be understood. It has been observed that in the summarization outputted by the baseline, a significant part of tweets are hard to read, which are short, or noisy, e.g., having many OOV words and grammatically incorrect. As an illustrative example, consider the following two tweets. The first one is short and not meaningful while the second one is informally written with low readability.

- Rodney Hood, folks, Rodney Hood....
- Rodney Hood cold . yeah he going pro in another year or so

Thirdly, because user diversity is ignored, too many tweets from the same Twitter account occur in the summarization.

Our system try to overcome these limitations by: 1) Incorporating social network features, i.e., re-tweeted times and follower numbers to make the salience score more reliable; 2) introducing the readability feature to make the outputted summarization more readable; and 3) considering user diversity, i.e., dropping a tweet if the number of selected tweets from the same Twitter account goes above a threshold.

Accordingly, we make three updates on the framework illustrated in Algorithm 1. First the $graph$ function is modified so that the weight between two tweets is computed according to Formula 8, where $a(j)$ is defined in Formula 9. $a(j)$ incorporates two kinds of evidences: 1) Social network features, which says a tweet is more important if it has been re-tweeted more times (retw(j)), or it is published by an account with more followers (foll(j)); and 2) Readability (readability(j)), which says more readable tweets are more favorable. With the updated graph, the same scoring function $scores$ is called to assign a salience score for each tweet.

$$w(i,j) = \frac{\text{sim}(\vec{t}_i, \vec{t}_j) \cdot a(j)}{\sum_{j'} \text{sim}(\vec{t}_i, \vec{t}_{j'}) \cdot a(j')} \tag{8}$$

$$a(j) = \text{retw}(j) \cdot \text{foll}(j) \cdot \text{readability}(j) \tag{9}$$

Secondly, we modify Algorithm 2 to add user diversity into the summarization. We calculate the number of different Twitter accounts of the input tweets, denoted by K, then define a threshold N according to Formula 10, where β is a systematic parameter with a positive real value. To decide if tweet t should be put into the outputted summarization, we check the number of the selected tweets from t's account. If that number is greater than N, we drop the tweet, otherwise we select it.

$$N = \left\lceil \beta \cdot \frac{M}{K} \right\rceil \tag{10}$$

We use Twitter APIs, i.e., http://twitter.com/#!/[account], to compute the number of followers for a given Twitter account. For example, filling “[account]" with “lxh5147" can

check out how many Twitter accounts are following “lxh5147". We estimate how many times a tweet is re-tweeted by analyzing the content of a large collection of reference tweets, which are crawled using Twitter APIs within the same day. For any two tweets, if the first one starts with “RT" followed by the content of the second one, we say the second tweet is re-tweeted by the first one.

Readability is the ease in which text can be read and understood. One widely adopted readability is measured according to the Flesch Formula 11, Where: ASL is the average sentence length (number of words divided by number of sentences) and ASW is the average word length in syllables (number of syllables divided by number of words).

$$206.835 - (1.015 \times ASL) - (84.6 \times ASW) \tag{11}$$

We enhance this formula by considering two additional factors: 1) The average number of OOV words, i.e., the number of OOV words divided by the total number of words, denoted by AOW; and 2) the average number of abnormal symbols, i.e., the number of abnormal symbols divided by the total number of words, denoted by AAS. We compile a dictionary of 1 million words[9], and a list of 125 symbols to identify OOV words and abnormal symbols, respectively.

The updated measurement is then defined in Formula 12, in which the coefficients (i.e., 10.5 and 9.8) are determined using linear regression. We further normalize the readability using Formula 13, where $readability^{(i)}$ is the readability of the i^{th} tweet computed using Formula 12. In Formula 13, we assume a normal distribution of tweet readability, whose mean and variance are defined in Formula 14 and 15, respectively, where n is the number of the input tweets.

$$206.835 - (1.015 \times ASL) - (84.6 \times ASW) - (10.5 \times AOW) - (9.8 \times AAS) \tag{12}$$

$$\text{readability}(i) = Pr(readability < readability^{(i)}) \tag{13}$$

$$\hat{\mu} = \frac{1}{n}\sum_{i=1}^{n} readability^{(i)} \tag{14}$$

$$\hat{\sigma}^2 = \frac{1}{n-1}\sum_{i=1}^{n}(readability^{(i)} - \hat{\mu})^2 \tag{15}$$

6 Evaluation

In this section, we evaluate our system on a manually annotated dataset. We also study the contribution of social signals, readability and user diversity, respectively.

[9]To get a copy of the dictionary, please contact the first author.

6.1 Data Preparation

Unlike such multi-document summarization tasks in Document Understanding Conference (DUC), no gold-standard dataset for tweet summarization is available. We manually annotate a dataset (DS) for automatic evaluation of summarization, as described below.

100 English trending topics from March 1^{st} to March 30^{th} 2010 are randomly selected. Some examples are "lady gaga", "Obama", "Denver", "james Cameron", and "ipad". For each trending topic, at most 1,000 English tweets are crawled using Twitter APIs. For each tweet, the information about its re-tweeted times and the number of followers of its account are computed. To facilitate future experiments, for each crawled tweet, stop words are removed and its metadata and keywords are extracted. The readability of each tweet is automatically calculated using Formula 13. Three annotators[10] are involved. For each topic, they independently select M tweets (computed using Formula 1) from the related tweets, thus forming the gold-standard dataset DS. 10 topics are randomly chosen for development and the remainder for testing, denoted by DS_T. The system parameters, i.e., λ, δ, ϵ and β are experimentally set to the optimal values (0.85, 0.0001, 0.2 and 10), which yield the best performance on the development dataset.

For any topic c and any pair of annotated results from two annotators, denoted by A_c and B_c, we compute the inter-agreement with Formula 16. The average inter-agreement (over all topics and all possible pairs) is 0.78.

$$\text{inter}-\text{agreement}(A_c, B_c) = \frac{|A_c \bigcap B_c|}{|A_c \bigcup B_c|} \tag{16}$$

6.2 Evaluation Metrics

We adopt the widely used ROUGE-N as performance metrics, which is an n-gram recall based statistic that can be computed as follows:

$$\text{ROUGE}-\text{N}(s) = \frac{\sum_{r \in R} \overrightarrow{\Phi_n(r)} \cdot \overrightarrow{\Phi_n(s)}}{\sum_{r \in R} \overrightarrow{\Phi_n(r)} \cdot \overrightarrow{\Phi_n(r)}} \tag{17}$$

Where: $R = \{r_1, r_2, \cdots, r_m\}$ is a set of reference summaries; s is a summary generated automatically by some system; $\overrightarrow{\Phi_n(d)}$ is a binary vector representing the n-grams contained in a document d; the i^{th} component $\Phi_n^i(d)$ is 1 if the i^{th} n-gram is contained in d and 0 otherwise.

6.3 Results

Table 1 reports the ROUGH-1 and ROUGE-2 of the baseline (BS) and our system (SS), with $\alpha = 0.05$. We observe a significant improvement of ROUGE-1 and ROUGE-2, showing the overall advantages of our system. We vary M, and find our method consistently outperforms the baseline, as showed in Table 2. As a case study, we list the outputs of our system and the baseline, respectively, in Table 3.

[10]They are native English speakers.

Social signals, readability and user diversity are added to the baseline, respectively, to study their contributions. The corresponded systems are denoted by BS_S, BS_R and BS_U, respectively. Table 4 shows the results, from which it can be seen that social signals are most helpful, followed by readability and then user diversity. We also combine any two of the three factors, add them to the baseline, and test the updated system. Results are listed in Table 5. The subscript letters S, R and U stand for social network features, readability and user diversity, respectively. We see the combination of S and R outperforms other settings.

System	ROUGE-1	ROUGE-2
BS	0.3591	0.2871
SS	0.4562	0.3692

7 Application to Twitter Search

Twitter search is an increasingly popular service of providing access to tweets. It returns a list of matched tweets for a given query, as illustrated in Figure 1. We observe two problems here. Firstly, there are often similar tweets in the search results. For example, the first and the second tweet in Figure 1 are almost the same. This kind of redundancy is annoying since in general users are more interested in “new" information when reading tweets. Secondly, a large number of tweets in search results, e.g., those about private conversations or those which are fragmented and hard to understand (e.g., the fifth tweet in Figure 1), are not meaningful for the general audience.

We apply our multi-tweet summarization system to the results of Twitter search, and build an end-to-end application, as illustrated in Figure 2. By default only representative tweets are displayed, and each of them has a “show similar results” link. Clicking the link will show at most 10 tweets most similar to the corresponded tweet.

We conduct user studies to evaluate whether our system is helpful to Twitter search. We first randomly sample 50 queries (DS_U) from the trending topics from March 1^{st} to March

System	ROUGE-1	ROUGE-2

Figure 2: An example of summarization of Twitter search results about “Obama".

30^{th} 2010. Then for each query in DS_U, results from Twitter search and our system are displayed side by side, and 3 users[11] are asked to choose which is better. For each user, we record how many queries our system is voted to be better. The inter-rater agreement[12] between users is also computed. Table 6 shows the results, suggesting that users tend to be more satisfied with our system. The inter-rater agreement is 0.74, indicating that users are more likely to agree with each other. Note that the values in the “Votes for ours" column are computed using Formula 18, where Q_u denotes the queries for which the user $u \in \{A, B, C\}$ believes our system gives better results than Twitter search, and Q denotes all queries in

[11]They are college students who did not receive any special training as preparation.

B	57
C	58

Table 6: Comparison between our system and Twitter search. A, B and C denote three annotators, respectively. The inter-rater agreement is 0.74.

8 Conclusion and Future work

We study the task of multi-tweet summarization, which selects a given number of representative tweets so as to keep important information while dropping noise and redundancy. One main motivation of this task is to provide a tool to help people efficiently access a large number of tweets, which are short and prone to noise. This is important considering that tweets are one increasing popular repository of fresh information. We advocate that multi-tweet summarization is an important building block for other information extraction tasks on tweets, in the sense that it allows these tasks to focus on important tweets.

One main challenge is the lack of information to compute a tweet's salience score. We propose a graph-based system which leverages social network features, readability and user diversity to address this challenge. On a manually annotated gold-standard dataset, we show our system outperforms the state-of-the-art baseline. We apply our system to Twitter search and demonstrate that it improves user's satisfaction to Twitter search.

In our experiments, we have observed that users are often more interested in tweets with events or opinions. Therefore, exploiting events and opinions in tweets represents a promising direction to explore in future.

ABSTRACT
Keyphrase extraction aims to find representative phrases for a document. Keyphrases are expected to cover main themes of a document. Meanwhile, keyphrases do not necessarily occur frequently in the document, which is known as the *vocabulary gap* between the words in a document and its keyphrases. In this paper, we propose Topical Word Trigger Model (TWTM) for keyphrase extraction. TWTM assumes the content and keyphrases of a document are talking about the same themes but written in different languages. Under the assumption, keyphrase extraction is modeled as a translation process from document content to keyphrases. Moreover, in order to better cover document themes, TWTM sets trigger probabilities to be topic-specific, and hence the trigger process can be influenced by the document themes. On one hand, TWTM uses latent topics to model document themes and takes the coverage of document themes into consideration; on the other hand, TWTM uses topic-specific word trigger to bridge the vocabulary gap between the words in document and keyphrases. Experiment results on real world dataset reveal that TWTM outperforms existing state-of-the-art methods under various evaluation metrics.

TITLE AND ABSTRACT IN CHINESE

采用基于主题的词触发模型进行关键词抽取

关键词抽取旨在发现文档中有代表性的词或者短语。抽取的关键词应当覆盖文档的主要话题。同时，关键词并不一定在文档中频繁出现，这就是所谓的文档与关键词间的“词汇鸿沟”问题。本文提出一种基于主题的词触发模型（TWTM）进行关键词抽取。该模型假设文档内容和关键词是在用不同的语言描述相同的话题。在这个假设下，关键词抽取就可以被建模为从文档到关键词的翻译过程。为了更好地覆盖文档话题，该模型的触发概率都是主题相关的，从而使触发过程受到文档主题的影响。一方面，该模型利用隐含主题对文档话题进行建模，从而将文档主题的覆盖度考虑在内；另一方面，该模型采用主题相关的词触发建立起了文档与关键词的桥梁。在真实数据上的实验结果表明，该模型优于已有关键词抽取方法。

1 Introduction

For information retrieval and management, people usually annotate a collection of keyphrases to a document as its brief summary. Keyphrases can be found in most digital libraries and information retrieval systems (Turney, 2000; Nguyen and Kan, 2007). Web information, most of which is in the form of text, is growing at a rapid rate. For the large volume of documents, it will be inefficient for human editors to manually index keyphrases. Therefore, automatically extracting keyphrases for documents is proposed as a challenging task in natural language processing. The task is also referred to as *keyphrase extraction*.

When we enter Web 2.0 era, social tagging is invented to help users manage and share information. The social tags can be regarded as a type of keyphrases. Various methods have been proposed for automatic social tag suggestion, which can be regarded as a special type of keyphrase extraction. In social tag suggestion, given a document, the system will select keyphrases from a controlled tag list instead of document itself. It indicates that keyphrases do not necessarily occur in the given document. It is obvious that it provides a more flexible and convenient scheme compared to traditional keyphrase extraction, and thus becomes the main application of keyphrase extraction. In this paper, we will focus on the new setting of keyphrase extraction, which is named as *keyphrase extraction from a controlled vocabulary*. In the following paper, unless specifically noted, we use keyphrase extraction as referred to the new setting.

As a summary of document, keyphrases are expected to represent and cover the main themes of the given document. Suppose there is an article talking about the "Apple" company and its smartphone "iPhone". The extracted keyphrases are expected to cover the both themes, i.e., "Apple" and "iPhone". This indicates that a set of keyphrases that focuses on only one theme will not be adequate. Meanwhile, representative keyphrases do not necessarily occur frequently in the document. Take the article for example again, it may mention "iPhone" (smartphone of Apple), "iPad" (tablet computer of Apple) and "Steve Jobs" (founder of Apple) for many times, but refer to "Apple" not so frequently. Nevertheless, it is intuitive that "Apple" should be a representative keyphrase of the document. We refer the phenomenon as a *vocabulary gap* between words in document and keyphrases. In summary, given a document, keyphrase extraction should: (1) find a set of representative keyphrases that can better cover the main themes of the document. (2) The selection of keyphrases should primarily rely on their semantic relatedness with the document rather than being constrained by their occurrence frequencies in the document. This requires keyphrase extraction can bridge the vocabulary gap between document content and keyphrases.

Many unsupervised methods have also been extensively explored for keyphrase extraction. The most simple unsupervised method is ranking the candidate keyphrases according to TFIDF (Salton and Buckley, 1988) and then selecting top-ranked ones as keyphrases. There are also graph-based methods (Mihalcea and Tarau, 2004; Wan and Xiao, 2008b,a; Liu et al., 2010), clustering-based methods (Grineva et al., 2009; Liu et al., 2009) and latent topic models (Heinrich, 2005; Blei and Lafferty, 2009) proposed for keyphrase extraction. Most of these methods take frequencies of candidate keyphrases as the crucial decision criteria, and thus tend to select those high-frequency ones as keyphrases. Given sufficient annotation data for training, we can adopt the classification-based approach for keyphrase extraction. For example, some methods (Frank et al., 1999; Witten et al., 1999; Turney, 2000) regard keyphrase extraction as a binary classification problem (is-keyphrase

or non-keyphrase). Keyphrase extraction can also be considered as a multi-label classification problem (Tsoumakas and Katakis, 2007), in which each keyphrase is regarded as a category label. Various methods such as Naive Bayes (Garg and Weber, 2008) and *k*NN (Li et al., 2009) have been explored. Some researchers proposed using latent topics to build semantic relations between words and tags. The representative methods include TagLDA (Krestel et al., 2009; Si and Sun, 2009) and Content Relevance Model (CRM) (Iwata et al., 2009). However, these methods usually suffer from the over-generalization problem.

Recently, a new approach based on word alignment models (WAM) in statistical machine translation (SMT) has been proposed for keyphrase extraction (Ravi et al., 2010; Liu et al., 2011b,a, 2012). WAM-based methods assume the content and keyphrases of a document are describing the same themes but written in different languages. Under this assumption, WAM-based methods regard keyphrase extraction as a translation process from document content to keyphrases. This process is modeled as a trigger from important words in document content to keyphrases according to trigger probabilities between words and keyphrases. WAM-based methods will learn trigger probabilities from sufficient document-keyphrase pairs. With the trigger probabilities, given a novel document, WAM-based methods are able to extract relevant keyphrases that do not necessarily occur so frequently in the document.

Although achieving significant improvement in bridging the vocabulary gap between document and keyphrases, WAM-based methods, however, cannot well guarantee the coverage of document themes. The crucial reason is analyzed as follows. WAM-based methods, formalizing trigger probabilities at *word level*, consider each single word in document and project from document content to keyphrases. However, the coverage of document themes should be appreciated at *topic level*, which is beyond the power of WAM-based methods.

A promising approach for representing document themes is latent topic models (Blei et al., 2003). In topic models, both words/keyphrases and documents are represented as probabilistic distributions over latent topics. Topic models are widely adopted as a guaranteed approach to represent document themes. Topic models themselves can also be used for keyphrase extraction, referred to as topic-based methods, by simply ranking keyphrases according to their semantic relevance with the document themes in terms of latent topics. Topic-based methods can be regarded as a trigger process at topic level, contrast to the trigger process at word level in WAM-based methods. Since common keyphrases receive larger probabilities given a topic, topic-based methods tend to select those keyphrases that are too general to tightly capture the main themes of the document. For example, it may select "IT" as keyphrase for the above mentioned document, which is so general that cannot reflect the document themes well.

Is there a way to leverage the power of both word-level projection and topic-level coverage in keyphrase extraction? Can the two techniques, i.e., word alignment models and latent topic models, be integrated together to complement each other for keyphrase extraction? To address the problems, we propose Topical Word Trigger Model (TWTM) for keyphrase extraction. TWTM inherits the advantage of WAM-based methods, and also incorporates latent topic models so as to promise the coverage of document themes.

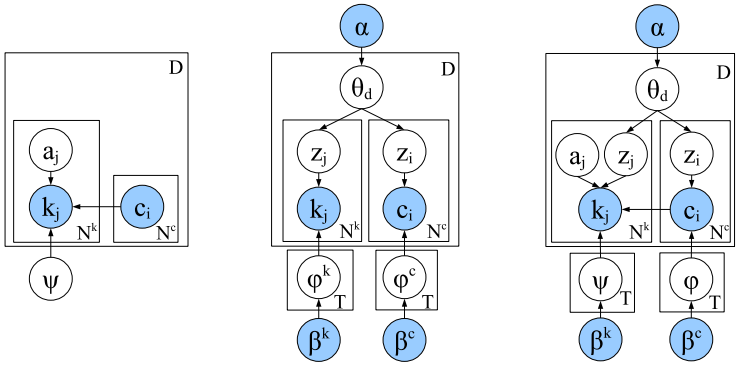
To compare and analyze the characteristics of different approaches for keyphrase extraction, we also introduce the method based on word alignment models, i.e., Word Trigger Model (WTM), and the method based on polylingual topic models, i.e., Topic Trigger Model (TTM).

As these names suggest, WTM identifies keyphrases by triggering at word level; while TTM triggering at topic level. TWTM, integrating their advantages, performs both word-level and topic-level triggers to extract keyphrases.

To demonstrate the effectiveness of our method, we carry out experiments on a real-world dataset crawled from a website with keyphrases having been annotated collaboratively by users. Experiment results show that TWTM can identify appropriate keyphrases with better coverage of document themes compared to existing WAM-based methods.

2 Our Method

In this section we first introduce two simple trigger methods, WTM and TTM, in which WTM performs triggering at word level while TTM at topic level. Afterwards, we introduce our method TWTM.



(a) WTM (b) TTM (c) TWTM

Figure 1: Trigger Models for keyphrase extraction.

2.1 Notations and Definitions

Before introducing baselines and our method, we give some notations. We denote a document as $d \in D$, where D is the document set. For each document d, we denote its content as a sequence of words $\mathbf{c} = \{c_i\}_{i=1}^{N^c}$ and its keyphrases as a set $\mathbf{k} = \{k_i\}_{i=1}^{N^k}$. The vocabulary of words in documents is denoted as W, and the vocabulary of keyphrases as V. Each word c_i in documents is an instance of a word type w in W, i.e., $c_i = w \in W$; each keyphrase k_i of documents is an instance of a keyphrase type v in V, i.e., $k_i = v \in V$.

We define keyphrase extraction as follows. Given a document d with its content $\mathbf{c}$, keyphrase extraction aims to seek a set of keyphrases $\mathbf{k}$ that maximizes $\Pr(\mathbf{k}|\mathbf{c})$. By simply assuming the keyphrases are independent conditional over d, we have $\Pr(\mathbf{k}|\mathbf{c}) = \prod_{k\in\mathbf{k}} \Pr(k|\mathbf{c})$. The optimal set of keyphrases $\mathbf{k}^*$ can be represented as follows:

$$\mathbf{k}^* = \arg\max_{\mathbf{k}} \Pr(\mathbf{k}|\mathbf{c}) = \arg\max_{\mathbf{k}} \prod_{k\in\mathbf{k}} \Pr(k|\mathbf{c}). \quad (1)$$

Suppose the number of keyphrases is pre-defined as N^k, we can simply find $\mathbf{k}^*$ by ranking

each candidate keyphrase $v \in V$ according to its score $\Pr(v|\mathbf{c})$ in descending order and selecting top-N^k keyphrases.

2.2 Word Trigger Model

Word Trigger Model (WTM) is inspired by IBM Model-1 (Brown et al., 1993), the most widely used word alignment models in SMT. WTM assumes the content and the keyphrases of a document are describing the same themes while written in two different languages: document content in one language while keyphrases in the other. From this perspective, keyphrase extraction can be regarded as a translation process from a given document content to keyphrases.

In more detail, the translation process is modeled as a trigger process as follows. First, WTM finds several important words in the document content as *trigger words*. Then, activated by these trigger words, WTM maps the document content into keyphrases. A *trigger* in the translation process can be regarded as a mapping function from the words in document to keyphrases.

WTM formalizes a trigger as a hidden variable $\mathbf{a}$. By assuming each keyphrase of a document is triggered by only one word in the content, a $\mathbf{a}$ maps each keyphrase at position j (i.e., k_j) as triggered by a word at position i in document content c (i.e., c_i), denoted as $a_j = i$. Given a document, its content $\mathbf{c}$ and keyphrases $\mathbf{k}$ can be connected by a trigger variable $\mathbf{a}$. The probability of triggering $\mathbf{k}$ from $\mathbf{c}$ can be formalized as

$$\Pr(\mathbf{k}|\mathbf{c}) = \sum_{\mathbf{a}} \Pr(\mathbf{k}, \mathbf{a}|\mathbf{c}) = \sum_{\mathbf{a}} \Pr(\mathbf{k}|\mathbf{a}, \mathbf{c}) \Pr(\mathbf{a}|\mathbf{c}). \tag{2}$$

Following the same assumptions of IBM Model-1 (Brown et al., 1993), for each document $d \in D$, WTM assumes the content $\mathbf{c}$ of d already exists, and the keyphrases $\mathbf{k}$ are generated from $\mathbf{c}$ as follows:

1. For each document d with content $\mathbf{c}$ and N^k keyphrases:
   (a) For j from 1 to N^k:
      i. Sample each word trigger link a_j from $1, \ldots, N^c$ according to a uniform distribution.
      ii. Sample each $k_j = v$ according to trigger probability $\Pr(k_j = v|c_{a_j} = w, \psi)$.

Here we denote the trigger probability from a word $w \in W$ to a keyphrase $v \in V$ as $\psi_{vw} = \Pr(v|w)$, and the trigger probabilities from W to V form a matrix ψ. The corresponding graphical representation is shown in Figure 1a. The boxes are "plates" representing replicates. In this graphical model, the variables $\mathbf{k}$ and $\mathbf{c}$ are shaded indicating that they are observed; while the unshaded variables, including $\mathbf{a}$ and ψ, are latent (i.e., unobserved). Under the same assumptions of IBM Model-1, we write

$$\Pr(\mathbf{k}|\mathbf{c}) \propto \frac{1}{(N^c)^{(N^k)}} \prod_{j=1}^{N^k} \sum_{i=1}^{N^c} \Pr(k_j = v|c_i = w) = \frac{1}{(N^c)^{(N^k)}} \prod_{j=1}^{N^k} \sum_{i=1}^{N^c} \psi_{vw}. \tag{3}$$

We see that, in WTM, trigger probabilities $\psi_{vw} = \Pr(k_j = v|c_i = w)$ are the key parameters for learning. WTM has global optimum, and is efficient and easily scalable to large training

data. We use Expectation-Maximization (EM) (Dempster et al., 1977) to estimate trigger probabilities ψ.

Using the estimated ψ, when given a novel document d with its content $\mathbf{c}$, we can rank each candidate keyphrase v as follows:

$$\Pr(v|\mathbf{c}) = \sum_{w \in \mathbf{c}} \Pr(v|w, \psi) \Pr(w|\mathbf{c}) = \sum_{w \in \mathbf{c}} \psi_{vw} \Pr(w|\mathbf{c}), \tag{4}$$

where $\Pr(w|\mathbf{c})$ indicates the weight of the word w in $\mathbf{c}$, which can be calculated using the TFIDF score of w in $\mathbf{c}$. From the ranking list in descending order, we can select the top-ranked ones as keyphrases of the given document.

2.3 Topic Trigger Model

WTM triggers keyphrases at the word level. We can also trigger at the topic level, and thus propose Topic Trigger Model (TTM) for keyphrase extraction. TTM is inspired by Polylingual Topic Models (Mimno et al., 2009), which is originally proposed to model parallel documents in multiple languages. TTM is an extension of latent Dirichlet allocation (LDA) (Blei et al., 2003).

Suppose there are T latent topics in TTM, and the number of topics $|T|$ can be pre-defined by users. TTM assumes that the content $\mathbf{c}$ and keyphrases $\mathbf{k}$ of a document d share the same distribution over $|T|$ topics (i.e., θ_d), which is drawn from a symmetric Dirichlet prior with concentration parameter α. TTM also assumes that each topic $t \in T$ corresponds to two different multinomial distributions over words, one for keyphrases (i.e., ϕ_t^k) and another for content (i.e., ϕ_t^c), each of which is drawn from a specific symmetric Dirichlet with concentration parameter, β^k or β^c. TTM can be viewed as a generative process of both document content and keyphrases as follows:

1. Sample word distribution ϕ_t^c from $Dirichlet(\beta^c)$ and sample keyphrase distribution ϕ_t^k from $Dirichlet(\beta^k)$ for each topic $t \in T$.
2. For each document $d \in D$ with N^c words and N^k keyphrases:
   (a) Sample topic distribution θ_d from $Dirichlet(\alpha)$.
   (b) For i from 1 to N^c
      i. Sample a topic $z_i = t$ from $Multinomial(\theta_d)$.
      ii. Sample a word $c_i = w$ according to multinomial distribution $\Pr(c_i = w|z_i = t, \phi^c)$.
   (c) For j from 1 to N^k
      i. Sample a topic $z_j = t$ from $Multinomial(\theta_d)$.
      ii. Sample a keyphrase $k_j = v$ according to multinomial distribution $\Pr(k_j = v|z_j = t, \phi^k)$.

The corresponding graphical model is shown in Figure 1b, where the observed variables (i.e., words $\mathbf{c}$, keyphrases $\mathbf{k}$ and hyper-parameters β^k and β^c) are shaded.

Given the observed words in a collection of documents, the task of TTM learning is to compute the posterior distribution of the latent topic assignments $\mathbf{z}$, the topic mixtures θ_d of

each document d, and the distributions over words ϕ_t^c and ϕ_t^k of each topic t. By assuming a Dirichlet prior β on ϕ, ϕ can be integrated according to the Dirichlet-multinomial conjugacy. In this paper, we use Gibbs Sampling to estimate parameters, which has been widely used as an inference method for many latent topic models. In Gibbs sampling, it is usual to integrate out the mixtures θ and topics ϕ and just sample the latent variables $\mathbf{z}$. The process is thus called *collapsed*.

Gibbs Sampling iteratively performs latent topic assignments for each word in the document set, and estimates the distributions over words of each topic (i.e., $\phi_{wt}^c = \Pr(c_i = w|z_i = t)$ and $\phi_{vt}^k = \Pr(k_j = v|z_j = t)$), and the distribution over topics of each document (i.e., $\theta_{td} = \Pr(z_i = t|d)$). Take a word token $c_i = w$ in d for example, given the current state of all but the variable z_i, the conditional probability of $z_i = t$ is

$$\Pr(z_i = t|c_i = w, \mathbf{c}^{\neg i}, \mathbf{z}^{\neg i}, \mathbf{k}) \propto \frac{N_{wt}^{c,\neg i} + \beta^c}{N_t^c - 1 + |W|\beta^c} \times \frac{N_{td}^{\neg i} + \alpha}{N_d^c + N_d^k - 1 + |T|\alpha}, \tag{5}$$

where z is the current topic assignments for all tokens in the document set; N_{wt}^c is the number of occurrences of word w that are assigned with topic t; N_t^c is the number of occurrences of all words that are assigned with topic t; N_{td} is the number of occurrences of topic t assigned in the current document d; N_d^c and N_d^k are the numbers of all tokens in the content and keyphrases of d, respectively; $\neg i$ indicates taking no account of the current position i.

According to the posterior probability $\Pr(z_i = t|c_i = w, \mathbf{c}^{\neg i}, \mathbf{z}^{\neg i}, \mathbf{k})$, we re-sample the topic assignment z_i of the c_i in d. Whenever z_i of c_i is assigned with a new topic drawn from Equation (5), N_{wt}^c and N_{td} are updated. We perform topic assignments in the same way for each word k_i in k of d. After enough sampling iterations to burn in the Markov chain, ϕ^c, ϕ^k and θ are estimated as follows:

$$\phi_{wt}^c = \frac{N_{wt}^c + \beta^c}{N_t^c + |W|\beta^c}, \quad \phi_{vt}^k = \frac{N_{vt}^k + \beta^k}{N_t^k + |V|\beta^k}, \quad \theta_{td} = \frac{N_{td} + \alpha}{N_d^c + N_d^k + |T|\alpha}. \tag{6}$$

When finishing the learning process, we obtain the distributions over words of each topic, i.e., ϕ^k and ϕ^c. Suppose we are asked to extract keyphrases from a novel document with only content $\mathbf{c}$. First, we infer topic assignments for each word in $\mathbf{c}$ with Gibbs Sampling. With the topic assignments, we summarize the distribution over topics of the content $\mathbf{c}$ as

$$\Pr(t|\mathbf{c}) = \frac{N_{td}^c + \alpha}{N_d^c + |T|\alpha}. \tag{7}$$

Triggered by the topics of $\mathbf{c}$, we rank each candidate keyphrase $v \in V$ as follows:

$$\Pr(v|\mathbf{c}) = \sum_{t \in T} \Pr(v|t, \phi^k) \Pr(t|c) = \sum_{t \in T} \phi_{vt}^k \theta_{td}, \tag{8}$$

and then select the top-ranked as keyphrases of the given document.

2.4 Topical Word Trigger Model

WTM and TTM perform trigger operations at either word or topic level. WTM addresses the problem of vocabulary gap between documents and keyphrases, and can thus suggest

keyphrases that are uncommon or even not showing up in the given document. TTM, on the other hand, takes the main themes of the given document in consideration when extracting keyphrases. In order to aggregate the advantages of the both methods, extended from WTM and TTM, we propose Topical Word Trigger Model (TWTM) for keyphrase extraction.

Similar to TTM, TWTM also assumes that topics are sampled at the word level. Each document is represented as a multinomial distribution over T latent topics. On the document content side, each topic $t \in T$ corresponds to a multinomial distribution over words, which is similar to TTM. On the keyphrase side, each topic $t \in T$ corresponds to a topic-specific translation table ψ_t. Given each document $d \in D$, the generative process of both document content and keyphrases is as follows:

1. Sample word distribution ϕ_t^c from $Dirichlet(\beta^c)$ for each topic $t \in T$.
2. Sample keyphrase distribution ψ_w^t from $Dirichlet(\beta^k)$ for each topic $t \in T$ and each word $w \in W$.
3. For each document $d \in D$ with N^c words and N^k keyphrases:
   (a) Sample topic distribution θ_d from $Dirichlet(\alpha)$.
   (b) For i from 1 to N^c
      i. Sample a topic $z_i = t$ from $Multinomial(\theta_d)$.
      ii. Sample a word $c_i = w$ according to multinomial distribution $\Pr(c_i = w | z_i = t, \phi^c)$.
   (c) For j from 1 to N^k
      i. Sample a topic $z_j = t$ from $Multinomial(\theta_d)$.
      ii. Sample each word trigger link a_j from all words in d that are generated from t according to a uniform distribution.
      iii. Sample each $k_j = v$ according to trigger probability $\Pr(k_j = v | c_{a_j} = w, \psi^t)$.

The graphical model is shown in Figure 1c. Topic-dependent translation probabilities ψ_t are the key parameters. Each ψ_t maintains the translation probability from each word $c_i = w$ in contents to each keyphrase $k_j = v$ under topic t, i.e., $\psi_{vw}^t = \Pr(k_j = v | c_i = w, t)$.

Given the observed words and keyphrases in a collection of documents, the task of TWTM learning is to compute the posterior distribution of the latent topic assignments $\mathbf{z}$, the topic mixtures θ_d of each document d, the distribution over words ϕ_t of each topic t, and the trigger probabilities ψ^t of each topic t. We can also use Gibbs Sampling to estimate parameters in TWTM. On the document content side, we can perform topic assignments $\mathbf{z}$ for each word as in TTM using Equation (5). On the keyphrase side, the problem is more complicated. Suppose we will assign each keyphrase k_j with a topic z_j and a trigger a_j. Take a keyphrase $k_j = v$ for example, given the current state of all but the variable z_j and a_j, the conditional probability of $z_j = t, a_j = i$ is calculated as follows,

$$\Pr(z_j = t, a_j = i | k_j = v, \mathbf{k}^{\neg j}, \mathbf{z}^{\neg j}, \mathbf{a}^{\neg j}, c_i = w, \mathbf{c}) \propto \frac{N_{vw}^{t,\neg j} + \beta^k}{N_w^t - 1 + |V|\beta^k} \times \frac{N_{td}^{\neg j} + \alpha}{N_d - 1 + |T|\alpha}, \tag{9}$$

where z is the current topic assignments for all translation pairs in the document set; N_{vw}^t is the number of occurrences that w is translated to v given topic t; N_w^t is the number of occurrences of word w in all translation pairs given topic t; N_{td} is the number of occurrences of topic t assigned in the current document d; N_d is the number of all translation pairs in

the current document d; $\neg j$ also indicates taking no account of the current position j. Given the conditional probability of $z_j = t, a_j = i$, we formalize the marginal probability of $z_j = t$ as follows,

$$\Pr(z_j = t | k_j = v, k^{\neg j}, z^{\neg j}, a^{\neg j}, c) \propto \sum_{i=1}^{N^c} \frac{N_{vc_i}^{t,\neg j} + \beta^k}{N_{c_i}^t - 1 + |V|\beta} \times \frac{N_{td}^{\neg j} + \alpha}{N_d - 1 + |T|\alpha}. \tag{10}$$

After re-assigning the topic $z_j = t$ for the current keyphrase according to Equation (10), we can further compute the trigger probability as follows:

$$\Pr(a_j = i | z_j = t, k_j = v, k^{\neg j}, z^{\neg j}, a^{\neg j}, c) = \frac{N_{vc_i}^{t,\neg j} + \beta}{N_{c_i}^t - 1 + |V|\beta^k}. \tag{11}$$

According to Equation (11), we re-assign trigger word c_i for the current keyphrase k_j. After enough sampling iterations to burn in the Markov chain, ϕ^c, ψ^t and θ are estimated as follows:

$$\phi_{wt}^c = \frac{N_{wt}^c + \beta^c}{N_t^c + |W|\beta^c}, \quad \psi_{vw}^t = \frac{N_{vw}^t + \beta}{N_w^t + |V|\beta}, \quad \theta_{td} = \frac{N_{td} + \alpha}{N_d^k + N_d^c + |T|\alpha}. \tag{12}$$

The potential size of topical trigger probabilities ψ is $|V| \times |W| \times |T|$. The size is comparative larger than ψ in WTM, and thus faces more serious problem of data sparsity. To remedy the problem, we use interpolation smoothing technique for ψ of TWTM. In this paper, we employ smoothing using ψ of WTM as follows:

$$\Pr_{SMOOTH}(v|w,t) = \lambda \Pr_{TWTM}(v|w,t) + (1-\lambda) \Pr_{WTM}(v|w,t), \tag{13}$$

where $\Pr_{SMOOTH}(v|w,t)$ is the smoothed topical trigger probabilities, $\Pr_{TWTM}(v|w,t)$ is the original topical trigger probabilities of TWTM, $\Pr_{WTM}(v|w,t)$ is the trigger probabilities of WTM. λ is the smoothing factor ranging from 0.0 to 1.0. When $\lambda = 0.0$, $\Pr_{SMOOTH}^t(v|w)$ will be reduced to non-topic trigger probabilities; and when $\lambda = 1.0$, there will be no smoothing in $\Pr_{SMOOTH}(v|w,t)$.

In TWTM, we perform keyphrase extraction as follows. Suppose we need perform keyphrase extraction for a document d with its content $\mathbf{c}$. We perform Gibbs Sampling to iteratively estimate the topic distribution of d (i.e., θ_d) according to document content $\mathbf{c}$. Afterwards, we select N^k keyphrases using the ranking score of each keyphrase v:

$$\Pr(v|\mathbf{c}) = \sum_{w \in \mathbf{c}} \sum_{t \in T} \Pr(v|w,t) \Pr(w|\mathbf{c}) \Pr(t|\mathbf{c}) = \sum_{w \in \mathbf{c}} \sum_{t \in T} \psi_{vw}^t \theta_{td} \Pr(w|\mathbf{c}), \tag{14}$$

where $\Pr(w|\mathbf{c})$ is the weight of the word w in document content c, which can be estimated by the TFIDF score of w in $\mathbf{c}$; $\Pr(t|\theta_d)$ is the probability of the topic t given the document d.

3 Experiments and Analysis

3.1 Dataset and Experiment Setting

To evaluate the performance of TWTM for keyphrase extraction, we carry out experiments on a real world dataset, crawled from `douban.com`, the largest product review website in China. Each product contains a description which is considered as a document content, and also contains a set of keyphrases annotated by users collaboratively which are considered

as standard keyphrases. The dataset consists of annotations for three types of products, i.e., book, movie and music. The statistics of the dataset is shown in Table 1, where $|D|$, $|W|$, $|V|$, $\hat{N}^c$ and $\hat{N}^k$ are the number of documents, the vocabulary of contents, the vocabulary of keyphrases, the average number of words and keyphrases in each document, respectively. In Table 1, we use DOUBAN to represent the whole dataset and use BOOK, MOVIE and MUSIC to show the statistics for instances for different product types.

Data	$\|D\|$	$\|W\|$	$\|V\|$	$\hat{N}^c$	$\hat{N}^k$
DOUBAN	71,525	160,276	99,457	86.30	10.53
BOOK	26,807	81,846	41,199	83.13	8.95
MOVIE	18,933	86,339	37,034	86.04	16.03
MUSIC	25,785	106,523	31,228	89.77	8.13

Table 1: Statistical information of dataset.

To evaluate the performance of our method and compare with other methods, we randomly select 1,000 instances from each of three types of products to form the test set with 3,000 instances, and use the rest of the dataset as training set.

In our experiments we select three evaluation metrics. The first metric is precision, recall and F-measure represented as $p = c_{correct}/c_{extract}$, $r = c_{correct}/c_{standard}$ and $F = 2pr/(p+r)$, where $c_{correct}$ is the total number of keyphrases that are correctly suggested by a method, $c_{extract}$ is the total number of automatic extracted keyphrases, and $c_{standard}$ is the total number of human-labeled standard keyphrases.

In fact, ranking order of extracted keyphrases also indicates the performance of different methods. A method is regarded better than another one if it ranks correct keyphrases higher. However, precision/recall/F-measure does not take the order of extracted keyphrases into account. To address the problem, we select the following two additional metrics. One metric is *binary preference measure* (Bpref) (Buckley and Voorhees, 2004). Bpref can consider the order of extracted keyphrases for evaluation. For a document, if there are R correct keyphrases within M extracted keyphrases by a method, in which r is a correct keyphrase and n is an incorrect keyphrase. It is defined as $\text{Bpref} = \frac{1}{R}\sum_{r\in R}\left(1 - \frac{|n \text{ ranked higher than } r|}{M}\right)$.

The other metric is *mean reciprocal rank* (MRR) (Voorhees, 2000) which is usually used to evaluate how the first correct keyphrase for each document is ranked. For a document d, $rank_d$ is denoted as the rank of the first correct keyphrase with all extracted keyphrases, It is defined as $\text{MRR} = \frac{1}{|D|}\sum_{d\in D}\frac{1}{rank_d}$, where D is the document set for keyphrase extraction.

3.2 Case Studies

Before quantitative evaluation, we perform case studies by looking into the topics learned by TWTM. By setting $T = 100$ of TWTM, We select two topics, i.e., Topic-59 and Topic-92 for study. In first several rows of Table 2, we list the top-10 words and top-10 keyphrases given the two topics separately (i.e., ranked by $\Pr(w|t)$ and $\Pr(v|t)$). From the top words and keyphrases, we can conclude that Topic-59 is about "art design" and Topic-92 is about "computer programming".

What will the topics influence the trigger probabilities? We pick a word "graphics" for example. In the context of the topic "art design", the word "graphics" always correlates with "design", "color" and "art"; while in the context of the topic "computer programming", the

word "graphics" generally refers to "computer graphics" and thus correlates to "programming", "software" and "programming language". At the bottom of Table 2, we show the top-6 keyphrases triggered by the word "graphics" with respect to the two topics. The value in the bracket after each keyphrase v is the probability $\psi^t_{vw} = \Pr(v|w,t)$, which is the topical specific trigger probability from w (here is the word "graphics") to v under the topic t. From the top triggered keyphrases by "graphics" under two topics, we can see they are discriminative with each other, and have intense topic characteristics.

	Topic-59		Topic-92	
Top	Words	Keyphrases	Words	Keyphrases
1	design	design	program	computer
2	creativity	creativity	develop	program
3	designer	designing	application	software engineer
4	magazine	handcraft	object	C++
5	fashion	graphic design	technology	programming
6	game	fashion	design	program design
7	work	game	system	program develop
8	color	product design	function	Linux
9	vision	industrial design	software	computer science
10	advertise	magazine	method	Alan
graphics	design (0.482)		game programming (0.201)	
	color science (0.089)		programming language (0.107)	
	font design (0.084)		Web 2.0 (0.094)	
	product design (0.077)		C (0.078)	
	landscape design (0.050)		Linux (0.077)	
	art design (0.039)		Computer Graphics (0.049)	

Table 2: Examples of topics learned with TWTM.

After investigating the topics, we look into keyphrase extraction results given a product description. Here we select a Japanese classical literature *The Tale of Genji* for example, which was written by *Murasaki Shikibu* in the early years of the 11th century [1]. The book recounts the life and love stories of a son of the Japanese emperor. In Table 3, we show the top-10 keyphrases extracted by WTM, TTM and TWTM, in which we use (—) to highlight the inappropriate keyphrases.

Method	Extracted Keyphrases
WTM	The Tale of Genji, classic, Japan, foreign literature, Murasaki Shikibu, politics (-), love, political science (-), eason (-), political philosophy (-)
TTM	novel, Japan, foreign literature, history, love, sociology (-), culture, literature, Russia (-), female (-)
TWTM	novel, foreign literature, The Tale of Genji, history, Japan, classic, literature, love, Murasaki Shikibu, politics (-)

Table 3: Examples of extracted keyphrases for the book *The Tale of Genji*.

From Table 3 we observe that: (1) WTM can suggest keyphrases that are closely related to the book, such as "The Tale of Genji" and "Murasaki Shikibu". However, due to not considering document themes, WTM will extract irrelevant keyphrases such as "politics", "political

[1] http://en.wikipedia.org/wiki/The_Tale_of_Genji.

science", "eason" and "political philosophy". (2) TTM triggers keyphrases with the favor of latent topics, which are usually too general to commendably represent the document main themes. We can see TTM fail to extract specific keyphrases such as "The Tale of Genji" and "Murasaki Shikibu". What is worse, TTM over-generalizes the document themes and extract inappropriate keyphrases "sociology", "Russia" and "female". (3) Taking advantages of both WTM and TTM, TWTM can extract specific and representative keyphrases and at the same time guarantee the coverage of document themes. We can see that TWTM achieves a smart balance between word-level projections and topic-level coverage.

3.3 Parameter Influences

There are two crucial parameters in TWTM, the number of topics T and the smoothing factor λ. In Table 4 and Table 5, we demonstrate the performance of TWTM for keyphrase extraction when parameters change.

T	Precision	Recall	F-measure	Bpref	MRR
10	0.313	0.304	0.309	0.313	0.825
30	0.337	0.325	0.331	0.337	0.837
50	0.339	0.329	0.334	0.339	0.827
70	0.351	0.339	0.345	0.351	**0.840**
100	**0.354**	**0.343**	**0.349**	**0.354**	0.838

Table 4: The influence of topic number T of TWTM for keyphrase extraction when $N^k = 10$ and smoothing factor $\lambda = 0.4$.

λ	Precision	Recall	F-measure	Bpref	MRR
0.0	0.310	0.254	0.279	0.310	0.676
0.2	0.318	0.314	0.316	0.318	0.823
0.4	0.354	0.343	0.349	0.354	**0.838**
0.6	**0.364**	**0.349**	**0.357**	**0.364**	0.812
0.8	0.350	0.334	0.342	0.351	0.764
1.0	0.323	0.306	0.314	0.324	0.731

Table 5: The influence of smooth factor λ of TWTM for keyphrase extraction when $N^k = 10$ and the number of topics $T = 100$.

From Table 4, we can see that, as the number of topics T increases from $T = 10$ to $T = 100$, the performance roughly improves. This indicates that the granularity of topics will influence the keyphrase extraction performance. When $T = 70$ and $T = 100$, the performance achieves a relatively stable good status. Hence, when comparing TWTM with other methods, we set $T = 100$ for TWTM.

As shown in Table 5, when the smoothing factor is set with $\lambda = 0.4$ or $\lambda = 0.6$, TWTM achieves the relatively best performance. When either $\lambda = 0.0$ (i.e., WTM), or $\lambda = 1.0$ (i.e., non-smoothed TWTM), the performance is much poorer compared to smoothed TWTM. This reveals that it is necessary to address the sparsity problem of TWTM by smoothing with WTM. Therefore, when comparing TWTM with other methods, we set $\lambda = 0.4$ for TWTM.

3.4 Performance Comparison

Besides WTM and TTM, we also select three representative methods as baselines for comparison: the classification-based method Naive Bayes (NB) (Garg and Weber, 2008), the topic-based method CRM (Iwata et al., 2009) and the word-projection method TAM (Si et al., 2010). We set $T = 1,024$ for CRM which achieves its best performance.

In Figure 2 we show the precision-recall curves of NB, CRM, TAM, WTM, TTM and TWTM on the dataset. Each point of a precision-recall curve represents extracting different number of keyphrases ranging from $N^k = 1$ (bottom right, with higher precision and lower recall) to $N^k = 10$ (upper left, with higher recall but lower precision), respectively. The closer the curve to the upper right, the better the overall performance of the method.

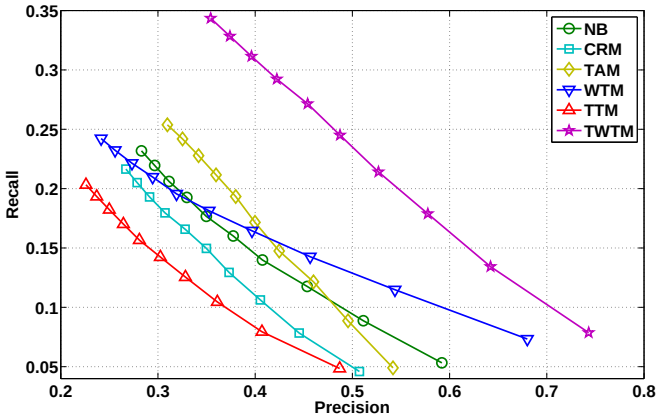


Figure 2: Precision-recall curves for keyphrase extraction.

Figure 2 clearly shows that TWTM outperforms other methods significantly. The interesting phenomena is that, when N^k is getting larger, the advantages of TWTM are more obvious compared to baselines. We know that when a system is asked to extract more keyphrases (i.e., N^k is larger), it is becoming important for extracted keyphrase to have a good coverage of document themes. Otherwise, the performance will drop sharply. This is the issue suffered by WTM. We can see that, although WTM is relatively excellent when suggesting top several keyphrases, it performs poor when suggesting more keyphrases due to the poor ability on ensuring coverage.

In Table 6 we list the comparison results of various methods when extracting $N^k = 10$ keyphrases. We can observe that TWTM outperforms the best baseline TAM by 7% of F-measure. Moreover, as mentioned above, the dataset consists of three types of products. In Table 6 we also demonstrate the results of TWTM on the test instances divided by product types, denoted as "BOOK", "MOVIE" and "MUSIC". The performance is consistently decent on the three types of instances. We also observe that F-measure scores on the three types of instances are proportional to the size of their training instances as shown in Table 1. Apparently, more training instances will enhance sufficiently learning of TWTM, which may

Method	Precision	Recall	F-measure	Bpref	MRR
NB	0.283	0.232	0.255	0.283	0.702
CRM	0.267	0.216	0.239	0.267	0.648
TAM	0.310	0.254	0.279	0.310	0.676
WTM	0.242	0.242	0.242	0.242	0.785
TTM	0.226	0.203	0.214	0.226	0.638
TWTM	**0.354**	**0.343**	**0.349**	**0.354**	**0.838**
BOOK	0.365	0.428	0.394	0.365	0.861
MOVIE	0.356	0.274	0.310	0.356	0.820
MUSIC	0.341	0.326	0.334	0.341	0.831

Table 6: Comparison results when extracting $N^k = 10$ keyphrases.

also eventually improve the performance of keyphrase extraction.

Conclusion and Future Work

This paper focuses on keyphrase extraction from a controlled vocabulary. The proposed TWTM has two features: (1) TWTM uses latent topics to represent document themes, and thus takes the coverage of document themes into consideration; (2) TWTM models topic-specific word triggers, which are more discriminative. Hence TWTM is able to bridge the vocabulary gap between document content and keyphrases more precisely. Experiment results on real world dataset demonstrate that TWTM outperforms existing state-of-the-art methods under various evaluation metrics. We also demonstrate that TWTM achieves a balance between word-level projection and topic-level coverage.

Moreover, TWTM is not restricted to supervised learning. TWTM can also be adopted in unsupervised fashion. So long as we can build appropriate translation pairs to represent semantic relations between documents and keyphrases, TWTM will be able to exert its capacity. For example, for news articles, we can use news titles and contents to build translation pairs, by regarding titles as an approximate language to keyphrases; for scientific papers, we can use abstracts and contents to build translation pairs.

We design the following research plans: (1) The number of topics in TWTM requires being pre-defined by users. We plan to incorporate Bayes Nonparametric (Blei et al., 2010) for TWTM to automatically learn the number of topics. (2) The trigger probabilities in TWTM do not take rich linguistic knowledge into consideration. We plan to incorporate more complicated alignment models from SMT into our model. (3) This paper focuses on supervised learning of TWTM. We plan to investigate unsupervised learning of TWTM for documents such as news articles and scientific papers. (4) The influence of product types for keyphrase extraction has not been thoroughly investigated in this paper. We plan to study the impact of product types and explore domain adaptation (Blitzer et al., 2006) for cross-domain keyphrase extraction using TWTM.

ABSTRACT

The easy-first non-directional dependency parser has demonstrated its advantage over transition based dependency parsers which parse sentences from left to right. This work investigates easy-first method on Chinese POS tagging, dependency parsing and joint tagging and dependency parsing. In particular, we generalize the easy-first dependency parsing algorithm to a general framework and apply this framework to Chinese POS tagging and dependency parsing. We then propose the first joint tagging and dependency parsing algorithm under the easy-first framework. We train the joint model with both supervised objective and additional loss which only relates to one of the individual tasks (either tagging or parsing). In this way, we can bias the joint model towards the preferred task. Experimental results show that both the tagger and the parser achieve state-of-the-art accuracy and runs fast. And our joint model achieves tagging accuracy of 94.27 which is the best result reported so far.

KEYWORDS: dependency parsing, POS tagging, perceptron, easy-first

Proceedings of COLING 2012: Technical Papers, pages 1731–1746,
COLING 2012, Mumbai, December 2012.

1 Introduction

To sequential labelling problems, such as POS tagging or incremental parsing, traditional approaches 1) decompose the input sequence into several individual items each of which corresponds to a token of the input sequence; 2) predict these items in a fixed left-to-right (or right-to-left) order (Collins 2002; Ratnaparkhi 1996). The drawback of such fixed order approach is that when predicting one item, only the labels on the left side can be used while the labels on the right side is still unavailable. (Goldberg and Elhadad, 2010) proposed the easy-first dependency parsing algorithm to relax the fixed left-to-right order and to incorporate more structural features from both sides of the attachment point. Comparing with a deterministic transition based parser which parses the sentence left-to-right, their deterministic easy-first parser achieves significant better accuracy.

The key idea behind their parsing algorithm is to always process the easy attachments in the early stages. The hard ones are delayed to late stages until more structural features on both sides of the attachment point are accessible so as to make more informed decision. In this work, we further generalize the algorithm of (Goldberg and Elhadad, 2010) to a general sequential labelling framework. We apply this framework to Chinese POS tagging and dependency parsing which has never been studied under the easy-first framework before.

One characteristic of Chinese dependency parsing is that parsing performance can be dramatically affected by the quality of POS tags of the input sentence (Li et al., 2010). Recent work (Li et al., 2010; Hatori et al., 2011; Bohnet and Nivre, 2012) empirically verified that solving POS tagging and dependency parsing jointly can boost the performance of both the two tasks. To further improve tagging and parsing accuracy, we also solve the two tasks jointly. While previous joint methods are either graph-based or transition-based algorithm, in this work we propose the first joint tagging and dependency parsing algorithm under the easy-first framework. In addition, we also adopt a different training strategy to learn the model parameters. Previous approaches all train their joint model with the objective of minimizing the loss between the reference and the predicted output. Those methods make no distinction between the loss caused by POS tagging and the loss caused by dependency parsing. Though such objective is proper for minimizing the total loss, it may not be optimal in terms of pursuing the best result of a certain individual task (neither tagging nor dependency parsing). To this end, our training method also incorporates additional loss which relates to only one of the individual tasks. And the losses are iteratively optimized on the training set. In this way we can bias the joint model towards the preferred task. Similar techniques have been used in parser domain adaptation (Hall et al., 2011). However, to our knowledge, no one has done this in joint tagging and dependency parsing before.

Experimental results show that under the easy-first framework, even deterministic tagger and parser achieve quite promising performance. For Chinese POS tagging, the tagger achieves an accuracy of 93.84[1] which is among the top Chinese taggers reported so far. Moreover, the tagging speed is about 2000 sentences per-second, much faster than the state-of-the-art taggers (Li et al., 2010; Hatori et al., 2011). For Chinese dependency parsing, when the input sentence is equipped with automatically assigned POS tags, the parser achieves an unlabelled score of 77.66 and runs at the speed of more 300 sentences per second. Such accuracy is among the state-of-the-art transition-based dependency parsers even those parsers are enhanced with beam

1 On the same data set, the best tagger so far reported achieves an accuracy of 93.82. Joint methods yield higher accuracy, but are not directly comparable.

search (section 4). For joint tagging and dependency parsing, we achieve significant improvement on both the two sub-tasks. In particular, we achieve the tagging accuracy of 94.27 which is the highest score reported on the same data set so far.

2 Easy-First POS tagging, dependency parsing and joint tagging and parsing

In this section, we first describe a generalized easy-first sequential labelling framework. Then we show how to apply this framework to the task of POS tagging and dependency parsing. Finally, we propose the joint POS tagging and dependency parsing algorithm under this framework.

2.1 Generalized easy-first sequential labelling algorithm

For solving sequential labelling problems, the first step is to decompose the input sequence into a list of small items $t_1, t_2, \ldots, t_n$. The items are then labelled separately. This list of items is the input of the generalized algorithm. In addition, the algorithm also requires a set of task specific labels $\{l_1, l_2, \ldots, l_m\}$ and a labelling function. Take POS tagging for example, t_i corresponds to the i-th word of the input sentence and the label set corresponds to the set of POS tags. The labelling function associates a word with a certain POS tag.

The pseudo-code of the algorithm is shown in Algorithm 1. Initially, all the items are marked as unprocessed (line 2). Then, the algorithm solves each of the unprocessed item t by labelling t with a suitable label l. After that, t is marked as processed. This process repeats until no items left unprocessed (line 3 to line 8).

One thing to note is that the small items are not processed in a $t_1, t_2 \ldots$ to t_n order. Instead, at each step the algorithm automatically chooses an item-label pair according to a scoring function $score(t, l)$ (line 4). This function is not only responsible for selecting a correct label for a certain item but also responsible for determining the order in which each of the items are processed. Ideally, the scoring function prefers to process easy items in the early stages and delay the hard ones to late stages. When dealing with the hard ones, the label information built on both sides of the current item become accessible. In this way, more informed prediction can be made and the extent of error propagation can be limited (Goldberg and Elhadad, 2010).

Algorithm 1 is a generalization of the easy-first parsing algorithm of (Goldberg and Elhadad, 2010). This generalized version can be naturally instantiated to a wide verity of applications.

2.2 Easy-first POS tagging

In this section, we show how to instantiate algorithm 1 into a POS tagger. The problem of POS tagging is to find a sequence of POS tags for the input sentence. For this problem,

- t_i corresponds to i-th word, w_i, of the input sentence.
- L corresponds to the POS tag set, **POS**. We use x to denote a certain tag in **POS.**
- The labelling function, $\text{labelling}^{pos}(w_i, x)$, set x as the POS tag of w_i

A concrete example of tagging the sentence "中国/China 对/to 外/outside world 开放/open 稳步/steadily 前行/advance" ("China's opening up steadily advances") is shown in figure 1. The challenging part of this sentence is w_4, "开放/opening up", which can be either a VV (verb) or a NN (noun). If we process this sentence in a left-to-right order, the word "开放" would be quite difficult. In the easy-first framework, this can be easily handled with the following steps.

Algorithm 1: Generalized Easy-First Sequential Labelling	
Input	T= t_1, t_2, …t_n: a sequence of items to be labelled L={l_1, l_2, …, l_m}: a set of task specific labels labelling: task specific labelling function
1	$nProcessed \leftarrow 0$
2	set each t_i as unprocessed
3	**repeat**
4	$(\bar{t}, \bar{l}) \leftarrow \text{argmax}_{l \in L, t.unprocessed=true} score(t, l)$
5	labelling $(\bar{t}, \bar{l})$
6	set $\bar{t}$ as processed
7	$nProcessed \leftarrow nProcessed + 1$
8	**until** nProcessed = |T|

Initially (step 0), all the six words w_1, …,w_6 are marked as unprocessed. Each step, the tagger enumerates all possible (w, x) pairs and chooses the most confident one according to the scoring function. Since the word "中国/China" always occurs as a NR (proper noun) in the training set, thus at the step 1, ("中国", NR) is selected[2] and the tagger tags "中国" with NR. After this step, "中国" is marked as processed.

At step 2, for those **unprocessed** words, the tagger re-computes the scores of all (w, x) pairs based on the local context, surrounding words and tags within a window, and selects the one with the highest score to deal with. This time, ("外", NN) is selected and the tagger tags "外" as a NN. Similarly, at step 3, the tagger assigns tag P (preposition) to word "对/to". Step 4 and so on.

At the last step (step 6), the only unprocessed word is w_4, "开放". Since for Chinese, an adverb always precede the verb which it modifies and succeeds the noun which is the subject. Therefore, based on the following tags o_5:AD and o_6:VV, the tagger can easily infer that the correct tag for "开放" is NN. After "开放" is tagged, all words are processed and the tagging procedure stops.

We see algorithm 1 can be easily instantiated to POS tagging, a relatively simple task. In the next sections, we show how to apply algorithm 1 to more complicated tasks.

2.3 Easy-first dependency parsing

The easy-first dependency parsing algorithm was originally proposed by (Goldberg and Elhadad, 2010), we re-describe it here for completeness and also to illustrate how algorithm 1 can be instantiated to dependency parsing.

Given an input sentence of n words, the task of dependency parsing is: for each word, find its lexical head which it modifies. One exception is the **head word** of the sentence which does not modify any other word. All the others each modify exactly one word and no one modifies itself. For dependency parsing:

- t_i corresponds to i-th word, w_i, of the input sentence.
- L corresponds to an action set **ACT** which contains three actions {attach_Left, attach_Right, set_Root}.

Note for dependency parsing, each label corresponds to an action which is designed to manipulate a list of partial analysis p_1,…, p_n, called pending (Goldberg and Elhadad, 2010). p_i re-

[2] At each step, the selected item is boldfaced. The underlined items are those marked as processed.

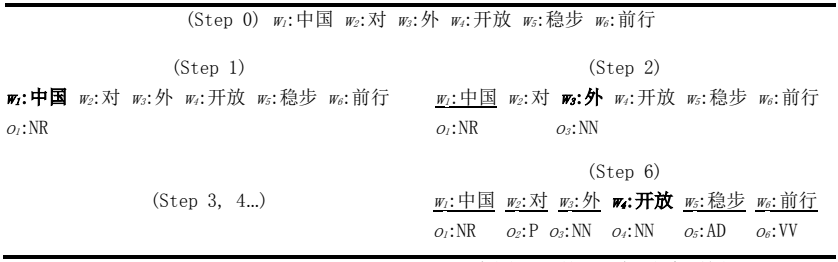

FIGURE 1 – A trace of easy-first tagger for sentence "中国 对 外 开放 稳步 前行" ("China's opening up steadily advances"). o_i denotes the POS tag of w_i

-cords the dependency tree rooted at w_i and p_i is initialized with w_i.

The main loop of easy-first dependency parsing is shown in figure 2. Each step, the parser computes the scores of all possible (p, a) pairs based on local context, surrounding partial analysis within a window, and then selects the best pair to feed to the labelling function, labelling^{dep}. Then labelling^{dep} performs the given action. In particular, labelling^{dep} (p_i, attach_Left) set p_i as the child of its left neighbour in the pending list. labelling^{dep} (p_i, attach_right) set p_i as the child of its right neighbour in the pending list. After that, the selected partial analysis p is marked as processed and removed from the pending list (line 7 to line 8).

Since at each step, one partial analysis is removed from the pending list, after $n-1$ steps, the pending list only contains one item, say p_h, which is the dependency tree of the whole sentence. In such satiation, (p_h, set_Root) is enforced to be the only choice and labelling^{dep} (p_h, set_Root) sets the root of p_h which is w_h as the head of the sentence.

An example of parsing the sentence "中国 对 外 开放 稳步 前行" is shown in figure 3. At the first step, (p_3, attach_Left) is selected and fed to the labelling^{dep} function. The labelling function set p_3 as the child of its left neighbour p_2 as shown in figure 2 (1). p_3 is then removed from the pending list. Note that, after p_3 is removed, p_2 and p_4 become neighbours. The following steps are executed in a similar way except for step 6 where only p_6 is left in the pending list. Thus, at step 6, (p_6, set_Root) is the only choice. The labelling^{dep} function sets w_6, "前行" as the head of the sentence. As all partial analysis are marked as processed, the parsing process stops. Head-modifier relationships can be directly read-off the dependency tree. That is, parent is the head of its children.

```
1   Set nProcessed ← 0
2   p_1, ... p_n ← w_1, ... w_n
3   Set each p_i as unprocessed
4   repeat
5     (p̄, ā) ← argmax_{p∈Pending, a∈ACT} score(p, a)
6     labelling^dep(p̄, ā)
7     set p̄ as processed,
8     remove p̄ from pending
9     nProcessed ← nProcessed + 1
10  until nProcessed = |T|
```

FIGURE 2 – Main loop of easy-first parsing algorithm

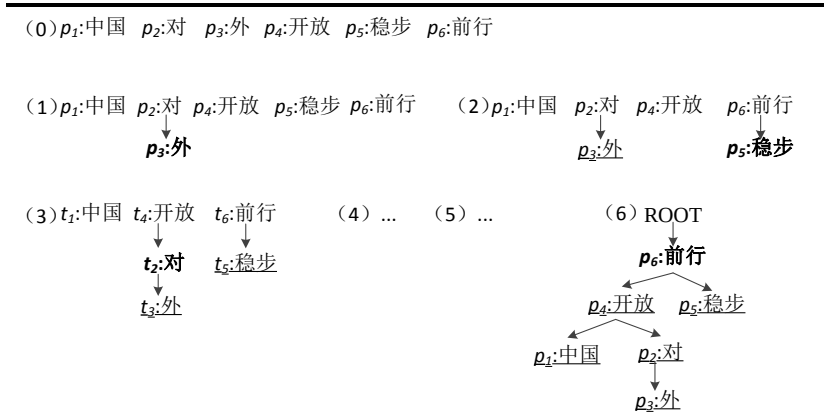

FIGURE 3 – A trace of easy-first parser for sentence "中国 对 外 开放 稳步 前行" ("China's opening up steadily advances")

2.4 The proposed easy-first joint POS tagging and dependency parsing method

In this section, we describe the joint tagging and dependency parsing method which is under the easy-first framework. Before we go into the details about the algorithm, one thing should be mentioned. That is, for dependency parsing, POS tag serves as indispensable information (Li et al., 2010). On the one hand, parsing barely based on bi-lexical features without POS tags hurt performance dramatically. On the other hand, if we tag the whole sentence first and then do dependency parsing, then syntactic features which are demonstrated to be effective for tagging disambiguation cannot be utilized. In order to provide POS tags for syntactic disambiguation and provide syntactic features for tagging disambiguation, we add a simple constraint to control the inference order: dependency relationships can only be extracted between two tagged words. Under such constraint, we can guarantee that at least POS tags for the pair of words from which dependency relation is to be extracted are already available. Also, syntactic feature can be utilize-

```
1   Set nProcessed ← 0,
2   p_1, ... p_n ← w_1, ... w_n
3   Set each p_i as unprocessed
4   repeat
5     Initialize valid
6     (p̄, l̄) ← argmax_{(p,l)∈valid} score(p, l)
7     labelling^Joint(p̄, l̄)
8     if (l̄ ∈ ACT)
9       Set p̄ as processed,
10        remove p̄ from pending
11      nProcessed ← nProcessed + 1
12  until nProcessed = |T|
```

FIGURE 4 – Main part of the joint tagging and dependency parsing algorithm

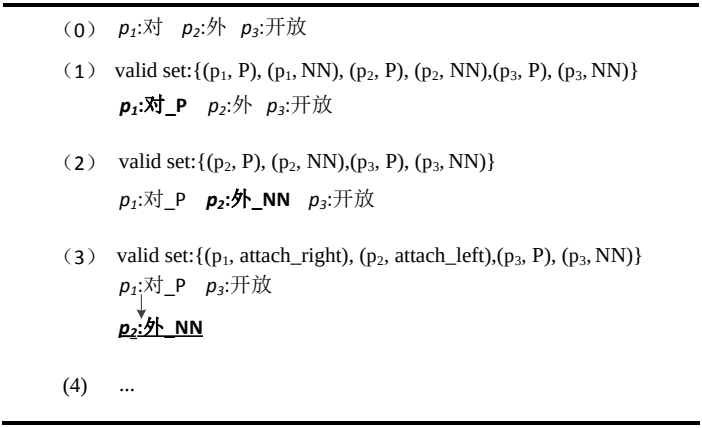

FIGURE 5 – A trace of easy-first joint tagging and parsing for "对 外 开放"

-d to process the untagged words. Under such constraint, the joint method can be constructed by a simple combination of easy-first POS tagging and easy-first dependency parsing.

Similar to previous tasks, for the joint task, t_i still corresponds to the i-th word of the input sentence w_i. Pending list is also used to record the partial dependency tree structures. The label set of the joint task is the union of **POS** and **ACT**. The labelling function of the joint task, $\text{labelling}^{\text{Joint}}$, behaves differently on the two types of labels. Particularly, $\text{labelling}^{\text{Joint}}$ (p_i, x) calls $\text{labelling}^{\text{POS}}$ (w_i, x) which associates w_i, the root of p_i, with POS tag x. $\text{labelling}^{\text{Joint}}$ (p_i, a) calls $\text{labelling}^{\text{Dep}}$ (p_i, a) which performs action a on p_i.

The main part of the joint method is shown in figure 4. Note that, to satisfy the constraint described above, at the beginning of each step, a **valid** set of (p, l) pairs are initialized (line 5). For the partial analysis p, if its root word is not yet tagged, only (p, x) are considered as valid where x is a certain POS tag. This enforces that partial analysis must be tagged first. For p which is already tagged, if its neighbour is also tagged, then attaches are allowed between the two neighbours.

After initializing the **valid** set, the joint algorithm computes scores of the (p, l) pairs from the **valid** set. Then the one with the highest score is selected and be fed to $\text{labelling}^{\text{Joint}}$. A partial analysis p is marked as processed only when p is attached to its neighbours or be set as the root of the sentence (line 8 to line 11). Figure 5 gives a toy example of the joint tagging and parsing procedure. The **valid** set of each step is also shown in the figure. For simplicity, we suppose that the POS tag set only contains two tags NN (noun) and P (preposition).

In summary, the key idea behind easy-first method is to always choose the easy items to process. The degree of easy or hard is determined by the scoring function. In the next section, we show how to learn the scoring function from training data.

3 Training

The scoring functions used in this work are all based on a linear model.

$$score(t, l) = \vec{w} \cdot \varphi(t, l)$$

Here, $\vec{w}$ is the model's parameter or weight vector and $\varphi(t, l)$ is the feature vector extracted from (t, l) pair. In this section, we first describe a general training algorithm which can be used to train models for all the tasks mentioned above and then introduce our training method which is specially designed for the joint model.

3.1 Easy-first training

The generalized easy-first training algorithm is shown in algorithm 2 which is based on the structured perceptron. Starting from a zero weight vector, the training process makes several iterations through the training set. Each iteration, algorithm 2 is utilized to process the training instances. A training instance consists of a sequence of items T together with its gold reference *R.* Here, R takes different forms in different tasks. For example, in POS tagging, R is the gold tag sequence of the input sentence. In dependency parsing, R is the gold dependency tree of the input sentence.

When $(\bar{t}, \bar{l})$ is not compatible[3] with R, the training algorithm updates the current parameter by punishing the features fired in the chosen $(\bar{t}, \bar{l})$ pair and rewarding the features fired in the (t, l) pair which is compatible with R. The algorithm will then move on to the next instance. Note that there might be more than one such pair that are compatible with R. For example, for figure 1 step (2), (w_2, P), (w_3, NN), (w_4, NN), (w_5, AD) and (w_6, VV) are all compatible with the gold tag sequence. Thus, at the beginning of each step, a **compatible** set of (*t, l*) pairs are initialized and

Algorithm 2: Easy-First Training

Input T: $t_1, \ldots, t_n$, R: gold reference of T, $labelling$: task specific function L:{ $l_1, \ldots, l_n$}, $\vec{w}$: feature weight vector, isAllowed: task specific function

Output $\vec{w}$: feature weight vector

$nProcessed \leftarrow 0$
set each t_i as unprocessed
repeat
  $\boldsymbol{compatible} \leftarrow \{(t, l) | isAllowed(t, l, R)_{\,t.state=unprocessed, l \in L} = true\}$
  $(\bar{t}, \bar{l}) \leftarrow \text{argmax}_{l \in L, t.state=unprocessed}\, score(t, l)$
  if $(\bar{t}, \bar{l}) \in \boldsymbol{compatible}$
    $labelling(\bar{t}, \bar{l})$,
    $\bar{t}.state \leftarrow processed$,
    $nProcessed \leftarrow nProcessed + 1$
  else
    $(\hat{t}, \hat{l}) \leftarrow \text{argmax}_{(t,l) \in \boldsymbol{goldAllowed}}\, score(t, l)$
    $\vec{w} \leftarrow \vec{w} + \varphi(\hat{t}, \hat{l}), \quad \vec{w} \leftarrow \vec{w} - \varphi(\bar{t}, \bar{l})$
    break
until $nProcessed = |T|$
return $\vec{w}$

[3] A (*t, l*) pair is compatible with *R* means that in *R*, *t* is labelled with *l*.

the one with the highest score is chosen to boost (Goldberg and Elhadad, 2010). Function isAllowed is used to check whether a candidate (t, l) pair belongs to the **compatible** set (line 4). Similar to the labelling function, isAllowed can be easily instantiated for different tasks. For POS tagging, $\text{isAllowed}^{\text{POS}}$ (w_i, x, R) checks whether x is the gold tag of w_i. For dependency parsing, $\text{isAllowed}^{\text{Dep}}$ (p_i, a, R) checks:

- Whether all p_i's children supposed by the gold dependency tree has already attached to p_i.
- Whether action a attaches p_i to the correct partial analysis.

For joint POS tagging and dependency parsing, $\text{isAllowed}^{\text{Joint}}$ behaves differently according to the types of labels:

- $\text{isAllowed}^{\text{Joint}}$ (p_i, x, R) returns $\text{isAllowed}^{\text{POS}}$ (w_i, x, R).
- $\text{isAllowed}^{\text{Joint}}$ (p_i, a, R) returns $\text{isAllowed}^{\text{Dep}}$ (p_i, a, R).

3.2 Training with additional loss

Algorithm 2 is a variant of the structured perceptron algorithm. The objective is to minimize the loss $\ell(R, \bar{R})$, usually hamming loss (Daumé III et al., 2009), between gold reference R and the predicted output $\bar{R}$. Whenever there is a positive loss, parameters are updated. For POS tagging, algorithm 2 minimizes $\ell^{POS}(R^{POS}, \bar{R}^{POS})$ where R^{POS} and $\bar{R}^{POS}$ are predicted and gold tag sequence respectively. For dependency parsing, algorithm 2 minimizes $\ell^{Dep}(R^{Dep}, \bar{R}^{Dep})$ where R^{Dep} and $\bar{R}^{Dep}$ are predicted and gold dependency tree, respectively.

For the joint task, algorithm 2 minimizes $\ell^{Joint}(< R^{POS}, R^{Dep} >, < \bar{R}^{POS}, \bar{R}^{Dep} >)$ where $< R^{POS}, R^{Dep} >$ denotes the pair of predicted tag sequence and dependency tree. Such loss has no distinction between tagging and parsing: either tagging error or parsing error will lead to non-zero loss and parameters are updated. This loss may not optimal in terms of achieving the best result of the individual tasks.

Inspired by (Hall et al., 2011), we slightly modify algorithm 2 to incorporate additional loss which only relates to one of the individual tasks so as to train the joint model towards the that task. Algorithm 3 shows the pseudo-code. The basic idea is that at each iteration of the training process, one of the three losses $\{\ell^{POS}, \ell^{Dep}, \ell^{Joint}\}$ is selected and parameters are updated acco-

Algorithm 3: Training with additional loss for joint POS tagging and parsing

Input T: $w_1, \ldots, w_n$, R:gold reference of T, $labelling^{Joint}$, $\boldsymbol{L^{Joint}}$, $\vec{w}$, $\text{isAllowed}^{\text{Joint}}$, ℓ: which can be either ℓ^{POS} or ℓ^{Dep} or ℓ^{Joint}.

Output $\vec{w}$: feature weight vector

1 Set $nProcessed \leftarrow 0$, $p_1, \ldots p_n \leftarrow w_1, \ldots w_n$
2 Set each p_i as unprocessed
3 **repeat**
4 Initialize $\boldsymbol{valid}$
5 $\boldsymbol{compatible} \leftarrow \{(p,l) | isAllowed^{Joint}(p,l)_{(p,l)\in \boldsymbol{valid}} = true\}$
6 **if** $(\ell = \ell^{POS})$
7 $\boldsymbol{compatible} \leftarrow \boldsymbol{compatible} \cup \{(p,l) | (p,l) \in \boldsymbol{valid} \wedge l \in \boldsymbol{ACT}\}$
8 **if** $(\ell = \ell^{Dep})$
9 $\boldsymbol{compatible} \leftarrow \boldsymbol{compatible} \cup \{(p,l) | (p,l) \in \boldsymbol{valid} \wedge l \in \boldsymbol{POS}\}$
10 $(\bar{p}, \bar{l}) \leftarrow \text{argmax}_{(p,l)\in \boldsymbol{valid}} score(p,l)$
11 **if** $(\bar{p}, \bar{l}) \in \boldsymbol{compatible}$
12 ... (*the following are exactly the same as algorithm 2*)

-rdingly: if ℓ^{Joint} is selected, then both tagging and parsing error cause parameter update; if ℓ^{POS} is selected, then only tagging errors can cause parameter update. This can be done by adding all valid attach actions to the **compatible** set regardless whether those actions are indeed compatible with the gold reference (line 6 to line 7); For ℓ^{Dep}, only parsing errors cause parameter update which can be achieved similar to the case of ℓ^{POS}.

4 Experiments

To make comparison with previous works, we use Penn Chinese Treebank 5.1 (CTB5) (Xue et al., 2005) to evaluate our method. We use the standard split of CTB5 as described in (Duan et al., 2007): section 001-815 and 1001-1136 are used as training set, section 886-931 and 1148-1151 are used as development set, section 816-885 and 1137-1147 are used as test set. Head finding rules of (Zhang and Clark 2008b) are used to convert the constituent trees into dependency trees. An Intel Core i7 870 2.93 GHz machine is used for evaluation. For POS tagging and dependency parsing, the number of training iterations are selected according to the model's performance on the development set. The model which achieves the highest score on the development set is selected to run on the test set.

4.1 POS tagging

Following Zhang and Clark (2008a), in the experiments, we also use a dictionary to limit the number of candidate tags for each word. That is, for a word which occurs more than M times in the training data, the tagger only considers the POS tags co-occurred with that word in the training data. We found 6 to be the optimal value on the development set. The feature templates we used in the experiments are shown in table 1. Z&C08 denotes the features templates of (Zhang and Clark, 2008a) which include uni-gram and bi-gram as well as some character based features. In addition to Z&C08, we also incorporate bi-directional POS tag features and the resulted feature set is denoted by feature set BD. For feature set OP, we include some order preference features with the goal to signal to the tagger that some words should be delayed to late stages until more surrounding tags are available and more informed prediction can be made.

Table 2 shows the performance for different feature set and also gives state-of-the-art results on the same data set. "Li-10" denotes the performance of the tagger of (Li et al., 2010) and Hatori-11 denotes the performance of the tagger of (Hatori et al., 2011). From table 2, we can see

Feature sets	Tagging Feature Templates
Z&C08	w_i, w_{i+1}, w_iw_{i+1}, w_iw_{i-1}, $FC(w_i)$, $LC(w_i)$, $TS(FC(w_i))$, $TS(LC(w_i))$, $C_n(w_i)$ (n=2…len(w_i) -1), $LC(w_{i-1})w_iFC(w_{i+1})$, $FC(w_i)C_n(w_i)$ (n=2…len(w_i)), $LC(w_i)C_n(w_i)$ (n=1…len(w_i) -1), $C_n(w_i)$ (if $C_n(w_i) = C_{n+1}(w_i)$), tag_{i-1}, $tag_{i-1}tag_{i-2}$
BD	Z&C08 + tag_{i+1}, $tag_{i+1}tag_{i+2}$, $tag_{i-1}tag_{i+1}$
OP^{POS}	BD + $w_itagged_{i+1}$, $w_itagged_{i-1}$, $w_itagged_{i-2}$, $w_itagged_{i+2}$ $w_itagged_{i-2}tagged_{i-1}$, $w_itagged_{i-1}tagged_{i+1}$, $w_itagged_{i+1}tagged_{i+2}$

TABLE 1 – Feature templates for easy-first POS tagging. Here w_i denotes the i-th word of the input sentence, tag_i denotes the POS tag of w_i, $FC(w_i)$/$LC(w_i)$ denotes the first/last character of w_i. $C_n(w_i)$ is the n-th character of w_i, TS(c) is the POS tag set that co-occurred with character c in the dictionary. $tagged_k$ denotes whether w_k has already been tagged

Feature Sets	Development Set			Test Set			Speed[4]
	Total	Seen	Unseen	Total	Seen	Unseen	
Z&C08	93.58	94.59	**77.16**	93.36	94.22	80.49	3001
BD	93.85	94.98	75.65	93.68	94.53	**80.83**	2733
OP	94.05	**95.13**	76.65	**93.84**	**94.73**	80.49	2070
Li-10	–	–	–	93.51	94.36	80.78	292
Hatori-11	**94.15**	–	–	93.82	–	–	210

TABLE 2 – POS tagging performance

that bi-directional features are effective for improving tagging performance. With bi-directional features, the tagger achieves the accuracy of 93.68 which is higher than Li-10 and slightly lower than Hatori-11. By incorporating order preference features, tagging accuracy increases to 93.84 better than both Li-10 and Hatori-11. Moreover, rather than using Viterbi or beam search, our easy-first tagger is deterministic which is easy to implement and runs in high speed, more than 2000 sentence per second.

4.2 Dependency parsing

We use root accuracy, complete match rate and word accuracy or dependency accuracy to evaluate the parser's performance. Feature templates for easy-first dependency parsing are shown in table 3. G&E10 denotes the feature templates used in (Goldberg and Elhadad, 2010) with some modification: the feature templates in the last row of G&E10 were originally designed to deal with English PP attachment ambiguity. Those templates are limited to be used only when

Feature sets	Parsing Feature Templates
G&E10	for p in p_{i-2}, p_{i-1}, p_i, p_{i+1}, p_{i+2}, p_{i+3}: len(p), nc(p)
	for p q in(p_{i-2}, p_{i-1}),(p_{i-1}, p_i),(p_i, p_{i+1}),(p_{i+1}, p_{i+2}),(p_{i+2}, p_{i+3}): dis(p, q), dis(p, q)$tag_p tag_q$

TABLE 4 – Parsing performance. H&S-10 and Z&N-11 denote parsers in Huang and Sagae (2010) and Zhang and Nirve (2011), respectively. H&S-H and Z&N-H denote Hatori et al., (2011)'s re-implementation of H&S-10 and Z&N-11, respectively. Li-10-O2/O3 denotes the 2rd/3rd graph based model of Li et al., (2010)

either tag_{p_i}or $tag_{p_{i+1}}$or $tag_{p_{i+2}}$is a preposition. For Chinese, PP attachment ambiguity is not as prevalent as that of English (Huang et al., 2009) and we found that use these features without any limitation yields better results. VTT includes valence features, tri-gram features and third order features which were proved useful for transition based parsers (Zhang and Nivre, 2011). For OP, some additional order preference feature templates are added.

Parsing results are shown in table 4. "GoldPOS" denotes the input with gold standard POS tag. "AutoPOS" denotes that the training set are assigned with gold standard POS tag while the test set are tagged by our easy-first tagger. "J-N" denotes that we use 10-fold Jack-Nifing to train the model. "Tag Accuracy" denotes the test set tagging accuracy. From table 4, we can see that valence and tri-gram features are also effective for easy-first parser. For GoldPOS, word accuracy boosted from 84.62 to 85.18. For AutoPOS and J-N, word accuracy also increased about 0.2 and 0.3 point, respectively. Order preference features are not as effective as it were for tagging. After adding these features, parsing performance rarely changed. One reason might be that some of the features of G&E10 already capture order information and the order preference features list in table 3 redundant to some degree. Comparing with other state-of-the-art parsers on this data set, the performance of the easy-first parser is still lower. This may due to the fact that our parser is greedy, thus more vulnerable to error propagation. Interestingly, for AutoPOS and J-N, the easy-first parser achieves the highest complete match rate. This is consistent with (Goldberg and Elhadad, 2010). One thing should be mentioned is that, the deterministic easy-first parser is both easy to implement and runs very fast, more than 350 sentences per second.

4.3 Joint tagging and parsing

Similar to (Hatori et al., 2011), for the joint task, we choose the model which performs the best on the development set in terms of word accuracy to run on the test set. Feature templates for joint POS tagging and dependency parsing are shown in table 5. The feature set is the union of the feature set used for POS tagging and the feature set used for dependency parsing. Besides, in-

Feature sets	Feature templates for Joint tagging and parsing
Syn	nc(p_{i-1}) $w_{p_{i-1}}$, nc(p_{i-1}) $tag_{p_{i-1}}$ nc(p_{i+1}) $w_{p_{i+1}}$, nc(p_{i+1}) $tag_{p_{i+1}}$ nc(p_{i-1})w_i $tag_{p_{i-1}}$, nc(p_{i-1})$w_i w_{p_{i-1}}$, nc(p_{i-1}) $tag_{p_{i-1}} lc_{p_{i-1}}$ nc(p_{i-1}) $tag_{p_{i-1}} rc_{p_{i-1}}$ nc(p_{i+1})$w_i tag_{p_{i+1}}$ nc(p_{i+1})$w_i w_{p_{i+1}}$ nc(p_{i+1}) $tag_{p_{i+1}} lc_{p_{i+1}}$ nc(p_{i+1}) $tag_{p_{i+1}} rc_{p_{i+1}}$
VVT^{Joint}	Syn + VVT^{DEP} + OP^{POS}

Table 5 Feature templates for joint POS tagging and dependency parsing.

-spired by (Hatori et al., 2011), we also incorporate some syntactic features that aim to improve tagging accuracy and theses features are denoted by Syn.

Table 6 shows the results for the joint model with different losses. Parsing performance, especially word level accuracy, is largely affected by the different loss settings. When training the joint model with a single loss ℓ^{Joint}, word level accuracy is 79.12. When training with $\ell^{Joint}$and $\ell^{Parsing}$, word level accuracy increased to 79.91. These results demonstrate that our training method can bias the joint model towards the desired task. However, as we try different losses, tagging accuracy rarely changes. This may because that the tagging accuracy is already very high and it is quite difficult to achieve further improvement.

Comparing with previous results on joint POS tagging and dependency parsing, our method achieves the best result in terms of complete match rate and POS tagging accuracy[5]. The word accuracy is still below the best result. This may due to the fact that our joint decoder is deterministic thus suffers more from error propagation comparing with beam search based or dynamic programming based decoders. However, our joint method can also be enhanced with beam search and we leave it to future work.

Model	losses	POS	Word	Root	Compl	Speed
Joint	ℓ^{Joint}	94.25*	79.12	72.02	30.66	70+
	$\ell^{Joint}, \ell^{Parsing}$	94.26*	79.91*	72.81	**30.76**	70+
	ℓ^{Joint}, ℓ^{POS}	**94.27***	79.04	71.44	30.29	70+
Pipeline	–	93.84	78.73	68.29	29.34	

Other Methods	POS	Word	Root	Compl	Speed
B&N-12	93.24	81.42	–	–	–
Li-10-V1-O2	93.08	80.74	75.80	28.24	1.7
Li-10-V2-O3	92.80	80.79	75.84	29.11	0.3
Z&N-Hatori	93.94	**81.33**	**77.92**	29.90	1.5
H&S-Hatori	94.01	79.83	73.86	27.85	9.5

TABLE 6 – Joint tagging and parsing results. B&N-12 denotes the result of (Bohnet and Nivre, 2012). Li-10-V1-O2 and Li-10-V2-O3 denote results from (Li et al., 2010). Z&N-Hatori and H&S-Hatori denote results from (Hatori et al., 2011). "*" denotes statistical significant ($p < 0.05$ by MeNemar's test) comparing with the pipeline method.

[5] Comparing with easy-first tagger, the joint model does better at disambiguiting NN-VV, DEC-DEG while poorer at JJ-NN. This result is similar to previous result (Hatori et al, 2011). For limited space, we omit the confusion matrix.

5 Related Work

The easy-first dependency parsing algorithm was first proposed by (Goldberg and Elhadad, 2010), they applied the algorithm to English dependency parsing and by combining results with transition based parser and graph based parser, state-of-the-art performance is achieved. This work is a generalization to their algorithm, and we applied the generalized algorithm to Chinese POS tagging and dependency parsing and also achieves good results in terms of both speed and accuracy. We also proposed the first easy-first joint tagging and parsing algorithm. By incorporating additional loss during training, our method achieves the best tagging accuracy reported so far. Shen et al. (2007) proposed a bi-directional POS tagging algorithm which achieves state-of-the-art accuracy on English POS tagging. Comparing to their method, our tagging algorithm in this paper is much simpler and we are the first to use order preference features in POS tagging. Also this is the first work that applies easy-first tagging on Chinese.

For joint POS tagging and (unlabelled, projective) dependency parsing, Li et al. (2010) proposed the first graph based algorithm. Lee et al. (2011) proposed a graphical model to solve the joint problem. Hatori et al. (2011) proposed the first transition based algorithm. Bohnet and Nivre (2012) extended Hatori et al. (2011) to labelled non-projective dependency parsing. Different from the works talked above, our method is based on the easy-first framework. In addition, all previous joint methods optimize a single loss in the training phase while we are the first to train the joint model with additional loss.

Hall et al. (2011) proposed the augmented-loss training for dependency parser that aims at adapting the parser to other domains or to downstream tasks such as MT reordering. They extended structured perceptron with multiple losses each of which is associated with an external training set. Our method is directly inspired by Hall et al. (2011). However, rather than domain adaptation, our method aims at training the joint model to pursue the best result of one of the individual task. Moreover, our method optimizes all loss on a single training set.

6 Conclusion

In this paper, we generalize the method of (Goldberg and Elhadad, 2010) to a general framework and apply the framework to Chinese POS tagging and dependency parsing. We also proposed the first joint tagging and dependency parsing algorithm under the easy-first framework. We show that by using order preference features, an easy-first POS tagger can achieve the state-of-the-art accuracy. We show a deterministic easy-first parser can surpass the transition-based parser when the input is associated with automatically generated tags. We also illustrate that by incorporating additional loss in the training process, we can bias the joint model towards the desired task.

ABSTRACT
In the present work we raise the hypothesis that eye-movements when reading texts reveal task performance, as measured by the level of understanding of the reader. With the objective of testing that hypothesis, we introduce a framework to integrate geometric information of eye-movements and text layout into natural language processing models via image processing techniques. We evidence the patterns in reading behavior between subjects with similar task performance using principal component analysis and quantify the likelihood of our hypothesis using the concept of linear separability. Finally, we point to potential applications that could benefit from these findings.

TITLE AND ABSTRACT IN JAPANESE

視線の動きとテキスト素性を用いた読み手の個性認識

本研究では、テキストを読む際の視線の動きから、テキストの理解度によって測定されるような読み手のタスクパフォーマンスが予測可能である、という仮説を立てる。この仮説を検証するため、我々はまず、画像処理技術を介して、視線の動きとテキスト配置に関する位置情報を、自然言語処理のモデルとして統合する枠組を導入する。次に我々は、近いタスクパフォーマンスの被験者間に共通した読解行動のパターンを主成分分析によって同定し、この線形分離可能性を求めることで我々の仮説の蓋然性を定量的に示す。最後に、我々はこれらの発見から恩恵を受け得る応用例について述べる。

1 Introduction

Reading is a common activity that is part of the process of information transfer between humans. However, despite of the important role it has played in recent history and its current wide use, this process of information transfer is not well understood. The difficulty in modelling the reading activity stems from the direct unobservability of human mental states and how the information is decoded and integrated into the brain, or simply forgotten.

The reading act can be seen as an interaction between the reader and the writer where the information and other aspects of the communication are transferred via the document. If we could observe the detailed editing process of a writer, that would indeed give us valuable information about the writer, useful to interpret the message to be sent. However, information on the editing process is usually not available, but the final result in the form of a document is. On the other side of the communication channel, the reader does not necessarily evidence any reading actions except for the movements of the eyes, and that is all we have to understand the reading process.

Several psycholinguistic studies (Rayner, 1998; McDonald and Shillcock, 2003) have shown that document characteristics influence on cognitive processing and that they are reflected on eye-movements in an on-line manner. There have been attempts to also quantify the influence of textual linguistic characteristics on reading behavior for certain types of reading tasks (Martínez-Gómez et al., 2012b), noting that although linguistic features of documents can be used to explain eye-movements and reading behavior, there might be other influencing factors.

In our work, we consider the document and the eye-movements of the reader as the only *observable* variables in the reading act, and our general objective is to unveil the *hidden* variables intervening and influencing the interaction, such as writer's and reader's personal characteristics. Examples of writer's personal characteristics are writer's intention, concerns or emotional state, while reader's characteristics could be the reading objective, nationality, domain of expertise or literacy. We think that personal characteristics of readers define the mechanisms of their cognitive activity, and that when performing certain tasks, the eye-movements may reflect part of these personal characteristics. One of the hidden variables of the reader is the task performance achieved after reading a text, which is an intimate piece of information about the reader that could only be extracted so far by explicitly inquiring the subjects. Due to the interest and the broad range of applications that could benefit from the recognition of reading performance from eye-movements and document characteristics, we will narrow our study to this variable.

The objective of this work is then to use the spatiotemporal data that can be obtained by an eye-tracker when a subject reads a text and the linguistic information of the text itself, to capture common patterns in reading behavior across subjects with similar task performance. Thus, our hypothesis states that:

Hypothesis. *Subjects with a high performance in reading tasks have characteristic patterns of reading behavior and can be distinguished from the subjects with low performance.*

There are multiple ways of measuring task performance in reading tasks. One could argue that the reading objective defines how to measure performance. For example, the factors to measure success when reading a document with the objective of writing a review or preparing a presentation are clearly different. However, for the sake of simplifying and unifying our

method to measuring task performance, we will resort to measuring the level of understanding of subjects after reading a text.

In the next section, we describe the efforts from the psycholinguistic community in understanding the relationship between eye-movements and cognitive processing, and how the present work builds upon them. Section 3 introduces the models of reading behavior that are used to capture patterns in the eye-movements. A description of the data collection and experiment conditions can be found in Section 4 and the quantification of the likelihood of our hypothesis can be read in Section 5. In Section 6, we point at our next steps in recognizing reader's personal characteristics and suggest some applications that could benefit from the current line of investigation, followed by our conclusions at the end of the paper.

2 Related work

With the emergence of eye-tracking devices, the study on the relationship between eye-movements and cognitive processes experienced important advances. An interesting survey can be found in Rayner (1998) condensing the findings on characteristics of elemental eye-movements, lexical processing and integration of information during reading tasks. In McDonald and Shillcock (2003), it was shown that probabilistic language models implemented as bi-grams could help to explain the on-line cognitive processing of our brains and predict fixation times. That work suggested that statistical models can be used to model cognitive processing and that hypotheses could be tested using evidence extracted from the observation of eye-movements. Other models of eye-movements when reading were developed, being the E-Z reader (Reichle et al., 2003) one of the most comprehensive. Remarkably, a corpus of eye-movement data (Kennedy and Pynte, 2005) was also built to test previous computational models and paving the way to establish a common ground of computational model development. Following these ideas, we work under the assumption that eye-movements reflect cognitive processes and that the analysis of these eye-movements and the linguistic features of the text can be used to indirectly recognize the current mental state of the reader.

Cognitive load is an important variable that has received a significant amount of attention since it is a good signal of task difficulty and cognitive demand. In Tomanek et al. (2010), variations in eye-movements were used to build a cognitive cost model to predict human annotation costs of named entities, while in Doherty et al. (2010), variations in eye-movements were used to recognize hidden linguistic features from machine translation output such as sentence understandability. Although these two works appear to share the same idea, they point at different directions. The former uses linguistic features and eye-movements to unveil hidden cognitive costs, while the latter uses certainty on cognitive load and eye-movements to recognize textual characteristics such as sentence understandability. Both directions fall within our research interests, but in the present paper we follow the philosophy of Tomanek et al. (2010), in that we use observations of the text and the eye-movements to infer a hidden personal characteristic such as the level of understanding.

The authors in (Biedert et al., 2012) assume that eye-movements reflect difficulties in understanding the document being read and attempt to automatically recognize the quality of the text by integrating eye data from multiple readers. In that work, the authors investigate how different features of the eye-movements can reflect the quality of the text, but do not take into consideration the influence of lexical, syntactic and semantic complexity of the text on the eye-movements. This idea is central to our work, and we will attempt to combine data from eye-movements and linguistic features to obtain stronger predictors.

Eye-movements have also proved to characterize individuals, and there is a growing list of applications that would benefit from the refined user models that can be obtained by automatically processing eye-movements on text and other media (Xu et al., 2008; Buscher et al., 2008; Xu et al., 2009; Buscher and Dengel, 2009). With this motivation in mind, this paper contributes to better recognize personal characteristics of readers by using information from their eye-movements and the linguistic characteristics of the texts they read.

3 Methodology

3.1 Synthesizing images of linguistic and gaze evidence

With the objective of modelling the reading act, we first need to identify what variables are present in the process. The interaction between the reader and the document has latent and patent variables, where only the latter can be observed and measured. Nowadays, there is a large quantity of text that is being consumed in the form of digital content that is projected on a display, and it is reasonable to think that the structure, the contents and the linguistic features of the document can be observed and automatically extracted in the form of *statistical evidence*.

In the present paper, we work under the assumption that eye-movements can also be observed by means of an eye-tracker system. There are multiple eye-movements that have been recognized and categorized (see (Rayner, 1998) for details), but we can roughly group them into *fixations* and *saccades*. Fixations are periods of time where the subject looks still at a certain location, and it is known to be used for object recognition in general tasks or for lexical processing in reading tasks. Saccades, on the contrary, are sudden eye-movements that are used to change the fixation location and it is believed that cognitive processing is suppressed during the eye-movement.

There is a strong need of finding a suitable, unified representation of linguistic and gaze data in order to integrate these two sources of information. Gaze data can be naturally represented using synthesized images out of the (x, y) coordinates of the position where the eye-tracker "believes" the reader is gazing at. At a constant sampling rate, areas in the image where the reader gazed at longer will have a larger amount of pixels with high values, each pixel representing a gaze sample. There is, however, another aspect of the temporal data that can be obtained by an eye-tracker that is related to the sequential order of the gaze samples. The sequential order of the eye-movements is valuable to detect regressions, which are backward saccades usually used by readers for disambiguation, refreshing previously read passages or resolve apparent contradictions. Although these eye-movements are very interesting to infer the current state of mind of readers, they will not be included in our data representations due to their complex nature.

As it was pointed out by several authors(Hornof and Halverson, 2002; Hyrskykari, 2005), there are important variable and systematic errors in gaze location that need to be taken into account when working with eye-tracking systems. For the purpose of smoothing the effect that those errors may cause on our operations, we apply a gaussian convolution (Haralick and Shapiro, 1992) to blur the image representation of the gaze evidence and adjust the intensity of the pixel values to compensate for subjects that spent more or less amount of time on the document. The left plot in Figure 1 depicts a typical image representation of raw gaze data from an eye-tracking session of a subject reading a document, where fixations (little clusters of black dots) only occur on words or phrases (since those were the only objects of interest displayed on the screen), and text rows can be appreciated as fixations aligned horizontally. On the right plot, we depict the adjusted blurred version of the raw gaze data.

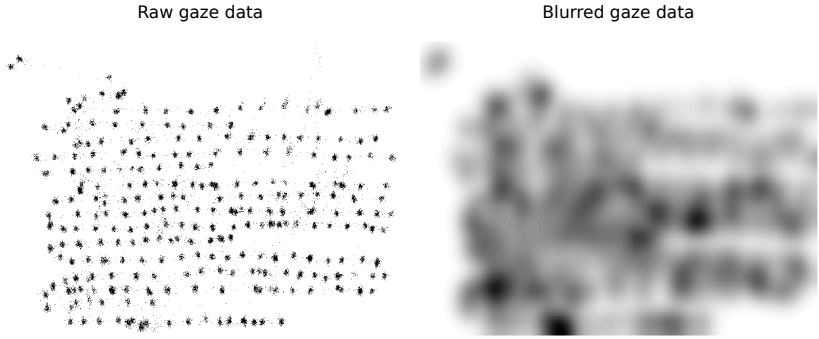

Figure 1: On the left, image representation of raw gaze data of an eye-tracking session. On the right, blurred image representation used to preserve uncertainty on the variable error introduced by the system. Pixel values are complemented for clarity.

Similarly, linguistic information can also be represented using synthesized images (Martínez-Gómez et al., 2012b), where the area of a word or phrase is filled with pixel values whose intensity is proportional to the quantification of a certain linguistic feature within the document. It should be noted at this stage that the image representations of linguistic features only quantify the presence of linguistic features within the document and does not take into account any gaze evidence. For this strategy of representation, there will be a synthesized image for each linguistic feature that we include in our model. The quantification of a linguistic feature can be normalized so that it falls within the $[0, 1]$ interval and the distribution of the pixel intensity values over that range can be adjusted in a similar manner as gaze images were, in order to compensate for linguistic features that occur too often or too rarely in the documents. An example of a binary feature that takes the values 1 or 0 to indicate whether a word is a noun or not can be seen on the left plot in Figure 2. The right plot in Figure 2 shows an image representation of a feature that quantifies the depth of a word in the parse tree of its corresponding sentence, normalized to fall within the interval $[0, 1]$.

In this work, we characterize reading behavior by the eye-movements of a subject when reading, which are in turn characterized by the distribution of fixations on parts of the text with certain linguistic features. It is thus useful to quantify this distribution of attention on each linguistic feature. Once we obtained the image representations of gaze evidence and the image representations of linguistic features, we combine these two sources of information by computing how well each linguistic feature explains the eye-movements. In line with our methodology, we will perform such combination by using image processing methods.

Within the image recognition field, image registration is the technique to find correspondences between two or more images with the purpose of estimating transformations for spatial alignment or detect temporal changes using pixel intensity differences. Although there is a wide variety of similarity measures that could be used to measure how well a certain linguistic feature explains the eye-movements, we opted for adapting precision, recall and F_1 scores as they are known in natural language processing, to the comparison of image representations.

Figure 2: On the left, image representation of a linguistic feature indicating what words are nouns (binary). On the right, image representation of a linguistic feature quantifying the word depth in a parse tree (normalized). Again, pixel values are complemented for clarity.

Computing the precision of how an image representation of a linguistic feature (source image) explains the image representation of gaze evidence (target image) consists in computing how much of pixel intensity in the source image is present in the target image, divided by the total amount of intensity across all pixels from the source image. Similarly, recall can be computed as the amount of pixel intensity from the source image that is present in the target image, divided by the amount of intensity across all pixels from the target image. Finally, the familiar expression $F_1 = 2 \cdot \frac{\text{precision} \cdot \text{recall}}{\text{precision} + \text{recall}}$ can be used to compute the F_1 score, which is a value in the interval $[0, 1]$. An example of the computation of precision, recall and F_1 scores between images of only four pixels can be found in Figure 3.

3.2 Representation of observations

A reading session consists of a subject reading a document. From every reading session, we can obtain data from the eye-movements and data about the linguistic features of the text. As we described in Section 3.1, we can synthesize an image representation of the data from the eye-movements, and an image representation for each linguistic feature. Using the F_1 score, we computed how well the image representation of linguistic feature i match (or explains) the image representation of the eye-movements, and obtained a number $o_i \in \mathscr{R}$ such that $0 \leq o_i \leq 1$. If we match the image representation of every linguistic feature against the image representation of the eye-movements, we can obtain a fixed-size feature vector $\mathbf{o} = [o_1, \ldots, o_L]$ that has as many components (or dimensions) as linguistic features (L). An overview of the architecture can be found in Figure 4.

Thus in our model, the reading behavior of a subject reading a document is defined as $\mathbf{o}$, which represents the distribution of attention (eye-movements) on every linguistic feature. Using fixed-size feature vectors to represent observations is a widely used technique that, although it has a limited expressivity, it allows to use very well known efficient analysis and inference techniques. Using this formalism, we will say that two subjects have similar reading behavior

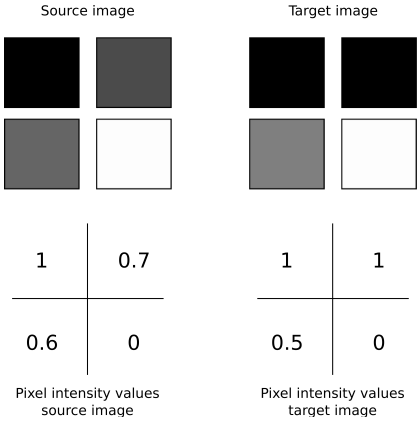

Figure 3: Example of computation of precision, recall and F_1 score between a source and a target image. On the top row, four pixels (complemented for clarity) are displayed, and their corresponding pixel values on the bottom row. Precision $= \frac{1+0.7+0.5}{1+0.7+0.6} = 0.96$. Recall $= \frac{1+0.7+0.5}{1+1+0.5} = 0.88$. Thus, $F_1 = 0.92$.

if they have similar feature vectors, as defined by a similarity metric in the feature space. For the sake of readability and ease of interpretation in posterior sections, we chose the euclidean distance between two observations $\mathbf{o}$ and $\mathbf{o}'$ as a similarity measure, defined as:

$$\text{dist}(\mathbf{o}, \mathbf{o}') = \sqrt{(f_1 - f_1')^2 + \cdots + (f_F - f_F')^2} \tag{1}$$

where the smaller the distance, the higher the similarity between $\mathbf{o}$ and $\mathbf{o}'$ is.

As it has been said, each reading session is represented by a feature vector $\mathbf{o}$ that defines a distribution on how well each linguistic feature helps to explain the gaze evidence from a certain subject. Our hypothesis is that this representation helps to discriminate between subjects with a low and a high task performance. In order to test this hypothesis, we will test for *linear separability*, that is, how well we can separate subjects with a hypersurface[1] in a certain reduced dimensionality.

4 Experimental framework

In order to collect data for experimentation purposes, 9 subjects were asked to read news and fiction documents in English following different reading strategies. Subjects were students from China (1), Indonesia (1), Japan (4), Spain (1), Sweden (1) and Vietnam (1) in Bachelor, Master, PhD and post-doctoral levels of education in computer science.

Three reading strategies were considered. The first strategy was *precise reading*, where subjects were told to read two documents with the objective of maximizing their comprehension and that their level of understanding would be tested after reading each document with yes-no questions,

[1] A straight line and a plane in 2 and 3 dimensions, respectively.

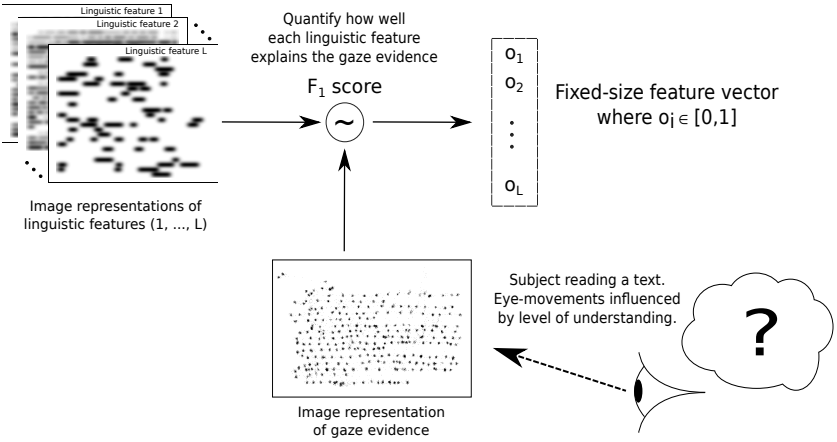

Figure 4: Schema of the methodology used in this work to estimate the distribution on how each linguistic feature explains subject's reading behavior. First, a collection of image representations of linguistic features is synthesized. Then, using the image F_1 score function, each linguistic feature is matched against the gaze data to obtain a measure on how well it explains reading behavior. The result is a fixed-size feature vector $\mathbf{o}$ representing a reading session.

multiple-choice questions and free-answer questions. The second strategy was *skimming*, with the objective of finding the answer to one or two questions (to each document, respectively) and the accuracy and completeness of their answer was measured after subjects claimed that they had found the necessary information to answer the questions. The third strategy was named *10-second reading*, where subjects were given 10 seconds to obtain as much information as possible from two documents (respectively), and were asked to show the amount of information they got and were scored proportionally to correctness and completeness. Table 1 summarizes basic statistics of the documents. The total duration of the reading sessions and question answering to obtain subject's level of understanding was, on average, 40 minutes.

Randomizing the presentation order of the documents is a standard practice in psycholinguistics. In the present work, however, the presentation order was kept constant, due to concerns about the effects of the randomization when working with a limited number of subjects. We believe that the results are not affected by this decision, since subjects were compared within the same document and reading strategy (thus, under the same experimental conditions).

In what follows, we assume that the score that subjects obtained in the questionnaires after reading every document represents the subject's level of understanding and that the highest score among all subjects represents a 100% of understanding. There were two rules used to partition subjects and test linear separability. In the first partition rule, we select the subjects whose understanding was below 33%, and try to find a linear decision boundary (in the form of a straight line or plane) that separates those subjects from the rest of the participants. In the second partition rule, we select the subjects whose understanding is above 66%, and proceed to test whether they can be linearly distinguished from the rest.

Reading strategy	Document	Avg. tokens / sent.	Num. sent.	Avg. reading time
10-second reading	doc. 1	23.4	11	10 s.
	doc. 2	22.6	14	10 s.
Skimming	doc. 3	20.9	13	70 ± 64 s.
	doc. 4	11.8	20	52 ± 38 s.
Precise reading	doc. 5	30.2	11	116 ± 49 s.
	doc. 6	20.3	12	95 ± 36 s.

Table 1: Statistics on the average number of tokens per sentence (Avg. tokens / sent.), number of sentences (Num. sent.) and average reading time (Avg. reading time). Statistics were collected across all subjects for the 6 documents used during the experiments, to record eye-movements and obtain the linguistic features of those documents.

With the intention of capturing all possible linguistic influence on reading behavior, we collected a set of lexical, syntactic and semantic linguistic features on every document. Among the lexical linguistic features, we measured word length, whether the word contains a digit or not, the presence of upper case letters or word unpredictability, as given by the perplexity from a 5-gram language model trained on a big corpus (Koehn, 2005) and smoothed using modified Kneser-Ney technique (Chen and Goodman, 1999). Syntactic features were also included in our model, such as whether a word is the head of a phrase, binary features indicating whether a word has a certain Part-of-Speech (POS) tag, total height of the parse tree of the sentence each word corresponds to, word position in the sentence, etc. We believe that semantic features also may influence greatly on the eye movements, since it is reasonable to think that an important part of the cognitive processing consists in an incremental integration of the information into the personal knowledge base, right after the lexical and syntactic processing happens. However, due to the difficulty in formally defining and properly quantifying semantic features, only two were considered, namely the word ambiguity, as given by the number of senses in WordNet (Miller, 1995) that a word may have, and a feature indicating whether a word or phrase is a named entity or not. The complete list of linguistic features included in our model can be found in Table 2, and will be used to synthesize image representations and compute how well they help to explain the gaze evidence.

Prior recording the eye-movements during the reading session, every subject was informed of the dynamics of the reading tasks. Tobii TX300 and Text2.0(Biedert et al., 2010) were used to capture the (x, y) coordinates of the gaze samples for every subject reading every document, and the eye-tracker was calibrated before every subject read every document. In order to avoid introducing tracking errors as much as possible, a chin rest was used for subjects to keep their heads stable. A text-gaze aligner (Martínez-Gómez et al., 2012a) based on an image registration method was also used to correct variable and systematic errors in the coordinates of the gaze samples, and further corrections were manually performed when necessary. Finally, the eye-tracking session data of a subject reading one of the documents in the 10-second reading task was discarded due to unrecoverable errors during the eye-tracking session.

Pixel intensity values were normalized in the image representations of the eye-movements and the image representations of the linguistic features, in order to compensate for subjects

Category	Linguistic feature	Type
Lexical	word length	Integer
	contains digit	Binary
	word unpredictability	Real
	contains uppercase	Binary
	is all uppercase	Binary
Syntactic	is head	Binary
	is POS `$tag` (23 features)	Binary
	height of parse tree of its sentence	Integer
	depth of the word in the parse tree	Integer
	word position in sentence	Integer
Semantic	is named entity	Binary
	ambiguity: number of senses from WordNet	Integer

Table 2: Lexical, syntactic and semantic linguistic features considered in this work. Examples of POS `$tag` are "Nouns", "Verbs" and "Prepositions". Heads and parse trees were obtained using an HPSG parser (Miyao and Tsujii, 2008).

spending different amount of time on the documents, and to account for rare or too-frequent linguistic features that have a different amount of total pixel intensity in the image. Thus, the intensity was adjusted in such a way that 1% of the highest and the lowest non-zero pixel values were saturated (i.e. totally dark and totally white).

5 Results

5.1 Patterns in the variance

In our hypothesis, we stated that subjects with different task performance would have different patterns in reading behavior. With the objective of revealing these differences at a preliminary stage, we proceed to analyze the variability of the distribution of attention on the linguistic features across all subjects participating in our experiments. Studying the variability of data is of special interest because patterns in variance are usually good signals to be considered to discriminate between subjects. Thus, Principal Component Analysis (PCA) (Jolliffe, 2002) will be used to obtain the directions in the feature space where the covariance matrix of the observations varies the most, as given by the eigen-vectors associated to the highest absolute eigen-values.

Then, we can project the observations (our subjects) onto the two or three directions that capture most of the variance. On the left plot of Figure 5, we can observe a projection onto the two dimensions with highest variability, capturing 74.8% of the total variance across all subjects in document 1 of the 10-second reading task. It can be appreciated that the three subjects with the lowest level of understanding (marked as x) are located on the left part of the plot, clearly separated from the rest of the subjects. On the right plot of Figure 5, subjects were projected on the three directions that capture most of the variability for the same document, capturing 85.6% of the total variance.

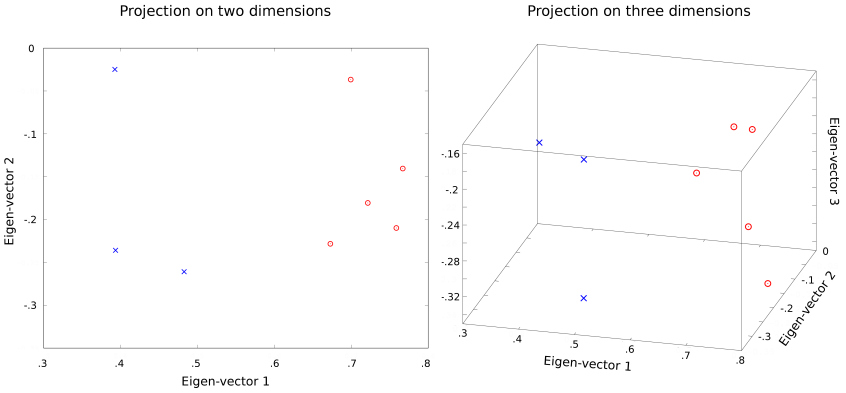

Figure 5: Principal Component Analysis on the covariance matrix of the subjects reading document 1 during the 10-second reading task. Subjects with low level of understanding are marked as x, and subjects with a high understanding are marked as o. On the left plot, a projection onto two dimensions capture 74.8% of the variance; on the right plot, a projection onto three dimensions capture 85.6%.

5.2 Separability

In order to reveal the differences in reading patterns (as described in Section 3.2), we will test for linear separability of subjects in a low dimensional space resulting from a principal component projection of the subjects. Despite of the apparently reduced number of subjects participating in the experimentation, linear separability of a number of subjects (i.e. 8 or 9) in a space of much smaller dimensionality (i.e. 2 or 3) is not likely to happen by pure chance.

The quantification of the linear separability can be found in Table 3. Subjects (observations **o**) were projected onto two and three dimensions using their two and three directions of highest variability respectively, following the PCA dimensionality reduction method. For every projection and every document, two partition rules (as described in Section 4) were considered to select the subset of subjects for which linear separability have to be tested. Then, a decision line (in two dimensions) or a plane (in three dimensions) was obtained such that maximizes the number of subjects from the subset of interest that are correctly separated from the rest of the subjects, without allowing subjects that do not belong to the subset of interest to be miss-classified. Every cell in Table 3 shows a fraction X/Y, where X denotes the number of subjects from the subset of interest (i.e. subjects with the lowest or the highest level of understanding) that were correctly separated from the rest of the subjects by using the best possible linear separation, and Y denotes the total number of subjects in the subset of interest.

In an instance of a positive example from Table 3, there were 8 subjects reading document 1 in 10-second reading task and those subjects were projected onto two dimensions. Using partition rule 1, the 3 subjects with the lowest level of understanding were selected, and all of them were correctly linearly separated. A negative example can be found at the 2-dimensional projection of the 9 subjects reading document 3 of the skimming task, where partition rule 1 is used to

Reading strategy	Document	Partition rule 1		Partition rule 2		Num. subjects
		2 Dim.	3 Dim.	2 Dim.	3 Dim.	
10-second reading	doc. 1	**3/3**	**3/3**	**2/2**	**2/2**	8
	doc. 2	**1/1**	**1/1**	0/1	0/1	9
Skimming	doc. 3	0/2	**2/2**	5/7	6/7	9
	doc. 4	**1/1**	**1/1**	**8/8**	**8/8**	9
Precise reading	doc. 5	1/4	2/4	**1/1**	**1/1**	9
	doc. 6	**1/1**	**1/1**	**1/1**	**1/1**	9

Table 3: Quantification of the separability for subjects reading two documents following 10-second, skimming and precise reading tasks. Subjects have been projected in two and three dimensions (Dim.), and linear separability have been tested for two different partition rules as described in Section 4. At every cell, X/Y denotes that Y subjects were selected by the partition rule to test their linear separability, and X of them were successfully separated from the rest of the subjects.

select the subset of subjects with the lowest level of understanding. From Table 3, it can be read that not a single subject with a low level of understanding can be linearly separated from the rest, thus not being distinguishable from the other subjects by using the patterns on reading behavior that are described in this paper. An illustration of these two examples can be found in Figure 6.

It can be observed that the subjects with a level of understanding below one third of the highest level of understanding can be linearly separated from the rest of the subjects in all documents of the 10-second and skimming reading strategies. This linear separation was feasible in two and three dimensions respectively[2]. At the precise reading strategy, only some subjects with the lowest level of understanding were found to be linearly separable from the rest of the subjects, indicating that the distribution of the attention over linguistic features only contains limited information about reading performance and that the eye-movements might be influenced by factors of different nature, which is consistent with (Martínez-Gómez et al., 2012b).

Table 3 also contains a quantification of how well subjects with a high level of understanding could be linearly differentiated from the rest of the subjects (columns corresponding to partition rule 2). Although it can be appreciated that results are not consistent across all reading tasks, there is a positive trend of linear separability. In document 1 of the 10-second reading task, two subjects were selected by the partition rule 2, and both of them were successfully linearly separated from the rest of the subjects in 2 dimensions. In document 2, however, the partition rule only selected one subject with the highest level of understanding, but neither projections in 2 nor 3 dimensions allowed for linear separability. In document 3 of the skimming task, 7 subjects (out of 9) were selected as having the highest level of understanding, and 5 and 6 of them were successfully linearly separated in 2 and 3 dimensions respectively. In document 4 of the same task, the partition rule 2 selected 8 subjects, and all of them were linearly separated from the remaining subject. Finally, in both documents of the precise reading task, only 1 subject in every document was selected as having the highest level of understanding, and the subject was positively linearly separated from the rest of the subjects in 2 and 3 dimensions.

[2]Note that if a subset is linearly separable in n dimensions, then it is also linearly separable in $n+1$ or more dimensions.

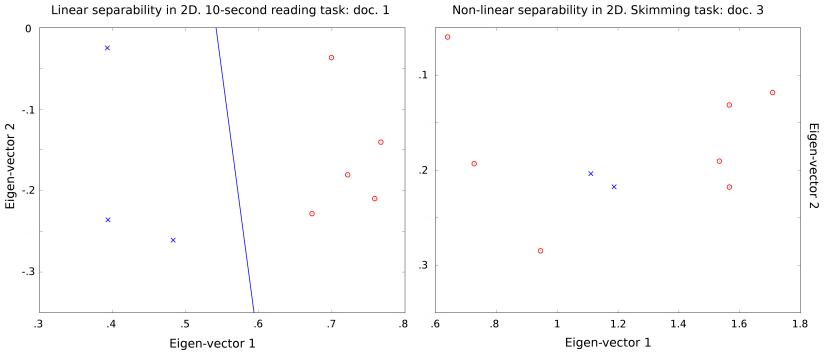

Figure 6: On the left, a positive example of linear separability in a projection on two dimensions of the subjects reading document 1 in the 10-second reading task. On the right, a negative example of a projection on two dimensions of the subjects reading document 3 of the skimming task, where subjects with low level of understanding (x) cannot be linearly differentiated from the rest of the subjects (o), using the patterns in reading behavior described in this work.

6 Future work and applications

The work presented in this paper is a step towards recognizing personal characteristics by using data extracted from the eye-movements in combination with the linguistic properties of the documents being read. We believe that there are other personal characteristics that can be extracted from eye-movements. Language ability is one of them, and it could be recognized by analyzing the proportions in the quantity of attention paid on words or phrases with certain linguistic features such as verbs or nouns. Subject's domain of expertise could also be recognized by analyzing fixation times on technical terms and comparing it to other subjects with different known domains of expertise. We also believe that the reading intention of users is also reflected on the eye-movements and it falls within our research road map. We are also interested in designing models to explain how the pupil size diameter depends on the linguistic characteristics and the amount of information contained in a text with the objective of quantifying the amount of surprise that readers received when exposed to the documents.

There are multiple applications that could benefit from refined user models that account for these personal characteristics such as user intention or domain of expertise. Information recommendation systems are a clear example, since recognizing users' intention is the first step in satisfying their information needs. Assistive technologies for reading and writing could also be developed since past records of users reading the same document would give hints on the text areas that require the highest amount of attention to maximize the understanding of the content, and writers could also use that information to optimize their documents for an efficient or pleasant reading experience. Applications for diagnosing learning difficulties in children and young people could also be developed following a similar strategy to the work it has been presented in this paper.

7 Conclusions

In the present work, we have introduced a method to represent subjects as fixed-size feature vectors that denote the distribution on how well each linguistic feature explains the eye-movements when reading a specific document. Information on gaze samples and linguistic features was integrated in a common framework by means of their encoding into synthesized images whose pixels quantify the strength of the statistical evidence. With the definition of image precision, recall and F_1 scores, we narrowed the gap between the image and natural language processing fields. Although traditional statistical models could be used with similar results, our method allows to include geometric information into our linguistic models in a natural manner.

Examples of image processing techniques that resulted useful were the image registration to perform text-gaze alignment, blurring images to carry the uncertainty of the error-correction into our subsequent models, capabilities to adjust intensity of pixel values to compensate for too common or too rare linguistic features, ease in visually analyzing our reading models and more importantly, estimating how well each linguistic feature explains eye-movements data without the need of testing for significant decreases in perplexity when those features are added into the traditional statistical models.

We analyzed the variability on the distribution over the personal feature vectors by projecting them onto a lower dimensional space for visual inspection. We observed patterns in the distribution of those feature vectors across all subjects, found that they are characteristic of every subject and that they relate to the subject's level of understanding. Finally, we tested the hypothesis that subjects with different levels of understanding can be distinguished from each other by using the information extracted from the combination of eye-movements captured by an eye-tracker and the linguistic information extracted from a document.

In order to test our hypothesis given the limited number of subjects, we used "linear separability", which is a very exigent condition to satisfy conditioned on the low dimensionality and the number of subjects that we presented. We consistently succeeded in linearly discriminating subjects with low level of understanding from the rest of the subjects at the 10-second and skimming reading tasks. However, subjects with low task performance were not consistently linearly separable for the task of precise reading, suggesting that other methods might be necessary to discriminate them. Linear separability of subjects with high level of understanding showed a positive but not decisive trend and we will say, for now, that subjects with lower level of understanding are easier to recognize by their eye-movements on the documents they read, when compared to subjects with high task performance. The ability to distinguish readers according to their level of understanding can further be accomplished in a less exigent scenario by relaxing the condition of separability into a higher dimensionality or non-linearity with a larger number of subjects.

Until now, recognizing the level of understanding of a subject when reading a document was only possible by requiring explicit feedback from subjects. The findings in this work demonstrate that the cognitive activity associated to a low or high level of understanding influences subject's eye-movements and that those eye-movements can be characterized in some readings tasks with the help of the linguistic characteristics of the text being read. Although the experiments presented in this paper are still limited, we have evidenced strong patterns in eye-movements that will allow us to unveil a larger portion of a person's state of mind.

ABSTRACT
We construct a new multilingual lexical resource from Wiktionary by disambiguating semantic relations and translations. For this task, we propose and evaluate an automatic disambiguation method that outperforms previous approaches significantly. We additionally introduce a method for inferring new semantic relations based on the disambiguated translations. Our resource fills the gap between expert-built resources suffering from high cost and small size and Wikipedia-based resources that are restricted to encyclopedic knowledge about nouns. We demonstrate this by applying our new resource to measuring monolingual and cross-lingual verb similarity. For the latter, our resource yields better results than Wikipedia and expert-built multilingual wordnets. We make our final resource and the evaluation datasets publicly available.

TITLE AND ABSTRACT IN GERMAN

Ein mehrsprachiges, lesartendisambiguiertes Wiktionary zur Bestimmung von Verbähnlichkeiten

Der vorliegende Beitrag beschreibt die Gewinnung einer neuen, mehrsprachigen lexikalischen Ressource aus Wiktionary-Daten, die durch Disambiguierung von semantischen Relationen und Übersetzungen entsteht. Zu diesem Zweck definieren und evaluieren wir eine automatische Methode zur Lesartendisambiguierung, die frühere Ansätze signifikant übertrifft. Wir stellen ferner eine Methode vor, um neue semantische Relationen auf Basis der disambiguierten Übersetzungen zu inferieren. Unsere Ressource schließt die Lücke zwischen von Experten erstellten Wissensquellen, die unter ihrer oft geringen Größe aber hohen Erstellungskosten leiden, und Wikipedia-basierten Ressourcen, die nahezu ausschließlich enzyklopädisches Wissen zu Substantiven enthalten. Beim Einsatz unserer neuen Ressource zur Bestimmung von einsprachigen und zweisprachigen Verbähnlichkeiten erreichen wir im letzteren Fall bessere Ergebnisse als für Wikipedia und die Expertenressourcen. Wir veröffentlichen unsere Ressource und die Evaluierungsdatensätze für zukünftige Forschungsarbeiten.

1 Introduction

Motivation. The advancing globalization and the permeation of the internet in our daily lives raises a strong demand for multilingual applications, such as machine translation, cross-lingual question answering, or information retrieval. Traditional multilingual approaches are knowledge-based using bilingual dictionaries (Neff and McCord, 1990) or multilingual wordnets (Tufiş et al., 2004). To date, these approaches are getting more and more replaced by statistical translation models, although it has been found that multilingual resources have the ability to substantially contribute to the performance of a system (Oepen et al., 2007; Herbert et al., 2011). One reason for the knowledge-based approaches being rarely employed is the challenging construction process of multilingual resources. They are either manually compiled by professional translators or lexicographers or automatically generated from large amounts of unstructured data. The former usually results in small resources due to the time and cost intensive work, whereas the latter often reaches only a limited quality. Although Wikipedia has been found as a promising alternative for obtaining multilingual knowledge (Medelyan et al., 2009), it is almost entirely restricted to nouns and focuses on encyclopedic rather than lexical-semantic knowledge.

Contribution. In this paper, we will explore the collaborative online lexicon Wiktionary[1] and how it can be used as a multilingual resource. Similar to Wikipedia, the contents in Wiktionary are edited by a large community of Web users. This collaborative construction approach, known as the "Wisdom of Crowds", yields very large resources. At the same time, this assures a considerable quality, as the numerous authors can quickly revise erroneous or unclear entries. Wiktionary offers a broad range of lexical-semantic knowledge including sense definitions, semantic relations, and translations. It fills the gap between the small, expert-built wordnets and the large Wikipedia-based resources restricted to nouns.

The contribution of our paper is threefold: (i) We propose and evaluate a method for disambiguating semantic relations and translations in Wiktionary; (ii) we infer new semantic relations based on the disambiguation result and create a novel sense-disambiguated Wiktionary that we make freely available; (iii) we demonstrate the usefulness of our new sense-disambiguated resource by employing it for calculating cross-lingual verb similarity. Measuring verb similarity is often a crucial technique for information extraction or (cross-lingual) question answering systems. In this paper, we experiment with English and German even though our methods can generally be adapted to over 170 languages covered by Wiktionary.

Overview. The English Wiktionary consists of about 475,000, the German Wiktionary of about 73,000 *word senses*.[2] For each of these word senses, multiple *semantic relations* (i.e., synonymy, antonymy, hyponymy, etc.) and *translations* may be encoded. We will use *relation* henceforth to refer to both semantic relations and translations and use the terms *source* and *target* to denote the endpoints of a relation. The Wiktionary entry for *(to) hang* distinguishes, for instance, fifteen word senses. The eighth word sense is defined as *"to exhibit (an object)"* with synonymy relations targeting at *exhibit* and *show* and translations into German *ausstellen*, French *exposer*, Dutch *ophangen*, and other languages.

The target of a relation is encoded using word forms. Thus, it remains underspecified which word sense a relation is pointing to. The synonym *exhibit* of the eighth word sense of *hang* can, for example, refer to the meaning of displaying something (e.g., exhibiting a drawing) or

[1] `http://www.wiktionary.org`

[2] All statistics are based on Wiktionary data of April 2011 accessed using JWKTL (Zesch et al., 2008a).

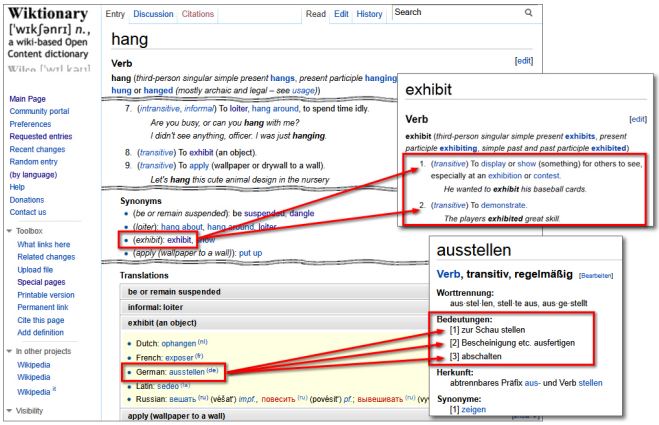

Figure 1: The synonym *(to) exhibit* of the English Wiktionary entry *(to) hang* and its German translation *ausstellen* have multiple possible target word senses.

demonstrating a skill (e.g., exhibiting a talent in acting). For humans, it is easy to recognize that *hang* is synonymous to the first word sense of *exhibit*, but not to the second. Natural language processing applications, however, cannot disambiguate such relations easily. The same applies to translations: The German *ausstellen* has, for instance, a meaning of (1) exhibiting an object, (2) certificating a document and (3) turning off smth. Figure 1 illustrates this kind of underspecification. In Section 3, we propose a solution to this issue by automatically disambiguating the semantic relations and translations in Wiktionary. Sense-disambiguated relations are a necessary precondition for many applications, such as computing semantic relatedness by measuring path lengths (Budanitsky and Hirst, 2006): if undisambiguated relations were used, then *exhibit* and *loiter* would be highly related as they both have a relation to *hang*.

Besides the information inherently found in Wiktionary, we infer new semantic relations based on our disambiguated translations. This is particularly useful for the English Wiktionary, which encodes only about 26,000 semantic relations (compared to 290,000 in the German edition). With our inference method, we are able to increase the number of semantic relations for the English language by almost ten times. Section 4 describes our inference method and provides statistics of our new resource. In Section 5, we apply this new resource to calculating monolingual and cross-lingual verb similarity as one example use case in the scope of our work. Thereby, we show that our resource is comparable to expert-built resources in the monolingual experiments and that it outperforms them in the cross-lingual setting by a large margin.

2 Related Work

The most closely related areas of work are the construction of multilingual resources, the disambiguation of relations and the inference of new semantic relations.

Multilingual resource construction. The most prominent multilingual resources are EuroWordNet (Vossen, 1998), BalkaNet (Stamou et al., 2002), and MultiWordNet (Pianta et al.,

2002). All of them are professionally crafted and provide a well-structured network of word senses and relations. Despite their high quality, the sizes vary largely. For English and German, there are, for instance, only 16,347 shared word senses in EuroWordNet (the only one encoding this language pair).[3] Another drawback of these wordnets is their high development cost which hinders the large-scale manual extension of their contents. Wikipedia-based multilingual resources is another strand of research. Well-known works are Yago (Suchanek et al., 2007), DBpedia (Bizer et al., 2009), and WikiNet (Nastase et al., 2010), which mostly differ in their structure and the way they extract the data. The bulk of knowledge in Wikipedia is, however, of encyclopedic nature, whereas our work aims at lexical-semantic knowledge.

The two most closely related research efforts to ours are Universal WordNet (de Melo and Weikum, 2009) and BabelNet (Navigli and Ponzetto, 2010). The former uses WordNet for bootstrapping a multilingual resource based on combined evidence found in existing wordnets, parallel corpora, and machine-readable dictionaries. It incorporates (undisambiguated) Wiktionary translations, but solely relies on semantic relations taken from WordNet. BabelNet aligns WordNet and Wikipedia at the level of word senses. Although this yields a large resource, the additional information from Wikipedia is almost entirely about nouns – there are hence no translations for verbs, adjectives, or the like. Our work provides a viable option towards closing this gap, as it makes use of lexical-semantic knowledge covering any part of speech.

Relation disambiguation. The task of disambiguating semantic relations (also called *sense linking* and *relation anchoring*) has been previously described in the context of machine-readable dictionaries (Krovetz, 1992) and ontology learning (Pantel and Pennacchiotti, 2008). Meyer and Gurevych (2010) discussed relation disambiguation for the German Wiktionary using a disambiguation method based on textual similarity. In Section 3.3, we will compare this approach to our system.

The disambiguation of all words in a sense definition (i.e. *gloss disambiguation*), as it has been done in the WordNet 2/eXtendend WordNet project (Harabagiu et al., 1999; Mihalcea and Moldovan, 2001), is very similar to the disambiguation of semantic relations. Therefore, many of the features defined in Section 3.1 are similar to those proposed by Moldovan and Novischi (2004). Note however that we use explicitly defined semantic relations rather than sense definitions as our disambiguation subjects. In addition to that, we adapt our method to Wiktionary instead of using WordNet-specific features and also extend this work to a cross-lingual setting. Very recently, Flati and Navigli (2012) proposed a graph-based method to gloss disambiguation outperforming previous approaches. While this method could in general be adapted to disambiguating relations, we observe that the graph induced by Wiktionary's semantic relations is very sparse. This would hinder finding the cycles and quasi-cycles required by the method.

The disambiguation of translations has been studied in the context of bilingual dictionaries and corpora (Kikui, 1999; Tsunakawa and Kaji, 2010). Mausam et al. (2009) discovered new translations in Wiktionary using a graph-based inference algorithm for Wiktionary translations. Although this also involves a disambiguation of translations, their work is not directly comparable to ours, since they do not strictly use the word senses encoded in Wiktionary but define them based on the translations shared across multiple languages. In contrast to that, we aim at exploiting a wide range of lexical-semantic knowledge and therefore need to rely on the word senses actually encoded in Wiktionary.

[3] `http://www.illc.uva.nl/EuroWordNet/finalresults-ewn.html` (accessed 2012-07-11)

Inference of relations. New semantic relations have been previously inferred when bootstrapping wordnets, i.e. translating the word senses and their definitions to a new language and reusing the relations from an existing wordnet. This has been done, for example, for constructing the Spanish (Atserias and Villarejo, 2004), French (Sagot and Fišer, 2008), and Thai (Thoongsup et al., 2009) wordnets. Such approaches differ from our work in that they do not require a disambiguation of relations. Huang et al. (2002) studied the cross-lingual inference of semantic relations when using imprecise translations. They measure an error rate of 11% for the inference of Chinese semantic relations based on the English WordNet.

3 Disambiguation of Wiktionary's Semantic Relations and Translations

In this section, we describe and evaluate our method for automatically disambiguating semantic relations and translations in Wiktionary.

3.1 Feature Definition

Let $t_j \in t$ be one of multiple possible target word senses for a relation (either a semantic relation or a translation) $r = (s_i, t)$. We define the following features based on our analysis of 200 Wiktionary relations (referred to as *development data*).

Definition overlap. A widely used method for word sense disambiguation is based on counting word overlaps between sense definitions (Lesk, 1986). Let $\text{gloss}(s_i)$ and $\text{gloss}(t_j)$ be the lemmatized and stop-word-filtered sense definitions of s_i and t_j. Their overlap is the number of shared words:

$$f_{\text{Lesk}} := |\text{gloss}(s_i) \cap \text{gloss}(t_j)|.$$

We additionally define f_{ExtLesk} by employing the extension by Banerjee and Pedersen (2003), i.e. we assign squared scores to consecutive sequences of words. If both definitions contain, for example, *"large carnivorous animal"*, we assign a score of $3^2 = 9$.

Source lemma. A special case of overlapping definitions is that the lemma of the source word sense is contained in the definition of the target word sense:

$$f_{\text{src}} := \text{lemma}(s_i) \in \text{gloss}(t_j).$$

This happens frequently, since a definition usually contains synonymous words or follows the *genus-differentia* pattern – i.e., providing a more specialized term (the *genus*) and the properties that distinguish the word from its co-hyponyms (the *differentia*). Consider, for instance, two word senses for *peck*: (i) "[…] *a dry measure of eight quarts"* and (ii) *"a great deal; a large or excessive quantity"*. The second one happens to be the correct disambiguation for the synonymy relation between *deal* and *peck* as it contains the source lemma *deal*.

Linguistic labels. Many word senses are domain-specific, such as the use of *host* as a certain kind of server in computer science. In dictionaries, domain-specific word senses are often marked by linguistic labels stating the domain, register, time, etc. this word sense is normally used in. An example is the sense *"(UK, pejorative) A working-class youth* […]*"* of *chav*. Relations usually connect two word senses of the same domain, register, etc. Hence, we add a feature

$$f_{\text{lbl}} := |\text{label}(s_i) \cap \text{label}(t_j)|$$

counting the number of labels shared by s_i and t_j. Since Wiktionary's linguistic labels are very heterogeneous and fine-grained, we manually grouped similar labels into broader categories; *zoology* and *ornithology* are, for instance, grouped into *biology*.

Inverse relation. Consider a relation between two polysemous words, such as the antonymy relation between $fall_i$ and *increase*. If there is a word sense j of *increase* for which an inverse antonymy relation ($increase_j$, *fall*) is encoded, then it is very likely that j is the correct disambiguation. Let relations(t_j) be the set of related lexical items of t_j. We define

$$f_{\text{inv}} := \text{lemma}(s_i) \in \text{relations}(t_j)$$

as the feature checking for inverse relations.

Relation overlap. The idea of inverse relations can be further extended by finding relations to other words shared by both the source and the target sense. A relation (*sweater*, *cloth*) can, for instance, be disambiguated by finding that one of their word senses shares a relation to *pullover* (a synonym of *sweater* and a hyponym of *cloth*). We define

$$f_{\text{rel}} := \frac{|\text{relations}(s_i) \cap \text{relations}(t_j)|}{|\text{relations}(s_i) \cup \text{relations}(t_j)|},$$

which is similar to the link-based similarity measure proposed by Milne and Witten (2008), who use hyperlinks from Wikipedia.

Commonness and Monosemy. The word senses of a lexicon are often ordered according to their usage frequencies in a corpus or the intuitions of the lexicographers. This has led to a very strong baseline for word sense disambiguation by always choosing the first sense. The same applies to the disambiguation of relations when choosing the first target sense. Therefore, we introduce a feature $f_{\text{idx}} := j$ that is set to the index of the target sense t_j.

Finally, we add a feature f_{mono} that is true if the target word has only one word sense, i.e. if it is monosemous. In these cases, it is most likely that this sense is the correct disambiguation; e.g., for the synonymy relation between *eggplant* and the monosemous word *brinjal*.

Cross-lingual features. Most of the features described above are also applicable in a multilingual setting when using translations instead of semantic relations. In order to also use the features based on sense definitions, we automatically translate them using the Bing translation[4] service. This opens up interesting research opportunities, since the definition of either the source or the target sense can be translated, i.e.

$$f_{\text{Lesk,TL}} := |\text{gloss}(\text{translate}(s_i)) \cap \text{gloss}(t_j)| \text{ or } f_{\text{Lesk,SL}} := |\text{gloss}(s_i) \cap \text{gloss}(\text{translate}(t_j))|.$$

There can even be a combined feature:

$$f_{\text{Lesk,SL\&TL}} := \tfrac{1}{2}(f_{\text{Lesk,SL}} + f_{\text{Lesk,TL}}).$$

Regarding the linguistic label feature f_{lbl}, we manually mapped English and German labels that represent the same meaning (e.g., *biology* and *Biologie*). This yielded a list of 19 label groups covering 1,267 distinct linguistic labels from two languages.

Constraints. In addition to the features introduced above, we can apply a threshold to convert a numeric feature into a boolean one. The notation $f_{\text{Lesk}\geq k}$ defines, for instance, a feature that is true if the sense definitions share at least k words. We use the notation $\hat{f}$ when only the target word sense with the highest feature value is used. The feature $\hat{f}_{\text{Lesk}\geq k}$ is thus true if, and only if, f_{Lesk} is higher than k and the maximum f_{Lesk} of all possible target word senses t.

[4] `http://www.microsofttranslator.com/`

3.2 Disambiguation Method

Let F be a set of features. Based on the notation introduced above, we define a generic relation disambiguating method

$$D\colon\ (r, t_j, F) \mapsto \{0, 1\},$$

returning 1 if t_j is a correct disambiguation for r and 0 otherwise. A basic method $D[f] = f$ uses only a single boolean feature $f \in F$. Thereby, we can model a most frequent sense baseline $MFS = D[f_{\text{idx}=1}]$ always using the first target word sense. One way of combining features is to concatenate them using a backoff strategy, i.e. a method

$$D[f_1 \circ f_2] = \begin{cases} D[f_1] & \text{if } f_1 \in F \\ D[f_2] & \text{otherwise} \end{cases}$$

relying on feature f_1 (if present) and f_2 otherwise. For example, $D[f_{\text{inv}} \circ f_{\text{idx}=1}]$ disambiguates those relations that have an inverse relation using f_{inv}. The remaining relations are disambiguated using a most frequent sense approach.

Based on the features introduced above, we now propose our disambiguation method

$$WKTWSD = D[f_{\text{mono}} \circ f_{\text{lbl}\geq 1} \circ f_{\text{rel}\geq 0.5} \circ f_{\text{src}} \circ f_{\text{inv}} \circ \hat{f}_{\text{ExtLesk}\geq 2} \circ f_{\text{idx}=1}]$$

that concatenates all features introduced above. For the cross-lingual datasets, we use $\hat{f}_{\text{ExtLesk}\geq 2,\text{SL\&TL}}$ instead of $\hat{f}_{\text{ExtLesk}\geq 2}$. The ordering and the thresholds have been chosen based on our analysis of the development data.

3.3 Empirical Evaluation

Comparison to previous work. Our experimental setup is directly comparable to the disambiguation of semantic relations in the German Wiktionary reported by Meyer and Gurevych (2010). They use a publicly available dataset, which consists of 250 manually disambiguated Wiktionary relations. Table 1 shows the performance of our proposed method in comparison with their text-similarity-based method *MG10*. Note that Meyer and Gurevych (2010) evaluated their system by measuring the agreement between the method and each of the two human raters. We therefore report A_O and Cohen's κ (Artstein and Poesio, 2008) following the original experimental setup. The inter-rater agreement serves as an upper bound and the most frequent sense baseline *MFS* is used as a lower bound. Our *WKTWSD* method outperforms their approach by a large margin. The improvement is statistically significant.[5]

Gold standard datasets. To our knowledge, there are no other evaluation datasets for disambiguating Wiktionary relations. That is why we create four new annotated datasets that consist of English semantic relations ($R_{\text{en:en}}$), German semantic relations ($R_{\text{de:de}}$), English–German translations ($R_{\text{en:de}}$), and German–English translations ($R_{\text{de:en}}$). The relations are sampled according to their type, the part of speech, and the number of candidates (i.e., possible target word senses) in order to create a balanced dataset.[6] Balancing out the datasets is very useful for being able to evaluate our approach separately for each sample group and to avoid datasets with a strong bias (e.g., on synonyms between nouns). None of the sampled relations occurs in our development data. Table 2 shows the numbers of sampled relations and the possible target senses (i.e., the number of annotations required).

[5] McNemar's test; $p < .05$

[6] Our sampling procedure is explained in detail in the supplementary material that is published with the datasets.

Method	$A_{O,1}$	$A_{O,2}$	κ_1	κ_2
MFS	.78	.79	.45	.50
MG10	.79	.82	.48	.57
WKTWSD	**.84**	**.85**	**.59**	**.65**
Human	.89	.89	.73	.73

Table 1: Comparison of our system to previous work

	$R_{\text{en:en}}$	$R_{\text{de:de}}$	$R_{\text{en:de}}$	$R_{\text{de:en}}$
Relations	394	459	204	204
Annotations	1,117	1,119	614	656
A_O	.91	.92	.89	.90
κ	.82	.85	.73	.75
F_1	.89	.92	.80	.83

Table 2: Statistics on our evaluation datasets

We then asked two human raters to annotate the monolingual datasets $R_{\text{en:en}}$ and $R_{\text{de:de}}$ and three raters to annotate the cross-lingual datasets $R_{\text{en:de}}$ and $R_{\text{de:en}}$. The raters should annotate each possible target word sense as being a correct ($D = 1$) or incorrect ($D = 0$) disambiguation for the given relation, for example:

s_i = *phenomenal*	D	t_j = *awesome*
(colloquial) Very remarkable; highly extraordinary; amazing.	0	Causing awe or terror; inspiring wonder or excitement.
(colloquial) Very remarkable; highly extraordinary; amazing.	1	(informal) Excellent, exciting, remarkable.

It was allowed to rate all target senses of a relation as incorrect (e.g., if the correct target sense has not yet been encoded in Wiktionary) or to rate more than one target sense as correct (e.g., if the target senses are more fine-grained than the source sense). Each rater was allowed to consult external sources such as lexicons, encyclopedias, etc. (and in particular Wiktionary itself). They were, however, not allowed to contact each other. The raters are native in German and speak English fluently. They have been trained using some example cases and an annotation guidebook that we publish along with the paper.

To estimate the reliability of our datasets, we measure the inter-rater agreement. Table 2 shows the observed agreement A_O and the kappa statistics κ for each dataset. We report Cohen's κ for the two rater case and Fleiss' κ (multi-π) for the three rater case (Artstein and Poesio, 2008). The raters agree on about 90% of the cases. The κ statistics of over .80 for the monolingual datasets suggests good reliability. The cross-lingual datasets have a slightly lower agreement. The disambiguation of translations hence seems to be more difficult for our raters. However, the κ scores are well above .67 and therefore allow us to draw tentative conclusions (Artstein and Poesio, 2008). We also provide F_1 scores for our datasets as suggested by Hripcsak and Rothschild (2005), which serve as upper bounds for our methods.

Finally, we create gold standard datasets based on the majority vote of the raters. As a tie breaker for the monolingual datasets, an additional adjudicator has been asked for a final decision. All datasets including analyses are freely available from our homepage.

Evaluation results. Table 3 shows the performance of our disambiguation method on the four gold standard datasets. We have counted the number of correct decisions $TP + TN$, the number of false positives *FP* and false negatives *FN*, which we use to report accuracy $A = \frac{TP+TN}{N}$, precision $P = \frac{TP}{TP+FP}$ (proportion of correctly disambiguated relations in the system result), recall $R = \frac{TP}{TP+FN}$ (proportion of correctly disambiguated relations in the gold standard), and the $F_1 = \frac{2PR}{P+R}$ score (Manning and Schütze, 1999). As a lower bound, we use the most frequent sense method *MFS*. The upper bound is human performance (*Human*) estimated by the inter-rater agreement A_O and the inter-rater F_1 score introduced above. Our *WKTWSD* method significantly outperforms the *MFS* baseline for each dataset. The only exception being the precision on the $R_{\text{de:en}}$ dataset, which is slightly lower than the precision of *MFS*.

Besides the lower and upper boundaries, we trained a number of machine learning classifiers for our set of features using the Weka toolkit (Hall et al., 2009). We report the results for a Naïve Bayes (*NB*) and a *J48* decision tree (a C4.5 clone) here, although we tried other classifiers as well, which generally yielded similar results. The training was done in a 5-fold cross validation. Note that we did not optimize the configuration in order to avoid overfitting to the datasets. In general, our *WKTWSD* method reaches a similar or even better performance than the machine learning classifiers. The main reason for this is the largely varying number of possible target word senses. While one relation might have only a single possible target sense, another one might have ten or even more. This tends to cause more false negatives in the machine learning methods and thus less relations that can be disambiguated. The finding is in line with previous work on gloss disambiguation: Moldovan and Novischi (2004) note that compiling a sufficient set of training examples is not possible in many cases. Despite this, the machine learning methods mostly achieve a slightly higher precision. *J48* even yields $P = .82$ for the $R_{\text{de:en}}$ dataset. However, this always comes at the cost of a lower recall.

Feature and error analysis. Table 4 shows the precision P and coverage C (proportion of items covered by this feature) of using each feature $f \in F$ individually. With the exception of $f_{\text{idx=1}}$ (most frequent sense strategy), none of the features is able to disambiguate the whole dataset, but most of them achieve a very high precision on the covered items. It is not surprising that f_{mono} performs extremely well ($P \in [.88, .96]$), since there is only one target word sense available for these cases. The feature f_{src} performs well on the monolingual datasets ($P \in [.87, .97]$), but does not work at all on the cross-lingual task ($P \in [.38, .50]$). The reasons for this are ambiguities in the sense definitions that are often not resolved by the machine translation service. Parallel ambiguities such as *commission* and *Kommission*, which both mean either a group of people or a transaction fee of a broker, is a main source of errors here. Similar errors also occur for f_{inv}. The word overlap feature $\hat{f}_{\text{ExtLesk}}$ generally shows a high precision. It is, in particular, higher than usually reported for word sense disambiguation tasks (Navigli, 2009). The reason might be that we do not compare a sense definition with context words, but two definitions with each other and hence benefit from comparing texts that are specially crafted to characterize word senses. Interestingly, the imprecise translation of certain words noted for f_{src} is less problematic for $\hat{f}_{\text{ExtLesk}\geq 2,\text{SL\&TL}}$, as there are usually at least some correctly translated words in the sense definition. In our experiments, we found that $\hat{f}_{\text{ExtLesk}\geq 2,\text{SL}}$ outperforms $\hat{f}_{\text{ExtLesk}\geq 2,\text{TL}}$, whereas $\hat{f}_{\text{ExtLesk}\geq 2,\text{SL\&TL}}$ is only marginally better than $\hat{f}_{\text{ExtLesk}\geq 2,\text{SL}}$. The English Wiktionary is very sparse in encoding semantic relations. The coverage of $f_{\text{rel}\geq 0.5}$ is therefore very low for all datasets involving English data.

Since we ordered the features manually for our *WKTWSD* method, we additionally define a method *BestOrder* which concatenates the features in descending order of their precision on

Method	$R_{\text{en:en}}$ A	P	R	F_1	$R_{\text{de:de}}$ A	P	R	F_1
MFS	.81	.75	.74	.74	.79	.78	.76	.77
WKTWSD	.84	.78	**.80**	**.79**	.84	.83	**.83**	**.83**
NB	.85	**.81**	.78	**.79**	.84	**.84**	.81	.82
J48	.83	**.81**	.71	.76	.84	.83	.82	**.83**
BestOrder	.85	.79	.80	.80	.85	.84	.83	.84
Human	.91			.89	.92			.92

Method	$R_{\text{en:de}}$ A	P	R	F_1	$R_{\text{de:en}}$ A	P	R	F_1
MFS	.79	.62	.72	.67	.79	.64	.66	.65
WKTWSD	.81	.64	**.75**	**.69**	.79	.62	**.71**	**.67**
NB	.81	.67	.69	.68	.82	.74	.61	**.67**
J48	.79	**.69**	.53	.60	.82	**.82**	.53	.64
BestOrder	.80	.63	.75	.69	.81	.67	.73	.70
Human	.89			.80	.90			.83

Table 3: Performance of our disambiguation methods on the four evaluation datasets

Feature	$R_{\text{en:en}}$ P	C	$R_{\text{de:de}}$ P	C	$R_{\text{en:de}}$ P	C	$R_{\text{de:en}}$ P	C
f_{mono}	.91	.21	.94	.22	.96	.08	.88	.08
f_{inv}	.78	.13	.89	.31	.68	.49	.67	.41
$f_{\text{lbl}\geq 1}$	.82	.07	.90	.05	.86	.02	.60	.04
f_{src}	.87	.10	.97	.07	.50	.20	.38	.18
$f_{\text{rel}\geq 0.5}$	.94	.04	.90	.14	.33	.01	.75	.01
$\hat{f}_{\text{ExtLesk}\geq 2}$	.89	.27	.99	.12	.87	.15	.93	.17
$f_{\text{idx}=1}$	.75	1.0	.78	1.0	.62	1.0	.64	1.0

Table 4: Precision and coverage of each feature

each dataset. The rationale behind this is that we make use of the best feature before moving to the next one. By comparing *WKTWSD* to *BestOrder*, we can measure the influence of our manually chosen ordering. Note, however, that *BestOrder* needs to be considered as an upper bound for *WKTWSD* rather than a separate method, because it made use of our analysis of the test data. The results can be found in Table 3. We observe that the order of the features plays only a minor role: *WKTWSD* and *BestOrder* are only slightly different although they concatenate the features in totally different ways. The largest difference accounts to .03 for the $R_{\text{de:en}}$ dataset and is mostly due to the low performance of f_{src}.

Summary. We conclude that our approach is better suited for disambiguating Wiktionary relations than previous works using textual similarity. The features are effectively applied using a concatenation method. The training of machine learning classifiers could not improve these results in our experiments.

	Our resource		Wordnets

4 A Multilingual, Sense-Disambiguated Wiktionary

Resource construction. We create our new multilingual resource by using all word senses encoded in a given set of Wiktionary language editions (English and German in our experiments). Then, we perform the automatic disambiguation of the semantic relations and translations to obtain a fully disambiguated resource. We use the *WKTWSD* method for this task, as it performed well on our evaluation datasets. The disambiguated translations allow for extracting lexical-semantic knowledge in multiple languages. The first sense of *(to) stroll* is, for instance, *"to wander on foot* […]*"* in the English Wiktionary. When following its translations, we are able to extract the German equivalent *spazieren*: *"gemächlich gehen* […]*"*. In this way, we can also obtain multilingual example sentences, linguistic labels, etc.

Inference of relations. For semantic relations, we can even further benefit from their disambiguated target senses: Let (s, t) be a disambiguated semantic relation in one of the Wiktionary language editions and let $(s, \psi(s))$ and $(t, \psi(t))$ be disambiguated translations of s and t into another language. Assuming a correct disambiguation of these three relations, we can infer a fourth relation $(\psi(s), \psi(t))$, since the meaning of s and t is preserved under the disambiguated translations. Figure 2 shows an example: For the German hypernym (*Katze*, *Haustier*) and the corresponding translations (*Katze, cat*) and (*Haustier, pet*), we can infer the English hypernymy relation (*cat, pet*) that is currently not encoded in the English Wiktionary. Note that the inferred relation is also sense-disambiguated, i.e. both *cat* and *pet* refer to the animal sense.

Size of our resource. Our final resource contains 215,353 English and 300,724 German semantic relations. The English Wiktionary benefits most from inferring new semantic relations: We increased the number of relations found in the original Wiktionary (26,965) by almost an order of magnitude. But also for the German language, we were able to infer 10,705 new semantic relations. In addition to that, our resource consists of 474,128 English and

73,500 German word senses as well as 79,382 translations (45,246 English–German and 34,136 German–English). Table 5 shows detailed statistics of our resource including the most common types of the encoded semantic relations. We compare our resource with the Princeton WordNet (Fellbaum, 1998) and GermaNet (Kunze and Lemnitzer, 2002) and their inter-lingual index (which is a part of EuroWordNet). Our resource surpasses the number of translations by a large margin, but contains less semantic relations than in the expert-built wordnets. The coverage of lexical entries and word senses is comparable or higher.

5 Measuring Verb Similarity

To demonstrate the usefulness of our resource, we carry out two experiments employing the newly created resource in a monolingual and cross-lingual verb similarity task. Judging verb similarity is of particular interest for applications such as cross-lingual word sense disambiguation (Lefever and Hoste, 2010), lexical substitution (Mihalcea et al., 2010), or question answering (Magnini et al., 2005). State of the art knowledge-based systems rely heavily on Wikipedia, which predominantly encodes encyclopedic knowledge about nouns. The large amount of multilingual lexical-semantic knowledge in Wiktionary let us expect good results not only for nouns, but also for other parts of speech and verbs in particular.

Monolingual verb similarity. Yang and Powers (2006) introduced an evaluation dataset for verb similarity that consists of 130 English verb pairs taken from TOEFL and ESL (English as a second language) questions. For each of them, a numerical score is provided expressing the human intuitions of their similarity. These scores are averaged over six human annotators that were asked to rate the similarity of each pair on a graded scale from 0 (*not at all related*) to 4 (*inseparably related*). Yang and Powers (2006) report a correlation of $r = 0.866$ between the raters. An example from their dataset is the verb pair (*approve, support*) with a score of 3.

To the best of our knowledge, Zesch et al. (2008b) reports the latest evaluation results on this dataset as shown in column *Z08* of Table 6. They use explicit semantic analysis, a method based on concept vectors (Gabrilovich and Markovitch, 2007) built from WordNet, Wikipedia, and the undisambiguated Wiktionary. Each entry from these resources (synsets in WordNet and wiki pages in Wikipedia and Wiktionary) is regarded as one concept. For a given word pair, two concept vectors are then created that consist of the word's tf-idf scores over the concepts. The similarity for this word pair is then expressed by the cosine of the two concept vectors. Although Zesch et al. (2008b) find Wiktionary to yield best results for computing semantic relatedness between nouns, the performance for verb similarity is substantially lower than using WordNet. One reason for that is the high degree of polysemy of verbs, which is not dealt with by their approach. Since our resource is completely sense-disambiguated, we can, in contrast, compute sense-disambiguated concept vectors using each word sense as one concept.

We reproduced the results of Zesch et al. (2008b), also using WordNet, Wikipedia, and the undisambiguated Wiktionary, and show them in the column $V_{\text{en:en}}$ of Table 6. Note that we use all 130 verb pairs, whereas Zesch et al. (2008b) used only the 80 pairs that were covered by all three similarity metrics they tried. Therefore, our scores slightly differ from *Z08*. In addition to the three resources, we report the performance when using the sense-disambiguated concept vectors derived from our resource. Using our resource yields better results than using Wikipedia or the undisambiguated Wiktionary. The previously best resource WordNet is slightly outperformed by our resource. This difference is, however, not statistically significant. All four concept-vector-based methods cover 100% of the dataset and are thus directly comparable.

Resource	*Z08*	$V_{\text{en:en}}$	$V_{\text{de:de}}$	$V_{\text{en:de}}$	$V_{\text{de:en}}$
WN/GN	**.71**	.69	**.57**	.31	.23
Wikipedia	.29	.27	.33	.23	.28
Wiktionary	.65	.63	.36	—	—
Our resource	—	**.73**	.52	**.53**	**.51**
Coverage	62%	100%	92%	95%	97%

Table 6: Evaluation results on the four verb similarity datasets using concept vectors from WordNet/GermaNet (WN/GN), Wikipedia, Wiktionary, and our new resource in comparison to previous work by Zesch et al. (2008b) (*Z08*). Performance is measured by Spearman's rank correlation coefficient using Horn's correction for tied ranks (Horn, 1942). All correlations significantly differ from random (two-tailed paired t-test; $p < .05$).

We also study German verb similarity and therefore translate the $V_{\text{en:en}}$ dataset. The verb pair (*approve, support*) is, for instance, translated to (*annehmen, unterstützen*) keeping its similarity score of 3. Table 6 shows the results for this new $V_{\text{de:de}}$ dataset. To create the concept vectors, we use GermaNet instead of WordNet as well as the German editions of Wikipedia and Wiktionary. We use only the 120 verb pairs covered by all four resources. Our resource is again able to outperform Wikipedia and the undisambiguated Wiktionary by a wide margin. The performance competes with the expert-built GermaNet, but is slightly lower than that. As opposed to the English language, GermaNet and the German part of our resource are similar in size (see Table 5), which can explain these results. This is why we expect better results with the growth of the German Wiktionary. Furthermore, we conclude that our resource can be a promising alternative for languages with less developed expert-built resources.

Cross-lingual verb similarity. Based on the English and the German verb pairs, we create two cross-lingual verb similarity datasets that use the first English verb together with the second German verb from each corresponding verb pair $V_{\text{en:de}}$ and, vice versa, the first German verb together with the second English verb $V_{\text{de:en}}$. For the example introduced above, this yields the two verb pairs (*approve, unterstützen*) and (*annehmen, support*), both with a score of 3.

Table 6 shows the evaluation results using these two datasets. To create the cross-lingual concept vectors, we use the inter-lingual index between WordNet and GermaNet, the interwiki links from Wikipedia, and the disambiguated translations from our new resource. Since the translations of the original Wiktionary are not sense-disambiguated, they cannot be used to build cross-lingual concept vectors.[7] As noted in Section 2, the inter-lingual index of WordNet and GermaNet (which is part of EuroWordNet) is very small. Consequently, we observe that the expert-built wordnets yield a substantially lower performance for $V_{\text{en:de}}$ and $V_{\text{de:en}}$ than in the monolingual setting. Wikipedia likewise yields low scores because of its lack of the knowledge about verbs, whereas our resource significantly outperforms ($p < .01$) both the expert-built wordnets and Wikipedia.

Our error analysis shows that many of the judgments derived from our resource are useful. The predominant problem is still the coverage of the translations. The similarity of the English–German verb pair *(concoct, ausarbeiten)* is, for instance, not yet backed up by a translation in Wiktionary and is hence underestimated by the system. While this is essentially the same problem as for the wordnets, the problem is much less severe for our resource.

[7] Wiktionary also encodes interwiki links for each wiki page, but they link to the same form (e.g. from *walk* in the English Wiktionary to *walk* in the German Wiktionary) rather than to translations and thus cannot be used.

Summary. Wikipedia-based resources are not very appropriate for computing verb similarity as they focus on encyclopedic knowledge about nouns. Expert-built wordnets work well for computing monolingual verb similarity, because they have a sufficient coverage and encode thoroughly elaborated lexical-semantic knowledge. Our new disambiguated Wiktionary-based resource competes with their quality. Since Wiktionary is available in over 170 languages, our approach is, however, also applicable to the languages lacking large expert-built resources. In a cross-lingual setting, this shows a different picture: Expert-built multilingual wordnets suffer from their small size. Since the disambiguated translations in our resource let us build cross-lingual concept vectors, they can be effectively utilized in this task.

Conclusion and perspectives

We have created a new multilingual, sense-disambiguated resource using the word senses from Wiktionary and interconnecting them by means of disambiguated semantic relations and translations. For the automatic disambiguation of the relations, we proposed and evaluated a rule-based method using seven different features. Our features are similar to those used by Moldovan and Novischi (2004), whereas we adjusted them to our specific task and generalized them to the cross-lingual setting. We found our method to significantly outperform a previous approach based on textual similarity (Meyer and Gurevych, 2010). In a second evaluation based on four newly created datasets, we obtained promising results exceeding the baseline in every case. Using the disambiguated relations, we inferred a large number of new semantic relations and thereby yielded almost a tenfold increase in the number of relations for the English language. Our final resource fills the gap between small expert-built multilingual wordnets and Wikipedia-based resources, which are mostly restricted to the encyclopedic knowledge about nouns. The new resource and all evaluation data is publicly available for research.[8]

We also employed our new resource in a monolingual and cross-lingual verb similarity task. Besides the standard dataset by Yang and Powers (2006), we created a novel German and two cross-lingual verb similarity datasets. Our resource competes with expert-built wordnets in the monolingual setting. Since Wiktionary is available in many languages, this allows for computing verb similarity also for languages lacking large expert-built resources. In the cross-lingual setting, our sense-disambiguated resource outperforms both Wikipedia and the expert-built wordnets. The former suffers from the small amount of knowledge about verbs and the latter lack coverage of the inter-lingual index.

In future work, we plan to combine our resource with BabelNet or UBY (Gurevych et al., 2012) in order to benefit from the heterogeneous knowledge found in WordNet, Wikipedia, and our resource. Extending our resource to other languages and exploring alternative disambiguation algorithms such as CQC are further promising options. We will also consider providing our inferred semantic relations to the Wiktionary community to contribute to the harmonization of Wiktionary data. Besides verb similarity, our sense-disambiguated resource has the potential to improve other natural language processing tasks as well, for instance, question answering.

Acknowledgments

This work has been supported by the Volkswagen Foundation as part of the Lichtenberg-Professorship Program under grant No. I/82806. We thank Christian Kirschner, Dr. Judith Eckle-Kohler, and Dr. Torsten Zesch for their contributions to this project as well as Dongqiang Yang and David M. W. Powers for sharing their verb similarity dataset.

ABSTRACT
We explore the contribution of distributional information for purely knowledge-based word sense disambiguation. Specifically, we use a distributional thesaurus, computed from a large parsed corpus, for lexical expansion of context and sense information. This bridges the lexical gap that is seen as the major obstacle for word overlap–based approaches. We apply this mechanism to two traditional knowledge-based methods and show that distributional information significantly improves disambiguation results across several data sets. This improvement exceeds the state of the art for disambiguation without sense frequency information—a situation which is especially encountered with new domains or languages for which no sense-annotated corpus is available.

TITLE AND ABSTRACT IN GERMAN

Über die Bestimmung lexikalischer Expansionen mittels distributioneller Ähnlichkeit und deren Einsatz in der wissensbasierten Lesartendisambiguierung

Wir untersuchen den Einfluss distributioneller Informationen auf die rein wissensbasierte Lesartendisambiguierung. Basierend auf einem distributionellen Thesaurus, den wir aus einem großen geparsten Korpus erzeugen, erweitern wir die Definition der Lesart und deren Kontext mit lexikalischen Expansionen. Dadurch schließen wir die 'lexikalische Lücke', die sich als Haupthindernis für Ansätze basierend auf Wortgemeinsamkeiten herausgestellt hat. Wir erweitern zwei klassische wissensbasierte Ansätze um lexikalische Expansionen und zeigen, dass dadurch die Qualität der Lesartendisambiguierung deutlich erhöht wird. Wir erzielen die bisher besten veröffentlichten Ergebnisse für Disambiguierung ohne Nutzung der Lesartenhäufigkeiten, was besonders für Domänen oder Sprachen relevant ist, für die keine Lesarten-annotierten Korpora zur Verfügung stehen.

KEYWORDS: word sense disambiguation, distributional thesaurus, lexical expansion.

1 Introduction

Word sense disambiguation (WSD)—the task of determining which sense a word carries in a particular context—is a longstanding core research problem in computational linguistics. Approaches to WSD can be classified according to what lexical resources are used: *knowledge-based* techniques rely only on machine-readable dictionaries (MRDs), lexical semantic resources (LSRs), and untagged corpora, whereas *supervised* approaches instead or additionally use manually annotated training examples. Though supervised systems generally perform better, their use is restricted to scenarios where a sufficient amount of hand-crafted training data is available. Estimates for the amount of time required to produce such training data are pessimistic (Mihalcea and Chklovski, 2003); this knowledge acquisition bottleneck is the principal motivation behind research into semi-supervised and knowledge-based WSD. The latter have the advantage that, unlike manually annotated corpora, MRDs and LSRs do exist for many languages and domains.

In the past, however, knowledge-based approaches have suffered from a variant of the lexical gap problem: when matching a sense description to a given context of a disambiguation target, it is often the case that the description and context do not have much vocabulary in common. We propose a new method to bridge this lexical gap which is based on statistics collected from a large, unannotated background corpus. Specifically, we enrich the textual information from the context and the MRD with lexical expansions produced by a distributional thesaurus.

We examine the contribution of these expansions to two popular knowledge-based algorithms, including one which tries to address the lexical gap through LSR-based augmentation of the sense description. We show that, especially in situations for which no sense frequency information is available, improvements from adding more knowledge and from adding lexical expansions add up, allowing us to improve over the state of the art for knowledge-based all-words disambiguation.

2 Background

MRD-based word sense disambiguation began with Lesk (1986), who proposed that two or more words in context could be simultaneously disambiguated by looking up their respective definitions in a dictionary and finding the maximum overlap between each combination of their senses. A popular variant is the "simplified" Lesk algorithm (Kilgarriff and Rosenzweig, 2000), which disambiguates one word at a time by comparing each of its definitions to the context in which the word is found. This variant avoids the combinatorial explosion of word sense combinations the original version suffers from when trying to disambiguate multiple words in a text.

Both the original and simplified versions of the Lesk algorithm suffer from low coverage due to the lexical gap problem: because the context and definitions are usually quite short, it is often the case that there are no overlapping content words at all. Various solutions to the problem have been proposed, with varying degrees of success. Lesk himself proposed increasing the size of the context window, though Vasilescu et al. (2004) found that performance was generally better for smaller contexts. Lesk also proposed augmenting the definitions with example sentences provided by some dictionaries; Kilgarriff and Rosenzweig (2000) found that including them (for simplified Lesk) led to significantly better performance than using the definitions alone. Banerjee and Pedersen (2002) observed that, where there exists a lexical resource like WordNet (Fellbaum, 1998) which also provides semantic relations between senses,

these can be used to augment definitions with those from related senses (such as hypernyms and hyponyms); their "extended" Lesk algorithm was found to be a great improvement over the original algorithm. Subsequent researchers (e.g., Ponzetto and Navigli (2010)) have combined the "simplified" and "extended" approaches into a "simplified extended" algorithm, in which augmented definitions are compared not with each other, but with the target word context.

Many successful approaches to automatic WSD in recent years rely on distributional information to model the "topicality" of the context and the sense definition.[1] They include using vector-space dimensionality reduction techniques like LSA (Gliozzo et al., 2005) or LDA (Cai et al., 2007; Li et al., 2010), additionally collected text material per sense as in topic signatures (Martínez et al., 2008), and clustering for word sense induction as features (Agirre et al., 2006; Biemann, 2012); the importance of bridging the lexical gap is reflected in all those recent advances, be it in knowledge-based or supervised WSD scenarios.

In this paper, we employ a source of semantic similarity whose application to automatic WSD has never before been explored: using a distributional thesaurus, or DT (Lin, 1998), we expand the lexical representations of the context and sense definition with additional terms. On this expanded representation, we are able to apply the well-known overlap-based methods to text similarity without any modification. Lexical expansion has already proven useful in semantic text similarity evaluations (Bär et al., 2012), which is a task related to matching sense definitions to contexts.

The intuition behind our approach is depicted in Figure 1: say we wish to disambiguate the word *interest* in the sentence, "The loan interest is paid monthly." The correct sense definition from our MRD ("a fixed charge for borrowing money") has no words in common with the context, and thus would not be selected by an overlap-based WSD algorithm. But with the addition of ten lexical expansions per content word (shown in smaller text), we increase the number of overlapping word pairs (shown in boldface) to seven.

Observe also that this expansion of linear text sequences into a two-dimensional representation makes conceptual associations (cf. the associative relations of de Saussure (1916)) explicit, allowing for purely symbolic matching instead of using a vector-space representation such as LSA. The main differences to vector-space approaches are the following: On the one hand, vector-space approaches usually use dimensionality reduction in order to handle sparsity, which results in a fixed number of topics/dimensions. While very salient collection-specific topics are handled well by this approach, rare topics are either conflated into a single rump topic, or distributed amongst the salient topics. Our DT-based expansion technique has no notion of dimensions since it works on the word level, and thus does not suffer from this kind of sampling error that is inevitable when representing a large vocabulary with a small fixed number of dimensions or topics. On the other hand, while vector-space models do a good job at ranking candidates according to their similarity,[2] they fail to efficiently generate a top-ranked list of possible expansions: due to its size, it is infeasible to rank the full vocabulary every time. Lexical expansion methods based on distributional similarity, however, generate a short list of highly similar candidates.

[1] Distributional information was also used in a much older, semi-automatic approach by Tugwell and Kilgarriff (2001). In their technique, "word sketches" consisting of common patterns of usage of a word were extracted from a large POS-tagged corpus and presented to a human operator for manual sense annotation. The pattern–sense associations were then used as input to bootstrapping WSD algorithm.

[2] See Rapp (2004) for an early success of vector-space models on a semantic task.

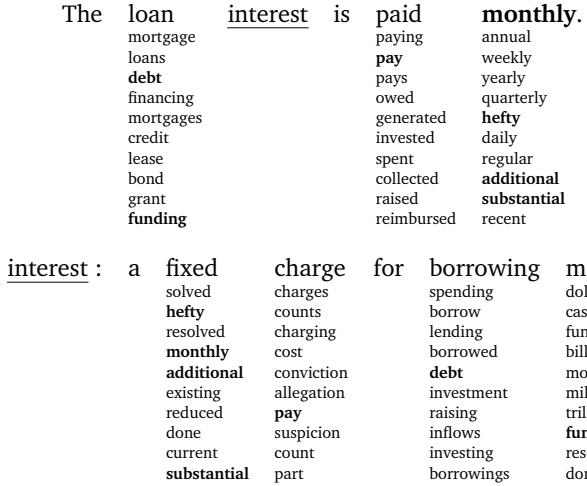

Figure 1: Example showing the intuition behind lexical expansion for matching a context (top) to a sense definition (bottom). The term to be disambiguated is underlined and the matching terms are in boldface.

The lexical expansions shown in Figure 1 were generated by the same DT used in our experiments. However, for the general case, we make no assumptions about the method that generates the lexical expansions, which could just as easily come from, say, translations via bridge languages, paraphrasing systems, or lexical substitution systems.

3 Experiments

Our experiments measure the contribution of various lexical expansion schemes to the simplified and simplified extended variants of the Lesk algorithm. We chose these algorithms because of their simplicity and transparency, making it easy for us to trace through their operation and see exactly how and where the lexical expansions help or hinder disambiguation. Furthermore, Lesk variants perform remarkably well despite their simplicity, making them popular choices as baselines and as starting points for developing more sophisticated WSD algorithms.

Our experiments with the simplified Lesk algorithm use only the definitions provided by WordNet; they are intended to model the case where we have a generic MRD which provides sense definitions, but no additional lexical semantic information such as example sentences or semantic relations. Such scenarios are typical of many languages and domains, where there is no WordNet-like resource and no manually sense-annotated corpus which could be used for supervised WSD or for a backoff to the most frequent sense. Accurate WSD systems that rely on the existence of an MRD only could pave the way to wider application of lexical disambiguation in NLP applications.

By contrast, the experiments with the simplified extended Lesk algorithm assume the existence of a WordNet-like resource with a taxonomic structure; the definition text for a sense is therefore constructed from the gloss, synonyms, and example sentences provided by WordNet, plus the

same information for all senses in a direct semantic relation. This setup specifically targets situations where such a resource serves as the sense inventory but no large sense-annotated corpus is available for supervised WSD (thus precluding use of the most frequent sense backoff). This is the case for many languages, where wordnets but not manually tagged corpora are available, and also for domain-specific WSD using the English WordNet. Whereas other approaches in this setting (Ponzetto and Navigli, 2010; Henrich et al., 2012) aim at improving WSD accuracy through the combination of several lexical resources, we restrict ourselves to WordNet and bridge the lexical gap with non-supervised, data-driven methods.

How one computes the overlap between two strings was left unspecified by Lesk; we therefore adopt the simple approach of removing occurrences of the target word, treating both strings as bags of case-insensitive word tokens, and taking the cardinality of their intersection. We do not preprocess the texts by lemmatization or stop word filtering, since the terms in the distributional thesaurus are likewise unprocessed (as in Figure 1), and because preliminary experiments showed that such preprocessing brought no benefit. We use the sentence containing the target word as the context. The sense with the highest overlap with the context is assigned a probability of 1; when $k \geq 2$ senses are tied for the highest overlap count, these senses are assigned a probability of $1/k$. All other senses are assigned a probability of 0. The probabilities are then used for scoring during evaluation (see §3.3).

3.1 Use of distributional information

We now describe the creation and the use of our distributional thesaurus. In the fashion of Lin (1998), we parsed a 10M sentence English news corpus from the Leipzig Corpora Collection[3] (Biemann et al., 2007) with the Stanford parser (de Marneffe et al., 2006) and used collapsed dependencies to extract features for words: each dependency triple (w_1, r, w_2) denoting a directed dependency of type r between words w_1 and w_2 results in a feature (r, w_2) characterizing w_1, and a feature (w_1, r) characterizing w_2. Words are thereby represented by the concatenation of the surface form and the POS as assigned by the parser. After counting the frequency of each feature for each word, we apply a significance measure (log-likelihood test (Dunning, 1993)), rank features per word according to their significance, and prune the data, keeping only the 300 most salient features per word. The similarity of two words is given by the number of their common features (which we will shortly illustrate with an example). The pruning operation greatly reduces run time at thesaurus construction, rendering memory reduction techniques like Goyal et al. (2012) unnecessary. Despite its simplicity and the basic count of feature overlap, we found this setting to be equal to or better than more complex weighting schemes in word similarity evaluations. Across all parts of speech, the DT contains five or more similar terms for a vocabulary of over 150 000 words.

To illustrate the DT, Table 1 shows the top three most similar words to the noun *paper*, together with the features which determine the similarities. Amongst their 300 most salient features as determined by the significance measure, *newspaper* and *paper* share 45, *book* and *paper* share 33, and *article* and *paper* share 28; these numbers constitute the terms' respective similarity scores.

The DT is used to expand the context and the sense definitions in the following way: For each content word (that is, adjectives, nouns, adverbs, and verbs) we retrieve the n most similar terms from the DT and add them to the textual representation. Since our overlap-based

approaches treat contexts and sense definitions as unordered bags of words, we do not need to take precautions with respect to the positions of words and expansions within the texts. The bags of words are filtered by removing occurrences of the disambiguation target. Then, we count the overlaps as usual between the expanded context and sense definitions. In our experiments we test $n = 10, 20, \ldots, 100$.

We had the intuition that the optimal number of expansions may depend on the part of speech of the word to be disambiguated, and perhaps also on the parts of speech of the words being expanded. Therefore, we parameterized our expansion procedure such that the part of speech of the target word determined the number of expansions, and also whether all words were expanded or only those of a certain part of speech.

3.2 Data sets

Data sets for WSD can generally be classified as *fine-grained* or *coarse-grained* according to the granularity of the sense inventory used for the annotations. Another common distinction is between the *all-words* task, in which the aim is to provide an annotation for every content word

in long running texts, and the *lexical sample* task, where several instances from the same small set of target words are annotated in (usually very short) contexts. We tested our systems on several coarse- and fine-grained data sets, and in both the all-words and lexical sample settings. However, most of our analysis will focus on the coarse-grained all-words scenario, as all-words provides a wider and more natural distribution of target words and senses, and because the fine sense distinctions of WordNet are considered a major obstacle to accurate WSD (Navigli, 2009). Additionally, as we discuss below, the fine-grained data sets available to us have various issues which render them unsuitable for comparisons with the state of the art.

Our coarse-grained data set is from the SemEval-2007 English all-words disambiguation task (Navigli et al., 2007). It consists of five non-fiction documents from various sources, where each of the 2269 content words (362 adjectives, 1108 nouns, 208 adverbs, and 591 verbs) has been annotated with clusters of WordNet 2.1 senses. For this data set only, we make a slight modification to our algorithm to account for this clustering: instead of choosing the WordNet sense with the highest overlap, we add up the overlap counts of each cluster's constituent senses, and then select the best cluster.

For our fine-grained experiments, we used the all-words and lexical sample tasks from Senseval-2 (Palmer et al., 2001; Kilgarriff, 2001) and Senseval-3 (Snyder and Palmer, 2004). With these data sets, however, several factors hinder direct comparison to previously published results. There are a number of errors in the gold standard annotations, and the methodology of the original task is different from what has subsequently become common. Specifically, not all of the target words have a corresponding entry in the sense inventory, and systems were originally expected to mark these "unassignable" senses as such. In the case of Senseval-2, the gold standard annotations were made using an unpublished (and now lost) version of WordNet. Subsequent researchers have adopted a variety of mutually incompatible methods for dealing with these issues. For our runs, we use Rada Mihalcea's WordNet 3.0 conversions of the corpora[4] and remove from consideration all "unassignable" target word instances. We do not fix the erroneous annotations, which means that even our baselines cannot achieve 100% coverage.

3.3 Baselines and measures

We use the evaluation metrics standard in word sense disambiguation research (Palmer et al., 2006; Navigli, 2009). Each disambiguation target receives a *score* equal to the probability the system assigned to the correct sense.[5] *Coverage* is the proportion of target word instances for which the system attempted a sense assignment, *precision* (P) is the sum of scores for the correct sense assignments divided by the number of target word instances for which the system made an attempt, and *recall* (R, also known as *accuracy*) is the sum of scores for the correct sense assignments divided by the number of target word instances. The *F-measure* is the harmonic mean of precision and recall: $F_1 = 2PR \div (P + R)$. Note that according to these definitions, $P \leq R$, and when coverage is 100%, $P = R = F_1$. In this paper we express all these measures as a percentage (i.e., in the range $[0, 100]$).

[4] `http://www.cse.unt.edu/~rada/downloads.html#sensevalsemcor`

[5] Where the probability is less than 1, this is mathematically equivalent to the average score which would have been obtained, over repeated runs, of choosing a sense at random to break any ties. It is effectively a backoff to a random sense baseline, ensuring 100% coverage even when there is no overlap.

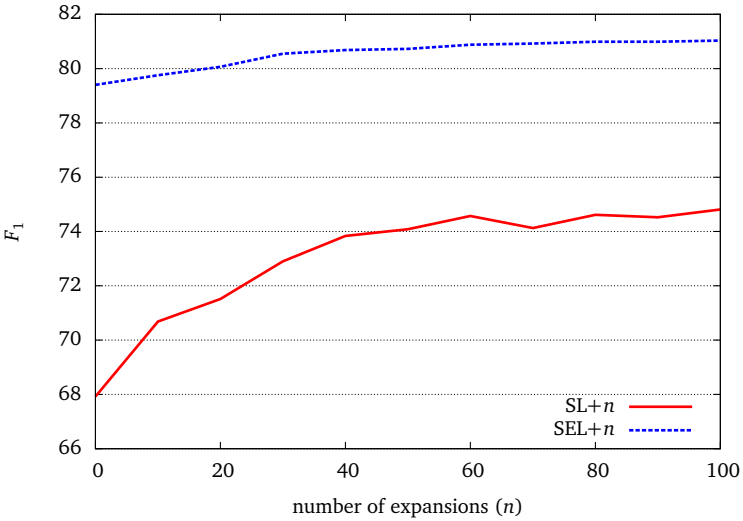

Figure 2: Results (F_1) on the SemEval-2007 corpus by number of lexical expansions

Our systems were compared against a computed random baseline which scores

$$P = R = F_1 = \frac{1}{|W|} \sum_{i=1}^{|W|} \frac{1}{|S(w_i)|},$$

where $W = \{w_1, w_2, \ldots\}$ is the set of target word instances in the corpus and $S(w_i)$ is the set of candidate senses for some target word w_i. This is equivalent to the score, averaged over repeated runs, of randomly choosing one of the candidate senses for each target word.

We also report accuracy of the most frequent sense (MFS) baseline, which always chooses the sense which occurs most frequently in SemCor (Mihalcea, 2008), a very large manually annotated corpus. Note that unlike our knowledge-based systems, MFS is a supervised baseline, and cannot actually be applied to the use cases for which our non-supervised systems are intended. Nonetheless, it is included here as it gives some idea of what accuracy could be achieved, at minimum, were one to go to the considerable expense of creating a manually tagged training corpus. Note that MFS is a notoriously difficult baseline to beat even for supervised systems.

3.4 Results

On the SemEval-2007 data set, the basic configuration of simplified Lesk (SL+0)—i.e., without any lexical expansions—achieves an overall F_1 of 67.92, which is already much better than the random baseline ($F_1 = 61.28$). When we tried adding a fixed number of lexical expansions to all content words, we observed that accuracy generally increased sublinearly with the number of

	part of speech				
system	**adj.**	**noun**	**adv.**	**verb**	**all**
MFS baseline	84.25	77.44	87.50	75.30	78.89
random baseline	68.54	61.96	69.15	52.81	61.28
SL+0	75.32	69.71	69.75	59.46	67.92
SL+100	82.18	76.31	78.85	66.07	74.81
SEL+0	87.19	81.52	74.87	**72.26**	79.40

WN^{++}-DC	—	79.4	—	—	—

Table 2: Results (F_1) on the SemEval-2007 corpus by part of speech

expansions. The highest accuracy was obtained by using 100 expansions (the maximum number we tried); we denote this configuration SL+100. SL+100's F-measure of 74.81 represents a relative increase of more than 10% over SL+0. The simplified extended Lesk configuration also benefitted from lexical expansions, though the effect was less pronounced: the basic version without expansions (SEL+0) achieves $F_1 = 79.40$, and adding 100 lexical expansions (SEL+100) yields a relative performance increase of just over 2%, to $F_1 = 81.03$. As with simplified Lesk, accuracy increased sublinearly with the number of expansions. This effect is visualized in Figure 2, which plots the F-measure for the two algorithms according to the number of lexical expansions used.

Table 2 shows the F-measure of our two baselines (top), our algorithms (middle), and some state-of-the-art knowledge-based systems (bottom), broken down by target word part of speech. In each column the best result, excluding the supervised MFS baseline, is shown in boldface. TKB-UO (Anaya-Sánchez et al., 2007) was the best-performing knowledge-based system at the SemEval-2007 competition; it is a clustering-based system which uses WordNet 2.1 (but not its sense frequency information) as its sole source of knowledge. Among later knowledge-based systems using this data set, MII+ref (Li et al., 2010), a topic model approach, achieves the highest result we are aware of. This work maps sense descriptions and target word contexts to a topic distribution vector as sampled by LDA (Blei et al., 2003). WN^{++}-DC (Ponzetto and Navigli, 2010) uses an altogether different approach: it disambiguates nouns in a sentence by building a graph of candidate senses linked by semantic relations, and then for each target word selecting the sense with the highest vertex degree. When using semantic relations from WordNet alone the method achieves $F_1 = 74.5$, but when WordNet is enriched with additional semantic relations from an online encyclopedia performance increases to $F_1 = 79.4$. Note that, uniquely among the results in the table, WN^{++}-DC does not achieve full coverage ($P = 87.3$, $R = 72.7$).

POS-optimized results. We also tried using different expansion strategies for target words of different parts of speech: for each target word POS, we tried expanding only adjectives, only nouns, etc., and tried each of these scenarios for the same eleven values of n as previously. Because this procedure involved tuning on the test data, we do not include the results for comparison in Table 2. However, they are interesting as they give an upper bound on per-

system	Senseval-2 lexical sample	Senseval-2 all-words	Senseval-3 all-words
MFS baseline	41.56	65.36	65.63
random baseline	15.46	39.54	32.89
SL+0	17.10	39.02	35.41
SL+100	20.92	45.69	37.17
SEL+0	28.60	54.22	48.76
SEL+30	32.72	57.77	53.09

Table 3: Results (F_1) on the Senseval-2 and -3 corpora

formance for the case where the expansions-per-POS parameters are optimized on a set of manually annotated training examples—that is, a mildly supervised variant of our otherwise knowledge-based algorithms.

For simplified Lesk, we found that accuracy for nouns, adverbs, and verbs remained highest when all content words were given 100 expansions, but adjectives fared better when all content words were given only 60 expansions. With this configuration we achieve an overall F_1 of 74.94. The best simplified extended Lesk configuration achieves $F_1 = 81.27$ when for adjectives we apply 20 expansions to all content words; for nouns, 60 expansions to all content words; for adverbs, 80 expansions to all content words; and for verbs, 30 expansions to adverbs only. That verbs benefit from adverb expansions is not surprising, given that the latter often serve to modify the former. Why the optimal *number* of expansions should vary with the target word part of speech is not as clear. In any case, the extra performance gains from POS expansion optimization were quite small, not exceeding a quarter of a percentage point over the non-optimized versions.

Fine-grained results. As with the coarse-grained task, we found that using lexical expansions resulted in an improvement in accuracy in the fine-grained tasks. However, in this setting we did not observe the same continuously improving accuracy from using more and more expansions; in all but one case, adding expansions helped to a point, after which accuracy started to decrease. This effect was particularly noticeable with simplified extended Lesk, where peak accuracy was achieved with around 30 expansions. For simplified Lesk, the optimum was less stable across the corpora, ranging from 60 to 100 expansions. We believe that this is because the expanded terms provided by the DT reflect broad conceptual relations which, taken in aggregate, do not precisely map to the narrow sense distinctions of the sense inventory. This is not a problem when we stick to the first highly salient expansions provided by the DT, but beyond this the conceptual relations become too tenuous and fuzzy to facilitate disambiguation.

Table 3 shows the results of our systems and baselines on the Senseval-2 lexical sample and all-words tasks and the Senseval-3 all-words task. For simplified extended Lesk we show the results of using 30 expansions (SEL+30); as simplified Lesk had no consistent peak accuracy we stick with 100 expansions (SL+100). The results, while quite expectedly lower than the coarse-grained scores in absolute terms, nonetheless validate the utility of our approach in fine-grained tasks. Not only does the use of expansions significantly increase the accuracy, but in the case of the Senseval-2 corpora, the relative increase is much higher than that of the coarse-grained tasks. For SL+100, the relative improvements over the unexpanded algorithms

for the lexical sample and all-words data sets are 22.3% and 17.1%, respectively, and for SEL+100 they are 14.4% and 6.5%, respectively.

4 Discussion

In this section, we discuss our results and put them in the perspective of applicability of WSD systems. Our lexical expansion mechanism leads to a relative improvement of up to 22% in the fine-grained evaluation and 10% in the coarse-grained evaluation for the "simple" setup. This is achieved by merely adding lexical items to the representation of the sense description and context, and without changing the algorithm. Especially in situations where there exists a reasonably coarse-grained MRD for the language or domain, this is a major improvement over previous approaches on applications where one is not in the comfortable situation of having sense frequency information. In our opinion, this scenario has been neglected in the past, despite occurring in practice much more often than the case where one has access to a rich LSR, let alone sufficient training data for supervised disambiguation.

The expansions from distributional similarity are complementary to those coming from richer knowledge resources, as our results for fitting simplified extended Lesk with DT expansions show: even in the situation where a richer lexical resource allows for bridging the lexical gap via descriptions from related senses, we still see an additional relative improvement of 2% to 14% when comparing the F-measure of the SEL+n system against the SEL+0 baseline. Not only does this system outperform all previous approaches to coarse-grained WSD without MFS backoff, it is also able to outperform the MFS baseline itself, both generally and for certain parts of speech.

We emphasize that while the DT uses additional text data for computing the similarity scores used in the lexical expansion step, the overall system is purely knowledge-based because it is not trained on sense-labelled examples; the DT similarities are computed on the basis of an automatically parsed but otherwise unannotated corpus. This marks an important difference from the system described in Navigli and Velardi (2005) which, although it also uses collocations extracted from large corpora, avails itself of manual sense annotations wherever possible.

While the comparison of results to other methods on the same coarse-grained data sets suggests that lexical expansion using a distributional thesaurus leads to more precise disambiguation systems than word or topic vectors, our point is somewhat different: Realizing lexical expansions and thus explicitly generating associated terms to a textual representation opens up a new way of thinking about bridging lexical gaps and semantic matching of similar meaning. In light of the fact that distributional similarity (Lin, 1998) and overlap-based approaches to WSD (Lesk, 1986) have existed for a long time now, it is somewhat surprising that this avenue had not been explored earlier.

4.1 Error analysis

In order to better understand where and how our system is succeeding and failing, we now present an error analysis of the results, both in aggregate and for some individual cases. To begin, we computed a confusion matrix showing the percentage of the 2269 SemEval-2007 target word instances for which the SL+0 and SL+100 algorithms made a correct disambiguation, made an incorrect disambiguation, or failed to make an assignment at all without resorting to the random choice backoff (see Table 4). Table 5 shows the same confusion matrix for the SEL+0

		SL+100			
		unassigned	**incorrect**	**correct**	**total**
SL+0	**unassigned**	0.2	8.1	9.7	18.0
	incorrect	0.1	14.1	6.2	20.4
	correct	0.0	2.8	58.8	61.6
	total	0.4	25.0	74.7	100.0

Table 4: Confusion matrix for SL+0 and SL+100

		SEL+100			
		unassigned	**incorrect**	**correct**	**total**
SEL+0	**unassigned**	0.1	3.5	4.0	7.6
	incorrect	0.0	14.9	2.8	17.7
	correct	0.0	1.9	72.9	74.7
	total	0.1	20.3	79.6	100.0

Table 5: Confusion matrix for SEL+0 and SEL+100

and SEL+100 algorithms.[6] As can be seen, the pattern of contingencies is similar. Because of the sheer size of the expanded sense descriptions and contexts with this task, however, in the following analysis we stick to the simplified Lesk scenario.

As we hypothesized, using lexical expansions successfully bridges the lexical gap: whereas the basic simplified Lesk was able to make a sense assignment (be it correct or incorrect) in only 82.0% of cases, SL+100 could do so 99.6% of the time. SL+100 was able to correctly disambiguate over half of all the target words for which SL+0 failed to make any sense assignment. This contingency—some 9.7% of all instances—accounts for the majority of SL+100's improvement over SL+0. However, in 6.2% of cases SL+100's improvement resulted from successfully revising an incorrect answer of SL+0. We randomly selected ten of these cases and found that in all of them, all the overlaps for SL+0 were from a small number of non-content words (*the*, *of*, *in*, etc.), with the chosen sense achieving only one or two more overlaps than the runners-up; thus, the lexical gap is still at fault here. By contrast, the expanded sense definitions and contexts used by SL+100 for these cases always contained dozens of overlapping content words, and the overlap count for the chosen sense was markedly higher than for the runners-up.

What is also interesting to consider is the 0.2% of cases where both algorithms neglected to make a sense assignment, apparently signifying SL+100's failure to bridge the lexical gap. We manually examined all of these instances and found that for all but one, the systems failed to disambiguate the target words because the sentences containing them were extremely short, usually with no other content words apart from the target word. It is unlikely that any knowledge-based algorithm restricting itself to sentential context could succeed in such cases, and no reasonable number of lexical expansions is likely to help. Our choice to use sentential context was motivated by simplicity and expediency; a more refined WSD algorithm could, of course, using a sliding or dynamically sized context window and thereby avoid this problem.

[6] Totals in both tables may not add up exactly due to rounding.

The remaining case was a sentence of normal length where SL+0 found no overlapping content words between the definition and the context, but SL+100 produced a two-way tie between two of the clusters, one of which was the correct one.

It is also of interest to know why SL+0 was able to correctly disambiguate some words which SL+100 could not; these represent 2.8% of the instances. Again, we drew a random sample of these instances, and observed that in all of them, the only overlaps found by SL+0 were for non-content words; the fact that it happened to choose the correct sense cluster can therefore be chalked up to chance.

Though it has been relatively easy to identify the reasons behind SL+100's correct assignments, and behind its failures to make any assignment at all, it is not so easy to deduce the causes of its incorrect assignments. We observe that the system had disproportionate difficulties with verbs, which constitute 35% of the incorrect disambiguations but only 26% of all target words in the corpus. Particularly troublesome were verbs such as *be*, *go*, *have*, and *do*, which are often used as auxiliaries. On their own they contribute little or no semantic information to the sentence, and their dictionary definitions tend to explain their grammatical function, so there is little opportunity for meaningful lexical or conceptual overlaps. A related problem was observed for adverbs and adjectives: the problematic cases here were often generic terms of restriction, intensification, or contrast (e.g., *different*, *just*, *only*, *so*) which are used in a wide variety of semantic contexts and whose dictionary definitions focus on usage, or else constitute concise rephrasings using equally generic terms. Purely definition-based disambiguation approaches are unlikely to help in any of these cases; an accurate knowledge-based approach would probably need to be aware and make use of information beyond the lexical-semantic level, such as verb frames and semantic roles, or incorporate the grammatical structure around the target word for matching.

Conclusion and further work

We have proposed a new method for word sense disambiguation based on word overlap between sense descriptions and the target word context. Our method uses lexical expansions from a distributional thesaurus, which is computed over dependency-context similarities over a large background corpus. We found that applying our conceptually simple extension to two traditional knowledge-based methods successfully bridged the lexical gap, resulting in performance gains exceeding that of state-of-the-art knowledge-based systems that do not make use of sense frequency information, and approaching or even exceeding the MFS baseline. The concept of lexical expansion is a promising avenue to enrich classic, word-based NLP algorithms with additional lexical material. The intuitions of overlap-based approaches are thereby complemented by a method that makes associations explicit and bridges the lexical gaps for semantically similar contexts that are expressed in a different wording.

There are a number of ways how our method could be improved. First of all, since a DT is static and thus not dependent on the context, it generates spurious expansions, such as the similar terms for *charge* in Figure 1, which is obviously dominantly used in its "criminal indictment" sense in the background corpus. At best, these expansions, which implicitly capture the sense distribution in the background corpus, result in less overlap with the correct sense description—but they might well result in assigning incorrect senses. A straightforward improvement would alter the lexical expansion mechanism as to be sensitive to the context—something that is captured, for example, by LDA sampling (Blei et al., 2003). A further extension would be to have the number of lexical expansions depend on the DT similarity score (be it static or

contextualized) instead of the fixed number we used here.

In the future, we would like to examine the interplay of lexical expansion methods in WSD systems with richer knowledge resources (e.g., Navigli and Ponzetto (2010); Gurevych et al. (2012)) and apply our approach to other languages with fewer lexical resources. Also, it seems promising to apply lexical expansion techniques to text similarity, text segmentation, machine translation, and semantic indexing.

Acknowledgments

We thank Richard Steuer for computing and providing us access to the distributional thesaurus.

ABSTRACT
In this paper, we present a new method that improves the alignment of equivalent terms monolingually acquired from bilingual comparable corpora: the Compositional Method with Context-Based Projection (CMCBP). Our overall objective is to identify and to translate high specialized terminology made up of multi-word terms acquired from comparable corpora. Our evaluation in the medical domain and for two pairs of languages demonstrates that CMCBP outperforms the state-of-art compositional approach commonly used for translationally equivalent multi-word term discovery from comparable corpora.

KEYWORDS: Comparable corpora, bilingual lexicon, compositionality, multi-word term, context information.

1 Introduction

The automatic compilation of bilingual dictionaries has received considerable attention in recent years for *language for special purposes (LSP)* (especially coming from scientific domains). LSP is characterised by the small amount of available textual data compared with general language, and a high proportion of specialised terms which are not be found in general language monolingual or bilingual dictionaries. For LSP, a specialised term could be either a single-word term (SWT) or a multi-word term (MWT), the latter being highly productive (Sag et al., 2002). A term is a lexical unit which represents a concept within a domain. As an example, in the medical domain, *cancer* is an SWT, *breast cancer* is an MWT.

Comparable corpora that are sets of texts in two or more languages without being translations of each other, seem to be the right solution to solve the textual scarcity of LSP: as monolingual productions, they are authentic texts, and the babel web ensures that there is a sufficient number of multilingual documents. The comparability of the corpus should be ensured by using various shared characteristics across languages that are checked during the compilation phase (McEnery, 2007). For LSP, the domain and sub-domain are requested as well as the communicative settings and the textual genre to identify reliable translations (Bowker and Pearson, 2002).

To build highly-specialised terminologies, the terms are first of all extracted monolingually from the comparable corpus. To collect close candidate terms across languages, it is necessary to use a term extraction program that applies the same method in the source and in the target languages. The translation of MWTs is the main need as they constitute around 80% of the domain-specific terms. See Nakagawa and Mori (2003) for the Japanese language.

Proceedings of COLING 2012: Technical Papers, pages 1797–1810,
COLING 2012, Mumbai, December 2012.

Our goal is to find the right translation for a source MWT in the set of MWT candidates in the target language. The simplest method assumes that the right translation of an MWT could be obtained by translating each component individually thanks to a general dictionary, by generating all the combinations of word positions, and then filtering the translated expressions using either the list of target MWTs (Morin and Daille, 2010), the target corpus (Robitaille et al., 2006) or the web (Grefenstette, 1999). This method is limited to the subset of MWTs that share the same compositional property - 48.7% were reported by Baldwin and Tanaka (2004) for English/Japanese N N compounds. However, even if the MWT is characterised by the compositional property, the translation is not found when some words, which are part of the MWTs, do not belong to the general bilingual dictionary or when the translated combinations do not exist or have not been extracted by the term extraction program in the target language.

Within this context, we propose to improve the compositional approach by using context information collected from LSP comparable corpora when one or several of the components, part of the MWTs, are not found in the dictionary. We demonstrate that the use of context information when performing terminology translation helped us to learn a significant number of additional correct lexical entries that could not be identified by the compositional method.

The remainder of this paper is organised as follows: Section 2 shows the intricate problems with the translations of MWTs. Section 3 presents the compositional method used for the automatic translation of MWTs. Section 4 introduces CMCBP that takes advantage of the context information to improve the compositional method. Section 5 describes the linguistic resources and the open-terminology extraction tool used for our experiments. Section 6 evaluates the influence of CMCBP on the quality of bilingual terminology extraction through experiments involving French as a source language, and English and German as target languages. Section 7 discusses works related to this study. Finally, Section 8 presents our conclusions.

2 Translation of MWTs

If MWTs are less polysemous (Savary and Jacquemin, 2003) and more representative (Nomura and M., 1989; Nakagawa and Mori, 2003) of domain specialities than SWTs, pinpointing their translations poses specific problems that are well-known, such as fertility, non-compositionality, or term variation[1]:

Fertility is known as a problem of difference of length between the source and the target MWT (Brown et al., 1993): for instance, the German SWT *axilladissektion* (1 content word) is translated into English by the MWT *axillary dissection* (two content words); the French MWT *dépistage du cancer du sein* (three content words) is translated into English by the MWT *breast screening* (two content words).

Non-compositionality is illustrated when the target MWT is not typically composed of the translation of its parts (Melamed, 2001). For instance the French MWT *curage axillaire* is translated into the English language as *axillary dissection* whereas the English word *dissection* is not the translation of the French word *curage*. Baldwin and Tanaka (2004) report that at least 50% of the Japanese N N compounds are not translated through a compositional strategy into English.

[1] The French/English/German examples in this paper are extracted from the specialized medical comparable corpus described in Section 5.

Term variation refers to an MWT that appears in texts in different forms reflecting either graphical, syntactic, morphological or semantic differences: for example, the French MWTs *cancer du sein* and *cancer mammaire* are both translated by the same English MWT *breast cancer*. Source and target MWTs can appear in different syntactic structures. For example, the French MWT *prolifération tumorale* of N A pattern is translated by the English MWT *tumour proliferation* of N N pattern, where the French adjective *tumorale* is linked through morphological derivation to the English noun *tumour*. The term variations could also involve paradigmatic variation when one element of the MWT is substituted by a synonym or a hypernym such as *tumour size* → *diameter tumour* in the source language and not in the target language such as *taille tumorale* (lit. 'tumour size').

It is quite difficult to design a general framework that can address all these problems simultaneously (Robitaille et al., 2006) and for any language. The non-compositionality has to be solved during the translation process as it involves an MWT and its translation. The term variant problem is generally handled at the monolingual level during the term extraction task. This is done in two steps: term variant extraction and term variant grouping. A sophisticated variant recognition and conflation program will handle several types of variants: graphical, but also morphological and syntactic variation, ideally paradigmatic variants and acronyms. Using a term variant program allows us to cluster a set of term-like sequences reflecting base or variant forms. This clustering could be interpreted as a terminology normalization in the same way as lemmatisation at the morphological level. Handling term variation could indirectly solve part of the fertility problem using the syntactic variant of MWTs: as an example, in French, the term *dépistage du cancer du sein* (lit. *breast cancer screening*) could be collected as a syntactic variant of the term *dépistage du sein* (lit. *breast screening*) and thus provides a word-to-word translation. In German, the fertility problem could be solved by establishing an equivalence relation between a morphological compound of the type $N_1|N_2$ where | is the concatenation operator, and a syntagmatic compound of N_1N_2 pattern: the noun *axilladissektion* that is morphologically analyzed as *axilla|dissektion* will be a variant of the MWT *axilläre dissektion*.

The compositional method with context-based projection that we introduce in Section 4 will take into account the non-compositionality and term variation problems and indirectly the fertility problem through the term variant and the German compound splitting treatments.

3 Compositional Approach

Compositionality is defined as the property where *"the meaning of the whole is a function of the meaning of the parts*" (Keenan and Faltz, 1985, p. 24-25): a *frying pan* is indeed a *pan* used for *frying*. The implementation of the principle of translation compositionality from a comparable corpus relies on the following steps (Grefenstette, 1999; Tanaka, 2002; Robitaille et al., 2006):

Translation of the source MWT For an MWT of the source language to be translated, each component of the MWT is translated by looking it up in a dictionary. The lexical form is examined without checking the part-of-speech (POS). For example, for the French MWT *examen clinique* (*clinical examination*), there are six English translations for *examen* (*consideration*/N, *examen*/N, *examination*/N, *inspection*/N, *review*/N, *test*/N) and two translations for *clinique* (*clinic*/N, and *clinical*/A).

Generation of the candidate translations All possible mappings are constructed regardless of word order with a total of $O(\prod_{i=1}^{p} t_i n!)$ possible mappings (where t_i is the number of translations of the content word i, and n the number of content words). In the above example, 24 combinations are obtained. The number of generated translations can be reduced using MWT POS patterns in the source and the target languages. For instance, Tanaka and Baldwin (2003) defined the following templates to filter translation candidates: N_1 N_2 Japanese structure is translated by N_1 N_2 (33.2% of the cases), A_1 N_2 (28.4%), N_2 of (the) N_1 (4.4%) English structures.

Selection of the candidate translations From the set of translation candidates, the most likely translations are selected according to term frequency in the target language. In the above example, the translations are MWTs of the target language identified by the terminology extraction system.

4 Compositional Method with Context-Based Projection (CMCBP)

The compositional approach that finds translations of multi-word terms is easy to implement, but it fails when:

1. At least one element of an MWT is not found in the bilingual dictionary and thus cannot be translated.
2. The translated combination is valid but is not provided by the term extraction program for the target language. One explanation could be that the target MWT does not occur in the comparable corpus, or the source concept occurs in the target corpora but under a non terminology-like form, or an error during the preprocessing of the corpora induces that the terminology extraction program misses the MWT.
3. The translated combination is not valid. One of the MWT translation problems has been encountered (see Section 2).

When there is no translation candidates for an MWT, a first solution would be to find its synonyms in the source language. Similar words are predicted by Pekar et al. (2006) for low-frequency words and by Sharoff et al. (2009) for wrong translations. CMCBP that deals with term variants performs a clustering of synonymic terms. The translations that are proposed are for the set of synonymic term variants.

CMCBP is designed to identify MWT translations in a comparable corpus on a large scale and is able to solve points 1 and 3. It includes the use of the context of the words (which are parts of the MWT to be translated) when the compositional approach fails. We refer to the two monolingual parts of the comparable corpus as the source and target corpus. CMCBP uses four steps:

Computing the context of the MWT For an MWT or a morphological compound in the source corpus defined as $C_{s1}C_{s2}\cdots C_{sk}$ to be translated (where k is the number of content words or autonomous morphemes), we look up each component C_{si} in the bilingual dictionary. When a component is not found in the bilingual dictionary, we replace it by co-occurrence information. We compute the co-occurrence information between a component C_{si} and the words that co-occur in a window of w words around C_{si} from

the source corpus. Mutual information or Likelihood-ratio are good measures of the co-occurrence relationship between 2 words. The co-occurrence information is expressed with a vector representation called context vector (V_{si}). As an example, let us consider the French MWT *antécédent familial* ($C_{s1}C_{s2}$). If the first component *antécédent* (C_{s1}) is not found in the bilingual dictionary then this component is replaced by its vector context: V_{s1} (see Figure 1).

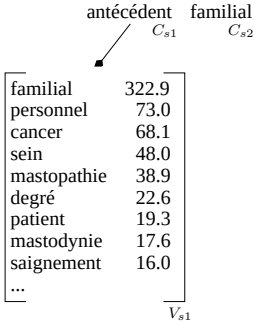

Figure 1: Computing context in the source corpus

Transfer of the MWT At this level, we are able to identify two situations depending on whether or not the components of the MWT are translated:

1. If the component C_{si} is found in the dictionary, we compute the co-occurrence information of each translation in the target corpus and store it in a context vector: V'_{si}.
2. If the component C_{si} is not found in the dictionary, we use the context vector of the source corpus V_{si}. The elements of V_{si} are projected into the target corpus using the bilingual dictionary and the transferred context vector becomes: V'_{si}. If the bilingual dictionary provides several translations for an element, all of them are used but the different translations are weighted according to their frequency in the target language. If an element is not found in the bilingual dictionary it is discarded.

In the previous example, if we find two English translations for the component *familial* (C_{s2}) such as *familial* and *family* in the target language then we obtain two context vectors: V'_{s2_1} and V'_{s2_2} (see Figure 2).

Generation of candidate translations Each MWT of the target language, for which each component C_{ti} is described by its context vector V_{ti}, is then compared to the transferred MWT through a similarity measure such as Cosine or Weighted Jaccard. For an MWT composed of two context vectors V_{t1} and V_{t2} in the target language and a transferred MWT composed of two context vectors V'_{s1} and V'_{s2}, two pairs of similarity scores corresponding to the possible mappings are computed: $sim(V_{t1}, V'_{s1})$ with $sim(V_{t2}, V'_{s2})$,

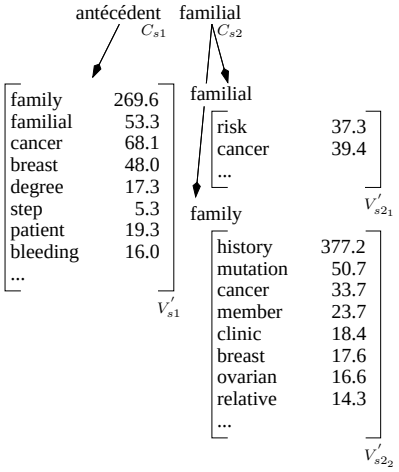

Figure 2: Projection in the target corpus

and $sim(V_{t1}, V'_{s2})$ with $sim(V_{t2}, V'_{s1})$. The combination score for each pair is then defined as the geometric mean of each similarity score: $\sqrt{sim(V_{t1}, V'_{s1}).sim(V_{t2}, V'_{s2})}$ and $\sqrt{sim(V_{t1}, V'_{s2}).sim(V_{t2}, V'_{s1})}$. Figure 3 illustrates this comparison for the previous example.

Ranking of candidate translations We rank the candidate translations in decreasing order of their combination score (see Figure 4).

5 Resources

In this section, we describe the different resources used for our experiments: the comparable corpus, the bilingual dictionary, and the multi-word term test set.

5.1 Comparable Corpora

The documents comprising the specialised comparable corpora were taken from the medical domain within the sub-domain of 'breast cancer'. These documents have been automatically selected from scientific paper websites where the title or the keywords of the articles contain the MWT 'breast cancer' in English, 'cancer du sein' in French and 'brustkrebs' in German. The compilation of the comparable corpus fulfils the requirements of an LSP comparable corpus: domain, sub-domain, communicative settings (experts-to-experts) and textual genre are common characteristics across languages. In this way, we collected 118 documents in English, 130 in French and 103 in German (about 530,000 words for English and French languages and 220,000 words for German language).

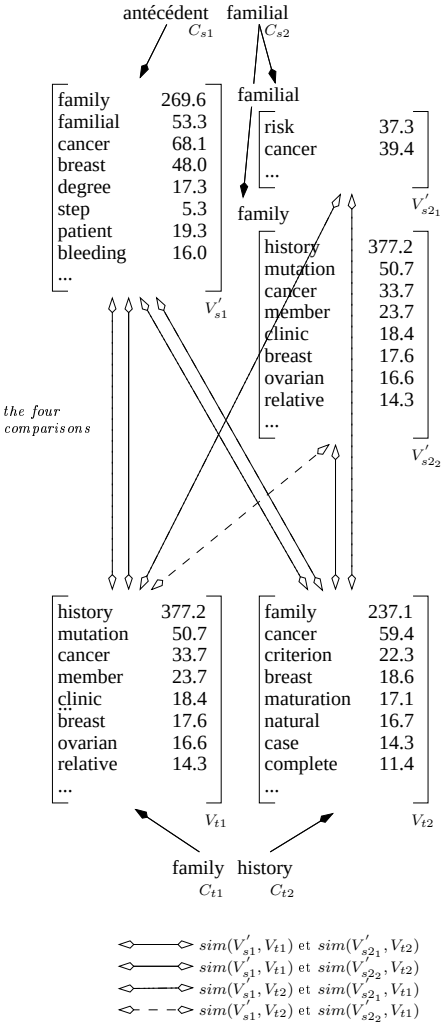

Figure 3: Comparison between the MWT to be translated and an MWT of the target corpus

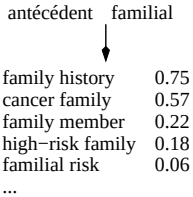

Figure 4: Rank list of candidate translations

5.2 Bilingual Dictionary

The bilingual dictionaries used in our experiments are the French/English dictionary ELRA-M0033 and the French/German dictionary ELRA-M0034 available from the ELRA catalogue[2]. The French/English dictionary contains 243,539 translations and the French/German dictionary 170,967 translations. These are two general language dictionaries which contain only a few terms related to the medical domain.

5.3 Multi-Word Term Test Set

Terms are extracted monolingually from the comparable corpora. To collect close candidate terms across languages, it is necessary to use a term extraction program that is multilingually designed. We choose the TTC TermSuite (Rocheteau and Daille, 2011)[3] that applies the same term extraction method to several languages including French, German and English. TermSuite first normalises the texts through the following linguistic pre-processing steps: tokenisation, part-of-speech tagging and lemmatisation using TreeTagger (Schmid, 1995). TermSuite then extracts SWTs and MWTs whose syntactic patterns correspond either to a canonical or a variation structure. The patterns are expressed using MULTEXT part-of-speech tags and are provided for each language. The main patterns, whatever the language is, are N and A for SWTs. The main patterns of MWTs are for:

- **French** N N: *ganglion sentinelle* (*sentinel lymph node*); N Sp N: *cancer du sein* (*breast cancer*); N A: *curage axillaire* (*axillary dissection*);
- **English** N N: *breast cancer*; A N: *far therapy*; N Sp N: ;
- **German** A N: *thromboembolischer vorfall* (*thromboembolic incident*); N Sp N: *patientin mit mammakarzinom* (*patient with breast cancer*); N D : g N: *erfahrung der früherkennung* (*experience of early detection*).

The variants handled for MWTs are graphical, morphological, and syntactic. Both SWTs and MWTs accept variants but some are more likely to concern one main type such syntactic variants for MWTs. TermSuite defines a morphological variant as a morphological modification of one of the components of the MWT, and a syntactical variant as the adding of another word at the frontier or inside the MWT. For example, in the French part of the comparable corpus, the MWT candidate *cancer du sein* (*breast cancer*) appears in the following forms where shared items are numbered with the same values.

[2] http://www.elra.info/
[3] http://code.google.com/p/ttc-project

- **base form** of N_1 $S_1 p$ N_2 pattern: *cancer du sein* (*breast cancer*);
- **inflexional variant**: *cancers du sein* (*breast cancers*);
- **syntactic variant** (insertion inside the base form of a modifier): N_1 A $S_1 p$ N_2 *cancer primitif du sein* (*primary breast cancer*);
- **syntactic variant** (expansion coordination of base form): N_1 Sp N $S_1 p$ N_2 *cancer des ovaires et du sein* (*ovarian and breast cancer*).

In German, it is necessary to reconsider the rough distinction between single- multi-word terms in order to take morphological compounds into account. The common German compounds of the type $N_1|N_2$ ("|" is the concatenation operation) are often translated by N Sp N patterns in French: *Produktionsstandort* ⟷ *site de production* or by the N N patterns in English. Morphological compounds are identified by tokenisation programs as single-word terms but they look quite similar to multi-word terms. We use the morphological splitter which is combined with a dictionary look-up developed by Weller and Heid (2012) in order to get the MWT syntagmatic equivalence of a German morphological compound.

In order to build the test set, we have selected the French MWTs extracted by TermSuite for which the number of occurrences is greater than or equal to 5. The test set is composed of 976 French MWTs for which 90% of the base forms are only composed of two content words.

6 Experiments

In this section, we evaluate the performance of the dictionary look-up, the compositional method and CMCBP on the quality of bilingual terminology extraction.

6.1 Dictionary Look-up

First of all, we count the number of terms of the test set directly translated by looking them up in the bilingual dictionaries. From the 976 French MWTs to be translated, 51 are recorded in the French/English dictionary and 12 in the French/German dictionary. Here, the MWTs correctly translated are mainly generic terms that are not specific to the thematic of breast cancer such as *traitement médical/medical treatment* and *acide aminé/amino acid:* in French/English and *analyse statistique/statistische untersuchung* (*statistical analysis*) and *effet secondaire/begleiterscheinung* (*side effect*) in French/German. In this instance we were unable to generate any translations for 836 French MWTs in English and for 964 French MWTs in German.

6.2 Compositional Method

We then evaluate the quality of the translations provided by the compositional method (the MWTs found in the dictionary are not used). Table 1 shows the results obtained for the translation from French/English and German/English. The first column indicates the number of French MWTs that are translated. Since the compositional approach can give several target translations for one French MWT, the last two columns indicate the Top_1 and Top_5 accuracy. To evaluate the Top_n accuracy, we first keep for each French word to be translated its n first candidate translations and then measure the accuracy of the ranked lists obtained, *i.e.* the proportion of lists comprising the expected translation. Here, the candidate translations are

ranked according to their frequency in the target part of the comparable corpus. The results of this experiment show that 140 of the 836 French MWTs are translated into English for the Top_5 with a high level of accuracy: 79.1%, and 87 of the 964 French MWTs are translated into German for the Top_5 with a high level of accuracy: 95.7%. Here, we were unable to generate any translations for 785 French MWTs in English and 877 French MWTs in German.

	# trans.	Top_1	Top_5
French/English	140	73.2%	79.1%
French/German	87	88.8%	95.7%

Table 1: Results for the compositional method

6.3 Compositional Method with Context-Based Projection

We now apply CMCBP (here again the MWTs found in the dictionary are not used). In this experiment, the parameters required for our approach are as follows: the size of the context window w is up to 3 (i.e. a seven-word window), the association measure is Mutual Information, and the distance measure is Cosine. Other combinations of parameters were assessed but the previous parameters gave the best performance. Table 2 presents the percentage of French terms for which the correct translation is obtained among the $Top_{1, 5, 10,}$ and $_{20}$ candidates translations from French to English and German. Table 2 shows that 514 of the 836 French MWTs are translated into English with the CMCBP with an accuracy of 42.1% for the Top_1 and 57.1% for the Top_{20} and 510 of the 964 French MWTs are translated into German with an accuracy of 44.3% for the Top_1 and 51.2% for the Top_{20}. These results indicate that the majority of the correct translated MWTs are in fact obtained from the Top_5. Moreover, the CMCBP retains the advantages of the compositional method. All translations obtained with the compositional method are found in the same rank with the CMCBP.

	# trans.	Top_1	Top_5	Top_{10}	Top_{20}
French/English	514	42.1%	55.4%	56.8%	57.1%
French/German	510	44.3%	49.4%	51.2%	51.2%

Table 2: Results for the compositional method enhanced with context alignments

From the MWTs that are correctly translated and not found by the compositional approach, we found a large majority of French MWTs involving a relational adjective. However, the French MWT *dépistage mammographique* is not translated by the compositional approach since the French relational adjective *mammographique* is not found in the dictionaries. In contrast, the correct English translation *mammographic screening* is found in the Top_3 with the CMCBP because we have associated the French context vector of *mammographique* with the English context vector of *mammographic* and the French/English pair *dépistage/screening* is found in the dictionary. The other French MWTs correctly translated are mainly MWTs with a compositional structure for which one element is not found in the dictionary such as: *amélioration significative/significant benefit* (Top_1), and *caractéristique tumoral/tumor charakteristik* (tumor characteristic) (Top_1) or without a compositional structure such as: *bras témoin/control arm* (Top_1),

and *curage axillaire/axillary dissection* (Top_{11}). From the MWTs incorrectly translated, we can point out two main cases. First, we find target MWTs semantically close to the French MWTs to be translated such as: *postmenopausalen frau* (*postmenopausal women*) (Top_5) and *prämenopausalen frau* (*premenopausal women*) (Top_7) for *femme ménopausé* (*menopausal women*). *Postmenopausalen frau* and *prämenopausalen frau* are morphological variants of *menopausalen frau* and should have been identified as thus by the term extraction program, but unfortunately the canonical form *amenopausalen frau* does not occur in the comparable corpora. Secondly, we found only a sub-part of the English MWTs such as: *node dissection* for *curage ganglionnaire* (*lymph node dissection*). This case needs further work as it deals with a fertility case that is not able to be solved with the term variant recognition program.

7 Related Work

The principle of translation compositionality is restrictive. Several studies have concentrated on enhancing the compositional approach: Robitaille et al. (2006) proposed a backing-off method: if there is insufficient data in the dictionary to translate an MWT of *n* content words, a scaled MWT with a length less than, or equal to, *n* is used instead. Morin and Daille (2010) proposed an extended compositional method that bridges the gap between MWTs of different syntactic structures through morphological links. The compositional approach is also called the "bag-of-equivalents" approach (Vintar, 2010) when the bilingual dictionary is built from a parallel corpus and contains all words that occur in the corpus and their suggested translation equivalents, together with a probability score. The "bag-of-equivalents" approach has been used for SMT to build a word-level translation lexicon from parallel corpora (Munteanu and Marcu 2006) and a cognate lexicon from comparable corpora (Koehn and Knight 2002).

Much of the work involving general or LSP comparable corpora has focused on extracting SWT translations using only contextual information (Fung, 1998; Rapp, 1999; Chiao and Zweigenbaum, 2002; Gaussier et al., 2004; Morin et al., 2007; Laroche and Langlais, 2010, among others). The contextual information method as defined by Fung (1998) gives very low results for MWTs: from the 785 non translated French MWTs, 483 French MTWS with an accuracy of 15.6% (Top_{10}) were found.

CMCBP is a new method dedicated to MWT that combines both the compositional and the contextual information. CMCBP significantly improves both the compositional method commonly used for bilingual alignment of MWTs extracted from comparable corpora, and the contextual information method we obtained from English: 514 French translations of MWTS with a precision of 56.8% and 510 German translations of MWTS with a precision of 51.2% for Top_{10}.

8 Conclusion

In this study, we have investigated the compilation of bilingual terminologies from a specialized comparable corpus and show how to push back the limits of the compositional approach used in alignment programs to translate MWTs. We have proposed CMCBP: a compositional method enhanced with pre-processed context information. The experiments that we carried out have shown that we increase the results of the compositional approach by providing a significant number of additional correct lexical entries that could not be identified either by the dictionary look-up or by compositional methods.

In future work, we will generalise this method to obtain an homogeneous modular design for all languages by reconsidering the rough distinction between simple and complex terms and applying the CMCBP both at the morphological and the lexical levels. We will investigate how

to improve the solving of the fertility problem for MWTs which produces incomplete translations. Fertility was only partially solved thanks to the term variation treatment associated to the CMCBP. We aim to modify the evaluation protocol by accepting one-to-many translations in the case of synonym or semantically-related translation candidates that are not handled through term variation processing.

Abstract
In natural language generation using symbolic grammars, state-of-the-art realisation rankers use statistical models incorporating both language model and structural features. The rankers depend on multiple structures produced by the particular large-scale symbolic grammars to rank the output; for languages with smaller resources and in-development grammars, we look at the feasibility of an alternative source of structural features, unsupervised parsers. We show that, in spite of their lower quality of structure, raw sets of unsupervised parse features can be helpful with smaller language models; and that the parses do contain particular elements that can be highly useful, improving performance on our classification task by up to 10% on 60% of the test set leading to an overall improvement under a back-off model.

Title and Abstract in French

Une mauvaise structure est-elle mieux que pas de structure du tout? L'analyse non supervisée pour la sélection des réalisations

Dans plusieurs systèmes récents de génération de texte basés sur des grammaires symboliques, les résultats sont ordonnés selon leur acceptabilité par des modèles statistiques qui incorporent des modèles de Markov et des traits structurels. Ces modules d'ordonnancement dépendent de diverses structures produites par la grammaire, ce qui présuppose une grammaire suffisamment développée. Pour les langues à faibles ressources ou pour les grammaires en cours de développement, nous étudions ici la viabilité d'une source alternative de traits structurels: les analyseurs non supervisés. Nous démontrons que, en dépit de la faible qualité des structures produites, elles contiennent des éléments qui peuvent être très utiles pour les langues peu dotées, permettant d'améliorer de 10% la performance de notre classificateur pour 60% des phrases de notre corpus de test.

Keywords: natural language generation, realization ranking, unsupervised parsing.

Keywords in French: génération de langue naturelle, analyseur statistique non supervisé.

1 Condensed 2-page version in French

Les systèmes de génération de textes peuvent produire plusieurs textes de qualité variable pour les mêmes données. Cela a mené à la création d'algorithmes de sélection pour choisir le meilleur texte (Langkilde-Geary, 2000; Velldal and Oepen, 2005; Cahill et al., 2007, par exemple). Charniak (2001) a proposé d'utiliser les analyseurs statistiques comme source de structures sur lesquelles baser les algorithmes de sélection. À notre connaissance, seuls des analyseurs supervisés ont été utilisés à cet effet. Cependant, pour les systèmes basés sur des grammaires symboliques de modeste envergure ou en développement, trop peu de données sont disponibles, et les modèles existants s'appliquent mal. Dans cet article, nous étudions donc la possibilité d'utiliser un analyseur statistique non supervisé (Naseem et al., 2010) comme source alternative d'information pour la sélection automatique des textes générés, malgré la faible qualité des structures qu'ils produisent.

Nos travaux sont basés notamment sur ceux de Cahill et al. (2007), qui à la suite de Velldal and Oepen (2006), ont développé un modèle log-linéaire de réalisation pour une grammaire Lexical Functional Grammar (LFG). Comme eux, nous utilisons la plateforme Xerox Linguistics Environment (XLE) et construisons une banque d'arbres symétrique en analysant puis en regénérant les phrases. Ceci nous fournit à la fois des exemples positifs et négatifs. Nous utilisons les sections 2 à 21 du Penn Treebank (38 008 phrases) pour l'entraînement et la section 23 (2245 phrases) pour l'évaluation. Nous les avons analysées en utilisant la grammaire ParGram de l'anglais sur XLE (Butt et al., 2002), puis nous les avons regénérées en renversant la même grammaire pour produire de multiples paraphrases candidates. Nous avons rejeté les cas où la grammaire ne regénérait pas plus d'une phrase, ou plus de 1000, pour obtenir un corpus d'entraînement de 20 613 ensembles de paraphrases et un corpus de test de 1168 ensembles de paraphrases. Souvent, la grammaire n'arrivait pas à reproduire la phrase originale. Nous avons donc calculé la distance d'édition pour chaque paraphrase. Nous utilisons comme cas positif pour l'entraînement et pour le test la phrase regénérée ayant la plus petite distance par rapport à la phrase originale. Comme exemple négatif, nous avons comparé deux alternatives : la phrase ayant la plus grande distance (greatest, dans nos tableaux), et une phrase choisie au hasard parmi celles qui n'avaient pas la plus petite distance (random, dans nos tableaux).

Pour la classification, nous avons utilisé le système à entropie maximale MegaM (cinquième version) de Hal Daumé III. Pour fins de comparaison, nous avons reproduit la même méthode avec deux analyseurs supervisés : celui de Stanford (Klein and Manning, 2003) et celui de Charniak et Johnson (2005) (ci-après, C&J). Nous couplons les analyseurs à des modèles de Markov : un grand, construit avec SRILM (Stolcke, 2002) sur le corpus Gigaword, et un petit, afin d'imiter les conditions de développement pour des petites grammaires. Nous utilisons ces modèles de Markov à la fois comme modèles de base et en combinaison avec les modèles structurels. En outre, parce que le principal obstacle à l'utilisation d'un analyseur non supervisé est la faible qualité des analyses qu'il produit (voir Figure 1 pour une analyse non supervisée, par opposition à l'analyse supervisée de la Figure 2). Nous avons comparé deux approches pour identifier les dépendances les plus fiables à utiliser comme traits : le calcul de précision des dépendances individuelles, et la méthode de gain d'information.

Les résultats de notre expérience montrent que, sans surprise, les analyseurs non supervisés donnent des résultats nettement moins bons que les analyseurs supervisés. Cependant, ils sont utiles s'ils sont couplés à un modèle de Markov, même de taille modeste. L'utilisation de traits d'analyse seuls donne quand même des résultats meilleurs qu'un simple modèle de Markov. En conclusion, donc, les analyseurs non supervisés peuvent être utiles. En général, les traits qu'ils fournissent contribuent à améliorer les résultats obtenus avec un modèle de Markov de taille modeste, du type qu'on trouve normalement pour les langues peu dotées. Ils contribuent aussi très fortement à améliorer

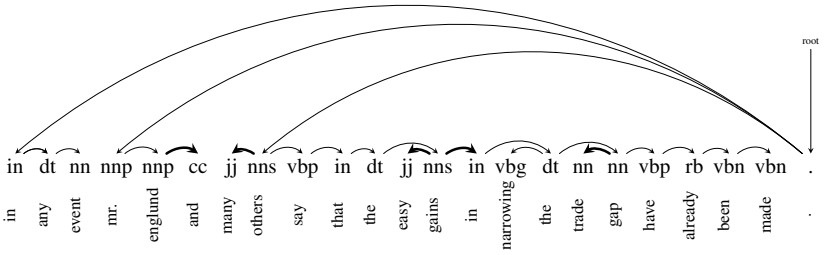

Figure 1 – Unsupervised dependency tree for a sample sentence.//Analyse non supervisée pour une phrase.

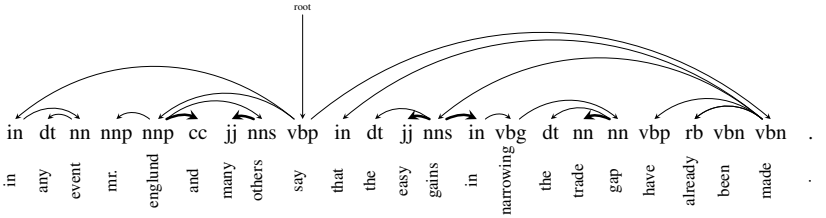

Figure 2 – Supervised dependency tree for sample sentence of Fig 1.//Analyse supervisée pour la même phrase qu'à la Figure 1.

les résultats pour un échantillon respectable du corpus de test, une fois que les traits utiles ont été identifiés par la méthode de gain d'information : nous avons observés des gains de précision de 10% dans 60% des phrases du corpus de test, ce qui rend possible l'utilisation d'un modèle de repli.

2 Introduction

Natural Language Generation (NLG) systems take some machine-oriented input such as databases, knowledge bases or logical forms and produce human-like text. The realization involves making many decisions on the surface representation of a sentence, including lexical selection, use of referring expressions, and word order. In general, such systems can thus generate multiple outputs, some of which are genuine good paraphrases, some of which may sound somewhat marked or odd out of context, and some of which may be (due to system limitations) incorrect.

This observation led to the idea of taking the possible outputs and ranking them, in the earliest work by use of a language model (LM) (Langkilde-Geary, 2000) and later by injecting new features like headwords, constituent category and Part of Speech (POS) tags (Langkilde-Geary, 2002). This idea was developed further for handcrafted symbolic grammars based on linguistic formalisms that have been used for generation. In the Head-driven Phrase Structure Grammar (HPSG) system LOGON, Velldal and Oepen (2005) improve on this by using a maximum entropy model incorporating both a LM and features derived from HPSG structures for the candidate outputs; this drew on earlier developments in the field of statistical parsing that used such features for reranking (Johnson et al., 1999; Riezler et al., 2002, for example). Cahill et al. (2007) and White and Rajkumar (2009) similarly show that ranking for Lexical Functional Grammar (LFG)- and Combinatory Categorial Grammar (CCG)-based systems respectively can be improved by models incorporating a LM and structural features.

All of these rankers depend on multiple structures produced by the respective large-scale symbolic grammars to rank the output. For much smaller symbolic grammars, and those in the process of development — e.g. LFG grammars for Indonesian (Arka et al., 2009) or Arrernte (Dras et al., 2012), or HPSG grammars for Persian (Müller, 2010) or Wambaya (Bender, 2008) — these multiple structures will not be available or will be quite impoverished. The goal of this paper then is to investigate using other sources of structural information that will be available for such languages: specifically — since such languages are also often unlikely to have treebanks — unsupervised statistical parsers. Unsupervised parsers have been motivated by possible application in contexts where large treebanks for training supervised parsers are absent (Klein and Manning, 2004, for example), but given their very modest performance with respect to supervised alternatives it is an open question as to whether the structures they produce have any extrinsic application. We aim to give an answer to this question in the context of realisation ranking.

In Section 3 we look at some previous work on reranking in realization in more depth, and more briefly note work on parser-based models for ranking and on unsupervised parsing. In Section 4 we describe our models based on statistical parsers, and the experimental set-up for investigating them. In Section 5 we discuss our results, and conclude in Section 6.

3 Related Works

Reranking in Realization Using statistical models that can combine a wide range of features to rank candidate outputs is standard across many applications, such as parse selection and Machine Translation (MT). They have also been applied to realisation ranking in NLG, to select the best of a set of candidate generated sentences. Here we review some of these, with a focus on the work of Cahill et al. (2007), as this is the setup closest to the one we use in this paper.

Velldal and Oepen (2006) implemented realisation ranking in the context of an MT system that uses a hand-crafted HPSG grammar to generate sentences from semantic specifications. Their system produced multiple candidate sentences which were ranked under three different models: an n-gram

LM; a discriminative maximum entropy model using (HPSG) structural features; and a combination of the two, which produced the best results.

To provide training data for the model, they constructed a 'symmetric treebank' (Velldal et al., 2004) composed of:

1. a set of pairings of surface forms and associated semantics;
2. a set of alternative analyses for each surface form; and
3. a set of alternative realisations of each semantic form.

The preferred realisations are automatically specified by comparing the yields of the generated sentences with the original strings in the treebank (for them, the Redwoods English treebank); this gives the sets of positive and negative (i.e. all non-original) examples for the maxent learner.

Cahill et al. (2007) drew on this to develop a log-linear model for realisation in an LFG context. They worked with a large-scale hand-crafted grammar of German, as they were investigating applicability of the approach to a language with freer word order than English, and generated from f-structures using the XLE system (Maxwell and Kaplan, 1993). They similarly constructed a symmetric treebank, and also had as their goal to re-generate the strings in the original treebank.

For structural features in their model, the authors defined 186,731 instantiated templates based on Riezler et al. (2002), Rohrer and Forst (2006) and Riezler and Vasserman (2004); 1,471 of these actually occurred in their training data. The feature templates included information from both c-structure (e.g. simple features such as number of times a particular category label occurs, or compound features such as number of times it dominates another) and f-structure (e.g. frequency of relative order of subject and object), sentence length and LM scores. Structural features here contributed more strongly than for English.

Which structural features are effective in realisation ranking is still an open question. For example, in the context of CCG, Rajkumar and White (2010) found that features reflecting animacy agreement between nouns and relative clauses, and number agreement between subject and verb, were helpful. White and Rajkumar (2012) found that explicitly representing dependency lengths led to shorter average dependencies, in line with psycholinguistic evidence for human-produced sentences, and to better generated text. And Filippova and Strube (2009) found that while trigram LMs are appropriate for phrase linearisation in German, at a clause level (longer) dependency features produced better results.

Parser-based Ranking Charniak (2001) proposed the idea of using statistical parsers as a kind of structural language model. The idea has been applied a number of times in MT, for example by Charniak et al. (2003) or Post and Gildea (2008); it has also been applied in NLG, where Mutton et al. (2007) showed that a combination of parser-based metrics correlated with human judgements of the quality of generated text. To our knowledge, all work applying parser-based ranking has used supervised parsers. There is also an interesting piece of work by Cherry and Quirk (2008) where implicit discriminative syntactic LMs are constructed, using a latent Support Vector Machine (SVM) to train an unlexicalised parser to judge sentences produced by an MT system. The authors discuss some similarities to unsupervised parsing, in that both sorts of parsers are trained on sentences without the benefit of annotated parse trees. Using unsupervised parse trees as we do in this paper, however, can benefit from lexicalisation and, potentially, linguistic knowledge embodied in the parser (see below).

Unsupervised Parsers The first unsupervised parser that convincingly beat fairly simple baselines, such as constructing a right-branching tree, was the DMV model of Klein and Manning (2004), which combined constituency and dependency parsing to produce a better unsupervised parser than either separately. There have been various developments in unsupervised parsing since then: Headden III et al. (2009) introduced basic valence frames and lexical information, along with a smoothing technique to handle resulting data sparsity; Berg-Kirkpatrick and Klein (2010) used a phylogeny-structured model of parameter drift; and Naseem et al. (2010) used a single set of manually specified language-independent rules characterising syntactic dependencies across languages, as a soft constraint during the inference of the probabilistic model. We use this last one in our work, as it gives state-of-the-art results, and embodies potentially useful hard-coded universal tendencies. Notwithstanding that state-of-the-art performance, directed dependency results for that system range from only 50.9% (Slovene) to 71.9% (English), and importantly, as in previous work, these cross-linguistic evaluations are only carried out on sentences of 10 or fewer words.

4 Experimental Setup

Our goal is to evaluate the usefulness of the structural information proposed by an unsupervised parser in assessing the quality of sentences generated by a symbolic grammar, given its noticeably lower quality than supervised parsers. Like Cahill et al. (2007), we use the XLE system and construct a symmetric treebank by parsing and re-generating sentences: this gives both positive examples (those that match the original sentence) and negative examples (those that don't). Details of the various aspects of this process follow.

4.1 Data and Evaluation

We took the Penn Treebank sections 2–21 for training, consisting of 38008 sentences, and section 23 for testing, consisting of 2245 sentences. We parsed them using XLE and the large-scale ParGram grammar of English (Butt et al., 2002), and then used XLE's re-generate facility to produce the multiple candidate realisations. As Cahill et al. (2007) did, we found that XLE could not parse and re-generate all sentences; and for the purposes of constructing a training set, only instances that re-generated more than one sentence were useful.[1] In addition, we excluded the few sentences that contained more than 1000 re-generated sentences. This resulted in a training set of 20613 (sets of) sentences and a test set of 1168 (sets of) sentences.

Also as Cahill et al. (2007) did, we found that not all sets of re-generated sentences contained the original sentence in its exact form: this was often because of small differences such as use of abbreviations (e.g. *Nov* for *November*) or use of punctuation. In contrast to their approach, where they discarded these cases, we used minimum edit distance (MED) to determine the re-generated candidate closest to the original.

Following this, we constructed training and test sets of pairs of re-generated sentences by taking as the positive example the one with smallest MED from the original sentence, and as the negative example one of two alternatives: either the one with largest MED (greatest) or a random selection from those candidates that did not have the smallest MED (random). greatest always gave the higher result in the classification experiments below, often by several percentage points (which is not surprising, as the differences are larger and the classification hence easier), so we mostly only report results for random.

[1] There is also a technical issue in re-generating numerals. To get around this problem, we preprocessed the text to change numerals to those that could be re-generated.

We used the maximum entropy learner MegaM (fifth release) by Hal Daumé III.[2] Our evaluation metric is the classification accuracy of predicting the positive example from each pair.

4.2 Parsers and Language Models

Before answering any questions about the usefulness of unsupervised parsers, we address the question, Do *supervised* parsers produce structural information that is useful for realisation ranking? If the answer is yes (and based on the work cited in Section 3 and others, we would think it likely), the supervised parsers and a large LM would constitute an upper bound on the efficacy of using parsers to rank candidate sentences generated by XLE. The supervised parsers we use are the Stanford parser (Klein and Manning, 2003) and the Charniak and Johnson (henceforth C&J) parser (Charniak and Johnson, 2005). These parsers are both quite accurate: the Stanford parser gets a labelled f-score of 85.61 on the WSJ, and the C&J 91.09.

From the Stanford parser we examined both horizontal slices of parse trees, in effect treating them as sets of CFG production rules, and dependencies; the production rules and dependencies were either lexicalised or unlexicalised, and the dependency relations either named or unnamed. This gives two constituency and four dependency feature representations from the Stanford parser: prod-rule-lex and prod-rule-unlex; and dep-lex-named, dep-lex-unnamed, dep-unlex-named and dep-unlex-unnamed.

C&J is a reranking parser; the reranker uses 13 feature schemas such as tuples covering head-to-head dependencies, preterminals together with their closest maximal projection ancestors, and subtrees rooted in the least common ancestor. We took two types of features from C&J: production rules; and the instantiated feature schemas from the parse reranking process, making them do 'double duty' as realisation ranking features. C&J is used as a complement to the Stanford parser here, with respect to production rules, as an easy way of getting something approximating the compound features used in realisation ranking discussed in Section 3.

The large LM was constructed using SRILM (Stolcke, 2002) on the Gigaword corpus.[3] We use the 64K 4-gram and the 64K 2-gram (where the size nK represents the use of the top n words occurring in the training text as vocabularies), which are at the two extremes of size. We refer to these as l-lm4 and l-lm2.

For the unsupervised structure that is the main interest of the paper, we used the parser of Naseem et al. (2010),[4] which constructs dependency trees. Relation names are not inferred, so the two alternative representations are lexicalised (unsuper-lex) and unlexicalised (unsuper-unlex).

For a small LM that would be of a realistic size for the scenario we are interested in — i.e. the development of a symbolic grammar for a language with few resources — we considered the size of corpora produced by *An Crúbadán*[5] (Scannell, 2007). This is a web crawler whose specific goal is the "automatic development of large text corpora for minority languages". As examples, it has produced corpora of ~2M words for Akan (Ghana), ~5M words for Tamil, and ~7M words for Turkmen. Consequently, we use the Penn Treebank (~4M words) as our realistically-sized LM. On this sized corpus, we derive both 4-gram and 2-gram LMs from SRILM using the default settings; we refer to these as s-lm4 and s-lm2.[6]

[2] MegaM software is available on `http://www.cs.utah.edu/~hal/megam/`.

[3] `http://www.keithv.com/software/giga/` was the source for these models. They used interpolated, modified Kneser-Ney smoothing, bigram cutoff 3, trigram cutoff 5.

[4] `http://groups.csail.mit.edu/rbg/code/dependency/`

[5] `http://borel.slu.edu/crubadan/`

[6] We note that these are in-domain LMs, in contrast to the Gigaword-derived ones, and so will have a bit of an advantage.

4.3 Models

Base models, supervised and unsupervised The basic models are then the structural models described above. We used the LMs both as baselines and in combination with the structural models. (Note that the C&J parser already includes a LM in its reranking feature templates that we use, so we do not combine in this case.) In the base cases, we use all structures (production rules, templates or dependencies as appropriate) returned by the relevant parser.[7]

For the unsupervised parser, the major issue is that the parses are generally of lower quality. As an illustration, Figures 1 and 2 represent unsupervised and supervised parses of the same sentence (common edges are indicated in bold). The supervised parse looks relatively reasonable, while the unsupervised parse makes some odd choices (*mr.* being a dependent of the root, the verb having no special status, etc), and contains many adjacent dependencies. Figures 3 and 4 represent another pair of parses, this one with a few longer dependencies than the previous pair of figures.

We take two approaches to finding higher quality individual dependencies for use as features: one is the calculation of fine-grained accuracy rates for dependencies, and the other is Information Gain (IG). In the case of fine-grained accuracy rates, we are assessing which dependencies are likely to be reliable, by comparison with a gold standard,[8] and in the case of IG, we identify which dependencies are particularly strongly associated with positive or negative examples.

Unsupervised with reliability-based selection To measure unsupervised dependency reliability, raw precision / recall scores would capture some of that notion — e.g. `VBD TO`, with 6593 gold-standard instances and 1520 correctly identified (recall = 0.231), is almost certainly more reliable than `NNP IN` with 7031 gold standard instances and only 547 correctly identified (recall = 0.078) — but they would obviously overrepresent low frequency dependency pairs, which are likely to be particularly unreliable. Taking the precision and recall scores as probabilities of correctness, we therefore adopted a prior α to smooth the scores. Given the relevant denominators N_p for precision or N_r for recall for each dependency pair type, our modified scores use $N_p + \alpha$ and $N_r + \alpha$ respectively; this leaves a probability mass $\frac{\alpha}{\alpha+N_p}$ (resp. $\frac{\alpha}{\alpha+N_r}$) for unseen instances of each dependency. By inspection of the actual raw scores on the training set, we chose $\alpha = 20$. We then select features with modified scores above various thresholds.

For lexicalised dependencies, with their much greater data sparsity issues, we based the choice on the corresponding unlexicalised dependency: if the parts of speech of the lexicalised dependencies matched an unlexicalised dependency above a particular threshold, we selected that lexicalised dependency. (So `the man` would deemed reliable if `DT NN` were deemed reliable.)

Unsupervised with IG selection We calculate IG over the training set, using a standard formulation of Yang and Pedersen (1997):

$$\begin{aligned} IG(r) = & -\sum_{i=1}^{m} \Pr(c_i) \log \Pr(c_i) \\ & + \Pr(r) \sum_{i=1}^{m} \Pr(c_i|r) \log \Pr(c_i|r) \\ & + \Pr(\bar{r}) \sum_{i=1}^{m} \Pr(c_i|\bar{r}) \log \Pr(c_i|\bar{r}) \end{aligned}$$

[7] In cases where the feature representation is the same for both positive and negative instances, we make a random choice.

[8] The Penn Treebank dependency gold standard was derived using `http://nlp.cs.lth.se/software/treebank_converter/`.

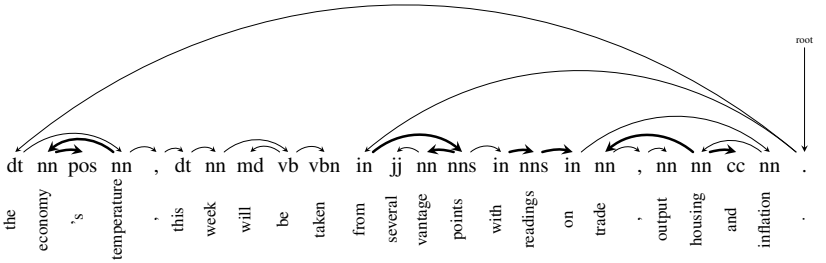

Figure 3: Unsupervised dependency tree for another sample sentence.

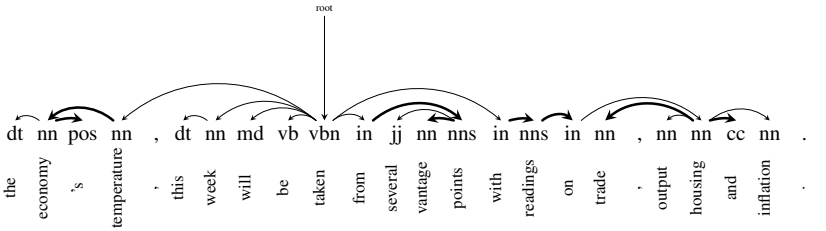

Figure 4: Supervised dependency tree for sample sentence of Fig 3.

with r representing a dependency, c a binary class, and $m = 2$. We then select features with IG scores above various thresholds. The application to unlexicalised features is straightforward: IG is applied to the unlexicalised dependencies, and some subset of these chosen based on the resulting ranking and a particular threshold. For lexicalised dependencies, there are two alternatives. One is to apply IG to the lexicalised dependencies directly (direct); the second is the same as the approach for unsupervised dependencies with reliability selection above, where we extract all the lexicalised dependencies that have corresponding selected unlexicalised dependencies (indirect).

Of course, both of these refinements of unsupervised parse features require some kind of annotation, and we discuss the implications for our scenario later in Section 5; but here we are just interested in the question of the extent to which unsupervied parsers can produce dependencies that are at all useful for realisation ranking.

5 Results

Base models (supervised) Table 1 gives classification accuracy results for the large LMs, and for the supervised parsers, both separately and in combination with the LM, all on the random test set. The key results here are:

1. Using parse features alone almost always outperforms the LM (except in the case of dep-unlex-

model	acc.%	+l-lm4	+l-lm2
l-lm4	68.36	-	-
l-lm2	64.16	-	-
C&J	90.50	-	-

dep-lex-unnamed	71.51	75.54	74.72
dep-unlex-named	69.88	72.92	71.55
dep-unlex-unnamed	63.41	66.75	65.04

Table 1: Classification scores for supervised parse features and large LM on random: accuracy on parse features; parse features plus large l-lm4 LM over these sentences; parse features plus large l-lm2 LM over these sentences

unnamed), and the combination with the LM always improves over just parse features alone. This is broadly in line with the findings discussed in Sec 3 on using structural features from symbolic grammars, and suggests that using external statistical parsers is a valid alternative approach to carrying out realisation ranking.

2. While the l-lm4 LM forms quite a strong baseline, the l-lm2 version is somewhat weaker. It does still, however, contribute to an improvement in performance when added to the dependency feature models, of around 2%. This is not unexpected, as it would be contributing information that is complementary to the dependencies, which (in the cases where the dependencies are not adjacent) give longer-distance information. For the same reason, adding this bigram data to the production rule models produces a much smaller improvement.

3. Production rule features are better than dependency features; presumably one reason for this is that there are more production rule features (i.e. the ones consisting of only non-terminal nodes in the tree).

4. The C&J parser's templates — one particular set of choices for representing compound structural features — outperform just production rules combined with a LM, quite substantially. This also fits with previous work on using compound features.

5. In comparison with the results for the greatest test set (Table 2), as mentioned above, random is always consistently lower, for each comparable cell in the table. This is expected on the assumption that our MED method for choosing positive and negative examples is an accurate reflection of their goodness with respect to the original sentence. There is generally the same pattern for subsequent results as well, so henceforth we only report random, as the more conservative of the two measures and as a more realistic scenario (comparing a reference sentence against some arbitrary one, not one that we know is the 'worst' of a set of candidates).

Base models (unsupervised) Table 3 gives results when unsupervised parse structures are combined with a large LM. Not surprisingly, these results are quite a lot worse than for the supervised: a drop of around 13% for lexicalised dependencies and 8% for unlexicalised. These are also lower than the LMs in Table 1. For a more detailed look, we calculated the classification accuracy over those sentences where the feature representation differed (which we refer to as the *effective test*

set) and hence the model makes a genuine prediction,[9] to see whether a back-off model would be appropriate: if the accuracy for the unsupervised models is higher than for the LM over the effective test set, the decision for that subset could be based on the unsupervised model decision, with a back-off to the LM. Table 3 includes the effective test set, and the unsupervised classification accuracy scores over that set, for each model.

The LMs may also differ over the effective test sets: we present the classification accuracies for these in Table 4 (for the large LMs) and Table 5 (for the small LMs). The tables include both the accuracy of the LMs alone (e.g. the column l-lm4), as well as the accuracy of the LM in combination with the unsupervised model (e.g. +l-lm4). It is apparent that the effective test sets for the unsupervised models are also in fact easier for the large LMs: their scores on these subsets are all higher than the overall LM accuracies. They are also higher than the unsupervised models, and the combinations are lower than for the LMs alone. The story is different for the small LMs: while the LMs are higher than the unsupervised models, the combinations are better than both, by 3% in the lexicalised case. The conclusion here would be that if a very large LM is available, raw unsupervised parse features would not be helpful; but if only a small LM is available, they would still contribute.

Unsupervised with reliability-based selection Table 6 presents the results for our recall-based reliability measure, along with the effective test set sizes for four thresholds across dependencies with a positive reliability score.[10] These are uniformly poor, and in fact marginally worse than the raw unsupervised features in Table 3, so we do not present combinations with the LMs. We looked at the 10 highest- and 10 lowest-ranked features under this measure (Table 7), along with their raw counts in the training corpus. The highest-ranked ones were believable as reliable instances of dependencies: infinitival *to* in VB TO seems likely to be often correct, as does existential *there* in the first three cases. However, it is quite possible that many of the reliable ones such as PRP VBZ are actually poor at distinguishing between positive and negative examples by virtue of their frequency — they may occur equally often with both, in the same way that words like *the* are useless in general text classification.

Another possibility is that our reliability metric is not capturing the right phenomenon: that it is flagging as errors systematic intentional choices that the unsupervised parser is making, just because they happen to disagree with the systematic choices of the gold standard. For example, in Figures 3 and 4, the unsupervised parse contains the dependency MD VB, choosing serial attachment of auxiliaries and modals to the main verb, while the supervised parser contains MD VBN, choosing attachment of all to the main verb instead. Here the unsupervised parser does not necessarily seem incorrect. Indeed, the very smallness of the proportion of correct instances in the lowest-ranking dependency pairs in Table 7 suggests that these are not just random (and almost always incorrect) choices by the unsupervised parser; four of them in fact appear to relate to the sort of verb attachment choices mentioned. The issue of the difficulty of comparing dependency treebanks in general, perhaps because of fairly arbitrary decisions about headedness, is raised in Zeman et al. (2012); this would appear to be relevant to the task here too.

[9] Recall that in cases where the model cannot make a prediction, it chooses at random.

[10] This consequently does not include dependencies with recall-based reliability zero. We do not present the precision-based ones here.

6–10	VB VBG	NNS TO	IN RBR	VBN TO	DT RP

Table 9: Highest ranking features based on IG.

Unsupervised with IG selection Table 8 shows the results for selecting the top $k\%$ unsupervised parse features ranked by positive IG scores.[11] We see a dramatic improvement in the lexicalised case (direct) over the raw features (Table 3). The effective test set also falls a lot more for the direct lexicalised case; this is not surprising, as the top (say) 25% lexicalised features on the training set are much less likely to occur in the test set than the top 25% unlexicalised features. On the other hand, the indirect lexicalised case — where lexicalised features are instantiated on the basis of IG-ranked *unlexicalised dependencies* — have a sentence coverage that is much greater, as would be expected, but perhaps surprisingly an accuracy that is comparable to the direct method, and in fact even higher for three of the four thresholds presented in Table 8. For the 25% threshold on the indirect method, the model performs around 10% higher on around 60% of the total test set, making a back-off model a very suitable option.

Table 9 presents the top 10 unlexicalised features. It is not immediately apparent why there is a preponderance of paired verbs, such as VB VBG or VB TO (with the infinitival *to* probably indicating another verb following). Perhaps verb sequences indicate poor sentences, although this would require further inspection of the data.

Illustration of Generated Content To see how unsupervised parses, though bad, might contribute useful structure, we present an example where the unsupervised parse model predicted the better candidate, while the other models did not. The original sentence is given in (1), the preferred candidate in (2), and the dispreferred candidate in (3). The preferred candidate is basically the same as the original, slightly odd punctuation notwithstanding, while the dispreferred candidate has obvious problems in terms of ordering.

(1) For example, their selling caused trading halts to be declared in USAir Group, which closed down 3 7/8 to 41 1/2, Delta Air Lines, which fell 7 3/4 to 69 1/4, and Philips Industries, which sank 3 to 21 1/2.

(2) For example their selling, caused trading halts to be declared in USAir Group which closed, down 3 7/8 to 41 1/2 Delta Air Lines which fell 7 3/4 to 69 1/4 and Philips Industries which sank 3 to 21 1/2.

(3) For example to be declared in USAir Group, their selling, caused trading halts which closed, down 3 7/8 to 41 1/2 Delta Air Lines which fell 7 3/4 to 69 1/4 and Philips Industries which sank 3 to 21 1/2.

Figure 5 shows the unsupervised (upper) and supervised (lower) parses for the preferred candidate (2). For the most part, the supervised parser makes sensible linguistic choices: it identifies as the head of e.g. *Delta Air Lines which fell 7 3/4 to 69 1/4* the final noun of the named entity, which in turn is a dependant of the head of the previous parallel clause; the unsupervised parser, by contrast,

[11] That is, those cases with an IG of zero — i.e. entirely non-distinguishing between positive and negative examples — are excluded, which is why the 100% scores are higher than for the raw features of Table 3.

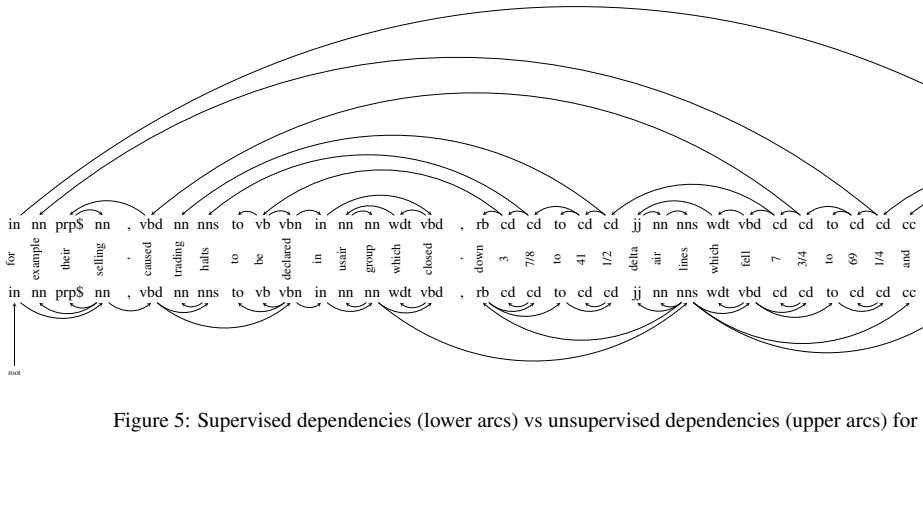

Figure 5: Supervised dependencies (lower arcs) vs unsupervised dependencies (upper arcs) for

has as the ultimate head the final numeral, with odd choices in the intermediate edges as well such as *which* being the head of the named entity in each case. However, the supervised parser makes a fundamental error in grouping two chunks of numerical quantities (i.e. *down 3 7/8 to 41 1/2* and *fell 7 3/4 to 69 1/4*) being associated with the same named entity. The unsupervised parse does not do this: while it makes odd choices, they are consistent odd choices. This consistency of choices may in fact not be accidental, and is further reason to reconsider our approach to assessing the reliability of unsupervised parse edges.

Implications If the reliability-based selection for unsupervised parse features had proved effective, it would have been necessary to find some mechanism to approximate a check against a gold standard, such as constructing a committee of unsupervised parsers and using only those dependencies that received a sufficient number of votes. However, this is not warranted by the results.

For the IG-based selection, what is necessary is a binary annotation of sentence pairs as preferred or dispreferred. This is much less intensive than treebank annotation, and so a reasonable alternative to constructing supervised parsers. As noted, a large LM outperforms raw unsupervised features; but even constructing large corpora (semi-)automatically for many of the world's languages, as per Scannell (2007), is challenging, and the IG-selected features in any case do better than the large LM alone and better still in conjunction with it.

6 Conclusion

For symbolic grammars that are small and/or in development, there may well not be many resources to draw on for building good realisation ranking models for natural language generation. In this paper we have examined unsupervised parsers as a possible source of structural features for such models, notwithstanding their generally much poorer quality of parses than supervised parsers.

We found that they can indeed be useful. In the general case, unsupervised parse features contribute in the case of smaller language models, of the sort that might be available for many less resourced languages. They also contribute very strongly over reasonable sized subsets of the test set once useful features have been identified by Information Gain: there are improvements of up to 10% in classification accuracy over 60% of the test set, making a model that uses unsupervised features and then backs off to a language model an attractive option. This would be feasible in scenarios where it is possible to annotate pairs of sentences as preferred and dispreferred.

Choosing features by a reliability-based measure did not prove useful. However, this may be related to systematic choices made by the unsupervised parser that were different from the gold standard's choices, rather than bad parsing; an option for aligning systematic choices is the HamleDT approach and software of Zeman et al. (2012). Another option for improving performance is the use of compound features, as is used in much of the work discussed in Section 3. The results in this paper for the supervised parsers showed that the model with compound (or 'higher order') features dramatically outperformed the ones with simple features; it could be promising to extend these to the dependency models, as for example in their use in parse reranking, such as by Hall (2007) and Wang and Zong (2011). In addition to evaluating the approach by measures other than binary classification accuracy (e.g. bleu or the ranking score of Cahill et al. (2007)), and examining other potential comparators (e.g. the treebank-trained generator of Belz (2005)), the next major step would be applying it to one of these smaller languages that has motivated the work in this paper.

ABSTRACT

Psycholinguistic phenomenon of communication accommodation (Giles et al., 1991) is probably one of the most important contributions in the interdisciplinary field of linguistics, psychology, information, and communication theory. Existing works have applied this theory to various domains like gesture, linguistics, backchannels, and even social media like tweets. In this work, we analyze the psycholinguistic phenomenon of linguistic style accommodation in online debates. First, we present a Joint Topic Expression (JTE) model for modeling debate posts and use it to generate our unique dataset for studying accommodation in debates. Specifically, we analyze the phenomenon across agreeing/disagreeing debating pairs generated using our JTE model. Second, we propose a formal framework for analyzing the linguistic phenomena of accommodation in online debates. Experiments on a large collection of real-life debate posts reveal very interesting insights about the complex phenomenon of psycholinguistic accommodation in online debates.

KEYWORDS : Linguistic style accommodation, linguistic convergence, accommodation in debates, online debate conversations.

Proceedings of COLING 2012: Technical Papers, pages 1831–1846,
COLING 2012, Mumbai, December 2012.

1 Introduction

The psycholinguistic theory of communication accommodation was developed by Howard Giles (Giles et al., 1991). It argues that "when people interact, they adjust their speech, their vocal patterns and their gestures, to accommodate to others". This adjustment or accommodation tends to occur unconsciously, i.e., people tend to instinctively converge to one another's communicative behavior. Over the past five decades, this phenomenon has received a great deal of attention across a myriad of domains: posture (Condon and Ogston, 1967), speech pause length (Jaffe and Feldstein, 1970), head nodding (Hale and Burgoon, 1984), generic linguistic style (Niederhoffer and Pennebaker, 2002), tweets (Danescu-Niculescu-Mizil et al., 2011), etc. This work presents a formal framework to model communication accommodation in online debates. Online debate forums are perhaps the most popular form of debates where people participate in discussions of various issues like politics, religions, society, human rights, etc. It is naturally very interesting to analyze the phenomenon of accommodation in debates.

In this work, we focus on linguistic style accommodation in debates. In detail, we will perform the following types of analysis: stylistic cohesion, stylistic accommodation, influence, and accommodation across both agreeing and disagreeing debate posts in online debates. We use the linguistic style markers in LIWC (Pennebaker et al., 2007) to measure the amount of linguistic accommodation exhibited. The underlying hypothesis behind the "measurement" of linguistic accommodation using linguistic style markers is based on the prior works in (Gonzales et al., 2010; Niederhoffer and Pennebaker, 2002; Taylor and Thomas, 2008), which have shown that linguistic accommodation being most pronounced in style dimensions is a good metric for measurement. Linguistic "style" here denotes content independent language constructs, i.e., *how* things are said as opposed *what* is said. Linguistic style has also been shown (Levelt and Kelter, 1982) to be exhibited somewhat unconsciously and hence it is an interesting target for analysis, especially in the domain of online debates. We will explain the meaning of these concepts in detail in the subsequent sections.

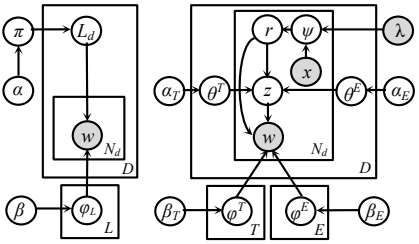
To perform these analyses, we need the right data. That is, we need to classify debate posts into those showing agreement and those showing disagreement. Given a large set of debate posts, this problem can be solved using supervised learning. Manually labeling of posts is also possible, but it is too time consuming because we will need to label a huge number of posts in order to ensure that we have enough data to produce statistically reliable results. We take a learning approach. However, the issue is the effective features that should be used for learning. An important characteristic of the debate posts is that they almost always use some specific expressions to express agreement or disagreement, e.g., "I agree," "you're correct," etc., for agreement and "I disagree," "you speak nonsense," etc., for disagreement. Discovering such expressions clearly help improve classification. Accurate classification is essential for our subsequent analysis.

We propose to use generative models for the discovery of such expressions and use them for classification. In fact, such models themselves can be used for classification directly too. In the next section, we propose the models for modeling debate posts, which include the Naïve Bayes model (both supervised and unsupervised) and the Joint Topic Expression (JTE) model. We also report classification results. Section 3 introduces the LIWC framework (Pennebaker et al., 2007). Section 4 presents our probabilistic framework where we analyze linguistic phenomenon like stylistic cohesion, accommodation, influence, and their effect across arguing nature of debating user pairs. Section 5 concludes our work.

2 Modeling debate posts for linguistic style analysis

We employ two generative models (Sections 2.1, 2.2) to accomplish the first task of debate post

classification and then generate the data for linguistic style experiments in Section 2.3. However, before proceeding, we briefly review related work on debates. Existing works have two major threads of research. The first thread puts debaters into support and oppose camps. Agrawal et al. (2003) used a graph method to place discussion participants into camps. Murakami and Raymond (2010) used a rule-based method to perform the same task. In (Somasundaran and Wiebe, 2009), opinions/polarities which were correlated with a debate-side were used to classify a post as for or against. However, this thread of research does not model agreements and disagreements in debates.



(a) Naïve Bayes (b) JTE

FIGURE 1: Graphical models in plate notations.

Another thread of research (Galley et al., 2004; Hillard et al., 2003; Thomas et al., 2006, Bansal et al., 2008; Burfoot et al., 2011) studies speaker interaction in the context of discourse and speech act classification of conversational speeches (e.g., U.S. Congress meeting transcripts). The above works mostly use three types of features: *durational* (e.g., time taken by a speaker, time separating two speakers, duration of speaker overlap, speech rate, etc.); *structural* (e.g., no. of speakers per side, no. of spurts with and without time overlap, no. of votes cast by a speaker on a bill, vote labels for and against the bill under discussion); and lexical (e.g., first word, last word, unigrams, *n*-grams, etc.) features to perform classification. While this is related to our approach of modeling agreeing and disagreeing debate posts, online debate forums (e.g., Volconco.com) are textual as opposed to conversational speeches. Thus, *durational* and *structural* features used in the prior works (e.g., time taken by a speaker, speech rate, speaker overlap, votes, etc.) are not directly applicable for our task.

Our approach relies on strong lexical features which we call AD-expressions. AD-expressions refer to Agreement (e.g., "I agree", "you're correct") and Disagreement (e.g., "I disagree", "you speak nonsense") expressions. As AD-expressions are an integral part of debates (because while arguing people invariably emit AD-expressions), our approach aims to first mine AD-expressions which serve as strong lexical features and further exploit them to classify debate discussions into agreeing and disagreeing posts. To model debate posts and lexical AD-expressions, we use hierarchical Bayesian generative models. Generative models like LDA (Blei et al., 2003) and PLSA (Hofmann, 1999) have been proved to be very successful in modeling topics and other textual information in an unsupervised manner. For our task of modeling and classifying debate posts we compare performance using two models. The first is the Naïve Bayes model (which serves as a baseline model) and the second is our Joint Topic Expression (JTE) model.

2.1 Naïve Bayes graphical model

This section introduces the well-known Naïve Bayes model in the light of unsupervised Bayesian graphical models. In generative models for text, words and phrases (*n*-grams) are viewed as random variables, and a document is viewed as a bag of *n*-grams and each *n*-gram takes a value from a predefined vocabulary. In this work, we use up to 4-grams, i.e., n = 1, 2, 3, 4. For simplicity, we use *terms* to denote both *words* (unigrams or 1-grams) and *phrases* (*n*-grams). We denote the entries in our vocabulary by $v_{1\ldots V}$ where V is the number of unique terms in the vocabulary. The entire corpus contains $d_{1\ldots D}$ documents. A document (e.g., debate post) d is represented as a vector of terms W_d with N_d entries. W is the set of all observed terms with

cardinality, $|W| = \sum_d N_d$. Also, let L_d denote the document class variable ($a$greeing or $d$isagreeing) we are trying to predict, i.e., $L_d = a$ or $L_d = d$. Lastly, let π denote the prior over document labels and φ_L the label specific distribution over vocabulary terms. Following Bayesian inference, our goal is precisely to choose L_d for W_d that maximizes $P(L_d|W_d)$. Applying Bayes rule, we get $L_d = \text{argmax}_L\, P(L|W_d) = \text{argmax}_L\, P(W_d|L)P(L)$. This lays the foundation for the generative process of the model (Figure 1a) which we detail as follows:

A. Draw $\pi \sim Beta(\alpha)$
B. For each label $L = \{a, d\}$, draw $\varphi_L \sim Dir(\beta)$
C. For each debate post $d \in \{1 \dots D\}$:
   i. Draw $L_d \sim Bernoulli(\pi)$
   ii. For each term $w_{d,j}, j \in \{1 \dots N_d\}$:
      a. Emit $w_{d,j} \sim Mult(\varphi_{L_d})$

To learn the model, we employ posterior inference using Monte Carlo Gibbs sampling. The samplers for L and φ_L are given as follows:

$$P(L_d = L|L_{\neg d}, W_{\neg d}, \varphi_L) \propto \frac{n_L + \alpha - 1}{D + 2\alpha - 1} \prod_{v=1}^{V} \left(\varphi_{L,v}\right)^{n_v^d} \quad (1)$$

$$\varphi_L \sim Dirichlet(n_v^L + \beta) \quad (2)$$

where n_L is the number of documents with label L, n_v^d is the number of times term v appears in document d, and n_v^L is the number of times term v appears in all documents with label L. Learning the model according to the Gibbs sampler in (1) and (2) results in a fully unsupervised Naïve Bayes model for document label (agreeing or disagreeing) prediction. However, if we have some labeled data (more details in Section 2.3), we can add supervision into the model using a simple trick. Given a set of labeled documents, D_{Train}, where each post has a document label (i.e., agreeing or disagreeing), we can employ a supervised Naïve Bayes model keeping the label variable, L_d of the training documents fixed to the supplied labels (i.e., we do not samples $L_d, d \in D_{Train}$). Fixing the labels will effectively serve the purpose of "ground truth" evidence for the distributions that created them.

2.2 JTE: A Graphical Model for Debates

We now present the Joint Topic Expression (JTE) model, which was proposed for analyzing debates in (Mukherjee and Liu, 2012). JTE is a hierarchical generative model motivated by the joint occurrence of various topics and AD-expressions in debate posts. A typical debate post mentions a few topics (using semantically related topical terms) and expresses some viewpoints with one or more AD-expression types (using semantically related expressions). This observation motivates the generative process of our model where documents (posts) are represented as random mixtures of latent topics and AD-expression types (Agreement and Disagreement).

Assume we have $t_{1\dots T}$ topics and $e_{1\dots E}$ expression types in our corpus. Note that in our case of Volconvo.com debate posts, based on reading various posts, we hypothesize that $E = 2$ as in such debates, we mostly find 2 expression types: Agreement and Disagreement[1]. Let $\psi_{d,j}$ denote the distribution over topics and AD-expressions with $r_{d,j} \in \{\hat{t}, \hat{e}\}$ denoting the binary indicator/switch variable (topic or AD-expression) for the j^{th} term of d, $w_{d,j}$. In this work, a document is viewed as a bag of n-grams and we use terms to denote both words (unigrams) and

[1] The hypothesis has been statistically validated using the perplexity metric in (Mukherjee and Liu, 2012). The model is however very general and can be used with any number of expression types, e.g., for modeling review comments in (Mukherjee and Liu, 2012a) with E = 6 expression types: Agreement, Disagreement, Thumbs-up, Thumbs-down, Question, and Answer-acknowledgement.

phrases (n-grams). $z_{d,j} \sim Mult(\theta_d)$ denotes the appropriate topic ($\theta^T_{d,t}$) or AD-expression type ($\theta^E_{d,e}$) index to which $w_{d,j}$belongs. Also let $\varphi^T_{t,v}$ and $\varphi^E_{e,v}$denote the topic and expression type specific multinomials over the vocabulary respectively. JTE is a switching graphical model performing a switch between expressions and topics similar to that in (Zhao et al., 2010). The switch is done using a maximum entropy (Max-Ent) model. The idea is due to the observation that topical and AD-expression terms usually play different syntactic roles in a sentence. Topical terms (e.g., "U.S. senate", "marriage", "income tax") tend to be noun and noun phrases while expression terms ("I refute", "how can you say", "probably agree") usually contain pronouns, verbs, wh-determiners, and modals. In order to utilize the part-of-speech (POS) tag information, we place the topic/AD-expression distribution $\psi_{d,j}$ (the prior over the indicator variable $r_{d,j}$) in the term plate (Figure 1) and set it from a Max-Ent model conditioned on the observed feature vector $\overrightarrow{x_{d,j}}$ associated with $w_{d,j}$ and the learned Max-Ent parameters λ. In this work, we encode both lexical and POS features of the previous, current and next POS tags/lexemes of the term $w_{d,j}$. More specifically, the feature vector is $\overrightarrow{x_{d,j}} = [POS_{w_{d,j}-1}, POS_{w_{d,j}}, POS_{w_{d,j}+1}, w_{d,j} - 1, w_{d,j}, w_{d,j} + 1]$. For phrasal terms (*n*-grams), all POS tags and lexemes of $w_{d,j}$ are considered as features. The generative process of JTE (Figure 1b) is given by:

A. For each C-expression type e, draw $\varphi^E_e \sim Dir(\beta_E)$
B. For each topic t, draw $\varphi^T_t \sim Dir(\beta_T)$
C. For each comment post $d \in \{1 \dots D\}$:
   i. Draw $\psi_d \sim Beta(\gamma \boldsymbol{u})$
   ii. Draw $\theta^E_d \sim Dir(\alpha_E)$
   iii. Draw $\theta^T_d \sim Dir(\alpha_T)$
   iv. For each term $w_{d,j}, j \in \{1 \dots N_d\}$:
      b. Draw $r_{d,j} \sim Bernoulli(\psi_d)$
      c. if $(r_{d,j} = \hat{e})$ // $w_{d,j}$is a C-expression term
            Draw $z_{d,j} \sim Mult(\theta^E_d)$
         else // $r_{d,j} = \hat{t}$, $w_{d,j}$is a topical term
            Draw $z_{d,j} \sim Mult(\theta^T_d)$
      d. Emit $w_{d,j} \sim Mult(\varphi^{r_{d,j}}_{z_{d,j}})$

We employ posterior inference using Monte Carlo Gibbs sampling. Denoting the random variables $\{w, z, r\}$ by singular subscripts$\{w_k, z_k, r_k\}$, $k_{1\dots K}$, where $K = \sum_d N_d$, a single iteration consists of performing the following sampling:

$$p(z_k = t, r_k = \hat{t} | W_{\neg k}, Z_{\neg k}, R_{\neg k}, w_k = v) \propto \frac{\exp(\sum_{i=1}^{n} \lambda_i f_i(x_{d,j}, \hat{t}))}{\sum_{y \in \{\hat{t}, \hat{e}\}} \exp(\sum_{i=1}^{n} \lambda_i f_i(x_{d,j}, y))} \times \frac{n^{DT}_{d,t\,\neg k} + \alpha_T}{n^{DT}_{d,(\cdot)\,\neg k} + T\alpha_T} \times \frac{n^{CT}_{t,v\,\neg k} + \beta_T}{n^{CT}_{t,(\cdot)\,\neg k} + V\beta_T} \quad (3)$$

$$p(z_k = e, r_k = \hat{e} | W_{\neg k}, Z_{\neg k}, R_{\neg k}, w_k = v) \propto \frac{\exp(\sum_{i=1}^{n} \lambda_i f_i(x_{d,j}, \hat{e}))}{\sum_{y \in \{\hat{t}, \hat{e}\}} \exp(\sum_{i=1}^{n} \lambda_i f_i(x_{d,j}, y))} \times \frac{n^{DE}_{d,e\,\neg k} + \alpha_E}{n^{DE}_{d,(\cdot)\,\neg k} + E\alpha_E} \times \frac{n^{CE}_{e,v\,\neg k} + \beta_E}{n^{CE}_{e,(\cdot)\,\neg k} + V\beta_E} \quad (4)$$

where $k = (d, j)$ denotes the j^{th} term of document d and the subscript $\neg k$ denotes assignments excluding the term at (d, j). Counts $n^{CT}_{t,v}$ and $n^{CE}_{e,v}$ denote the number of times term v was assigned to topic t and expression type e respectively. $n^{DT}_{d,t}$ and $n^{DE}_{d,e}$ denote the number of terms in document d that were assigned to topic t and AD-expression type e respectively. $\lambda_{1\dots n}$ are the parameters of the learned Max-Ent model corresponding to the n binary feature functions $f_{1\dots n}$ from Max-Ent. Omission of the latter index denoted by $(\cdot)$ represents the marginalized sum over the latter index. We employ a blocked sampler jointly sampling r and z as this improves convergence and reduces autocorrelation of the Gibbs sampler (Rosen-Zvi et al., 2004).

JTE (agreement expressions)	JTE (disagreement expressions)

2.3 Dataset Generation using Models

This section uses the models to classify agreeing and disagreeing debate posts which is a pre-requisite for this work. The hyper-parameters for the models were set to the heuristic values $\alpha = 1$, $\beta = 0.1$ for NB and $\alpha_T = 50/T$, $\alpha_E = 50/E$, $\beta_T = \beta_E = 0.1$ for JTE as suggested in (Griffiths and Steyvers, 2004). For both NB and JTE, we estimate model parameters using 5000 Gibbs iterations with a burn-in of 1000. To learn the Max-Ent parameters λ, we randomly sampled 500 terms from our corpus appearing at least 10 times[3] and labeled them as topical (361) or AD-expressions (139) and used the corresponding feature vector of each term (in the context of posts where it occurs) to train the Max-Ent model. Please note that this is term-level labeling which is very different from document labels or "tags" used in LabeledLDA (Ramage et al., 2009). LabeledLDA uses tagged data from del.icio.us setting the number of topics to the number of unique labels in the corpus. It restricts document-topic distributions to be defined only over the topics that correspond to the observed document-labels. For JTE, we induce $T = 100$ topics and $E = 2$ (agreement and disagreement) AD-expression types as in debate forums, there are usually two expression types. Values for $E > 2$ were also tried, but they did not produce any new dominant expression type. Instead, the expression types: *disagreement* and *agreement* became somewhat less specific as the expression-term ($\Phi^E_{E\times V}$) space became sparser. There was also slight increase in the model perplexity showing that values of $E > 2$ do not fit the data well.

Table 1 lists some top AD-expressions discovered by JTE. We see that JTE can cluster many correct AD-expressions, e.g., "I agree", "you're correct", "agree with you", etc. in agreement and "I disagree", "I refute", "don't accept", etc. in disagreement. In addition, it also discovers and clusters highly specific and more "distinctive" expressions beyond those used in Max-Ent training (marked *blue* in italics), e.g., "valid point", "rightly said", "I do support", and "very well put" in agreement; and phrases like "I don't buy your", "can you prove," "you fail to", and "you have no clue" in disagreement. We will later see that these AD-expressions serve as high quality lexical features for debate post classification. Note that we don't quantitatively evaluate topics, perplexity of the JTE model here as our focus is to classify agreeing and disagreeing posts using discovered AD-expression for our linguistic accommodation experiments on debates.

We now turn our attention to debate post classification. In this work, we use debate forum posts from Volconvo.com. We extracted 309376 debate posts from various domains like Politics, Religion, Society, Science, etc. To evaluate model performance, we construct a validation set. We randomly sampled 2000 posts from the corpus and asked two judges (CS grad students) to

[2] Clustering errors is a known issue with unsupervised generative models for text because the objective function of the model does not always correlate well with human judgments (Chang et al., 2009).
[3] A minimum frequency count of 10 ensures that the training data is representative of the corpus.

Feature Setting	Agreement			Disagreement		
	P	R	F_1	P	R	F_1
NB-unsupervised	0.69	0.65	0.67	0.71	0.69	0.70
NB-supervised	0.72	0.73	0.72	0.75	0.76	0.75
JTE-unsupervised	0.70	0.71	0.70	0.73	0.73	0.73
W+POS 1-4 grams + SVM (all terms)	0.75	0.76	0.75	0.80	0.81	0.80
W+POS 1-4 grams + SVM + χ^2 (top 1%)	0.79	0.77	0.78	0.84	0.84	0.84
W+POS 1-4 grams + SVM + χ^2 (top 2%)	0.80	0.78	0.79	0.85	0.85	0.85
AD-Expressions, Φ^E (top 1000) + SVM	0.84	0.81	0.82	0.88	0.86	0.87
AD-Expressions, Φ^E (top 2000) + SVM	0.86	0.83	0.84	0.88	0.87	0.87

TABLE 2: Precision (P), Recall (R) and F_1 scores of different models. Improvements in F_1 using AD-expression as features (Φ^E) are statistically significant (p<0.001) using paired t-test across 5-fold cross validation.

label the overall arguing nature of each post as agreeing or disagreeing or none[4]. We obtained strong agreement using κ_{Cohen} = 0.87. This is not surprising, as debate post classification is a fairly easy task and one can almost certainly make out whether a post expresses agreement or disagreement. Finally, we deemed a post as agreeing or disagreeing if both judges deemed it so. This yielded 1268 disagreement, 621 agreement posts. Out of the rest 111 posts, 39 are labeled "none" while 72 had no consensus among judges. We evaluate our models on the validation set, D_V, of 1268 disagreement and 621 agreement (1889) posts.

We consider the following classifiers:

i) NB-unsupervised, i.e., estimating the model (document labels) directly from D_V.
ii) NB-supervised, which performs 5-fold cross validation (CV) on D_V.
iii) JTE-unsupervised, which estimates the posterior on θ_d^E over D_V and classifies a post as agreeing if $\theta_{d,e=Agreement}^E > \theta_{d,e=Disagreement}^E$ else disagreeing. We call this unsupervised because although JTE uses Max-Ent term-level supervision for switching between topics and AD-expressions, it does not use the document-labels produced by judges.
iv) SVM + W+POS n-gram. We train a SVM classifier with the linear kernel[5] using standard word and POS n-gram features and 5-fold CV.
v) SVM + W+POS n-gram + χ^2. We extend (iv) by employing feature selection using Chi-Squared test[6].
vi) SVM+AD-expressions. We induce a SVM classifier using AD-expressions as features over 5-fold CV.

For unsupervised learners (no learning), we compute precision and recall on the corresponding bin of testing for 5-fold CV. For feature selection using χ^2, and AD-expressions (as they are basically rankings from φ_e^E), we try two settings: top 1% and 2% features. Results across agreement and disagreement posts are summarized in Table 2. For SVM, we used SVM^{light} (Joachims, 1999). We see that AD-expressions+SVM performs the best. This shows that AD-expressions discovered by JTE are of high quality. Next in order is SVM + χ^2. This shows that feature selection (FS) is useful. AD-expressions can be thought of as an FS scheme where a set

[4] First posts of thread who start a topic, ambiguous, vague, partly agreeing/disagreeing posts, etc. belong to the "none" category.
[5] Polynomial, RBF, and sigmoid kernels were tired but yielded poorer results hence not reported. Linear kernel has been shown very effective for text classification problems by many researchers, e.g., (Joachims, 1998).
[6] We also tried other feature selection schemes like Information Gain, Mutual information. However, they yielded poorer results than Chi-Squared test and hence not reported.

of highly discriminative lexical features are selected using JTE. It is understandable that the unsupervised methods are inferior to the supervised baselines. But JTE does attain a respectable F_1 of 0.70 for agreement and 0.73 for disagreement and is better than NB-unsupervised.

We now turn to our task of generating the debate dataset (agreeing and disagreeing posts) for linguistic accommodation study. While the ideal situation would involve manually labeling all 309376 debate posts under study, it is impractical. Hence we resort to SVM+AD-expression as our classifier. Since the labeled data contains three categories, we train a multiclass SVM using our labeled data: agreement (621), disagreement (1268), and none (39) with AD-expressions. Classification on our debate corpus resulted in 123751 agreement, 177087 disagreement, and 8538 none (e.g., first posts of thread that start a topic, ambiguous, vague, partly agreeing/disagreeing posts, etc.) posts. While this classification is not perfect and may have some noise, labels on our unlabeled debate posts are sufficiently reliable as the confidence of the classifier (SVM+AD-expression) is reasonably high on the validation set. Our database consists of 7973 authors and 4387 author pairs who have debated/interacted with each other [7] and 6828 discussion threads. We now proceed to linguistic accommodation experiments.

3 LIWC: A metric for Linguistic Style

To study the general phenomenon of linguistic accommodation in debates, we need a metric for linguistic style. Following prior work on linguistic accommodation in stylometry and psycholinguistics (Niederhoffer and Pennebaker, 2002; Taylor and Thomas; 2008), we use the psycholinguistic framework Linguistic Inquiry and Word Count (LIWC) (Pennebaker et al., 2007). LIWC measures word usage in psychologically meaningful style dimensions (e.g., articles, pronouns, emotion words, etc.) and has been proven useful in the analysis of personality (Yee et al., 2010); gender, age (Mukherjee and Liu, 2010; Argamon et al., 2007); deceptive opinions (Ott et al., 2011); social relations (Scholand et al., 2010), etc. In this work, we focus on 14 strictly non-topical style dimensions detailed in Table 3 [8], i.e., we study the linguistic phenomenon of accommodation in debates over those 14 style dimensions. Please refer to (Pennebaker et al., 2007) for full list of terms. A debate post is said to exhibit a style dimension if it contains at least one word form that respective LIWC category.

[7] As it may not be interesting to study linguistic accommodation across pairs who interacted only a few times, we only consider pairs who interacted at least 20 times.
[8] Other dimensions like Family, Sexuality, Religion, etc. do not convey any style information.

4 Probabilistic Framework

This section introduces a probabilistic framework to model the linguistic phenomenon of accommodation in a principled manner.

4.1 Stylistic Cohesion

Stylistic cohesion is the general phenomenon which is grounded on the following hypothesis: Related conversations tend to be stylistically closer (hence the nomenclature, cohesion) than unrelated conversations. In the context of online debates, this transforms as follows: Related debate posts (i.e., post pairs comprising of the original post, say d and another post, say r which quotes or replies to d. Related debate posts are denoted by $d \leftrightarrow r$ from now on) exhibit significantly higher stylistic cohesion than unrelated posts. Formally, for a given style dimension, s, we can measure stylistic cohesion on s using the following probabilistic expression:

$$Coh(s) \triangleq P(d^s \wedge r^s | d \leftrightarrow r) - P(d^s \wedge r^s | d \nleftrightarrow r) \quad (5)$$

where d^s , r^s denote the event that debate posts d, r respectively exhibit style dimension s. Thus, statistically, if the former probability expression in Eq. (5) tends to be greater than the latter, we say that related debate posts $d \leftrightarrow r$ tend to "agree" on the style dimension s. $d \nleftrightarrow r$ denotes that d and r do not form a conversation pair. Before proceeding, it is worthwhile to test the hypothesis on our debate domain. Establishing that stylistic cohesion is exhibited in online debates corresponds to rejecting the null hypothesis that the two probabilities in Eq. (5) are equal. A two tailed *t*-test rejects the null hypothesis with p-value < 0.001 for all 14 style dimensions in Table 4. Table 4 (a) shows the differences of expected probabilities[9] across each style dimension over all posts in our debate database.

Having established that stylistic cohesion is exhibited in online debates, we now turn our

TABLE 4 (b)

Table 4: (a)**:** Effect of stylistic cohesion across each style dimension. The differences are statistically significant (*: p<0.0001 **: p<0.001) over two-tailed *t*-test. (b): Cohesion across agreeing and disagreeing debate discussions. Differences are significant p<0.001.

[9] The expectation was taken over discussion threads, i.e., the probabilities in Eq. (5) were computed for each thread and averaged over all threads in our database. We do so because $|d \nleftrightarrow r|$ is very large $\approx \binom{309376}{2}$, for our database.

attention to the analysis of stylistic cohesion across agreeing and disagreeing debate posts. Let $d \xleftarrow{Agree} r$ denote the post pair where the post r is an agreement post and it quotes/replies to d. Analogously, we have $d \xleftarrow{Disagree} r$ when post r is a disagreement post. Extending the definition of (5), stylistic cohesion in related posts expressing agreement, $Coh_{Agree}$is given by:

$$Coh_{Agree}(s) \triangleq P\left(d^s \wedge r^s \middle| d \xleftarrow{Agree} r\right) - P(d^s \wedge r^s | d \leftrightarrow r) \quad (6)$$

and $Coh_{Diagree}$ is given by:

$$Coh_{Disagree}(s) \triangleq P\left(d^s \wedge r^s \middle| d \xleftarrow{Disagree} r\right) - P(d^s \wedge r^s | d \leftrightarrow r) \quad (7)$$

Table 4 (b) compares Coh_{Agree} and $Coh_{Diagree}$ across 14 style dimensions. We find that cohesion across agreeing conversations is significantly ($p<0.001$) more than cohesion in disagreeing conversations except for the style dimension Negation. This gives a very interesting insight to the phenomenon. While it is intuitive that agreeing discussions tend to have more cohesion for most style dimensions, the situation becomes reversed for negation. We believe this is so because owing to the very nature of debates, when people disagree over conversations (i.e., chain of post interactions debating via arguing and disagreeing), they try to negate the views of the other partner resulting in more cohesion.

4.2 Stylistic Accommodation

We now throw light on our key objective: linguistic style accommodation in debates. The theory of communication accommodation in linguistics (Giles et al., 1991) hinges on the general observation that during conversations/communications both textual and spoken, people try to unconsciously converge to one another's communicative behavior. In other words, there exists some coordination among conversers across a variety of dimensions like words, syntax, style, etc. Extending our probabilistic framework, we measure accommodation of a user b to another user a (where a and b are conversing pairs, i.e., they interact via reply/quote relations) as whether the stylistic dimension s in the initial post (of user a) increases the probability of s in the reply (of user b) beyond what is normally expected from user b. Formally:

$$Acc_{(a \leftarrow b)}(s) \triangleq P(d_b^s | d_a^s, d_a \curvearrowright d_b) - P(d_b^s | \, d_a \curvearrowright d_b) \quad (8)$$

where d_a^s and d_b^s denote the event that posts d_a and $d_b$exhibit style dimension s respectively by users a and b. $d_a \curvearrowright d_b$ denotes the reply/quote relation from b to a. We want to emphasize the temporal aspect ($\curvearrowright$ relation) of our modeling which offers us two crucial advantages. First, accounting the temporal aspect of accommodation (i.e., a user can accommodate to his/her conversation partner only after receiving his/her input), we minimize the effects of background style similarity like homophily. Secondly, encoding the temporal aspect gives a richer formulation than prior works (Niederhoffer and Pennebaker, 2002; Taylor and Thomas; 2008) which used correlation based measures[10]. Eq. (8) defines pairwise accommodation and can be extended to compute global accommodation for a given style dimension, s by taking the expectation over all conversing pairs, i.e.,$Acc(s) = E[Acc_{(a \leftarrow b)}(s)]$.

Establishing that linguistic phenomenon of stylistic accommodation is observable for a given dimension s is reduced to showing that $Acc(s) > 0$. Denoting $\bar{P}(d_b^s | d_a^s, d_a \curvearrowright d_b)$ as the expected value of the subtrahend and $\bar{P}(d_b^s | \, d_a \curvearrowright d_b)$ as the expected value of the minuend in Eq. (8),

[10] This is so because, correlation based measures do not distinguish between the case when the initial post exhibits a style dimension *s* but the reply/quote does not, and the reverse case when the initial post does not exhibit *s* but the reply does.

Table 6 (a) shows the differences in these means. The expectation is taken over all ordered pairs in our database. Differences between these means are statistically significant using a two-tailed *t*-test for all style dimensions (except 2nd person pronoun and 1st person singular pronoun. See caption of Table 6 (a)). It is clear from Table 6 (a) that accommodation exhibits significantly across major style dimensions. In fact, we find the highest accommodation in the *negation* style dimension. This is intuitive as debates usually involve a lot of negation (especially while disagreeing, more details follow in the next section).

Validating the existence of accommodation in online debates paves the way for comparative analysis of accommodation across agreeing and disagreeing pairs in debates. We define the notion of mutual accommodation $Acc_{(a,b)}(s)$ of a pair (a, b)as the expected accommodation of each with the other:

$$Acc_{(a,b)}(s) = \frac{1}{2}\left[Acc_{(b \leftarrow a)}(s) + Acc_{(a \leftarrow b)}(s)\right] \quad (9)$$

With mutual accommodation of a pair defined, we now analyze mutual accommodation across agreeing and disagreeing pairs. To perform this experiment, it is required to classify the 4387 pairs in our database into agreeing and disagreeing pairs. Before proceeding, we note the following important aspect of agreement and disagreement in debates. It reflects the intuition that when a user (say a) mostly agrees with the views of his conversing partner b (i.e., (a, b) form a conversing pair), b also agrees (or at least does not completely disagree) with a. Similarly, if a mostly disagrees with the views of b, it is highly unlikely that b completely agrees with a, i.e., b also inherently disagrees or at least does not completely agree with a. This hypothesis is grounded on the very human psychological nature of debating and arguing with others. Building on this intuition of human arguing/debating nature, it is reasonable to deem a pair of users as:

1. agreeing, if more than *k*% of their interactions (posts) exhibit agreement.
2. disagreeing, if more than *k*% of their interactions (posts) exhibit disagreement.
3. mixed, (i.e., partly agreeing and partly disagreeing), otherwise.

Choosing the threshold k is somewhat subjective as the definition of agreeing and disagreeing pairs may have different degrees of strictness according to end users. In this work, we experiment with two thresholds k = 65% and k = 75%. The thresholds are reasonable because a threshold of 50% says that the pair is mixed while if any one of the arguing nature (agreeing or disagreeing) is more pronounced then that nature is dominant. As we have the labels (agreeing or disagreeing) for each post (using our classifier in Section 2), each pair in our database was classified as agreeing, disagreeing or mixed according to the above scheme. It resulted in the following split:

k	Agreeing	Disagreeing	Mixed
0.65	1360 (31%)	2588 (59%)	439 (10%)
0.75	1141 (26%)	2676 (61%)	570 (13%)

TABLE 5: Distribution of split according to two thresholds.

As it may not be interesting to study accommodation over pairs with mixed nature (they also comprise a relatively small percentage), we focus on agreeing and disagreeing pairs. Table 6(b) shows the difference in average mutual accommodation over agreeing ($\overline{Acc}_{(a,b)}^{Agree}(s)$) and disagreeing ($\overline{Acc}_{(a,b)}^{Disagree}(s)$) pairs across each style dimension using the threshold k = 0.75. Table 6 (c) reports the corresponding results using the threshold k = 0.65. From Tables 6 (b), we note the following. For most style dimensions, mutual accommodation across agreeing pairs is more than that for disagreeing pairs. However, for 4 style dimensions, *negation*, *exclusive*, *discrepancy*, and *2nd person pronoun*, we find the trend reversed (values marked in bold).

(c)

TABLE 6: (a): Effect of accommodation across each style dimension. The differences are statistically significant (*: p<0.0001 **: p<0.001) over two-tailed *t*-test. Table 6 (b, c): Average mutual accommodation over agreeing and disagreeing pairs using two different thresholds, *k*: Table 6 (b): k = 0.75 Table 6 (c): k = 0.65.

Disagreeing pairs happen to accommodate more. The effect is most pronounced for *negation* style dimension. We believe this is because disagreeing pairs in debates invariably emit the above 4 style dimensions to other partners who in turn also emit the same style dimensions to counter/debate. To get an intuitive feeling, we list some of the frequent expressions among disagreeing posts as follows: "**your** claim **should**", "I **would** disagree", "**you cannot exclude**", "**without** knowing", "**you** do **not**", "**I don't** accept **your**", etc. We mark the words in **red** (**bold**) which appear in the above mentioned 4 style dimensions. Lastly, we note that the results follow a similar trend for the threshold k = 0.65 used to split agree/disagree pairs (Table 6(c)). This renders confidence in our results. Also interesting to note is that the mutual accommodation differences between agreeing and disagreeing pairs have reduced when k = 0.65 (Table 6(c)) than the results using k = 0.75 (Table 6 (b)). This is not surprising as the agree/disagree pair split using k = 0.75 creates a better demarcation of pairs based on their arguing nature.

4.3 Stylistic Influence

Linguistic accommodation has a unique characteristic of asymmetry, i.e., the accommodation of a user b to another user a over a style dimension s, $Acc_{(a \leftarrow b)}(s)$ is potentially different from the accommodation of a to b over the dimension s, $Acc_{(b \leftarrow a)}(s)$. This gives rise to the notion of stylistic influence. Theoretically, considering the following probabilistic expression:

$$I_{a,b}(s) = |Acc_{(a \leftarrow b)}(s) - Acc_{(b \leftarrow a)}(s)| \quad (10)$$

when $I_{a,b}(s) > 0$, we have the following two *exclusive* cases:

Case 1: $Acc_{(a \leftarrow b)}(s) > Acc_{(b \leftarrow a)}(s)$
Case 2: $Acc_{(b \leftarrow a)}(s) > Acc_{(a \leftarrow b)}(s)$.

However, both cannot happen simultaneously. In either case, it implies that there is a difference in the amount one user accommodates to the other. Put in other words, one of the users has an "influence" over the other. If case 1 holds, then b accommodates to a more than a does to b on

style dimension s, i.e., a is influencing b to emit style dimension s. If case 2 holds, then b is influencing a to emit style dimension s.

Before proceeding to analyze this interesting and fine-grained linguistic phenomenon of stylistic influence in debates, we need to statistically validate the existence of stylistic influence in online debates. Precisely, we are interested in answering the following question: In general, across various conversing pairs, is one of the users (former) forming the pair stylistically influencing (or causing the other user (latter) to accommodate) more than the extent to which he/she (the former user) is accommodating to him/her (the latter user)?

39	41	18	2

(b) Disagreeing

TABLE 7: Percentage of Agreeing (TABLE 7 (a)) and Disagreeing (TABLE 7(b)) pairs exhibiting different types of accommodation.

Answering the above question is reduced to the following statistical test: can we reject the null hypothesis that $E\left[I_{a,b}(s)\right] = 0$? Put in simple language, whether in expectation there is an imbalance (in either way[11]) between the amounts of accommodation among users in a conversing pair (this is the alternate hypothesis) or there is balance and each user accommodates to the other in almost the same extent in expectation (this is the null hypothesis). The key term here is "in expectation". Establishing that stylistic influence is exhibited in debates corresponds to rejecting the null hypothesis, H_1: $E\left[I_{a,b}(s)\right] = 0$. As $I_{a,b}(s)$ is an absolute value as defined in Eq. (10), we also need to test the hypothesis, H_2:

$$E\left[\max\left(Acc_{(a\leftarrow b)}(s), Acc_{(b\leftarrow a)}(s)\right)\right] = E\left[\min\left(Acc_{(a\leftarrow b)}(s), Acc_{(b\leftarrow a)}(s)\right)\right]$$

We subject H_1 and H_2 to a paired t-test over all pairs in our database. Paired t-test rejects both H_1 (with p-value < 0.0001) and H_2 (with p-value < 0.002) for all style dimensions. This empirically validates that stylistic influence is exhibited in online debates.

4.4 Accommodation across Arguing Nature

Having established that stylistic influence is exhibited in online debates, we now further investigate this intriguing phenomenon across arguing nature.

In psycholinguistic literature (Giles et al., 1991), it has been observed that when accommodation is exhibited, it can occur symmetrically (when both partners accommodate to each other) or asymmetrically (when only one of the conversers accommodates). Using our probabilistic framework, given a pair of interacting/debating user pair (a, b), the following cases arise for a style dimension s:

Case 1: Symmetry: When both $Acc_{(a\leftarrow b)}(s) > 0$ and $Acc_{(b\leftarrow a)}(s) > 0$, i.e., both of the conversers accommodate to each other.

Case 2: Asymmetry: When only one of $Acc_{(a\leftarrow b)}(s)$ or $Acc_{(b\leftarrow a)}(s)$ is > 0, i.e., only one

[11] Hence we need to employ a two-tailed t-test for testing the hypothesis.

accommodates. This further gives rise to the following two subcases. Say $Acc_{(a \leftarrow b)}(s) > 0$, i.e., b accommodates to a, then we can have:

Case 2 (a): Default asymmetry: The other non-accommodating converser maintains his "default" behavior, i.e., $Acc_{(b \leftarrow a)}(s) = 0$.

Case 2 (b): Divergent asymmetry: The non-accommodating converser accentuates his communication behavior in the opposite direction, i.e., *diverges* and $Acc_{(b \leftarrow a)}(s) < 0$

Case 3 No accommodation: None of the conversers accommodates, i.e., both $Acc_{(a \leftarrow b)}(s)$ and $Acc_{(b \leftarrow a)}(s)$ are ≤ 0.

To investigate the above cases, we compute the percentage of various forms of accommodation mentioned above across agreeing and disagreeing debating pairs in Table 7. For nomenclature, we use the following acronyms: Symmetric accommodation (SA), Default asymmetry (AS), Divergent asymmetry (DA), No accommodation (NA). However, we report results for agree/disagree pair split using threshold $k = 0.75$ (see Table 5) only as split using a higher threshold ensures better demarcation of agreeing/disagreeing pairs. We note the following interesting observations from Table 7 (a, b):

i) From column SA, we find that among agreeing pairs, percentage of pairs exhibiting symmetric accommodation (i.e., both members of a pair accommodating to each other) is more than that for disagreeing pairs. However, for style dimensions *negation* and *2nd person pronoun*, percentage of symmetric accommodating pairs among disagreeing pairs is more than that in agreeing pairs (shown in bold in SA column). The reason can be linked to the similar phenomenon in Section 4.2, i.e., disagreeing pairs in debates invariably emit style dimensions like *negation* and *2nd person pronoun* to other partners who in turn also emit the same style dimensions in order to counter/debate eventually resulting in somewhat symmetric accommodation.

iii) From column DA, we find that percentage of pairs exhibiting divergent asymmetry is more in disagreeing posts than agreeing posts. This is intuitive as divergent asymmetry calls for the non-accommodating converser to accentuate his communication behavior in the opposite direction so as to signal a stylistic "disagreement" along with a disagreement of views.

iv) Percentage of non-accommodating pairs among disagreeing pairs is in general more than that in agreeing pairs (See column NA in Table 7 (a, b)). This is reasonable and a plausible reason for such phenomenon is that pairs express "disagreement" in linguistic style by not accommodating at all. However, it is important here to note the following point. Earlier in Section 4.2, we showed that $Acc(s) > 0$ and accommodation is expressed in online debates. But in Table 7 we find that there are some pairs with $Acc(s) \leq 0$. It should not be considered as a contradiction to our results in Section 4.2. The key point is that we are interested in the "expected" accommodation over pairs and $E[Acc_{(a \leftarrow b)}(s)] > 0$ for all style dimensions.

Lastly, we note that the above experiments reveal no specific trend for percentage of pair exhibiting default asymmetry (DA) among agreeing and disagreeing posts based on our dataset of debate posts from Volconvo.com.

5 Conclusion

This paper studied the sociolinguistic phenomenon of accommodation in online debates. It first discussed a graphical model to perform debate post analysis to generate the required data for linguistic experiments. It then carried out a comprehensive analysis of various complex linguistic phenomena like stylistic cohesion, stylistic accommodation, influence, and accommodation across both agreeing and disagreeing debate posts. Several interesting results were obtained which dovetail with the intuitive psychology of online debaters, i.e., agreement and disagreement are also exhibited in the "style" dimension (beyond mere content) using symmetric and divergent asymmetric accommodation respectively. To our knowledge, this is the first study to report such fine-grained analysis of the linguistic phenomenon of accommodation in online debates. All experimental results were empirically validated using a large number of real-life debate posts.

ABSTRACT

We propose a lightweight method for using discourse relations for polarity detection of *tweets*. This method is targeted towards the web-based applications that deal with *noisy, unstructured* text, like the *tweets*, and cannot afford to use heavy linguistic resources like *parsing* due to frequent failure of the parsers to handle noisy data. Most of the works in micro-blogs, like *Twitter*, use a bag-of-words model that ignores the discourse particles like *but, since, although etc*. In this work, we show how the discourse relations like the *connectives* and *conditionals* can be used to incorporate discourse information in any bag-of-words model, to improve sentiment classification accuracy. We also probe the influence of the semantic operators like *modals* and *negations* on the discourse relations that affect the sentiment of a sentence. Discourse relations and corresponding rules are identified with minimal processing - just a list look up. We first give a linguistic description of the various discourse relations which leads to conditions in rules and features in SVM. We show that our discourse-based bag-of-words model performs well in a noisy medium (*Twitter*), where it performs better than an existing Twitter-based application. Furthermore, we show that our approach is beneficial to structured reviews as well, where we achieve a better accuracy than a state-of-the-art system in the *travel review* domain. Our system compares favorably with the state-of-the-art systems and has the additional attractiveness of being less resource intensive.

KEYWORDS : Sentiment Analysis, Discourse, Twitter, Connectives, Micro-blogs

Proceedings of COLING 2012: Technical Papers, pages 1847–1864,
COLING 2012, Mumbai, December 2012.

1 INTRODUCTION

An essential phenomenon in natural language processing is the use of discourse relations to establish a coherent relation, linking phrases and clauses in a text. The presence of linguistic constructs like *connectives, modals, conditionals* and *negation* can alter sentiment at the sentence level as well as the clausal or phrasal level. Consider the example, "*@user share 'em! i'm* **quite excited** *about Tintin, despite* **not really liking** *original comics. Probably because Joe Cornish had a hand in."* The overall sentiment of this example is *positive*, although there is equal number of positive and negative words. This is due to the connective *despite* which gives more weight to the previous discourse segment. Any bag-of-words model would be unable to classify this sentence without considering the discourse marker. Consider another example, "*Think i'll stay with the whole 'sci-fi'* **shit***. but this time...a* **classic** *movie."* The overall sentiment is again *positive* due to the connective *but*, which gives more weight to the following discourse segment. Thus it is of utmost importance to capture all these phenomena in a computational model.

Traditional works in *discourse analysis* use a discourse parser (Marcu 2000; Zirn *et al.*, 2011, Wellner *et al.*; 2007; Pitler *et al.*, 2009; Elwell *et al.*, 2008) or a dependency parser (Vincent *et al.*, 2006). Many of these works and some other works in discourse (Taboada *et al.*, 2008; Zhou et al., 2011) build on the Rhetorical Structure Theory (RTS) proposed by Mann *et al.* (1988) which tries to identify the relations between the nucleus and satellite in the sentence.

Most of these theories are well-founded for *structured text*, and *structured* discourse annotated corpora are available to train the models. However, using these methods for micro-blog discourse analysis pose some fundamental difficulties:

1. Micro-blogs, like *Twitter*, do not have any restriction on the form and content of the user posts. Users do not use formal language to communicate in the micro-blogs. As a result, there are abundant *spelling mistakes, abbreviations, slangs, discontinuities* and *grammatical errors*. This can be observed in the given examples from real-life *tweets*. The errors cause natural language processing tools like *parsers* and *taggers* to fail frequently (Dey *et al.*, 2009). As the tools are generally trained on structured text, they are unable to handle the noisy and unstructured text in this medium. Hence most of the discourse-based methods, based on RST or parsing of some form, will be unable to perform very well in micro-blog data.

2. The web-based applications require a fast response time. Using a heavy linguistic resource like *parsing* increases the processing time and slows down the application.

Most of the works in micro-blogs, like *Twitter*, (Alec *et al.*, 2009; Read *et al.*, 2005; Pak *et al.*, 2010; Gonzalez *et al.*, 2011) use a bag-of-words model with features like part-of-speech information, unigrams, bigrams *etc.* along with other domain-specific, specialized features like *emoticons, hashtags etc.* In *most* of these works, the *connectives, modals* and *conditionals* are simply ignored as stop words during feature vector creation. Hence, the discourse information that can be harnessed from these elements is completely discarded. In this work, we show how

the *connectives, modals, conditionals* and *negation* based discourse information can be incorporated in a bag-of-words model to give better sentiment classification accuracy.

The roadmap for the rest of the paper is as follows: Related work is presented in Section 2. Section 3 presents a comprehensive view of the different discourse relations. Section 4 studies the effect of these relations on sentiment analysis and identifies the critical ones. Section 5 discusses the influence of some semantic operators on discourse relations for sentiment analysis. We develop techniques for using the discourse relations to create feature vectors in Section 6. Lexicon based classification and supervised classification systems are presented in Section 7 to classify the feature vectors. Experimental results are presented in Section 8, where we use *three* different datasets, from the *Twitter* and *Travel review* domain, to validate our claim. The results are discussed in Section 9, followed by conclusions.

2 RELATED WORK

2.1 Discourse Based Works

Maru (2000) discussed probabilistic models for identifying elementary discourse units at clausal level and generating trees at the sentence level, using lexical and syntactic information from discourse-annotated corpus of RST. Wellner *et al.* (2007) considers the problem of automatically identifying arguments of discourse connectives in the PDTB. They model the problem as a predicate-argument identification where the predicates are discourse connectives and arguments serve as anchors for discourse segments. Wolf *et al.* (2005) presents a set of discourse structure relations and ways to code or represent them. The relations were based on Hobbs (1985). They report a method for annotating discourse coherent structures and found different kinds of crossed dependencies.

In the work, *Contextual Valence Shifters* (Polanyi *et al.,* 2004), the authors investigate the effect of *intensifiers, negatives, modals* and *connectors* that changes the prior polarity or valence of the words and brings out a new meaning or perspective. They also talk about pre-suppositional items and irony and present a simple weighting scheme to deal with them.

Somasundaran *et al*. (2009) and Asher *et al.* (2008) discuss some discourse-based supervised and unsupervised approaches to opinion analysis. Zhou *et al.* (2011) present an approach to identify discourse relations as identified by RST. Instead of depending on cue-phrase based methods to identify discourse relations, they leverage it to adopt an unsupervised approach that would generate semantic sequential representations (SSRs) without cue phrases.

Taboada *et al*. (2008) leverage discourse to identify relevant sentences in the text for sentiment analysis. However, they narrow their focus to adjectives alone in the relevant portions of the text while ignoring the remaining parts of speech of the text.

Most of these discourse based works make use of a *discourse parser* or a *dependency parser* to identify the scope of the discourse relations and the opinion frames. As said before, the parsers fare poorly in the presence of noisy text like *ungrammatical sentences* and *spelling mistakes* (Dey *et al.,* 2009). In addition, the use of parsing slows down any real-time interactive system due to

increased processing time. For this reason, the micro-blog applications mostly build on a bag-of-words model.

2.2 Twitter Based Works

Twitter is a micro-blogging website and ranks second amongst the present social media websites (Prelovac, 2010). A micro-blog allows users to exchange small elements of content such as short sentences, individual pages, or video links. Alec *et al.* (2009) provide one of the first studies on sentiment analysis on micro-blogging websites. Barbosa *et al.* (2010) and Bermingham *et al.* (2010) both cite noisy data as one of the biggest hurdles in analyzing text in such media.

Alec *et al.* (2009) describe a distant supervision-based approach for sentiment classification. They use *hashtags* in tweets to create training data and implement a multi-class classifier with topic-dependent clusters. "*The # symbol, called a hashtag, is used to mark keywords or topics in a Tweet. It was created organically by Twitter users as a way to categorize messages*"[1].

Barbosa *et al.* (2010) propose an approach to sentiment analysis in Twitter using POS-tagged n-gram features and some Twitter specific features like *hashtags.* Joshi *et al.* (2011) propose a rule-based system, *C-Feel-It*, which classifies a tweet as positive or negative based on the opinion words present in it. It uses sentiment lexicons for classification and twitter-specific features like *emoticons, slangs, hashtags etc.* Use of *emoticons* is common in social media and micro-blogging sites, where the users express their sentiment in the form of accepted symbols. Example: ☺ *(happy)*, ☹ *(sad).*

Read *et al.*, (2005) and Pak *et al.* (2010) propose a method to automatically create a training corpus using micro-blog specific features like *emoticons*, which is subsequently used to train a classifier. Gonzalez *et al.* (2011) discuss an approach to identify sarcasm in tweets. To create a corpus of *sarcastic, positive* and *negative* tweets, they rely on the user provided information in the form of *hashtags.* They claim that the author is the best judge for determining whether the tweet is sarcastic or not, which is indicated by the *hashtags* used by the author in the post.

Our work builds on the discourse-related works of Polanyi *et al.* (2004), Wolf *et al.* (2005) and Taboada *et al.* (2008) and carries the idea further in the sentiment analysis of micro-blogs. We exploit the various features discussed in the Twitter specific works to develop a bag-of-words model, in which the discourse features are incorporated to give better sentiment classification accuracy.

We evaluate our system on three datasets using lexicon-based classification as well as a supervised classifier (SVM). We use a manually labeled tweet set of 8,507 tweets and an automatically annotated set of 15,204 tweets using *hashtags*, to establish our claim. We, further, use a dataset from the *travel review* domain by Balamurali *et al.* (2011) to show that our method is beneficial to structured reviews as well, which is indicated by the improved classification accuracy over the compared work.

3 CATEGORIZATION OF DISCOURSE RELATIONS

"An important component of language comprehension in most natural language contexts involves connecting clauses and phrases together in order to establish a coherent discourse" (Wolf *et al.,* 2004). A coherently structured discourse is a collection of sentences having some relation with each other. A coherent relation reflects how different discourse segments interact (Hobbs 1985; Marcu 2000; Webber *et al.,* 1999). Discourse segments are non-overlapping spans of text. The interaction relations between discourse segments may be of various forms as listed in *Table 1*.

Coherence Relations	Conjunctions
Cause-effect	because; and so
Violated Expectations	although; but; while
Condition	if…(then); as long as; while
Similarity	and; (and) similarly
Contrast	by contrast; but
Temporal Sequence	(and) then; first, second, … before; after; while
Attribution	according to …; …said; claim that …; maintain that …; stated
Example	for example; for instance
Elaboration	also; furthermore; in addition; note (furthermore) that; (for , in, with) which; who; (for, in, on, against, with) whom
Generalization	in general

Table 1: Contentful Conjunctions used to illustrate Coherence Relations (Wolf *et al.* 2005)

Our work, almost entirely, rests on this platform, where we identify the relations from *Table 1*, which can affect the analysis of opinions most in a discourse segment. *Table 2* provides some examples, taken from *Twitter*, to illustrate the effect of conjunctions in discourse analysis. These examples are similar to the ones in Polanyi *et al.* (2004) and Taboada *et al.* (2008). The words in *bold* connect the discourse segment in brackets. The relations are broadly classified in ten categories in *Table 2*.

4 DISCOURSE RELATIONS CRITICAL FOR SENTIMENT ANALYSIS

Not all of the discourse relations are significant from the point of view of sentiment analysis. This section examines the role of the critical ones in SA.

1. Violated Expectations and Contrast - A simple bag-of-words model will classify *Example 2* (*Table 2*) as neutral. This is because it has one positive term *excited* and one negative phrase *not*

really liking. However, it represents a positive emotion of the opinion holder, due to the segment after the connective *despite*. In *Example 5*, *brightened* is positive and *poorly* is negative. Hence the overall polarity is un-decided. But it should have been *positive*, since the segment following *but* gives the overall impression of the opinion-holder which is positive.

Violating expectation conjunctions oppose or refute the neighboring discourse segment. We further categorize them into the following *two* sub-categories: *Conj_Fol* and *Conj_Prev.*

Conj_Fol is the set of conjunctions that give more importance to the discourse segment that follows them. *Conj_Prev* is the set of conjunctions that give more importance to the previous discourse segment.

Thus, in *Example 5* of *Table 2*, the discourse segment following *but* should be given more weight. In *Example 2*, the discourse segment preceding *despite* should be given more weight.

1. Cause-effect: *(YES! I hope she goes with Chris)* **so** *(I can freak out like I did with Emmy Awards.)*

2. Violated Expectations: *(i'm quite excited about Tintin),* **despite** *(not really liking original comics.)*

3. Condition: **If** ***(****MicroMax improved its battery life), (it wud hv been a gr8 product).*

4. Similarity: *(I lyk Nokia)* **and** *(Samsung as well).*

5. Contrast: *(my daughter is off school very poorly),* **but** *(brightened up when we saw you on gmtv today).*

6. Temporal Sequence: *(The film got boring)* **after a while**.

7. Attribution: ***(****Parliament is a sausage-machine: the world)* **according to** *(Kenneth Clarke).*

8. Example: *(Dhoni made so many mistakes…)* **for instance**, *(he shud've let Ishant bowl wn he was peaking).*

9. Elaboration: **In addition** *(to the worthless direction), (the story lacked depth too).*

10. Generalization**: In general**,*(movies made under the RGV banner) (are not worth a penny).*

Table 2: Examples of Discourse Coherent Relations

2. Conclusive or Inferential Conjunctions - These are the set of conjunctions, *Conj_infer*, that tend to draw a conclusion or inference. Hence, the discourse segment following them (*subsequently* in *Example 11*) should be given more weight.

Example 11: @User *I was nt much satisfied with ur so-called gud phone and* **subsequently** *decided to reject it.*

3. Conditionals - In *Example 3 (Table 2),* both *improve* and *gr8* represent a *high degree* of positive sentiment. But the presence of *if* tones down the final polarity as it introduces a hypothetical situation in the context. The *if…then…else* constructs depict situations which may or may not happen subject to certain conditions.

In our work, the polarity of the discourse segment in a conditional statement is toned down, in *lexicon-based classification*. In *supervised classifiers*, the conditionals are marked as features. Such statements are not completely ignored as objective, as they bear some sentiment polarity.

4. Other Discourse Relations - Sentences under *Cause-Effect, Similarity, Temporal Sequence, Attribution, Example, Generalization and Elaboration,* provide no contrasting, conflicting or hypothetical information. They can be handled by taking a simple majority valence of the individual terms, as in a bag-of-words model.

Table 3 lists all the essential discourse relations discussed in this section. The relations have been compiled from Hobbs (1985), Polanyi *et al.* (2004) and Taboada *et al.* (2008).

5 SEMANTIC OPERATORS INFLUENCING DISCOURSE RELATIONS

There are some semantic operators that influence the discourse relations connecting the phrases. In the sentence *You may like the movie despite the bad reviews,* the connective *despite* gives more weightage to the discourse segment preceding it and hence, *like* is weighed up. But the uncertainty resulting from *may* that pulls down the weightage is completely ignored. Similarly, in the sentence *He put a lot of effort for the finals, but still it was not good enough to win the match,* the connective *but* upweights *good* and *win* ignoring the negation operator *not*. In this section, we consider the semantic operators like the *modals* and *negation*, ignoring which results in an incorrect interpretation of the sentiment.

Relations	Attributes
Conj_Fol	*but, however, nevertheless, otherwise, yet, still, nonetheless*
Conj_Prev	*till, until, despite, in spite, though, although*
Conj_Infer	*therefore, furthermore, consequently, thus, as a result, subsequently, eventually, hence*
Conditionals	*If*
Strong_Mod	*might, could, can, would, may*
Weak_Mod	*should, ought to, need not, shall, will, must*
Neg	*not, neither, never, no, nor*

Table 3: Discourse Relations and Semantic Operators Essential for Sentiment Analysis

1. Modals - Events that have happened, events that are happening or events that are certain to occur are called *realis events.* Events that have possibly occurred or have some probability to occur in the distant future are called *irrealis events.* Thus, it is important to distinguish between

real situations and *hypothetical* ones. The modals (*might, may, could, should, would etc.*) depict *irrealis events. Example 3 (Table 2)* does not necessarily talk of MicroMax being *great*, but talks of its *possibility* of being *great* subject to certain conditions (its *battery life*). These constructs cannot be handled by taking a simple majority valence of terms.

We further divide the modals into *two* sub-categories: *Strong_Mod* and *Weak_Mod*.

Strong_Mod is the set of modals that express a higher degree of uncertainty in any situation.

Weak_Mod is the set of modals that express lesser degree of uncertainty and more emphasis on certain events or situations.

In our work, the polarity of the discourse segment neighboring a *strong modal* is toned down in *lexicon-based classification*, similar to the *conditionals*, as it expresses a higher degree of uncertainty. In *supervised classifiers*, the modals are marked as features.

Example 12 (Strong Modals): *Unless I missed the announcement their God is now featured on postage stamps, it* **might** *be a hard sell.*

He **may** *be a rising star.*

Example 13 (Weak Modals): *G.E 12* **must** *be the* most *deadly General Election for politicians ever.*

Our civil service **should** *work without TD interference.*

2. Negation - The negation operator (Example: *not, neither, nor, nothing etc.*) inverts the sentiment of the word following it. The usual way of handling negation in SA is to consider a window of size *n* (typically 3-5) and reverse the polarity of all the words in the window. In *Example 14*, negating all the words in a window of size 5 reverses the polarity of "*like*" for Samsung as well; this is undesirable. We consider a negation window of size 5 and reverse all the words in the window, till either the window size exceeds or a *violating expectation* (*or a contrast*) conjunction is encountered. Hence, the scope of reversing polarity is limited to the appearance of *but* in the given example.

Example 14 (Negation): *I do not like Nokia but I like Samsung.*

6 ALGORITHM TO HARNESS DISCOURSE INFORMATION

The discourse relations and the semantic operators (identified in *Section 4* and *Section 5*) are used to create a feature vector, according to the following algorithm.

Let a user post R consist of 'm' sentences s_i $(i=1…m)$, where each s_i consist of n_i words w_{ij} $(i=1…m,\ j=1…n_i)$. Let f_{ij} be the weight of the word w_{ij} in sentence s_i, initialized to 1. Let A be the set of all discourse relations in *Table 3*. Let $flip_{ij}$ be a variable which indicates whether the polarity of w_{ij} should be flipped or not. Let hyp_{ij} be a variable which indicates the presence of a *conditional or a strong modal* in s_i.

for $i=1…m$
  for $j=1…n_i$
    f_{ij}=1;
    hyp_{ij}=0;
1. **if** $w_{ij} \in$ Conditionals *or* $w_{ij} \in$ Strong_Mod
      hyp_{ij}=1;
    end if
  end for

  for $j=1…n_i$
    $flip_{ij}$=1;
2. **if** $w_{ij} \in$Conj_Fol *or* $w_{ij} \in$ Conj_Infer
      for $k=j+1…n_i$ *and* $w_{ij} \notin A$
        f_{ik}+=1;
      end for
    end if
3. **else if** $w_{ij} \in$ Conj_Prev
      for $k=1…j-1$ && $w_{ij} \notin A$
        f_{ik}+=1;
      end for
    end if
4. **else if** $w_{ij} \in$ *Neg*
      for $k=1…$*Neg_Window and* $w_{ik} \notin$ *Conj_Prev and* $w_{ik} \notin$ *Conj_Fol*
        $flip_{i,j+k}$=-1;
      end for
    end if
  end for
end for
Input: Review *R*
Output: w_{ij}, f_{ij}, $flip_{ij}$, hyp_{ij}

Algorithm 1: Using the Discourse Relations to Create the Feature Vector

In *Step 1*, we mark all the *conditionals* and *strong modals* which are handled separately by the lexicon-based classifier and the supervised classifier.

In *Step 2* and *Step 3*, the weight of any word appearing before *Conj_Prev* and after *Conj_Fol* or *Conj_Infer* is incremented by 1.

In *Step 4*, the polarity of all the words appearing within a window (*Neg_Window* is taken as 5), from the occurrence of a negation operator and before the occurrence of a *violating expectation* conjunction, are reversed.

Finally, we get the feature vector $\{w_{ij}, f_{ij}, flip_{ij}$ and $hyp_{ij}\}$ for all the words in the review.

Here, the assumption is that the effect of any conjunction is restricted to continuous spans of text till another conjunction or the sentence boundary.

7 FEATURE VECTOR CLASSIFICATION

We devised a lexicon based system as well as a supervised system for feature vector classification.

7.1 Lexicon Based Classification

The Bing Liu sentiment lexicon (Hu *et al.*, 2004) is used to find the polarity $pol(w_{ij})$ of a word w_{ij}. It contains around 6800 words which are manually polarity labeled. The polarity of the review (*pos* or *neg*) is given by,

$$sign(\sum_{i=1}^{m}\sum_{j=1}^{n_i} f_{ij} \times flip_{ij} \times p(w_{ij}))$$

$$where\ p(w_{ij}) = pol(w_{ij})\ \ if\ hyp_{ij} = 0$$
$$= \frac{pol(w_{ij})}{2} \quad if\ hyp_{ij} = 1 \qquad \ldots\ Equation\ 1$$

Equation 1 finds the weighted, signed polarity of a review. The polarity of each word, $pol(w_{ij})$ *being +1 or -1*, is multiplied with its discourse-weight f_{ij} (assigned by *Algorithm 1*), and all the weighted polarities are added. $Flip_{ij}$ indicates if the polarity of w_{ij} is to be negated.

In case there is any *conditional* or *strong modal* in the sentence (indicated by $hyp_{ij} = 1$), then the polarity of every word in the sentence is toned down, by considering half of its assigned polarity ($\frac{+1}{2}$ *or* $\frac{-1}{2}$).

Thus, if *good* occurs in the user post twice, it will contribute a polarity of $+1 \times 2 = +2$ to the overall review polarity, *if* $hyp_{ij} = 0$. In the presence of a *strong modal* or *conditional*, it will contribute a polarity of $\frac{+1}{2} \times 2 = +1$.

All the *stop words*, *discourse connectives* and *modals* are ignored during the classification phase, as they have a zero polarity in the lexicon.

7.2 Supervised Classification

The Support Vector Machines have been found to outperform other classifiers, like *Naïve Bayes* and *Maximum Entropy*, in sentiment classification (Pang *et al.*, 2002). Hence, in our work, SVM's are used to classify the set of feature vectors $\{flip_{ij}, w_{ij}, f_{ij}$ and $hyp_{ij}\}$.

Features used in the Support Vector Machines:

N-grams – *Unigrams* along with *Bigrams* are used.

Stop Words – All the stop words (like *a, an, the, is etc.*) and discourse connectives are discarded.

Feature Weight – In the *baseline bag-of-words* model, the feature weight has been taken as the feature frequency *i.e.* the number of times the unigram or bigram appears in the text. In the *discourse-based bag-of-words* model, the *discourse-weighted frequency* of a word is considered. *Algorithm 1* assigns a weight f_{ij} to every occurrence of a word w_{ij} in the post. If the same word occurs multiple times, the weights from its multiple occurrences will be added and used as a feature weight for the word.

Modal and Conditional Indicator – This is a Boolean variable which indicates the presence of a strong modal or conditional in the sentence (i.e. $hyp_{ij}=1$).

Stemming – All the words are stemmed in the text so that "*acting*" and "*action*" have a single entry corresponding to "*act*".

Negation – A Boolean variable ($flip_{ij}$) is appended to each word (w_{ij}) to indicate whether it is to be negated or not (i.e. $flip_{ij}=1$ or $flip_{ij}=0$).

Emoticons – An emoticon dictionary is used to map each emoticon to a *positive* or *negative* class. Subsequently, the emoticon class information is used in place of the emoticon.

Part-of-Speech Information – The part-of-speech information is also used with a word.

Feature Space - In the *lexeme feature space* individual words are used as features; whereas in the *sense space*, the sense of the word (synset-id) is used in place of the word. A synset is a set of synonyms that collectively disambiguate each other to give a unique sense to the set, identifiable by the *synset-id*. This is beneficial in distinguishing between the various senses of a word.

For example, the word *bank* has 18 senses (10 Noun senses and 8 Verb Senses). Consider the two senses of a *bank* – 1) *Bank* in the sense of "*a financial institution*", identifiable by the synset "*depository financial institution, bank, banking concern, banking company"*, and 2) *Bank* in the sense of *relying*, identifiable by the synset "*trust, swear, rely, bank"*. Now, the first sense has an objective polarity whereas the second sense has a positive polarity. This distinction cannot be made in the lexeme feature space, where we consider only the *first* sense of the word.

8 EVALUATION

8.1 Dataset

We performed experiments on three different datasets to validate our approach:

Dataset 1: Twitter is crawled using a Twitter API and 8507 tweets are collected based on a total of around 2000 different entities from 20 different domains. The following domains are used for crawling data: *Movie, Restaurant, Television, Politics, Sports, Education, Philosophy, Travel, Books Technology, Banking & Finance, Business, Music, Environment, Computers, Automobiles,*

Cosmetics brands, Amusement parks and *Eatables and History.* These are manually annotated by 4 annotators into four classes - *positive, negative, objective-not-spam* and *objective-spam.* The objective-not-spam category contains tweets which are objective in nature but are not spams. The objective-spam category contains spam tweets which are subsequently ignored during evaluation.

Dataset 2: Following the works of Read *et al.* (2005), Alec *et al.* (2009), Pak *et al.* (2010) and Gonzalez *et al.* (2011) we create an artificial dataset using *hashtags*. The Twitter API is used to collect another set of 15,214 tweets based on *hashtags*. Hashtags *#positive, #joy, #excited, #happy etc.* are used to collect tweets bearing positive sentiment, whereas hashtags like *#negative, #sad, #depressed, #gloomy, #disappointed etc.* are used to collect negative tweets. *Hashtag keywords are subsequently removed from the tweets.*

Dataset 3: *Travel Review* Dataset in Balamurali *et al.* (2011) contains 595 polarity-tagged documents for each of the positive and negative classes. All the words in the travel review documents are automatically tagged with their corresponding synset-id's using *Iterative Word Sense Disambiguation* algorithm (Khapra *et al.*, 2010).

8.2 Evaluation on the Twitter Dataset 1 and 2

The crawled tweets are pre-processed before evaluation. All the *links* (urls) in the tweets are replaced by *#link*. All the *user id's* in the tweets are replaced by *#user*.

Manually Annotated Dataset 1				
#Positive	#Negative	#Objective Not Spam	#Objective Spam	Total
2548	1209	2757	1993	8507
Auto Annotated Dataset 2				
#Positive		#Negative		Total
7348		7866		15214

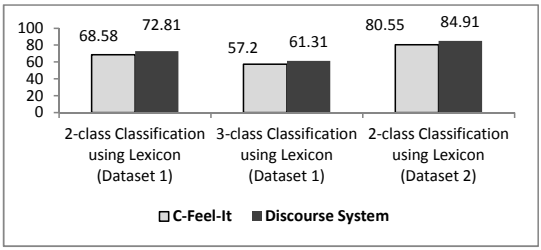
Table 4: Twitter Datasets 1 and 2 Statistics

Evaluations are performed in *Dataset 1* and *2* under a *2-class* and a *3-class* classification setting. In the 2-class setting, only *positive* and *negative* tweets are considered; whereas in the 3-class setting *positive, negative* and *objective-not-spam* tweets are considered. All the experiments in these two datasets are performed in the *lexeme feature space* using *lexicon-based classification* as well as *supervised classification*.

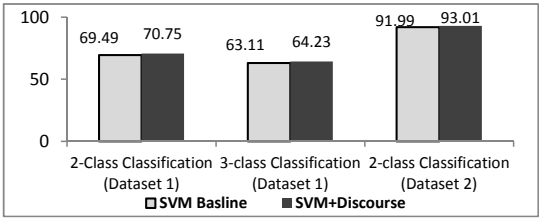
The baseline system, for this part of the evaluation, is taken as *C-Feel-It* (Joshi *et al.*, 2011). It is a rule-based system which implements a bag-of-words model using lexicon-based classification. The accuracy comparisons between C-Feel-It and the discourse system are performed under identical settings. The only difference between the two systems is the handling of *connectives, modals, conditionals* and *negation*, as indicated by *Algorithm 1*.

Graph 1 shows the accuracy comparison between C-Feel-It and the discourse system, in Datasets 1 and 2, using lexicon-based classification under a 2-class and a 3-class setting. *Graph 2* shows

the accuracy comparison between baseline SVM and SVM integrated with discourse features, in Datasets 1 and 2, under a 2-class and a 3-class setting. All the SVM features discussed in *Section 7.2*, except the discourse features arising out of the incorporation of *discourse weighting*, *modal and conditional indicator* and *negation*, are used in the baseline SVM model. A linear kernel, with default parameters, is used in the SVM (Chang *et al.*, 2011) with 10-fold cross-validation.



Graph 1: Accuracy Comparison between C-Feel-It and Discourse System using Lexicon in Datasets 1 and 2



Graph 2: Accuracy Comparison between Baseline SVM and SVM with Discourse in Datasets 1 and 2

8.3 Evaluation on the Travel Review Dataset 3

The *travel review* dataset (Balamurali *et al.*, 2011) is used to determine whether our discourse-based approach performs well for structured text as well. This evaluation is done under a 2-class classification setting in the *lexeme space* as well as the *sense space*. *Table 5* shows the accuracy comparison between the baseline bag-of-words model and bag-of-words model integrated with discourse features using lexicon-based classification, in dataset 3, under a 2-class setting.

Sentiment Evaluation Criterion	**Accuracy**
Baseline Bag-of-Words Model	69.62
Bag-of-Words Model + Discourse	**71.78**

Table 5: Accuracy Comparison between Bag-of-Words and Discourse System using Lexicon in **Dataset 3**

An automatic word sense disambiguation algorithm, *Iterative Word Sense Disambiguation* (Khapra *et al.*, 2010), has been used to auto-annotate the words in the review with their corresponding synset-id's. The same dataset is used in this work. A linear kernel, with default parameters, is used in the SVM with 5-fold cross-validation, similar to the compared system (Balamurali *et al.*, 2011). *Table 6* shows the performance of the discourse system along with the compared system using different features, on Dataset 3, using supervised classification. The features used in the SVM, for this part of the evaluation, include *stop word removal*, *no stemming*, *part-of-speech information* and *unigrams*. These features are used in all the systems in *Table 6*, including the discourse one. *Table 6* shows the system accuracy under four scenarios:

1. When only unigrams are used
2. When only sense of unigrams are used
3. When unigrams are used along with their senses (synset-id's)
4. When unigrams are used with senses and discourse features

9 DISCUSSIONS

Accuracy improvements over the baseline and the compared systems in all the datasets clearly signify the effectiveness of incorporating discourse information for sentiment classification. The bag-of-words model integrated *with discourse information* outperforms the bag-of-words model, *without this information*, under all the settings; although, the performance improvements vary in different settings. Statistical tests have been performed and all the accuracy improvements have been found to be statistically significant with *99%* level of confidence.

Systems	Accuracy (%)
Only Unigrams	84.90
Only IWSD Sense of Unigrams [26]	85.48
Unigrams + IWSD Sense of Unigrams [26]	86.08
Unigrams + IWSD Sense of Unigrams + Discourse Features	**88.13**

Table 6: Accuracy Comparisons in Travel Review Dataset 3

9.1 Accuracy Comparison between C-Feel-It and Discourse System

These comparisons are performed under a 2-class and a 3-class classification setting, using lexicon-based classification, in the lexeme space under identical settings - the only difference being the incorporation of discourse features. In *Dataset 1*, there is an accuracy improvement of around *4%* over C-Feel-It for both 2-class and 3-class classification. The discourse system accuracy at *72.81%* for 2-class classification is higher than that of the 3-class classification accuracy of *61.31%*. This shows that 3-class classification of tweets is much more difficult than 2-class classification.

9.2 Accuracy Comparison between Baseline SVM and Discourse System

These comparisons are performed under a 2-class and a 3-class classification setting, using supervised classification, in the lexeme space. A similar feature set, except the discourse features, is used for both the systems. In *Dataset 1*, there is an accuracy improvement of *1%* in both the 2-class and 3-class classification, which has been found to be statistically significant. In *Dataset 2*, there is an accuracy improvement of *2%* over baseline SVM for 2-class classification. It is observed that in the 2-class setting, the discourse system performs better in the lexicon-based classification with an accuracy of *72.81%* compared to the supervised classification accuracy of *70.75%*. This is contrary to the common scenario in text classification, where the supervised classification system always performs much better than the lexicon-based classification. This may be due to the very sparse feature space, owing to the length limit of tweets (140 characters).

9.3 Accuracy Comparison in Dataset 3

In the *Travel review* dataset, lexicon-based classification yielded an accuracy improvement of *2%* for the discourse model over simple bag-of-words model, in the *lexeme space*. In the SVM classification, in the *sense space,* under a 2-class setting, the discourse system achieved an accuracy of *88%* compared to *86%* accuracy of Balamurali *et al.* (2011). A similar feature set has been used in both the models, which indicates that the performance improvement is due to the incorporation of discourse features in SVM.

9.4 Drawbacks

The lexicon-based classification suffers from the usage of a generic lexicon in the *lexeme space*, where it cannot distinguish between the various senses of a word. The lexicons do not have entries for the interjections like *wow*, *duh etc.* which are strong indicators of sentiment. The frequent spelling mistakes, abbreviations and slangs used in the tweets do not have entry in the lexicons. For example, *love* and *great* are frequently written as *luv* and *gr8* respectively, which will not be detected. A spell-checker may help the system in this regard.

The supervised system suffers from a sparse feature space due to very short contexts. A concept expansion approach, to expand the feature vectors, may prove to be useful. This is due to the extensive world knowledge embedded in the tweets. For example, the tweet "*He is a Frankenstein*" is tagged as objective. The knowledge that *Frankenstein* is a negative concept is not present in the lexicon. The IWSD algorithm for automatic sense annotation has an F-Score of *70%*, which means many of the word-senses were wrongly tagged. In case a better WSD algorithm is used, higher system accuracy can be achieved in the travel review dataset.

In the absence of *parsing* and *tagging* information, due to the noisy nature of the tweets, the scope of the discourse marker has been heuristically taken till the sentence boundary or till the next discourse marker. Consider the sentence, "*I wanted to follow my dreams and ambitions despite all the obstacles, but I did not succeed.*" Here *want* and *ambition* will get the polarity *+2 each*, as they appear before *despite*; *obstacle* will get a polarity *-1* and *not succeed* will get a polarity *-2*. Thus the overall polarity is *+1*, whereas the overall sentiment should be *negative*.

This is because we do not consider the *positional importance* of a discourse marker in the sentence and consider all the discourse markers to be equally important. A better method is to give a ranking to the discourse markers based on their *positional* and *pragmatic* importance.

10 FUTURE WORKS AND CONCLUSIONS

In this work, we showed that the incorporation of discourse markers in a bag-of-words model improves the sentiment classification accuracy by *2 - 4%*. This approach is particularly beneficial for - 1) applications dealing with noisy text where *parsing* and *tagging* do not perform very well, and 2) applications, requiring a fast response time, where employing a heavy linguistic tool like *parsing* will be detrimental to its performance due to the increased processing time.

Most of the works in micro-blogs, like *Twitter*, build on a bag-of-words model that ignores the discourse markers. We demonstrated an approach to incorporate discourse information to improve their performance, retaining the simplicity of the bag-of-words model. We validated this claim on two different datasets (manually and automatically annotated) from *Twitter*, where we achieved an accuracy improvement of *4%* for lexicon-based classification over an existing application (Joshi *et al.*, 2011), and 2% for supervised classification over the baseline SVM with advanced features. We also showed that our method fares well for structured reviews as well, where we achieved similar accuracy improvements over Balamurali *et al.*, 2011.

[‡]Dept. of Computer Science and Engineering, IIT Bombay
subhabmu@in.ibm.com, pb@cse.iitb.ac.in

ABSTRACT

In this paper, we propose a *weakly supervised* system, *YouCat*, for categorizing Youtube videos into different genres like *Comedy, Horror, Romance, Sports* and *Technology* The system takes a *Youtube video url* as input and gives it a belongingness score for each genre. The key aspects of this work can be summarized as: (1) Unlike other genre identification works, which are *mostly* supervised, this system is *mostly unsupervised,* requiring *no labeled data for training.* (2) The system can easily incorporate new genres without requiring labeled data for the genres. (3) YouCat extracts information from the *video title*, *meta description* and *user comments* (which together form the *video descriptor*). (4) It uses *Wikipedia* and *WordNet* for concept expansion. (5) The proposed algorithm with a time complexity of $O(|W|)$ (where (|W|) is the number of words in the video descriptor) is efficient to be deployed in web for real-time video categorization. Experimentations have been performed on real world Youtube videos where YouCat achieves an F-score of *80.9%*, without using any labeled training set, compared to the supervised, multiclass SVM F-score of *84.36%* for *single genre prediction*. YouCat performs better for multi-genre prediction with an F-Score of *90.48%*. Weak supervision in the system arises out of the usage of manually constructed WordNet and genre description by *a few root words.*

KEYWORDS : Youtube, Genre Prediction, Comments, Metadata, Wikipedia, WordNet

Proceedings of COLING 2012: Technical Papers, pages 1865–1882,
COLING 2012, Mumbai, December 2012.

1 INTRODUCTION

In recent times there has been an explosion in the number of online videos. With the gradually increasing multimedia content, the task of efficient query-based video retrieval has become important. The proper genre or category identification of the video is essential for this purpose. The automatic genre identification of videos has been traditionally posed as a supervised classification task of the features derived from the audio, visual content and textual features. Whereas some works focus on classifying the video based on the *meta data (text)* provided by the uploader (Cui *et al.*, 2010; Borth *et al.*, 2009, Filippova *et al.*, 2011), other works attempt to extract low-level features by analyzing the *frames, signals, audio etc.* along with textual features (Ekenel *et al.*, 2010; Yang *et al.*, 2007). There have been some recent advances in incorporating new features for classification like the social content comprising of the *user connectivity* (Zhang *et al.*, 2011; Yew *et al.*, 2011), *comments* (Filippova *et al.*, 2011), *interest etc.*

All the above approaches pose the genre prediction task as supervised classification requiring a large amount of training data. It has been argued that a *serious challenge* for supervised classification is the availability and requirement of manually labeled data (Filippova *et. al*, 2010; Wu *et. al*, 2010; Zanetti *et. al*, 2008). For example, consider a video with the descriptor "*It's the NBA's All-Mask Team!*". Unless there is a video in the training set with *NBA* in the video descriptor labeled with *Sport*, there is no way of associating *NBA* to *Sport*. It is also not possible to associate *NBA* to *Basketball* and then to *Sport*. As *new genre-related concepts* (like new sports, technologies, domain-dependent terms *etc.*) appear every day the training set should expand incorporating all these new concepts, which makes training very expensive. As the number of categories or genres is increased the data requirement goes up compounded. The problem is enhanced by the *noisy* and *ambiguous* text prevalent in the media due to the *slangs, acronyms etc.* The *very short text* provided by the user, for *title* and *video description*, provide little context for classification (Wu *et al.*, 2012). The focus of this paper is to propose a system that requires no labeled data for training and can be easily extended to identify new categories. The system can easily adapt to changing times, incorporating world knowledge, to overcome the labeled data shortage. It extracts all the features from the video uploader provided meta-data like the *video title, description of the video* as well as the *user comments.* The system incorporates social content by analyzing the user comments on the video, which is essential as the meta-data associated with a video is often absent or not adequate enough to predict its category. *WordNet* and *Wikipedia* are used as world knowledge sources for *expanding* the video descriptor since the uploader provided text is frequently very short, as are the user comments. WordNet is used for knowing the meaning of an unknown word whereas Wikipedia is used for recognizing the *named entities* (which are mostly absent in the WordNet) like "*NBA"* in the given example. In this work, we show how the textual features can be analyzed with the help of WordNet and Wikipedia to predict the video category without requiring any labeled training set.

The only weak supervision in the system arises out of the usage of a root words list (~ 1-3 words) used to describe the genre, WordNet which is manually annotated and a simple setting of the parameters of the model.

The paper is organized as follows: Section 2 gives the related work and compares them with our approach. Section 3 discusses the unsupervised feature extraction from various sources. Section 4 gives the algorithm for feature vector classification and genre identification. Section 5 discusses the parameter settings for the model. The experimental evaluations are presented in Section 6 followed by discussions of the results in Section 7. Section 8 concludes the paper with future works and conclusions.

2 RELATED WORK

The video categorization works can be broadly divided under 3 umbrellas: 1. Works that deal with low level features by extracting features from the video frames like the audio, video signals, colors, textures *etc.* 2. Works that deal with textual features like the title, tag, video description, user comments *etc.* 3. Works that combine low-level features like the video frame information with the high-level text features. In this section, we discuss only those works that include text as one of the features. Our work is similar to text classification but for a different application.

Filippova *et al.* (2011) showed that a text-based classifier, trained on imperfect predictions of weakly supervised video content-based classifiers, outperforms each of them taken independently. They use features from the video title, description, user comments, uploader assigned tags and use a maximum entropy model for classification.

Wang *et al.* (2010) considers features from the text as well as low-level video features, and proposes a fusion framework in which these data sources are combined with the small manually-labeled feature set independently. They use a Conditional Random Field (CRF) based fusion strategy and a Tree-DRF for classification.

The content features are extracted from training data in Cui *et al.* (2010) to enrich the text based semantic kernels to yield content-enriched semantic kernel which is used in the SVM classifier.

Borth *et al.* (2009) combines the results of different modalities like the uploader generated tags and visual features which are combined using a weighted sum fusion, where SVM's are used with bag of words as features. These categories are refined further by deep-level clustering using probabilistic latent semantic analysis.

Query expansion is performed in Wu *et al.* (2012) by using contextual information from the web like the related videos and user videos, in addition to the textual features and use SVM in the final phase for classification.

Some works have used user information like the browsing history along with other textual features. Zhang *et al.* (2006) develop a video categorization framework that combined multiple classifiers based on normal text features as well as users' querying history and clicking logs. They used Naïve Bayes with a mixture of multinomials, Maximum Entropy, and Support Vector Machines for video categorization.

Most of the works are similar to Huang *et al.* (2010) which use different text features and classifiers like the Naïve Bayes, Decision Trees and SVM's for classification.

Yang *et al*. (2007) propose a semantic modality that includes concept histogram, visual word vector model and visual word Latent Semantic Analysis (LSA); and a text modality that includes titles, descriptions and tags of web videos. They use various classifiers such as Support Vector Machine(SVM), Gaussian Mixture Model(GMM) and Manifold Ranking (MR) for classification.

Song *et al*. (2009) developed an effective semantic feature space to represent web videos consisting of concepts with small semantic gap and high distinguishing ability where Wikipedia is used to diffuse the concept correlations in this space. They use SVM's with fixed number of support vectors (n-ISVM) for classification.

All the above works build on supervised classification systems, requiring labeled data for training, mostly using the Support Vector Machines. In this paper, we propose a system that requires no labeled data for training, which is the primary difference of our work with those surveyed. Also, the usefulness of Wikipedia and WordNet for concept expansion has not been probed much in earlier video categorization tasks, save a few. We use many of the ideas from the above works and integrate them into YouCat.

3 FEATURE CONSTRUCTION

Given a *Youtube video url*, the objective is to assign scores to it which represent its belongingness to the different genres. The video genres are categories like *romance*, *comedy*, *horror*, *sports* and *technology*. The genre names are pre-defined in the system along with a small set of *root words* for each genre. The root words act like a description of the genre. For example, *funny* and *laugh* act as the key characteristics of the *comedy* genre. This allows *new* genres to be easily defined in the system in terms of the root words as well as to have a fine distinction between the genres.

A *seed list* of words is *automatically* created for each genre by searching a *thesaurus* using the roots words for that genre. A *concept list* is created for each genre with *relevant words* from the *WordNet* and *named entities* in *Wikipedia*, with the help of the seed list of the corresponding genre. Given a video descriptor consisting of the *video title*, the *meta-description of the video* and the *user comments*, the seed list and the concept list for each genre are used for finding appropriate matches in the *video descriptor* to predict appropriate tags or categories for the video using the scores.

3.1 Data Pre-Processing

3.1.1 Seed List Creation using Root Words

A set of tags is pre-defined in the system along with a set of 1-3 *root words* for each tag. A *seed list* of words is created for each genre (*defined in the system*) which captures the key characteristics of that category. For Example, *"love", "hug", "cuddle" etc.* are the characteristics of the *Romance* genre. *Root words of the genre* are taken and all their synonyms are retrieved from a thesaurus. *The root words list and the genre names are pre-defined in the system. Table 1* shows the root-words list for the *five* genres used in this work. An automatic breadth-first search is done on the thesaurus based on the root words to retrieve only the most relevant synonyms or

associated concepts. For example, the word *Laugh* is taken for its genre *Comedy* and all its first level synonyms are retrieved which are again recursively used to retrieve their level-one synonyms till a certain depth. A thesaurus is used for this purpose which gives every day words and slangs. In our work, the following thesaurus[1] retrieves the words *rofl, roflmao, lol etc*. when the word *Laugh* is looked up from the *Comedy* genre. A *snapshot* of the seed lists with number of words in the lists is shown in *Table 2*.

The set of root words can help in *fine genre distinction* as the seed list will have only *associated* concepts. For example if the *Transport* genre is sub-categorized into *Road* and *Railways*, the corresponding root words {car, road, highway, auto} and {train, rail, overhead wire, electricity, station} will distinguish between the two.

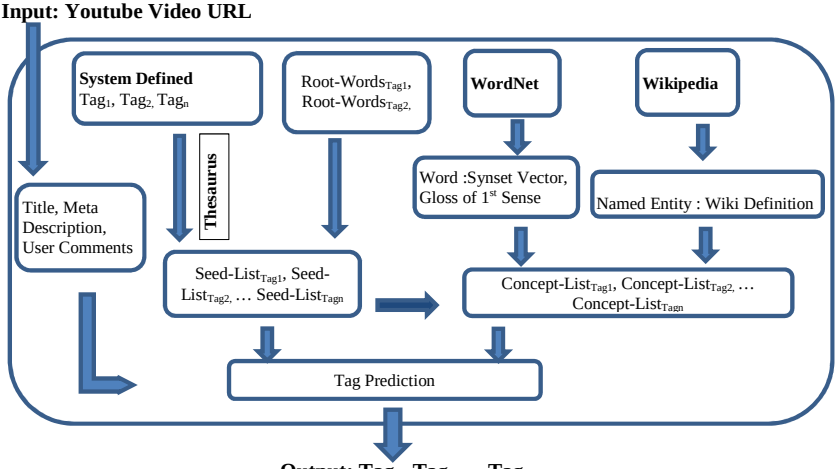

Fig. 1. System Block Diagram

Comedy	comedy, funny, laugh
Horror	horror, fear, scary
Romance	romance, romantic
Sport	sport, sports

Table 1. Root Words for Each Genre

[1] www.urbandictionary.com/thesaurus.php

Comedy (25)	funny, humor, hilarious, joke, comedy, roflmao, laugh, lol, rofl, roflmao, joke, giggle, haha, prank
Horror (37)	horror, curse, ghost, scary, zombie, terror, fear, shock, evil, devil, creepy, monster, hell, blood, dead, demon
Romance (21)	love, romantic, dating, kiss, relationships, heart, hug, sex, cuddle, snug, smooch, crush, making out
Sports (35)	football, game, soccer, basketball, cheerleading, sports, baseball, FIFA, swimming, chess, cricket, shot
Tech (42)	internet, computers, apple, iPhone, phone, pc, laptop, mac, iPad, online, google, mac, laptop, XBOX, Yahoo

Table 2. Snapshot of Seed List for Each Genre

3.1.2 Concept Hashing

Each word (used as a *key* for hashing) in the WordNet, that is not present in any seed list, is hashed with the set of all its synsets and the gloss of its first sense.

A synset is a set of synonyms that collectively disambiguate each other and give a unique sense to the set. For example, the word *dunk* has the synsets - {*dunk, dunk shot, stuff shot*; *dunk, dip, souse, plunge, douse*; *dunk*; *dunk, dip*}. Here the first synset {*dunk, dunk shot, stuff shot*} has the sense of a basketball shot. The meaning of a synset is clearer with its gloss. A gloss[2] is the definition or example sentences for a synset which portrays the context in which the synset or sense of the word can be used. For example, the gloss of the synset {*dunk, dunk shot, stuff shot*} is {*a basketball shot in which the basketball is propelled downward into the basket*}.

Technically, we should have taken only the words in the synset of its most appropriate sense. But we do not perform word sense disambiguation[3] to find out the proper synset of the word. Taking only the first sense provides fewer contexts while classifying the feature vector, and so the information from all the senses of a given word is used. The gloss of the first sense is frequently used, as in many cases the first sense is the best sense of a word (Macdonald *et al.*, 2007).

Wikipedia is necessary for *named entity recognition*, since the WordNet does not contain most of these entries. All the *named entities* in Wikipedia with the *top 2 line definition* in their corresponding Wiki articles are stored in a hashtable. For example, *NBA* is stored in the hashtable with its definition from the Wikipedia article as {*The National Basketball Association (NBA) is the pre-eminent men's professional basketball league in North America. It consists of thirty franchised member clubs, of which twenty-nine are located in the United States and one in Canada.*}.

Most of the named entities in practice are not unigrams like *Michael Jordon*. If the unigrams in this named entity are expanded separately, a different sense for each would be retrieved. This is not desirable. In this work, we use a simple heuristics method based on *capitalization* of the

[2] http://en.wikipedia.org/wiki/WordNet
[3] http://en.wikipedia.org/wiki/Word-sense_disambiguation

letters to identify the named entities. Any sequence of consecutive words such that each of them starts with a capital letter, and the sequence does not start or end with any *Stop Word* is considered a named entity. Stop Words are allowed within this sequence, provided the number of such Stop Words between any two consecutive words is less than or equal to two. Thus named entities like *United States of America, Lord of the Rings, Bay of Bengal etc.* are recognized. This method captures a lot of false positives. One such example can be the usage of capitalization in the social media in the form of pragmatics to express the intensity of emotions (Example: *I just LOVED that movie*). However, false positives are not a concern in our case as such entries, *if valid*, will only add to the concept lists. The named entity is considered as a single token and treated just like the unigrams.

3.2 Concept List Creation

Let *w* be any given word and its expanded form given by WordNet (*set of all its synsets* and the *gloss of its first sense*) or Wikipedia (*top 2 line definition*) be denoted by w'. Let w'_j be the j[th] word in the expanded word vector. Let $seed_k$ and $root_k$ be the seed list and root words list, respectively, corresponding to the k^{th} genre. The genre of *w* is given by

$$genre(w) = argmax_k \sum_j \mathbf{1}_{w'_j \in seed_k, w'_j \in root_k}$$

$$\ldots Equation\ 1$$

Here, **1** is an indicator function which returns 1 if a particular word is present in the seed list or root words list corresponding to a specific genre and 0 otherwise. In the given example, with the pre-defined 5 genres (*Table 1*), *dunk* and *basketball* both will be classified to the *Sports* genre as they have the maximum matches (*"shot", "basketball"*) from the seed list corresponding to the *Sports* genre in their expanded concept vector.

Finally, a *concept list* is created for each genre containing *associated* words in the WordNet (ignoring those in the seed lists) and named entities in the Wikipedia.

3.3 Video Descriptor Extraction

Given a video url, the *video title*, the *meta description* of the video and all the *user comments* on the video from Youtube are retrieved. A *stopwords* list is used to remove words like *is, are, been etc.* A lemmatizer is used to reduce each word to its base form or lemma. Thus "*play*", "*played*", "*plays*", "*playing*" are reduced to its lemma "*play*".

Consider the sentence in a video descriptor, "*It was an awesome slam dunk in the NBA finals by Michael Jordan*". None of the words here is present in any seed list. But *dunk* and *NBA* are present in the concept list corresponding to *Sports* genre and thus the given sentence is associated to *Sports*. The association (*Sports* via *Basketball*) can also be captured by considering the named entity *Michael Jordon* in Wikipedia.

4 FEATURE VECTOR CLASSIFICATION

Let the video descriptor *f* consist of *n* words, in which the j^{th} word is denoted by $word_j$. The *root word list*, *seed list* and the *concept list* for the k^{th} genre are denoted by $root_k$, $seed_k$ and $concept_k$ respectively. The score of f belonging to a particular $genre_k$ is given by,

$$score(f \in genre_k; w_1, w_2, w_3) = w_1 \times \sum_j \mathbf{1}_{word_j \in root_k} + w_2 \times \sum_j \mathbf{1}_{word_j \in seed_k} + w_3 \times \sum_j \mathbf{1}_{word_j \in concept_k}$$
$$where \quad w_3 < w_2 < w_1 \qquad \ldots Equation\ 2$$

Here, $\mathbf{1}$ is an indicator function that returns 1 if a word is present in the root words list, seed list or concept list corresponding to $genre_k$ and 0 otherwise. Weights w_1, w_2 *and* w_3 are assigned to words present in the root words list, seed list and the concept list respectively. The weight assigned to any root word is maximum as it has been specified as a part of the genre description manually. Lesser weightage is given to the words in the seed list as they are automatically extracted using a thesaurus. The weight assigned to concept list is the least to reduce the effect of *topic drift* during concept expansion (Manning *et al.*, 2008). The topic drift occurs due to the enlarged context window, during concept expansion, which may result in a match from the seed list of some other genre than the one it actually belongs to.

The score of a video belonging to a particular genre is,

$$score(video \in genre_k; p_1, p_2, p_3) = p_1 \times score(f^{Title} \in genre_k) + p_2 \times score(f^{Meta\ Data} \in genre_k) + p_3 \times score(f^{Comments} \in genre_k)$$
$$\ldots Equation\ 3$$

Here p_1, p_2, p_3 denote the weight of the feature belonging to the *title*, *meta data (meta description of the video)* and *user comments* respectively where $p_1 > p_2 > p_3$. This is to assign more importance to the title, then to the meta data and finally to the user comments. The genre to which the video belongs is given by,

$$video_{genre} = argmax_k\ score(video \in genre_k)$$
$$\ldots Equation\ 4$$

This assigns the highest scoring genre as the desired category for the video. However, most of the popular videos in Youtube can be attributed to more than one *genre*. Thus to allow multiple tags to be assigned to a video, a thesholding is done and the prediction is modified as:

$$video_{genre} = k, if\ score(video \in genre_k) \geq \theta$$
$$where\ \theta = \frac{1}{k} \sum_k score(video \in genre_k)$$
$$\ldots Equation\ 5$$

If the score of the video for any genre is greater than the average score of all the genres, then it is assigned as a possible tag for the video. In case the genre scores for the 5 categories are something like {*400, 200, 100, 50, 10*} with *avg=152*, then the first 2 genres are chosen. If any of the genre score is very high compared to the others, the average will rise decreasing the chance of other genres being chosen. *Algorithm 1* describes the genre identification steps in short.

Pre-processing:

1. *Define Genres* and *Root Words List for each genre*
2. *Create a Seed list for each genre by breadth-first-search in a Thesaurus, using root words in the genre or the genre name*
3. *Create a Concept List for each genre using all the words in WordNet (not present in Seed Lists) and Named Entities in Wikipedia using Equation 1*

Input: Youtube Video Url

1. *Extract Title, Meta Description of the video and User Comments from Youtube to form the video descriptor*
2. *Lemmatize all the words in the descriptor removing stop word.*
3. *Use Equations 2-4 for genre identification of the given video*

Output: Genre Tags

Algorithm 1. Genre Identification of a Youtube Video

5 PARAMETER SETTING

The upweighting of document zones by giving more weightage to some portions of the text than others is common in automatic text summarization and information retrieval (Manning *et al.*, 2008). A common strategy is to use extra weight for words appearing in certain portions of the text like the title and use them as separate features, even if they are present in some other portion of the text (Giuliano *et al.*, 2011). As a rule-of-thumb the weights can be set as integral multiples, preferably prime, to reduce the possibility of ties (Manning *et al.*, 2008).

We follow this line of thought in our work and upweight certain portions of the text like the *title*, *meta data*, *user comments* separately. We also assign different weight to words belonging to different lists according to importance.

There are 6 parameters for the model we used: $w_1,\ w_2,\ w_3,\ p_1,\ p_2,\ p_3$. The parameters can be best trained if some label information is available. However, in the absence of any label information, we adopt a simple approach to parameter setting as mentioned above. We took the first set of integers, satisfying all the constraints in *Equations 2 and 3*, and assigned them to the 6 parameters: $w_1 = 3,\ w_2 = 2, w_3 = 1,\ p_1 = 3,\ p_2 = 2,\ p_3 = 1$.

Semi-Supervised Learning of Parameters

This work *does not* evaluate this dimension for parameter learning, since our objective has been to develop a system that requires no labeling information. However, if some category information is available, a robust learning of parameters is possible.

Equation 1 and 2 can be re-written as:

$$score\left(f_k^{position} \in genre_k; w_1, w_2, w_3\right) = w_1 \times X_{1,k}^{position} + w_2 \times X_{2,k}^{position} + w_3 \times X_{3,k}^{position}$$

$$score(video_k \in genre_k; p_1, p_2, p_3) = Y_k = \sum_{position} p_{position} \sum_j w_j \times X_{j,k}^{position}$$

$= \sum_i \sum_j w'_{ij} X_j^i \quad (where\ w'_{ij} = p_i \times w_j)$

$$Or, Y_k = \boldsymbol{W}.\boldsymbol{X}_k\ (where\ \boldsymbol{W} = \left[w'_{1,1}\ w'_{1,2} \ldots w'_{3,3}\right]^T_{9\times 1}, \qquad \boldsymbol{X}_k = [X^1_{1,k}\ X^1_{2,k} \ldots\ X^3_{3,k}]_{1\times 9}$$

$$Or, \boldsymbol{Y} = \boldsymbol{W^T}.\boldsymbol{X}$$

This is a linear regression problem which can be solved by the ordinary least squares[4] method by minimizing the sum of the squared residuals i.e. the sum of the squares of the difference between the observed and the predicted values (Bishop *et al.*, 2006). The solution for $\boldsymbol{W}$ is given by $\boldsymbol{W} = (\boldsymbol{X^T X})^{-1}\boldsymbol{X^T Y}$

A regularizer can be added to protect against over-fitting and the solution can be modified as: $\boldsymbol{W} = (\boldsymbol{X^T X} + \delta \boldsymbol{I})^{-1}\boldsymbol{X^T Y} \quad where\ \delta\ is\ a\ parameter\ and\ \boldsymbol{I}\ is\ the\ identity\ matrix.$

6 EVALUATION

6.1 Data Collection

The following 5 genres are used for evaluation: *Comedy*, *Horror*, *Sports*, *Romance and Technology*. 12,837 videos are crawled from the Youtube following a similar approach like (Cu *et al.*, 2010; Wu *et al.*, 2012; Song *et al.*, 2009). Youtube has 15 pre-defined categories like *Romance*, *Music*, *Sports*, *People*, *Comedy etc.* These videos are automatically categorized in Youtube based on the user-provided tags while uploading the video and the video description. We crawl the videos directly from those categories using the Youtube API. *Table 3* shows the number of videos from each genre.

Comedy	Horror	Sports	Romance	Tech	Total
2682	2802	2577	2477	2299	12837

Table 3: Number of Videos in Each Genre

Only the 1st page of user comments is taken with comment length less than 150 characters. Short length comments are chosen as they are typically to the point, whereas long length comments often stray off the topic. The user comments are normalized by removing all the punctuations and reducing words like "*loveeee*" to "*love*". The number of user comments varied from 0 to 800 for different videos. *Table 4* shows the average number of user comments for the videos in each genre.

Comedy	Horror	Sports	Romance	Tech
226	186	118	233	245

Table 4: Average User Comments for Each Genre

The first integer values satisfying the constraints in the equations are taken as parameter values, which are set as: $w_1 = 3,\ w_2 = 2, w_3 = 1,\ p_1 = 3,\ p_2 = 2,\ p_3 = 1.$

[4] http://en.wikipedia.org/wiki/Ordinary_least_squares

6.2 Baseline System

All the words in the video descriptor consisting of the title, meta-description of the video and the user comments are taken as features for the SVM. A Multi-Class Support Vector Machines Classifier[5] with various features, like combination of unigrams and bigrams, incorporating part-of-speech (POS) information, removing stop words, using lemmatization *etc.*, is taken as the baseline. *Table 5* shows the baseline system accuracy with various features. A *linear kernel* is used with *10-fold* cross validation. SVM with lemmatized unigrams and bigrams as features, ignoring stop words, gave the maximum accuracy of *84.36%*.

SVM Features	**F_1-Score(%)**
All Unigrams	82.5116
Unigrams+Without stop words	83.5131
Unigrams+ Without stop words +Lemmatization	83.8131
Unigrams+Without stop words +Lemmatization+ POS Tags	83.8213
Top Unigrams+Without stop words +Lemmatization+POS Tags	84.0524
All Bigrams	74.2681
Unigrams+Bigrams+Without stop words+Lemmatization	**84.3606**

Table 5: Multi-Class SVM Baseline with Different Features

6.3 YouCat Evaluation

Experiments are performed on the videos *with* and *without user comments* as well as *with* and *without concept expansion*, to find out their effectiveness in video categorization. The system does not tag every video. It will not tag a video if it does not find a clue in the video descriptor that is present in the seed list or the concept list (*i.e.* the scores are all *zero*); or when there are ties with scores for multiple genres being equal. The precision, recall and f_1-score for each genre are defined as:

$$precision = \frac{number\ of\ videos\ correctly\ tagged}{number\ of\ videos\ tagged} \times 100$$

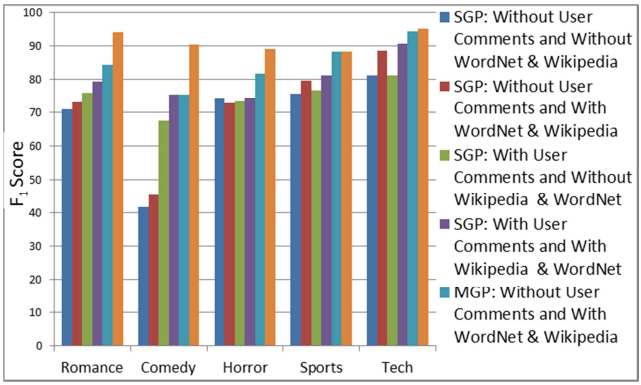
$$recall = \frac{number\ of\ video\ correctly\ tagged}{number\ of\ videos\ present\ in\ the\ genre} \times 100$$

$$f_1\ score = \frac{2 * precision * recall}{precision + recall}$$

Graph 1 shows the incremental *f_1-score* improvement for each of the genres with and without *concept expansion* as well as with and without incorporating *user comments*. It also shows the genre-wise f_1-score improvement for multi-genre prediction model.

[5] http://www.csie.ntu.edu.tw/~cjlin/libsvm/

The prediction is taken to be correct if the originally labeled tag is one of the predicted tags in a multi-genre prediction model. It may seem that the performance improvement for multiple genre identification, in our case, is trivial to achieve as the system can achieve 100% accuracy by simply assigning all the given genres to a video. This is because the prediction is taken to be correct if *any* of the predicted tags matches with the labeled tag. Thus an important performance measurement parameter is the *number of predicted tags* for each video. *Table 6* shows the average number of predicted tags for each video in each genre, with and without user comments.



SGP: Single Genre Prediction, MGP: Multiple Genre Prediction

Graph 1: Genre-wise F_1-Score Improvement for Different Models

Genre	Average Tags/Video Without User Comments	Average Tags/Video With User Comments
Romance	1.45	1.55
Comedy	1.67	1.80
Horror	1.38	1.87
Sports	1.36	1.40
Tech	1.29	1.40
Average	**1.43**	**1.60**

Table 6: Average Predicted Tags/Video in Each genre

Table 7 shows the confusion matrix when single genre prediction is done with User Comments, Wikipedia & WordNet. *Table 8* shows average f_1-score for the different models used.

Genre	Romance	Comedy	Horror	Sports	Tech
Romance	80.16	8.91	3.23	4.45	3.64
Comedy	3.13	77.08	3.47	9.03	7.29
Horror	10.03	9.34	75.78	3.46	1.38
Sports	0.70	7.30	0	89.05	2.92
Tech	0.72	5.07	0.36	1.81	92.03

Table 7: Confusion matrix for Single Genre Prediction

Model	Average F_1 Score
Multi-Class SVM Baseline: With User Comments	84.3606
Single Genre Prediction : Without User Comments + Without Wikipedia & WordNet	68.76
Single Genre Prediction : With User Comments + Without Wikipedia & WordNet	74.95
Single Genre Prediction : Without User Comments + With Wikipedia & WordNet	71.984
Single Genre Prediction : With User Comments+ With Wikipedia &WordNet	*80.9*
Multi Genre Prediction : Without User Comments + With Wikipedia & WordNet	84.952
Multi Genre Prediction : With User Comments + With Wikipedia & WordNet	**91.48**

Table 8: Average F_1-Score of Different Models

7 EVALUATION

7.1 Multi-Class SVM Baseline

The SVM has been taken as the baseline as it is found to perform the best in text classification and video categorization works. Ignoring stop words in the feature vector improved the accuracy of SVM over the all-unigram feature space. Further accuracy improvement is achieved by lemmatization. This is because all the related unigram features like *laugh, laughed, laughing etc.* are considered as a single entry *laugh*, which reduces the sparsity of the feature space.

The part-of-speech information further increased accuracy, as they help in *crude* word sense disambiguation. Consider the word *haunt* which has a noun synset and gloss as {*haunt, hangout, resort, repair, stamping ground -- (a frequently visited place)*}. It also has 3 verb synsets where the first verb sense is {*haunt, stalk -- (follow stealthily or recur constantly and spontaneously to; "her ex-boyfriend stalked her"; "the ghost of her mother haunted her")*}. Using POS information, the word haunt will have two entries now corresponding to *Noun_haunt* and *Verb_haunt*. Although the second sense is related to the *Horror* genre, the first sense is not which can only be differentiated using the POS tags.

Top unigrams help in pruning the feature space and removing noise which helps in accuracy improvement. Using *only bigrams* however decreases the accuracy as many unrelated pairs are captured which do not capture the domain characteristics. Using bigrams along with unigrams gives the highest accuracy. This is because the entities like *Michael Jordon* can be used as features as a whole, unlike in unigrams.

7.2 Overall Accuracy

Our system could not beat the multi-class SVM baseline of *84.36%* in single genre prediction; but it nevertheless achieved an f_1 score of *80.9%, without using any labeled data for training.* The multiple genre prediction, however, beats the baseline with *91.48%* f_1 score.

7.3 Effect of User Comments

The user comments often introduce noise through the off-topic conversations, spams, abuses *etc.*; the slangs, abbreviations and pragmatics prevalent in the user posts make proper analysis difficult. However, an improvement of *6 percentage point* and *9 percentage point* in the f_1 score for single genre prediction (without and with concept expansion respectively) using the comments, suggest that the greater context provided by the user comments provide more clues about the genre to help in genre identification. The corresponding improvement in the multiple genre prediction using concept expansion is around *7 percentage point*.

When concept expansion is not used, user comments contribute a performance improvement of *5 percentage point* in Romance, *1 percentage point* in Sports and a huge *26 percentage point* in Comedy. This suggests that the user information mostly helps in identifying funny videos, as well as romantic videos to some extent. Horror videos undergo mild performance degradation by incorporating user comments. Using concept expansion, user comments contribute an accuracy improvement of *6 percentage point* in Romance, a huge *30 percentage point* in Comedy and *2 percentage point* in the other genres.

7.4 Effect of Concept Expansion

In the genre identification task, using a seed set for each genre runs the risk of *topic drift*. This may occur as a concept may be identified to belong to an incorrect genre due to off-topic words by considering a larger context. However, less weightage is given to concept expansion than to a direct match in the seed list to alleviate this risk. In single genre prediction using concept expansion, an f_1 score improvement of 3 *percentage point* (when user comments are not used) and 6 *percentage point* (when user comments are used) show that Wikipedia and WordNet help in identifying unknown concepts with the help of lexical and world knowledge.

When user comments are not used, concept expansion contributes a performance improvement of *3 percentage point* in Romance, *4 percentage point* in Comedy, Sports and 7 *percentage point* in Tech. This suggests that the external knowledge sources help in easy identification of new technological concepts. Horror videos undergo mild performance degradation. Using the comments, concept expansion contributes an improvement of *8 percentage point* in Comedy and

9 percentage point in Tech. Again, the performance improvement in Comedy using Wikipedia can be attributed to the identification of the concepts like *Rotfl, Lolz, Lmfao etc.*

7.5 Average Number of Tags per Video in Multiple Genre Prediction

The number of predicted tags in multiple genre identification for each video, on an average, is *1.43* and *1.6* in the two cases (without and with user comments). This suggests that mostly a single tag and in certain cases bi-tags are assigned to the video. It is also observed that the average number of tags per video increases when user comments are used. This is due to the greater contextual information available from user comments leading to genre overlap.

7.6 Confusion between Genres

The confusion matrix indicates that Romantic videos are frequently tagged as Comedy. This is often because many Romantic movies or videos have light-hearted Comedy in them, which is identifiable from the user comments. The Horror videos are frequently confused to be Comedy, as users frequently find them funny and not very scary. Both Sports and Tech videos are sometimes tagged as Comedy. The bias towards Comedy often arises out of the off-topic conversation between the users in the posts from the *jokes, teasing etc.* Overall, from the precision figures, it seems Sports and Tech videos are easy to distinguish from remaining genres.

7.7 Issues

Many named entities in the Youtube media, especially unigrams, are ambiguous. Incorrect concept definition retrieval from the Wikipedia, arising out of ambiguity may inject noise into the system or can be ignored. For Example, a Sports video with the title "*Manchester rocks*" refers to the *Manchester United Football Club*. But Wikipedia returns a general article on the *city of Manchester* in England. None of the words in its definition matches any word in seed word lists and the entity is ignored.

Considering only WordNet synsets gives less coverage. Considering the gloss information helps to some extent. For example, if the word "*shot*" is not present in the seed list for *Sports*, then "*dunk*" cannot be associated to the *Sports* genre. But this association can be properly captured through the gloss of the WordNet first sense of "*dunk*" (- *a basketball shot in which the basketball is propelled downward into the basket*). However, it runs the risk of incorporating noise. Consider the word *good* and the gloss of one of its synsets {*dear, good, near -- with or in a close or intimate relationship*}. Here the word "*good*" is associated to *Romance* due to the presence of "*relationship*", which is incorrect.

Uploader provided video meta-data is typically small and require concept expansion to extract useful information. User comments provide a lot of information but incorporate noise as well. Auto-generated bot advertisements for products, off-topic conversation between users, fake urls, mis-spelt words, different forms of slangs and abbreviations mar the accuracy. For example, an important seed word for the *Romance* genre will not be recognized if "*love*" is spelt as "*luv*", which is common.

8 CONCLUSION

In this work, we propose a weakly supervised system, *YouCat*, for predicting *possible genre tags* for a video using the *video title*, *meta description* and the *user comments*. *Wikipedia* and *WordNet* are used for expanding the extracted concepts to detect cue words from a genre-specific seed set of words. The weak supervision arises out of the usage of a root words list (~ 1-3 words) used to describe the genre, usage of WordNet which is manually tagged and the simple parameter setting for the model. There are a number of parameters which have been simplistically set. Tuning the parameters using labeled data may improve the accuracy. An accuracy of *80.9%* in single genre prediction and *91.48%* in multiple genre prediction is obtained without using *any labeled data*, compared to the supervised multi-class SVM baseline of *84.36%* in single genre prediction. The accuracy suffers due to the inherent noise in the Youtube media arising out of the user comments and incorrect concept expansion due to ambiguity. A pre-processing filter that allows only relevant user comments about the video and a WSD module will boost the performance of the system. This work is significant as it does not use any manually labeled data for training and can be automatically extended for multiple genres with minimal supervision. This work also exhibits the usefulness of user information and concept expansion though WordNet and Wikipedia in video categorization.

Abstract

This paper presents a novel approach to document-based discourse analysis by performing a global A* search over the space of possible structures while optimizing a global criterion over the set of potential coherence relations. Existing approaches to discourse analysis have so far relied on greedy search strategies or restricted themselves to sentence-level discourse parsing. Another advantage of our approach, over other global alternatives (like Maximum Spanning Tree decoding algorithms), is its flexibility in being able to integrate constraints (including linguistically motivated ones like the Right Frontier Constraint). Finally, our paper provides the first discourse parsing system for French; our evaluation is carried out on the Annodis corpus. While using a lot less training data than earlier approaches than previous work on English, our system manages to achieve state-of-the-art results, with F1-scores of 66.2 and 46.8 when compared to unlabeled and labeled reference structures.

Keywords: Discourse Structure, Discourse Parsing, Dependency Structures, Constrained Decoding, A*.

1 Introduction

Discourse analysis involves the identification of coherence relations between discourse units, which can be either elementary ones—typically clauses or sentences—or complex ones, spanning larger chunks of text. These larger units play similar roles to elementary ones. Coherence relations categorize discourse units in terms of their argumentative, thematic or causal links to other units. Together these relations and the units they relate form the global structure of a discourse.

This structure is important as it reflects the thematic organization at various levels of granularity, and constrains semantic interpretations, for instance with respect to anaphora resolution or temporal interpretation. Discourse processing is thus a crucial part of natural language understanding, and it has potentially many applications—opinion detection and classification, question answering, information extraction, recognizing textual entailment, evaluating text coherence, or knowledge extraction to name a few (Stede, 2011; Verberne et al., 2007; Somasundaran et al., 2009; Lin et al., 2011; Gerber et al., 2010)

Producing a discourse structure automatically is a complex task, however. Coherence involves syntactic and lexical factors, and relies heavily on the semantic interpretation of its parts. Most existing work tends to focus on restricted aspects of the full problem.

The task of building a discourse structure involves three subtasks: (1) identifying discourse units (DUs), (2) "attaching" DUs to one another, and (3) labeling their link with a coherence relation. Of these, the first one is usually considered easiest (see for instance Hernault et al., 2010), the second is arguably the hardest; and as a consequence, researchers have focussed attention on the third one, labelling discourse relations (Lin et al., 2009; Feng and Hirst, 2012; Sporleder and Lascarides, 2008; Wellner et al., 2006; Louis et al., 2010). Research on discourse structure also divides into two orthogonal categories: some researchers limit themselves to intra-sentential discourse structure (Wellner et al., 2006; Sagae, 2009; Joty et al., 2012); others tackle the problem of identifying the full discourse structure of a text (Hernault et al., 2010; Subba and Di Eugenio, 2009). The latter rely on "local" models to predict potential coherence relations, assuming independence between the decisions, and build the structure guided by greedy heuristics. The exception is (Baldridge and Lascarides, 2005), who use a generative model, in the case of specific task-oriented dialogues.

In this paper, we propose a more general approach to discourse structure prediction at the document level: (i) it performs a global search over the space of possible structures and optimizes a global criterion over the set of potential coherence relations; (ii) it can also take into account linguistically motivated constraints on the predicted structure. Specifically, our approach relies on the A* search algorithm, which is particularly well suited in allowing to capture constraints such as the so-called Right Frontier Constraint (or RFC), various versions of which have been a staple of theoretical linguistic approaches to discourse (Polanyi, 1988).

Another contribution of our paper is to provide a simple formalism that captures many of the commonalities across particular representation models for full discourse structure by considering a more general graph-based model, which can nevertheless integrate framework specific constraints. Previous work relies on several different discourse representation theories and corpora—e.g., the Penn Discourse Tree Bank (PDTB) of (Prasad et al., 2008), which assumes a light-weight linear structure; Rhetorical Structure Theory (RST) and the RST treebank (Carlson et al., 2003), which assumes a constituent tree structure; Segmented Discourse Representation Theory (SDRT) from which derive the Discor and Annodis corpora

(Baldridge et al., 2007; Afantenos et al., 2012), with directed acyclic graphs; or GraphBank (Wolf and Gibson, 2006), with little if any constraints on a graph-based structure.

Incidentally, we also deliver the first discourse parsing system for French. Our evaluation is performed on the ANNODIS corpus (Afantenos et al., 2012).

The paper is structured as follows. Section 2 positions in more detail our work with respect to the existing literature on discourse parsing. Section 3 describes our approach to discourse structure "decoding". Section 4 introduces the data we use from the Annodis corpus, and sections 5-6 present our experiment design. Finally section 7 reports our results and an analysis, especially with respect to comparable work.

2 Related work

Apart from a few exceptions, research on automatic discourse analysis has focused on specific aspects of the general problem. Most work concerns the task of discourse relation labeling between pairs of DUs. Examples of this line of work are: Marcu and Echihabi (2002), Sporleder and Lascarides (2005) and Lin et al. (2009). This setting makes an unwarranted assumption, as it assumes one decision concerning labeling is independent from another. Alternatively, researchers have considered the task of predicting full discourse structures, but only at the sentence level. An example of sentence-level discourse parsing is Soricut and Marcu (2003), which makes use of dynamic programming along with a standard bottom-up chart parsing. In this case, probabilities for each sentence level discourse tree are calculated as the product of the probabilities for the structure and the relation. More recently, Sagae (2009) has developed a shift-reduce algorithm for intra-sentential discourse analysis. Their stack contains the current discourse subtree and it consumes a sequence of EDUs. Like Soricut and Marcu (2003), Sagae (2009) use the RST Discourse Treebank. RST trees are "lexicalized" through head percolation using the so-called nucleus/satellite distinction. The shift operation removes the next EDU from the sequence and pushes a subtree containing only that EDU onto the stack. The reduce operation is either unary or binary: unary reduce just pops the stack and pushes a subtree with the popped item as the only child and it's lexicalized head as its mother, while the left and right binary reduce operations pop two nodes, attach them and push them back—left and right being used to judge nuclearity.

There are two main reasons why the full task of discourse parsing has eluded NLP researchers. The first is that annotating discourse structures is a very expensive procedure. There are but modest amounts of data that have been annotated, and structured prediction views each document as a single instance. Consequently, training is not very reliable. The second reason is that the two largest discourse-annotated corpora (the PDTB and the RST corpus) enforce strong constraints on the structure (namely attachment to adjacent DUs) and are thus naturally biased toward local approaches where only attachment to the left or right DU should be considered, ignoring the interdependence of local decisions. This problem can be tackled more easily at the sentence-level, where structures are simpler with only a few discourse units. Sentences can be considered independently of one another, and provide more training instances and more reliable predictions.

Among the few attempts to build document-level discourse parsers are Subba and Di Eugenio (2009) and duVerle and Prendinger (2009). Like Sagae (2009), Subba and Di Eugenio (2009) use a transition-based approach. As in the intra-sentential work cited above, the

shift operation places the next segment on top of the stack, but there is only a *binary* reduce operation which may result in the triggering of more reduce operations. In case no reduce operation is triggered then a shift is automatically performed. Consequently, only the reduce operations need to be learned. In case that the input string is empty but the stack is not, a reduce with the relation LIST is (continuously) performed. Subba and Di Eugenio (2009) use rich linguistic features and Inductive Logic Programming for training. All results are reported on an in-house corpus, and they barely surpass the baseline that consists in always attaching to the last DU.

duVerle and Prendinger (2009), and its sequel Hernault et al. (2010) both rely on locally greedy methods, and in line with all previous works, treat attachment prediction and relation label prediction as independent problems. Specifically, they start by computing probabilities of attachments for adjacent pairs of EDUs and greedily select the highest scoring. A second classifier, applied in cascade, determines the relation for the two DUs. The pair is replaced by the created "span" and the procedure continues in a bottom up way. The recent work of Feng and Hirst (2012) extend this approach by additional feature engineering but is restricted to sentence-level parsing. These three papers all use the RST-DT.

Joty et al. (2012) deserve special mention because they consider inter-dependence of local decisions, but nonetheless limit themselves on the level of intra-sentential parsing. As a first step, they compute the *joint* probabilities for structure plus relation for all possible combinations of structures and relations within a single sentence. For the computation of those joint probabilities they use a Dynamic CRF. Once all the possible joint probabilities have been computed, they perform a classic CKY chart parsing using dynamic programming. They use features representing text organization, dominance sets, contextual information and hierarchical dependencies. This is a very interesting approach but it does not easily scale up for the whole text, at least using a CRF-like approach. This is where we distinguish ourselves by adopting a local model and then a constraint-based decoding mechanism for identifying the optimal global structure.

Another relevant paper (Baldridge and Lascarides, 2005) presents a comparable problem, namely predicting the rhetorical structure of dialogues, from the Verbmobil corpus. Dialogues are considered as documents with relations between utterances, and the authors train a PCFG to produce tree representations of the dialogue structure. It is unclear how this approach, which works on very specific task-oriented dialogues, would perform in a more general framework, especially since they require some semantic features that were annotated manually.

3 Discourse decoding under constraints

In order to recover the rhetorical structure of a document, we take as our starting point two locally-trained classifiers predicting the attachment of discourse units and the labelling of their relations, much in the same way as (Hernault et al., 2010; Subba and Di Eugenio, 2009). Our models are also "local" in the sense that the training criterion that they optimize is still local and the features they use are defined over pairs of DUs. But we differ from previous approaches in the way we use the outputs of the local classifiers to predict the overall discourse structure, as well as in the use of constraints (such as the Right Frontier Constraint) during this "decoding" phase. Yet another difference is that we predict attachment decisions and relation labeling decisions in a joint fashion, rather than in pipeline as it is done in previous work.

Before getting into the details of the decoding, let's first consider the type of structure we intend to produce. An important challenge with discourse analysis is the lack of consensus among discourse theorists as to the relevant type of representations that one should use to encode discourse structure. These theoretical differences are directly reflected in the various existing discourse annotation corpora, as most of them are based on one particular theoretical framework. As a result, the different existing systems being trained on a specific resource are framework-specific. One of our goals in this paper is to abstract away from these differences and provide a more generic approach to the problem of discourse parsing.

Consider RST-DTs. RST representations are similar to constituent-based syntactic trees, since relational structures are recursively built bottom-up from elementary discourse units to form complex discourse units and adjacency is enforced at each level. Users of RST also often assume the so-called "nuclearity principle", by which complex RST segments have a distinguished EDU as a sort of head, a procedure similar to head percolation in syntax, when converting to a constituent-based to a dependency based representation. Other frameworks like SDRT or GraphBank assume more general structures (respectively directed acyclic graphs and graphs). One uniform way to capture commonalities between these different types of representation is to convert them into a dependency graph between EDUs. Many of the differences between frameworks can be encoded with different, additional structural constraints. To capture RST up to complex segments, one translates an RST tree recursively taking the nuclearity principle into account. SDRT also has complex segments, and we address how they can be dealt with in section 4. In SDRT, discourse interpretation is supposed to be an incremental process that respects a "right frontier constraint" (RFC) (Polanyi, 1988): discourse units are supposed to be processed one by one, and the current unit can only be attached to a node on the "right frontier" formed by the last introduced node and nodes "above" it (assuming a hierarchical structure). These theories distinguish between relations that are "coordinating" (additive relations, also called multinuclear in RST) or "subordinating" (expanding relations, or nuclear-satellite in RST). In that case subordinating relations add a level to the discourse hierarchy while coordinating stay at a given level of granularity.

Dependency structures have become very prominent for *syntactic* parsing, and a number of approaches have been applied successfully to the problem. So, a natural question is whether techniques developed therein could be directly used for discourse analysis. As noted, there have been some initial attempts at adapting shift-reduce parsers to discourse. An alternative to transition-based parsing is the graph-based parsing proposed e.g. by McDonald et al. (2005). This approach is particularly appealing since it builds upon an exact search procedure for finding the best possible dependency tree: it is the Maximal Spanning Tree (or MST) on the fully connected graph defined on the sentence words. One could in principle use this approach for discourse parsing, but as with transition-based parsing, there is no obvious way to easily integrate global constraints as the RFC.

Our solution is to express the problem of discourse parsing as a state-space search with different state-space definitions and constraints, and apply a general A* exploration strategy. A* search is shortest-path search through the state of possible results (dependency graphs in our case), which orders the search considering an estimated cost of a partial solution as the sum of the cost of the part of the solution already built and the estimated cost of the remaining part to be built. Transitions between states should be here the choice of an edge between two DUs, to be added to the desired solution. Since transition costs must

be additive, the cost of an edge will be -log its probability, as given by the models for attachment and relations. The general form of such a search is shown as algorithm 1. The estimation, or "heuristics", guarantees an optimal solution under certain conditions, the most common being that the heuristics is "admissible", i.e. it always underestimates the cost of the remaining exploration.

Algorithm 1 General A* decoding. S_0 is an initial state, problem dependent. Functions g and h are the cost of 'current' so far, and the estimated cost. An example of state generation is shown in algorithm 2

```
procedure astarSearch(S_0)
    queue ← {S_0}
    while not(queue.isEmpty()) do
        current ← removeBest(queue)                    ▷ best according to g+h(current)
        if isSolution(current) then return current
        else
            newStates ← generate(current)              ▷ well formed wrt desired constraints
            queue = queue ∪ newStates
        end if
    end while
end procedure
```

In contrast to the greedy approaches of (Hernault et al., 2010; Subba and Di Eugenio, 2009), we have more control on the solution yielded by the procedure. With an admissible heuristics, A* guarantees an optimal solution with respect to the cost function on state transitions (here, the probability of a given relation between two discourse units). Limited search can further be implemented as a special case if the state-space proves to be combinatorial, by restricting A* with a beam (a pending queue of fixed size, but then losing completeness). A* has also been used in syntactic parsing because of these advantages (Pauls and Klein, 2009). Another advantage offered by A* search and used in the previous paper, lies in its ordering of hypotheses, that easily yields the n best solutions by continuing the exploration of the state space. This is useful for instance to apply reordering or ranking techniques.

The most delicate aspect of using A* is in the heuristics chosen to guide the search. We will discuss possible heuristics in section 6, as they are rather orthogonal to the current discussion.

The state-space exploration works as an incremental building of a solution and must specify mainly: (1) a starting state for building a solution and (2) allowed states from a given state. For instance an MST approach could be implemented (inefficiently, though) with a starting state consisting of just one discourse unit, or as a fake node related to the others depending on the probability of a segment to be the head of the discourse (as is done in syntactic parsing). Following states could then only add a relation between a new node and one and only one of the already chosen nodes, until all nodes are attached.

To implement the RFC, we only need to restrict the previous procedure so that new nodes can only be attached to the set of accessible nodes assuming the RFC, see for details algorithm 2.

In case one wants to stay within the RST framework, the starting state would be empty, and new states should be built by adding a relation between two adjacent active units. Active units are all elementary units at the beginning, each EDU being replaced by a complex one

as they are attached during the decoding procedure.

Algorithm 2 Example state generation for building a tree incrementally under the RFC constraint, taking the first segment as the root. For simplicity, (1) relations are ignored since the best for each edge are incorporated in the cost evaluations, and (2) no difference is made between additive or expanding relation for updating the right frontier RF. The treatment below correspond to expanding relations only. For additive relations, the new attached unit replaces the attachment point in the RF, so the RF update should be new.RF = new.RF[:k-1] + [next].

Let I = $[u_1, ..., u_n]$ the list of elementary discourse units, in text order.
And let a general state S = $\langle V, E, RF \rangle$ where V is the list of DU to be attached, E is a set of edges making up a tree, and RF is a list of accessible nodes according to the right frontier constraint. We will note the state parts as S.V, S.E and S.RF.
Initially, S = $\langle I[2:], \emptyset, [u_1] \rangle$, as we take the first segment as the root. The following will generate a tree structure respecting the RFC, approximating a SDRT DAG:

```
procedure generate(S)
    result = ∅
    next = head(S.V)
    for k in 1 to len(S.RF) do          ▷ This loop generate hypotheses attaching 'next' to every u ∈ RF.
        new = newState()
        new.V = pop(copy(S.V))                          ▷ Next is removed from the nodes to attach.
        new.E = E ∪ (next,S.RF[k])                ▷ The attachment is added to the current structure.
        new.RF = new.RF[:k] + [next]      ▷ Next is appended to the RF after its parent, everything
                                                        else below the parent is thrown out.
        result.add(new)
    end for
    return result
end procedure
```

4 The corpus used

A number of different corpora have been annotated with discourse structures. These differ in the discourse formalism they are grounded in, and from our perspective in the type of constraint they impose on the attachment of DUs. The one with the heaviest constraints on discourse attachment, and consequently the simplest structures, is PDTB (Prasad et al., 2008), as most attachment are between *adjacent EDUs*, creating no further complex structures. To be fair, the main focus of PDTB is not discourse structure *per se*, but instead the study of explicit and implicit discourse relations—as signaled by discourse markers or absence thereof. Based on *Rhetorical Structure Theory* (RST) (Mann and Thompson, 1987; Marcu, 2000), the RST Discourse Treebank (RST-DT) does have recursive structures, but it imposes heavy constraints by still enforcing adjacency (Marcu, 2000). More specifically, in RST an EDU can be attached either to its adjacent EDUs (forming what is called a *span*) or to any other adjacent span, recursively thus creating a tree.[1] Less constrained structures are found in two other approaches, first from Wolf and Gibson (2006) (the GraphBank corpus) which creates graph structures with apparently no constraints whatsoever, second from SDRT (Asher and Lascarides, 2003) which creates directed acyclic graphs imposing only the RFC. Two different annotations campaigns have used the SDRT framework: DISCOR (Baldridge et al., 2007) for English and ANNODIS (Afantenos et al., 2012) for French.

[1] It can be the case that more than two DUs (*always adjacent*) could be attached together for relations such as LIST.

We have used the ANNODIS corpus: it is a collection of French discourse annotated newspaper and Wikipedia articles; specifically, we used the so-called "expert" annotations from the sub-corpus that deals with rhetorical relations. The chief reason for choosing a corpus based on SDRT is that it provides a compromise between simplistic approaches to discourse (attachment on adjacent DUs) and completely unrestricted approaches (such as the GraphBank corpus). SDRT manages to capture fine grained discourse phenomena, such as for example long distance attachments and pop-ups, while at the same time imposing a few constraints through the distinction between hierarchical and additive relations, such as the right frontier constraint.

The relation set used in the ANNODIS annotation campaign is a strict subset of the set of relations described in Asher and Lascarides (2003) (for example, there are no meta-relations); their semantics was also simplified in order to be accessible to naive subjects. Relation distribution is shown in table 1.

relation name	#	%	relation name	#	%
alternation	18	0.5	explanation	130	3.9
attribution	75	2.2	flashback	27	0.8
background	155	4.6	frame	211	6.3
comment	78	2.3	goal	95	2.8
continuation	681	20.3	narration	349	10.4
contrast	144	4.3	parralel	59	1.8
Eelab	527	15.7	result	163	4.9
elaboration	625	18.6	temploc	18	0.5
total # relations		3355	total # EDUs		3188
total # CDUs		1395	total # texts		86

Table 1: Corpus statistics from the ANNODIS corpus

In order to be able to apply techniques from syntactic dependency parsing, we transformed SDRT Annodis annotations into dependency graphs by replacing complex discourse units with their *recursive heads*. Annotations indeed mix EDU (elementary DU) and sets of EDUs, which are comparable to large spans in RST, with less constraints on their members, and this procedure is then another kind of head percolation. The *head* of a CDU is the highest DU in its subgraph (in terms of hierarchical/subordinate relations) and leftmost or older DU in the discourse with respect to additive/coordinate relations if there is more than one. In case that the DU is a complex one, the procedure is recursively applied until an EDU is reached, in which case that is the recursive head of the CDU. This transformation is graphically depicted in figure 1 which also contains the corresponding text and segmentation in the original French language.

5 Local models

Our discourse parsing is based on two locally-trained classifiers, one that predicts the attachment site of each DU, the other that predicts a discourse relation for attached pairs of DUs. In both cases, we trained probabilistic classifiers, using two different types of model: Naive Bayes (NB) and logistic regression (aka maximum entropy, or MaxEnt for short).[2]

[2]Pamameter estimation for the latter was performed using (Daumé III, 2004), `http://www.cs.utah.edu/~hal/megam/`. We also used utilities provided by the Orange library of (Curk et al., 2005).

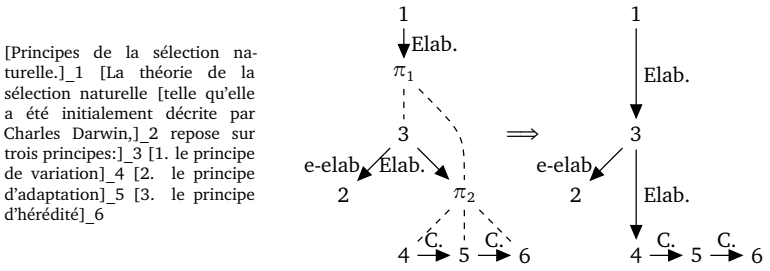

Figure 1: **An example of discourse annotation**. The nodes correspond to discourse units; the EDUs are represented by their numbering; the CDUs start with π. Dotted edges represent inclusion to a CDU while edges with arrows represent rhetorical relations. Elab. = Elaboration, e-elab = Entity Elaboration, C. = Continuation. The second graph is the result of the transformation.

The use of probabilistic models is guided by the way we combine the two models during decoding, and will be explained in Section 6.

We used two different, partially overlapping, feature sets for attachment and labeling. Overlapping features reflect an inclusion in the same sentence or paragraph, an EDU being the first of the paragraph, the number of tokens in an EDU, the number of intervening EDUs between source and target EDUs, whether the source is embedded in the target and conversely. Features specific to attachment include the presence of a discourse marker, whether the target is embedded in an EDU other than the source and a boolean feature triggered by a set of syntactic rules determining whether source (or target) is an apposition or relative clause embedded in its main clause. Features specific to labeling include: the presence of a verb, boolean features indicating which discourse relations are triggered from all discourse markers in the EDU, the syntactic category of the head token, the presence of a negation, tense agreement between head verbs of both source and target (the last three make use of syntactic dependency parses[3]) and features inspired from coreference resolution (based on pronouns and NPs).

Evaluation for the two tasks, based on 10-fold cross validation on the document level, is shown in table 2. For the relation labeling task, we use the whole set of 18 relations annotated in the Annodis corpus, but since this is a relatively small corpus, we also considered a smaller sets of relations. Following other hierarchies of relations (RST and PDTB), we grouped SDRT-inspired relations into four main groups: "structural" (parallel, contrast, alternation, conditional); "sequence" (result, narration, continuation); "expansion" (frame, elaboration, e-elaboration, attribution, comment, explanation); and "temporal" (temploc, goal, flashback, background). This corresponds roughly to the PDTB upper-level 4-way distinction, namely temporal, causal ("contingency"), comparison and expansion, with comparison being almost the same as structural without the logical relations, but the sets of fine-grain relations are somewhat different. Our 4-way coarse grain classification is also

[3]We have used Malt as a syntactic parser, trained on the french treebank `http://alpage.inria.fr/statgram/frdep/fr_stat_dep_malt.html`

more evenly distributed between relations (and instances, as it turns out).

For both tasks, we perform our experiments using a set that contains all possible pairs of EDUs, and a set that considers only pairs of EDUs whose distance is between 1 and 5 (noted "w5" for window of 5 in the table). This window was decided upon using a small development test, whose analysis revealed that around 92% of the attachment decisions fell within a window of 5 DUs. The class imbalance inherent to the attachment problem was thus reduced: the ratio of positive instances (i.e., attachments) went up roughly from 2% to 20%.

	MaxEnt	NB	Majority
w5 (18 relations)	**44.8**	34.7	19.1
full (18 relations)	43.3	32.9	19.7
w5 (4 relations)	**65.5**	62.1	51.2
full (4 relations)	63.6	60.1	50.1

	MaxEnt	NB
w5	**67.4**	61.1
full	63.5	51.3

Table 2: Relation classification accuracy (left) and F1 score for positive attachment (right), in %. For both classifications tasks the difference between Maxent and Naive Bayes is significant at $p<0.01$, using McNemar's test. The upper limit recall for the latter task in w5 configuration is 92%.

These results show that Maxent is the best model in isolation, for both tasks (it is better in both precision and recall). As expected, we also notice that the resampling increases performance in both cases; although it isn't reported here, it does however produce a small decrease in recall for the attachment task. On this task, Maxent appears to be more robust to class imbalance than NB, as shown by the relative differences between attachment F1-scores with and without resampling.

6 Parsing experiments

We divided the ANNODIS corpus in two parts: a main part and a small development set on which we had a look on the impact of some features, and most importantly on the distribution of distances between discourse units actually attached. As explained in Section 5, this leads to different sampling strategies for training the local classifiers. This will also impact decoding in pre-pruning the hypothesis space.[4]

Our various experiments are based on different combinations of classifier models (as detailed in the previous section) and decoding strategies. For attachment, we consider as instances either every pair of DUs in the same text or every pair in a distance equal to five or less. For labeling, the training is made only on attached discourse units in the training set and predictions are made on every pair tested for attachment. Features for each training procedures were detailed in section 5. As decoders, we tested a few baselines as well as MST and A*, all detailed further in this section. The last two algorithms take as input G, the complete graph over discourse units, where each edge (u, v) is labelled with the relation R having the best probability according to the relation labeling model, and the cost or weight

[4]Note that DUs are always ordered based on their left boundary. This will be important for A* decoding, which needs an ordered set of DUs in order to respect the right-frontier constraint. Practically, it means that embedded segments are attached only once their containing segment has been processed. An embedded segment is considered to be at distance one to its container.

of an edge is given by:

$$cost((u,v)) = -\log(Pr(attach(u,v) = True) \times max_R Pr(R|attach(u,v) = True))$$

This way of computing each arc cost means that we are in effect taking attachment and labeling decisions jointly, and not in a cascade as is done in the baselines.

Baselines We use two baseline decoders. The first one always selects the previous unit for attachment to the current one (noted "last"). We have also implemented a locally greedy approach similar to that of (Hernault et al., 2010). DUs are ordered based on their left boundary (embedded segments are considered to be at distance 1 from their containers). Then for all pair of adjacent units[5] (e_i, e_j) we greedily select the one that has the highest attachment probability. We remove e_i from the ordered list and continue the process until there is only one unit left in the list.

Using the Chu-Liu Edmonds algorithm The structures that result from the replacement of CDUs with their recursive heads in Annodis annotations are directed acyclic graphs, with few edges reaching a given node; they are thus very close to non-projective trees with directed arcs. Naturally then, we can apply a Maximum Spanning Tree (MST) approach, as applied by McDonald et al. (2005) in the context of syntactic dependency parsing for directed non-projective dependency trees. MST can consider an almost complete graph with a "root" as the only node with no incoming edges. In our case this node will be the first (leftmost) EDU. Using either NB or MaxEnt, we calculate the probabilities of attachment between each pair of EDUs, except for the first (root) EDU for which we calculate only the outgoing edges. We can then apply the Chu-Liu Edmonds algorithm (Chu and Liu, 1965; Edmonds, 1967), whose complexity is $O(n^3)$. MST is expected to perform well in the case that there are no additional constraints to be respected. Nonetheless, adding additional constraints is not a trivial matter.

Using the A* algorithm The general schema for A* search has been shown in section 3. Here we detail the heuristics that we have used to guide the search. In A* search, the pending queue is ordered by the estimated cost of a solution whose intermediary state is the current state s. The estimated cost is $f(S) = g(S) + h(S)$ where g is the cost of what decisions have already been taken, here the sum of the cost of selected relations so far (see above). When we build a tree under the right-frontier constraint, we have a set of discourse units yet to be attached. A heuristic yields an optimal solution if it underestimates the remaining cost (it is then an "admissible heuristic"), so that a usual way of estimating this cost is to solve the remaining problem while leaving out some constraints. To be useful the heuristics must also discriminate between comparable states, and be as close as possible to the real cost, so for instance the trivial h(s) = 0, while admissible, is useless. A more classical approach is to consider what would be the best possible decision at a given stage, if no constraint was present. For instance here, we could take, for the estimated cost of attaching a given unit, the best cost of attaching this unit to any other DU already chosen. The remaining cost of the solution is then the sum over the set of remaining DUs. Let's call this h_best. As there can be a lot of variance in the costs, another practical solution is to consider the average of attachments to every remaining nodes. This is potentially not

[5]Two units are adjacent if their distance equals 1.

admissible any more, as it can overestimate the real cost, but can yield good solutions faster. We will call this heuristics h_average. When tested on the development set, the predictions made using h_best and h_average were almost the same so we used h_average in the real experiments because it made decoding faster. Then:

$$f(S) = g(S) + h_{average}(S) = \sum_{(u,v)\in S.E} cost(u,v) + \sum_{u\in S.V} \left(\frac{\sum_{(v\in I/\{u\}} cost(v,u)}{||I||}\right)$$

For each experimental setup, we perform a document-based ten-fold cross-validation[6] on the main part of the corpus.

7 Results

This section reports on the performance obtained for our different systems. Recall that our overall goal is to evaluate labeled discourse structures, encoded here as labeled dependency graphs, produced by the different combinations of local models and decoding strategies. We also have two different training algorithms (NB vs. Maxent) and two settings based on pre-pruning possible attachment points or not. Finally, we are also interested in comparing the joint decoding of the attachments and the relation labels compared to the pipe-lining of the two procedures.

For evaluation, we take the most natural metric for dependency graphs: we compare the set of edges predicted to the reference edges, with precision, recall and F1-measure. We average on the set of all edges on all tested documents (as mentioned in the previous section, we did a cross-validation using 10 document-based folds).

Table 3 presents the results only for attachment of DUs. Besides pruning of the hypothesis space, we tested prediction of attachment alone, and prediction of attachment taking into account the probabilities of the best relations predicted to weight possible attachment (noted "joint unlabeled" evaluation in table 3). Statistical significance was tested by comparing set of scores on documents using Wilcoxon sign-ranked test for paired samples.

Training model	Naive Bayes			Maxent			∅
Decoding method	greedy	MST	A*	greedy	MST	A*	Last
attachment alone (w5)	61.2	65.7	**66.2**	62.1	65.7	65.7	62.4
attachment alone	58.5	62.0	62.1	62.2	*65.7*	*65.7*	62.4
joint/unlabelled (w5)	59.7	61.7	64.8	62.2	65.1	*65.3*	62.4
joint/unlabelled	57.9	57.0	59.6	62.3	65.1	*65.4*	62.4

Table 3: Results for unlabeled structures i.e. attachment of DUs (F1 scores, %). Windowed attachment is marked with (w5). Bold scores are the best overall while italicized scores are the best on a given setup (line). Joint unlabeled evaluation are evaluation of attachments when relations are also used to evaluate the probability of a link between DUs. A* and MST decoding do not differ significantly, but differ from all other methods. Confidence intervals at 95% are all about ± 0.9-1.2% wrt to given scores. Predicting relations does not seem to make a difference for attachment prediction.

[6]Each fold contains instances from a tenth of all documents, every document appearing in only one fold.

We see that A* and MST decoding perform at the same level without significant differences, but largely outperform all other methods. The type of learner used does not seem to make a difference in the pruned version, while Maxent is clearly better when given the whole decision space. This is clearly in line with the extra robustness noted in the classification results in the previous section.

We can observe that the best overall scores are close the F1 score for the pure attachment classification task. This seems to indicate that the impact of our global decoding strategy is not directly captured in the (edge-based) evaluation metric, and is therefore mostly a matter of exhibiting structures with desirable properties, like obeying the RFC. These might in turn be potentially useful for latter processings, such as anaphora resolution.

Training model		Naive Bayes			Maxent			
Decoding method		greedy	MST	A*	greedy	last	MST	A*
joint(w5)	4 rels	38.9	29.3	41.7	42.2	42.2	31.6	*44.1*
joint	4 rels	38.7	26.7	39.6	44.6	44.5	30.0	**46.8**
pipe-line(w5)	4 rels	39.5	42.1	42.5	42.1	42.2	*44.3*	*44.3*
pipe-line	4 rels	38.7	40.8	40.8	44.5	44.5	**46.8**	**46.8**
joint(w5)	18 rels	22.0	8.2	23.7	28.7	28.6	4.8	*30.1*
joint	18 rels	23.4	4.1	24.0	34.2	34.1	5.4	**36.1**
pipe-line(w5)	18 rels	22.5	24.0	24.5	28.7	28.6	*30.2*	*30.2*
pipe-line	18 rels	23.9	24.7	24.8	34.0	34.1	**36.1**	**36.1**

Table 4: Results of for full, labelled structures (F1 scores, %). Windowed attachment is marked with (w5). The 'last' baseline now uses a maxent model for prediction of relations. Bold scores are the best overall while italicized scores are the best on a given setup (line). Confidence intervals at 95% are all about ± 2% wrt to given scores. Best scores on each line are significantly better than the next one at $p<0.01$, except for ties. The best joint and pipe-lined scores are not significantly different from each other.

We now turn to the results on *labeled* discourse structures. The main thing to observe here is that the best decoding methods are still MST and A*, but the (expected) drop induced by relation labeling has confused the attachment results in the case of joint decoding: pipe-lining relation prediction after unlabeled attachment performs significantly better than joint decoding, at least for the best systems. It is also noticeable that pruning the attachment space is not worth it in this configuration (apart from efficiency considerations, of course). The main consequence is that we should refine our relation prediction model before drawing definite conclusions, and extend the approach to larger corpora. In hindsight, fully separating predictions within sentences or between sentences, as done in comparable work, is also something that should have been tried (we only provided features to that effect).

How can we compare these results to similar work? Taking directly Hernault et al. (2010) published scores is not easy, since they produce RST constituent trees, and use dedicated measures, namely the Parseval measures, which compares common subtrees. That is why we tried to reproduced their overall method of decoding on our data (the greedy procedure). We can still have a look at their classification scores for attachments, and the range of their evaluation for the whole structure. In their framework, it is equivalent to the tasks they call

"structure" and "nuclearity", the first being finding a pair to link, the second one being the choice of direction of the attachment, choosing the "head" of the result. When using perfect segmentation, as we do, (Hernault et al., 2010) have a F1 score of 68.4%. In (Subba and Di Eugenio, 2009), structure is predicted as relation argument spans with a F1 score of 70%, but this is similar to the attach-to-last baseline, and nuclearity is at 50% (the same baseline is at 48). It is also interesting to consider simple attachment predictions as made in (Feng and Hirst, 2012). Without knowledge of the rest of the structure, they have a F1 score of 69.84% on attachment decisions.

Again, it is hard to compare, since we don't have information about baselines comparable to ours, but we can observe the scores are in the same close ranges, while we have a simpler model with less features, trained on much less instances. Hernault et al. (2010) have 17k positively attached pairs, 77k overall, for a ratio of 23%, while we have, in the pruned version, 2.5k positive instances out of 13k (ratio $\leq$20%), and 2.7k out of 125k for the full version (2%).

For labelled structured, (Subba and Di Eugenio, 2009) report a F1 score of 35%, with 15 relations and a baseline of 22%, slightly less than our 18-relation model, while the accuracy of their relation labeler reaches 60% (a much better score than ours).

Finally, Baldridge and Lascarides (2005), who use 30 relations on the very specialized corpus of Verbmobil dialogues, report F1 scores of 68% for unlabeled structures (very close to dependency graphs), and 43% for labelled structures. The task is arguably easier since dialogues are more constrained, and since they manually annotated some features used by their probabilistic model (e.g. semantic tags, utterance mood).

Conclusions

We have proposed a general approach to discourse structure prediction at the document level, performing a global search over the space of possible structures while optimizing a global criterion over the set of potential coherence relations, in order to take into account linguistically motivated constraints on the predicted structure (e.g. the RFC). We tested this approach on a corpus of French texts which assumes theoretical aspects from SDRT, but it could and will be adapted to other type of discourse annotations, such as RST corpora, using a simple algorithm alluded to above for translating RST into dependency graphs. The results for our general approach are at least comparable to similar approaches which are arguably more specific to a given corpus and have significantly more data to train. Our relation prediction model is slightly less accurate, being induced from a smaller dataset and poorer features than the best models, but the global decoding improvements are significant over other decoding approaches, while the predictions respect the desired properties on discourse structures. Besides improving our relation model, we intend to separate completely the predictions of links for intra-sentential discourse units from other relations, as many approaches have shown that sub-problem to be much easier. We also intend to have a more structured approach to learning the structures, first by integrating decoding within the learning phase, as is done in the syntactic analysis literature we took inspiration from, and secondly by studying the usefulness of k-best parsing on the overall result.

Acknowledgments

We wish to thank our colleagues M. Serrurier and J. Mengin.

ABSTRACT

This paper presents a supervised machine learning approach to incrementally learn and segment affixes using generic background knowledge. We used Prolog script to split affixes from the Amharic word for further morphological analysis. Amharic, a Semitic language, has very complex inflectional and derivational verb morphology, with many possible prefixes and suffixes which are used to show various grammatical features. Further segmentation of the affixes into valid morphemes is a challenge addressed in this paper. The paper demonstrates how incremental and easy-to-complex examples can be used to learn such language constructs. The experiment revealed that affixes could be further segmented into valid prefixes and suffixes using a generic and robust string manipulation script by the help of an intelligent teacher who presents examples in incremental order of complexity allowing the system to gradually build its knowledge. The system is able to do the segmentation with 0.94 Precision and 0.97 Recall rates.

1 Introduction

Amharic is a Semitic language, related to Hebrew, Arabic, and Syriac. Next to Arabic, it is the second most spoken Semitic language with around 27 million speakers (Sieber, 2005; Gasser, 2011). As the working language of the Ethiopian Federal Government and some regional governments in Ethiopia[1], most documents in the country are produced in Amharic. There is also an enormous production of electronic and online accessible Amharic documents.

One of the fundamental computational tasks for a language is analysis of its morphology, where the goal is to derive the root and grammatical properties of a word based on its internal structure. Morphological analysis, especially for complex languages like Amharic, is vital for development and application of many practical natural language processing systems such as machine-readable dictionaries, machine translation, information retrieval, spell-checkers, and speech recognition.

While various approaches have been used for other languages, Amharic morphology has so far been attempted using only rule-based methods. In our previous work, we have tried to apply a machine learning approach to learn morphological rules. In the experiment, we were able to learn various affixes attached to the stem and analyze the internal stem structure of the verb which is one crucial task in Semitic morphology. The major limitation of the work concerns words made up of the stem and more than one adjacent prefix or suffix; in those cases the system fails to segment the affixes. This work presents the continuation of our previous system and attempts to further segment the affixes into valid prefixes and suffixes using generic and incremental learning without any initial knowledge of the prefixes and suffixes of the language.

2 Amharic Verb Morphology and Affixation

Amharic, with all its complex word formation nature, has been more or less thoroughly studied by linguists (Sieber, 2005; Dawkins, 1960; Bender, 1968). In addition to lexical information, the morphemes in an Amharic verb convey subject and object person, number, and gender; tense, aspect, and mood; various derivational categories such as passive, causative, and reciprocal; polarity (affirmative/negative); relativization; and a range of prepositions and conjunctions.

2.1 Amharic Verb Morphology

For Amharic, like most other languages, verbs have the most complex morphology. In addition to the affixation, reduplication, and compounding common to other languages, in Amharic, as in other Semitic languages, verb stems consist of a root + vowels + template merger (e.g., sbr + ee + CVCVC, which leads to the stem seber ሰበር[2] 'broke') (Yimam, 1995; Bender, 1968). This non-concatenative process makes morphological analysis more

[1] Some of these are: Addis Ababa City Council, Amhara Region, Benishangul-Gumuz Region and Dire Dawa Administrative Council

[2] Amharic is written in the Geez writing system. For our morphology learning system we romanize Amharic orthography, and we cite these romanized forms in this paper.

complex than in languages whose morphology is characterized by simple affixation. The affixes also contribute to the complexity. Verbs can take up to four prefixes and up to five suffixes, and the affixes have an intricate set of co-occurrence rules.

Grammatical features on Amharic verbs are not only shown using the affixes. The intercalation pattern of the consonants and the vowels that make up the verb stem will also be used to determine various grammatical features. For example, the following two verbs have the same prefixes and suffixes and the same root while the pattern in which the consonants and the vowels intercalate is different, resulting in different grammatical information.

*?-**sebr**-alehu* (እሰብራለሁ)→ *1s pers. sing. simplex imperfective*
Gloss*: 'I will break'*
*?-**seber**-alehu* (እሰበራለሁ)→ *1stpers.sing.passive imperfective*
Gloss*: 'I will be broken'*

FIGURE 1 – Stem template variation example

In this second case, the difference in grammatical feature is due to the affixes rather than the internal root template structure of the word.

*te-**seber**-ku* (ተሰበርኩ)→ *1st pers. sing. passive perfective*
Gloss*: 'I was/have been broken'*
***seber**-ku* (ሰበርኩ)→ *1st pers. sing. simplex perfective*
Gloss*: 'I broke'*

FIGURE 2 – Affix variation example

As in many other languages, Amharic morphology is also characterized by alternation rules governing the form that morphemes take in particular environments. The alternation can happen either at the stem affix intersection points or within the stem itself. Suffix-based alternation is seen, for example, in the second person singular feminine imperfect and imperative. Amharic is also characterized by alternation between morphemes of the affixes. For example, the prefix ***'ye'*** if it comes before the negative prefix ***'al'***, alternation occurs and the form changes to ***'yal'*** where the ***'e'*** sound gets deleted.

2.2 Affixation in Amharic

Languages having multiple morphemes concatenated to form prefixes and suffixes show some interrelationship and co-occurrence sequences. Affixes have predefined slots in a language. The slots constrain the occurrence of the affixes, and a generic morphological learning system should be flexible enough to learn the slots and the morphemes that can fill each of them. Such morphology learning systems may be unsupervised (Goldsmith, 2001; Hammarström & Borin, 2011; De Pauw & Wagacha, 2007) or supervised (Oflazer *et al* 2001; Kazakov, 2000). Unsupervised systems are trained on unanalyzed word forms and have the obvious advantage of not requiring segmented data. The segmentation result will help to learn rules by using thin supervised examples.

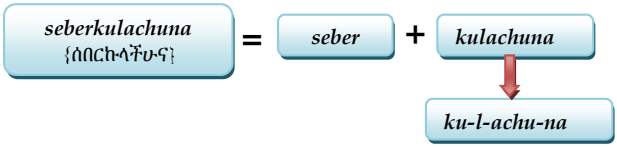

FIGURE 3 – Stem Suffix Analysis Example

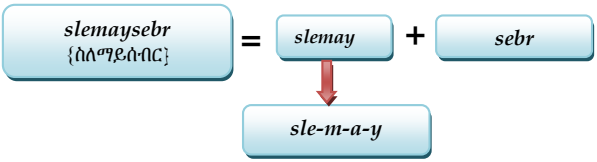

FIGURE 4 – Stem Prefix Analysis Example[3]

3 Incremental Affix Segmentation and ILP

Incremental learning dictates the use of less complex structures to be learned at early stages and move on to more complex and sophisticated structures using knowledge of previous structures as a basis. Such learning process can be implemented using Inductive Logic Programming (ILP) which is a machine learning approach that learns rules from positive and negative examples.

3.1 Incremental Learning

The problem of language acquisition has been one of the central issues in cognitive science, as well as in linguistics. Within the framework of Universal Grammar (Chomsky, 1981), language acquisition is assumed to be the process of setting the values of parameters, which are conceived of as innately-specified points of grammatical variations that have multiple consequences for the different aspects of the surface grammar. Here, Chomsky argued that language is so complex that the only way it could be learned is through innate constraints on what was a possible grammar using its parameters. More recently and in opposition to Chomsky's and others' innatist (or nativist) view, there have been arguments from psychologists and cognitive linguists who support empiricist theories of language acquisition. Among other things, they argue that innate constraints are not needed (this is one instance of the large "nature vs. nurture debate"). One of these simplifications come from what is "child-directed speech" (CDS), the simplified speech that adults naturally use when speaking to children. But of course adults adjust CDS as children get older, making it more and more complex. Thus, one argument claims that the only way children are able to learn language is through the graded simplification made by adults to the input that the child receives. This supports the idea of incremental learning, by which examples with less

[3] *The last two suffixes {a-y} are the result of the actual suffixes {al - y} transformed due to the assimilation process*

complex word structure are presented first and the knowledge of affixes acquired from early training becomes the basis of the more complex knowledge acquired later.

The ability to acquire and use language and its constructs is a key aspect that distinguishes humans from other beings. Learning is the process of acquiring knowledge over time from different realities we are exposed to. The same is true for acquiring language related facts and rules by human beings (Pirrelli & Herreros, 2005). The brain learns by observing, constantly labelling and creating its own rules that define or explain what has been observed. This learning process demands massive amount of data or exposure to relevant and interesting instances to deduce rules from. In cases where no such data is available or the aim is to learn from few examples, incremental learning through strategic example coverage would be suitable. Inspired by features of child language acquisition, the best way to learn language is by applying child language learning methods. Children observe and are able to identify similarities and add to their database such common features relating it to the meaning or the form of a word. For example, as presented by Sara Finley, when a child encounters words like {*dogs*, *cats*, *chairs*, *boys}*, he can discover part of the word forming feature similarity through the suffix 's', plural marker in this case (Finley, 2012). Thus, distributional cues are very important for children to find where relationship between words lie and find patterns for future use.

At early ages it is common to see children make such mistakes of segmenting part of the main word as affix or attaching affix on fully formed words. These actions are considered to be part of the learning process.

In morphology, learning constituents of a word in distributional or structural cues proved to be effective (Cavar, 2005) and be linked with incremental learning to teach the learner in a more logical manner. Such language processing by means of data-oriented methods emphasize the assumption that human language perception and production works with representations of concrete past language experiences, rather than with abstract grammar rules (Rens & Remko, 1996). The next section describes such incremental learning for affix segmentation task.

3.2 Incremental Affix Segmentation

Incremental learning of morphological affix segmentation results in knowledge acquisition when the system encounters new affixes, through the further segmentation of the string based on previous knowledge (Altenbek 2009). The first step in the segmentation process is to detach the affix from the main stem. This has been done using our previous system that employs inductive logic programming to learn stems and affixes as well as internal stem structure from examples (Mulugeta & Gasser, 2012). The system takes the main word and keeps database of valid affixes where the challenge relies on how to further analyze the affix into a valid list. In this regard, Prolog programming language is more suited for such action due to its easy knowledge acquisition and database manipulation features.

While we focus on Amharic verb affix segmentation and morphology learning, our goal is a general-purpose ILP morphology learner that automatically segments affixes based on previous knowledge during the learning process. Thus we seek background knowledge that is plausible across languages that can be combined with language-specific examples and

intelligent ways of presenting examples to yield rule hypotheses that generalize to new examples in the language.

3.3 Inductive Logic Programming

In induction, one begins with some plausible and selected examples during the training phase. Then, it determines what general conclusion can logically be derived from those examples. For morphological analysis, the learning data would be expected to guide the construction of word formation rules, the affix segmentation and interactions between the constituents of a word.

There have been only a few attempts to apply Inductive Logic Programming (ILP) to morphology. Most of these have dealt with languages with relatively simple morphology handling few affixations (Kazakov, 2000; Manandhar et al, 1998; Zdravkova et al, 2005). These attempts consider the affixes extracted as one singleton morpheme which is not the case for complex languages like Amharic. However, their results are found to be encouraging. The enhancement to such learning systems would be the task of further analysis of the affixes. The analysis shall include but not limited to prefix and suffix knowledge capturing through segmentation process to help build database of prefixes and suffixes for deep grammar scrutiny. This learning and knowledge acquisition task has been done using CLOG.

CLOG is a Prolog based ILP system, developed by Manandhar *et al* (1998)[4], for learning first order decision lists (rules) on the basis of positive examples only. A rule in Prolog is a clause with one or more conditions. The right-hand side of the rule (the body) is a condition and the left-hand side of the rule (the head) is the conclusion. The operator between the left and the right hand side (the sign '***:-***') means ***if***. The body of a rule is a list of goals separated by commas, where commas are understood as conjunctions. For a rule (the head) to be true, all of its conditions/goals must be evaluated to be true. In the expression below, there are two ways of evaluating the goal ***p*** even with two different results. Accordingly, ***p*** is true if ***q*** and ***r*** are true or if ***s*** and ***t*** are true[5].

$$\left.\begin{array}{l} p :- q, r. \\ p :- s, t. \end{array}\right\} \quad p \Longleftrightarrow (q \wedge r) \vee (s \wedge t)$$

*Where **q**, **r**, **s** and **t** could be facts or predicates and **p** is a predicate with any number of arguments.*

CLOG relies on output completeness, which assumes that every form of an object is included in the example and everything else is excluded (Mooney & Califf, 1995). We preferred CLOG over other ILP systems because it requires only positive examples and runs faster than the other variants (Manandhar *et al*, 1998). CLOG uses a hill climbing strategy to build the rules, starting from a simple goal and iteratively adding more rules to satisfy the goal until there are no possible improvements. The evaluation of the rules generated by the learner is validated using a gain function that compares the number of positively and negatively covered examples in the current and previous learning stages (Manandhar et al, 1998).

---

[4] CLOG is a freely avalable ILP system at: (http://www-users.cs.york.ac.uk/suresh/CLOG.html)

4 Experiments and Integration with Morphology Learning System

ILP is a rarely used method for morphology and language related learning. The approach demands well crafted background knowledge with the level of depth required for supervision and a set of positive and/or negative examples to learn from. Our previous experiment, which also uses ILP, is able to extract verb morphological rules and internal stem structure as well as orthographic alternation rules from examples on Amharic subject markers (Mulugeta & Gasser, 2012). Our system takes examples of the form shown in Figure 5 and extract morphological rules based on the various generic background knowledge crafted for the learning task.

In Figure 5, the predicate *'stem'* provides a word and its stem to permit the extraction of the affixes and root template structure of the word. The first two parameters specify the input word and the stem of the word after affixes are removed. The third parameter is the codification of the grammatical features (tense-aspect-mood, voice, subject and object) of the word. The codification is a simple knowledge about the various grammatical features of the word. For example, the fourth value in the third argument represents the object marker of the word where 2 means second person singular masculine, 6 means third person plural neuter and so forth.

```
stem([s,e,b,e,r,k,u,l,h],[s,e,b,e,r] [1,1,1,2]).
stem([s,e,b,e,r,k,l,a,c,h,w],[s,e,b,e,r], [1,1,2,6]).
stem([s,e,b,e,r,x,l,n],[s,e,b,e,r], [1,1,3,8]).
```

FIGURE 5 – Sample training examples for the learning process

The background knowledge added to handle the affix segmentation and database manipulation is generic in its nature making it applicable for any language of interest. In addition, the background predicate also includes scripts for string manipulation and root extraction. Both are language-independent, making the approach adaptable to other similar languages.

The previous system is able to generate rules of the following structure by taking the examples of the form shown in Figure 5 above.

```
stem(Word, Stem, [1, 2, 7, 0]):-
        set_affix(Word, Stem, [y], [], [u], []),
        feature([1, 2, 7, 0], [simplex, imperfective, tppn, noobj]),
        template(Stem, [1, 0, 1, 1]).

stem(Word, Stem, [2, 1, 1, 2]):-
        set_affix(Word, Stem, [te], [], [kulh], []),
        feature([2, 1,1, 2], [passive, perfective, fpsn, spsm]),
        template(Stem, [1, 0, 1, 0, 1]).
```

FIGURE 6 – Learned affix identification rule example

Accordingly, the rules learned through ILP contain three major background predicates:

- The ***'set_affix'*** predicate uses a combination of multiple 'split' operations to identify the prefixes and suffixes attached to the input word. This predicate is used to learn the affixes from examples presented by taking only the Word and the Stem parameters (the first two arguments from the example). The last four arguments of ***set_affix*** predicate represent the prefix and suffix pairs in the Word and Stem parameters.
- The ***'template'*** predicate is used to extract the valid template for Stem. The predicate manipulates the stem to identify positions for the vowels. This predicate uses the list of vowels (vocal) in the language to assign '0' for the vowels and '1' for the consonants.
- The ***'feature'*** predicate is used to associate the identified affixes and root CV pattern with the known grammatical features from the example. This predicate uses a codified representation of the grammatical features in the language, which is also encoded as background knowledge. This predicate is the only language-dependent background knowledge we have used in our implementation.

The two example rules in Figure 6 show that the prefixes *[y]* and *[te]* as well as the suffixes *[u]* and *[kulh]* are extracted from the examples with the respective root template structure. The output is limited with no further segmentation of the affixes to relate it with the grammatical features for further analysis. The current experiment includes a module which tries to do affix segmentation in incremental manner. The following algorithm and script presents how the segmentation is done in an incremental manner based on the experiment setup. While the algorithm is generic for any affix presented, the illustration shown later demonstrates that the order in which the examples are presented will dictate the knowledge acquired by the learner.

For each Suffix A extracted
    Take A as a possible Suffix
    Take any nonempty leftmost segment B of A
    Check if B exists in the Suffix database
    If B is a valid Suffix
        Remove A from the Suffix database
        Assign A to be the remaining substring
        Repeat the suffix segmentation process
End if there are no strings to segment

FIGURE 7 – Suffix segmentation algorithm

```
segS([ ]):-!.
segS(A):-
        findall(D, (append(C,D,A),C\==[ ],suffix(C),segS(D)), Segs),
        Segs==[ ]->assertz(suffix(A));!.

seg_suffix([ ],[ ]).
seg_suffix(A,[C|B]):-
        append(C,D,A),
        C\==[ ],
        suffix(C),
        seg_suffix(D,B).
```

FIGURE 8 – Suffix segmentation and list generation Prolog script

* ***segS*** *segments suffixes and updates the database whenever a new suffix is identified through the assertz predicate.*
* ***seg_suffix*** *convert one affix string into a list of morphemes enclosed in a square bracket. For example, [kulhna] will be changed to [[ku],[lh],[na]] based on prior affix knowledge.*

The system works progressively by picking examples from the training data and learning the affixes, stem template structure and alternation rules. Along with affix extraction, the systems takes each affix from the example and iteratively build its database and segment upcoming affixes based on this knowledge. The following analysis and knowledge acquisition example illustrates how the affix segmentation incrementally learns a suffix based on the examples presented.

Iteration 1
Initial Suffix Database: *{Ø}*
Training Example 1: *stem([s,e,b,e,r,k,u],[s,e,b,e,r] [1,1,1,0]).*
Stem Extraction Result: *[ ], [s,e,b,e,r], [k,u]*
Affix Identification*: [k,u] *no further segmentation as the database is empty*
Updated Suffix Database: *{ suffix([k,u])}*

Iteration 2
Initial Suffix Database: *{ suffix([k,u])}*
Training Example 2: *stem([s,e,b,e,r,k,u,l,h],[s,e,b,e,r] [1,1,1,2]).*
Stem Extraction Result: *[ ], [s,e,b,e,r], [k,u,l,h]*
Affix Identification*:{[k,u], [l,h]} *as [k,u] is already identified earlier*
Updated Suffix Database: *{ suffix([k,u]), suffix([l,h])}*

Iteration 3
Initial Suffix Database: *{ suffix([k,u]), suffix([l,h])}*
Training Example 2: *stem([s,e,b,e,r,k,u,l,h,n,a],[s,e,b,e,r] [1,1,1,2]).*
Stem Extraction Result: *[ ], [s,e,b,e,r], [k,u,l,h,n,a]*
Affix Identification*:{[k,u],[l,h],[n,a]} *as [k,u] and [l,h]are already identified earlier*
Updated Suffix Database: *{ suffix([k,u]), suffix([l,h]), suffix([n,a])}*

Iteration 4
Initial Suffix Database: *{ suffix([k,u]), suffix([l,h]), suffix([n,a])}}*
Training Example 2: *stem([s,e,b,e,r,k,u,l,a,c,h,u],[s,e,b,e,r] [1,1,1,6]).*
Stem Extraction Result: *[ ], [s,e,b,e,r], [k,u,l,h,n,a]*
Affix Identification*:{[k,u],[l,a,c,h,u]} *as [k,u] is already identified earlier*
Updated Suffix Database: *{ suffix([k,u]), suffix([l,h]), suffix([n,a]), suffix([l,a,c,h,u])}*

FIGURE 9 – Suffix learning and segmentation process illustration

The illustration in Figure 9 (only suffix learning as a show case) shows that, at the beginning of the learning process (iteration 1), the prefix and suffix database is empty assuming that the first examples to be presented shall have only a single prefix and suffix. These prefixes and suffixes shall be taken as the primary knowledge acquired. The upcoming and remaining affixes shall be learned based on this previous knowledge. After iteration 4, four suffixes are leaned that are results of incremental learning starting from an empty database and systematic presentation of examples. It should be noted here that if the example in iteration 2 has been presented first, the initial database would have been *{suffix([k,u,l,h])}* and the first example with the suffix *[k,u]* would not have any impact on its previous knowledge of suffix. This indicates that the system requires the skill of the teacher to guide the learner with more logical flow.

One potential drawback of such incremental learning is the need for an intelligent teacher. What does our teacher need to know? The most important requirement is information about the number of prefixes and suffixes that a word contains. The main constraint in presentation of words is the order of the example based on the number of affixes it contains. We would expect a literate native speaker of the language with a little linguistic training to have this awareness. One advantage of the current implementation is that, the rules learned with the segmented affixes are easily understandable by linguists. This will help the teacher to restructure the examples to formulate more logical rules and segments.

5 Results and Error Analysis

ILP has proven to be applicable for word formation rule extraction for languages with simple rules like English. Our experiment shows that the approach can also be used for complex languages with more sophisticated background predicates and more examples. While Amharic has more prefixes and suffixes for various grammatical features, our system is able to further segment the affixes into possible and valid prefixes and suffixes. With 140 training examples containing words, the stem and codified morphological features, the system is able to learn and extract 6 prefixes and 25 suffixes. Moreover, the system has learned 70 stem affix extraction rules. As stated in the experiment section, one major limitation of the approach is that the system is not able to look back on previously acquired affixes and do further segmentation.

```
stem(Word, Stem, [2, 1, 1, 2]):-
        set_affix(Word, Stem, [te], [], [[ku],[lh]], []),
        feature([2, 1,1, 2], [passive, perfective, fpsn, spsm, pos]),
        template(Stem, [1, 0, 1, 0, 1]).

stem(Word, Stem, [2, 1, 1, 2]):-
        set_affix(Word, Stem, [[al],[te]], [], [[ku],[lh],[m]], []),
        feature([2, 1,1, 2], [passive, perfective, fpsn, spsm, neg]),
        template(Stem, [1, 0, 1, 0, 1]).
```

FIGURE 10 – New Rules with Affix Segmentation Result

Another main advantage of such learned rules is the ability to review the rules and be verified by a linguist for correctness. This benefit can also be used by the teacher to decide on how to order the examples for better knowledge acquisition. If a certain example presentation generates wrong or incorrect segmentation, the teacher can easily rearrange the list of examples and see a corrected or better segmented result. Such experiments by the example provider could also help to identify complexity of word structure which is taken to be trivial for experts.

An experiment was also done to see the effect of order of examples has on the segment learning predicate. The attempt showed that most of the errors in the segmentation process arise from the ordering of examples. Thus, for example, if the system encounters the affix *[kulh]* before *[ku]*, then, the system puts *[kulh]* in its database of suffixes rather than segmenting it into *[[ku],[lh]]*. With the same token for the suffixes *[ku]* and *[k]* which are subject first person and second person masculine markers, the order of presentation might confuse the learner. If the system encounters a word with the suffix *[k]* first, then the second suffix will be spuriously segmented into *[[k], [u]]* .This necessitates that example presentation to the system should be done in an incremental way by an intelligent teacher. One of the limitations of the system, as explained above, is lack of correcting previously acquired knowledge to reformulate such rules.

In Amharic, as in many other languages with multiple affixes, the affixes may change their form in particular phonological or orthographic environments. In finite-state morphology, these changes are captured in alternation rules. Although our ILP system succeeds in learning some of the alternation rules that play a role in root-template combination and at the boundaries between stems and prefixes or suffixes, we have not yet incorporated the learning of alternation rules into the component of the system that learns to segment prefixes and suffixes through incremental presentation of examples. In the future, we will experiment with the possibility of taking advantage of the teacher's knowledge of the alternate forms of an affix to learn from successive presentations of the same affix in different environments.

The other limitation of ILP for morphology learning is the inability to learn rules from incomplete examples. In languages such as Amharic, there is a range of complex interactions among the different morphemes, but we cannot expect every one of the thousands of morpheme combinations to appear in the training set. When examples are limited to only some of the valid morpheme combinations, CLOG is inadequate because it is not able to use variables as part of the body of the predicates to be learned.

To measure the effectiveness of the system, precision and recall is used to see the ratio of valid segmentation that exists in the data with the segmentation done by the system. From the 140 words provided to the system, a linguist extracted 221 valid segmentations. It should be noted here that some of the segmentations might appear in a number of instances in the data. From the same data set the system is able to extract 227 segmentations while 215 of this segmentation are correct segmentations that match with the linguist's analysis. The system has shown over generation of segments. The following figure shows the precision and recall values according to the statistics presented above.

$$Precision = \frac{Number\ of\ Correct\ Segmentation}{Total\ Number\ of\ Segmentations\ Found} = \frac{215}{227} = 0.94$$

$$Recall = \frac{Number\ of\ Correct\ Segmentation}{Total\ Number\ of\ Segmentations\ in\ the\ Data} = \frac{215}{221} = 0.97$$

FIGURE 11 – Precision and Recall result

The precision and recall result is satisfactory enough to implement the system in large scale examples and words with more complexity.

We are currently implementing the concept of mutual information to build knowledge from already known facts and rules entertaining partial information. The concept of partial information could be integrated with ILP to generate more rules from rules handling features and affix co-occurrences not found in the training example.

Conclusion

We have shown in this paper that ILP can be used to fast-track the process of learning morphological rules of complex languages like Amharic with a relatively small number of examples. Our experiment also showed that affixes could further be segmented into possible valid prefixes and suffixes during the learning process by building knowledge of affixes on the fly using incremental learning methods. Our previous implementation have gone beyond simple affix identification and confronts one of the challenges in template morphology by learning the root-template extraction as well as stem-internal alternation rule identification exhibited in Amharic and other Semitic languages. The current update aiming on affix manipulation also succeeds in segmenting affixes into valid prefixes and suffixes using database generated on the fly during the training phase. As the rules and segmentations are presented in easy and human understandable list of rules, the teacher could restructure the examples and feed the learner to gain better result as needed.

Semi-supervised Noun Compound Analysis with Edge and Span Features

Yugo MURAWAKI Sadao KUROHASHI
Graduate School of Informatics, Kyoto University
Yoshida-honmachi, Sakyo-ku, Kyoto, 606-8501, Japan
{murawaki, kuro}@i.kyoto-u.ac.jp

ABSTRACT
In this paper, we propose the use of *spans* in addition to edges in noun compound analysis. A span is a sequence of words that can represent a noun compound. Compared with edges, spans have good properties in terms of semi-supervised parsing. They can be reliably extracted from a huge amount of unannotated text. In addition, while the combinations of edges such as sibling and grandparent interactions are, in general, difficult to handle in parsing, it is quite easy to utilize spans with arbitrary width. We show that spans can be incorporated straightforwardly into the standard chart-based parsing algorithm. We create a semi-supervised discriminative parser that combines edge and span features. Experiments show that span features improve accuracy and that further gain is obtained when they are combined with edge features.

TITLE AND ABSTRACT IN JAPANESE

スパンとエッジ特徴量を用いた半教師あり名詞句解析

名詞句解析において，エッジだけでなくスパンを手がかりとして使うことを提案する．スパンは名詞句を表しうる単語列であり，エッジと比べて半教師あり学習に適した性質を持っている．すなわち，大量の生テキストから高い信頼性をもって抽出可能である．さらに，エッジは解析時に組み合わせ (兄弟や孫の関係など) を考えることが一般に難しいのに対して，スパンは任意の長さの組み合わせを自明に利用できる．この論文では，スパンが動的計画法による標準的な構文解析手法に簡単に組み込めることを示し，エッジとスパン特徴量を組み合わせた半教師ありの識別型構文解析器を提案する．実験により，スパン特徴量が解析精度を改善し，エッジと組み合わせることでさらに精度が向上することが示された．

1 Introduction

Words are used as a basic unit in a broad range of applications in natural language processing. However, it often happens that what we need to recognize turn out to be longer than single words. They are phrases, noun compounds in particular, that consist of more than one word.

A noun compound is not just a sequence of words but has a latent structure. Consider the following example in Japanese.

[*jidou* [*onsei ninshiki*]]
automation speech recognition
automatic speech recognition

The brackets indicate the internal structure of the noun compound. In addition to the right-branching structure, it has another possible interpretation.

[[*jidou onsei*] *ninshiki*]
automation speech recognition
recognition of automatic speech

Our goal is to recognize that the former is semantically coherent while the latter is not. In order to analyze the internal structures of noun compounds, we need some automatic method because they are too large in number and too productive to be covered by a hand-crafted lexicon. This task is called noun compound analysis.

Noun compound analysis can be seen as a task of dependency parsing (Lauer, 1995). However, it is different from usual full-sentence parsing in that part-of-speech tags help little, if at all. A noun compound is just a sequence of nouns and lacks grammatical markers. For this reason we take fully lexicalized approaches in noun compound analysis.

Fully lexicalized approaches often suffer from the data sparseness problem. Apart from the observation that nouns have much higher domain specificity than other words, a model needs to learn the lexical association of a pair of words. However, we can never create an annotated corpus that covers the combinations of tens of thousands of words.

To overcome data sparseness, it seems promising to take semi-supervised approaches that exploit a huge amount of unannotated text. In fact, recent studies have shown that web statistics greatly improve the accuracy of noun compound analysis (Lapata and Keller, 2004; Nakov and Hearst, 2005a; Bergsma et al., 2010; Pitler et al., 2010).

One problem with incorporating web statistics into the dependency model is that dependency relations (edges) are latent and cannot be observed in unannotated text. Edge counts are approximated by bigrams of successive words (Nakov and Hearst, 2005a) or rely on a search engine's `NEAR` operator (Lapata and Keller, 2004). These counts are noisy as they may not represent true dependency relations.

In this paper, we propose the use of *spans* in addition to edges. A span is a sequence of words that can form a noun compound. Spans have two advantages over edges. First, unlike noisy edges, spans can be reliably extracted from unannotated text without abandoning a large portion of data. Second, it is quite easy to handle spans with arbitrary width in a parsing model. We show that web span counts can be used straightforwardly in the standard chart-based parsing algorithm. By contrast, combinations of edges such as sibling and grandparent interactions cannot easily be incorporated into dynamic programming.

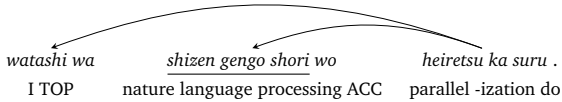

Figure 1: *Bunsetsu*-based dependency parsing for "I parallelize natural language processing." The dependency relations are drawn between *bunsetsu* phrases. The internal structure of the noun compound (underlined) is left unanalyzed.

We create a semi-supervised discriminative parser that can combine multiple factors: features learned directly from training data, web-derived edge features and web-derived span features. In addition, we introduce web-derived paraphrase features, which can be seen as mixtures of edges and spans.

Experiments show that span features improve accuracy and are robust across domains. It is also shown that the edge and span features play complementary roles. The combination of these features boost performance in out-of-domain data.

2 Related work

2.1 Background of the task

The phrase structure grammars dominated English parsing research for a long time although dependency parsing has seen rapid progress in the last decade. The most influential annotated corpus for the phrase structure grammars would be the Penn Treebank (Marcus et al., 1993). Unfortunately, the original Penn Treebank does not annotate the internal structures of noun compounds but leaves them flat. The situation changed when Vadas and Curran (2007a) added internal structures to noun compounds in the Penn Treebank and gave rise to supervised approaches to English noun compound analysis (Vadas and Curran, 2007b; Bergsma et al., 2010; Pitler et al., 2010).

Japanese parsing faces a similar situation but dependency parsing is the preferred choice in order to handle its flexible word order (Uchimoto et al., 1999; Kudo and Matsumoto, 2002). In Japanese dependency parsing, dependency relations are drawn between phrasal units called *bunsetsu* although there is an attempt at word (morpheme)-based dependency parsing (Flannery et al., 2011). In a *bunsetsu* phrase, one or more content words are followed by zero or more function words (morphemes). This means that, as illustrated in Figure 1, the internal structure of a noun compound is left unanalyzed because it is contained in a *bunsetsu* phrase. Thus noun compound analysis has a complementary relationship with full-sentence dependency parsing.

2.2 Noun compound analysis

Noun compound analysis, also called noun compound bracketing, is the task of analyzing the internal structure of a given noun compound. There is an old debate between what are called the adjacency model and the dependency model. Figure 2 compares the two models for three-word noun compounds, which were the primary focus of early work. The adjacency model (Marcus, 1980; Liberman and Sproat, 1992; Pustejovsky et al., 1993; Resnik, 1993) examines the lexical association between neighboring words. It checks if the pair of N_2 and N_3 is more strongly associated than the pair of N_1 and N_2. The dependency model (Lauer, 1995) compares the association between N_1 and N_3 against that between N_1 and N_2. Lauer (1995) and subsequent studies demonstrate that the dependency model performs better than

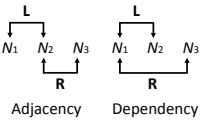

Figure 2: Adjacency and dependency models. A reproduction of Figure 1 in Lauer (1995).

the adjacency model. In this paper, however, we show that a generalization of adjacency is useful for noun compound analysis.

Since dependency relations (edges) are latent, annotated data are required to learn the true lexical association. Otherwise we need some approximation methods with which the lexical association is estimated from unannotated text. In an unsupervised setting, Lauer (1995) investigated two methods of approximation:

1. counts from two-word noun compounds, and
2. co-occurrences of a pair of nouns within some fixed window.

The former was shown to outperform the latter.

Subsequent studies have focused on the use of web statistics. We can today obtain huge amounts of text from the web. With this situation, various studies in various fields of natural language processing report performance improvement with the use of web-scale text (Banko and Brill, 2001; Brants et al., 2007; Sasano et al., 2009). In noun compound analysis, Lapata and Keller (2004) and Nakov and Hearst (2005a) used search engine hit counts. Bergsma et al. (2010) and Pitler et al. (2010) utilized Google's N-gram.

Web-based approaches need approximation methods because the web is essentially unannotated text. Lapata and Keller (2004) used a search engine's `NEAR` operator, which might correspond to co-occurrence statistics. Nakov and Hearst (2005a) relied on phrase search. The result can be interpreted as bigrams of successive words. Bergsma et al. (2010) and Pitler et al. (2010) seem to have used bigram counts (plus unigram counts to calculate probabilities).

2.3 Use of arbitrarily sized chunks

The use of arbitrarily sized chunks is relatively new in natural language analysis. Traditionally it has been done by decomposing an input into minimal elements. In probabilistic context-free grammars, for example, the probability of generating a tree is the product of the probabilities of generating each derivation rule. Similarly, a first-order dependency parser defines the score of a dependency tree as the sum of the score of all edges in the tree (McDonald et al., 2005).

The use of arbitrarily sized chunks resulted in a huge success in statistical machine translation (Koehn et al., 2003). Recent studies successfully make use of arbitrarily sized chunks in various tasks of natural language analysis too. Chunks range from sequences (Wood et al., 2011) to tree fragments (Post and Gildea, 2009) and subtrees (Johnson et al., 2007) of phrase-structure grammars. They are usually realized by non-parametric Bayesian models, which provide a way to balance between data fitting and model complexity.

A drawback of non-parametric Bayesian inference is high computational cost that makes it difficult to scale to the web. This is especially the case when Markov chain Monte Carlo sampling is used for inference because it is difficult to parallelize in a theoretically sound way. For this reason, we seek a different kind of statistics that are applicable to a huge amount of web text.

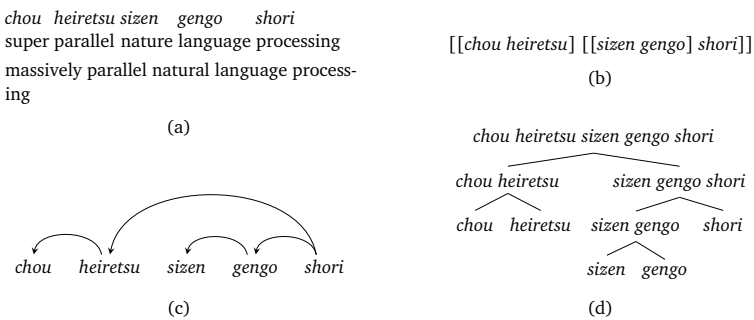

Figure 3: Various representations of a noun compound. (a) Word sequence with word-by-word and full translations. It is taken as the input by our parser. (b) Bracketed representation for its internal structure. (c) Equivalent dependency tree with edges. (d) Span-based binary tree representation.

3 Noun compound analysis

3.1 Task settings

In noun compound analysis, the model takes each noun compound as input and outputs its internal structure. The input is a word sequence as shown in Figure 3a. Since Japanese does not delimit words by white-space, we assume that a word sequence is provided either manually or by some automatic analyzer.

The internal structure of a noun compound can be denoted by brackets (Figure 3b). Bracketing of a noun compound can equivalently be represented as a binary tree. We assume the head-final order for dependency. In other words, a non-final word always modifies a word on its right. With this assumption, we can transform the bracketing structure of a noun compound into an equivalent dependency tree (Figure 3c) and thus noun compound bracketing can be formalized as a parsing problem. Also we can avoid some complex issues that arise from bidirectional parsing (Eisner and Satta, 1999; Johnson, 2007).[1] Alternatively we can use a span-based binary tree representation (Figure 3d). As the output we may think of any representation above.

Formally, our parser is given a word sequence $\boldsymbol{n} = n_1, \cdots, n_L$ as input. Its goal is to output the correct tree $\boldsymbol{t}$. We ignore noun compounds if length $L < 3$ because we assume that their structures are unambiguous. We consider a (semi-)supervised setting. The annotated noun compounds $\mathcal{T} = \{(\boldsymbol{n}_i, \boldsymbol{t}_i)\}_{i=1}^{T}$ are used to train our parser.

3.2 Initial dependency parser

We treat noun compound analysis as a structure prediction problem. Previous studies focused on three word noun compounds that only require a single binary decision per input (Lauer, 1995; Lapata and Keller, 2004; Nakov and Hearst, 2005a; Bergsma et al., 2010), handled longer noun compounds but relied on a series of local decisions (Barker, 1998; Vadas and Curran, 2007b), or used a pseudo-generative model based on a local discriminative classifier (Pitler et al., 2010). By contrast, we directly score entire trees for a given noun compound. We do not

[1] We speculate that our span features, described below, are technically applicable to bidirectional parsing. We leave the application to non-Japanese languages for future work.

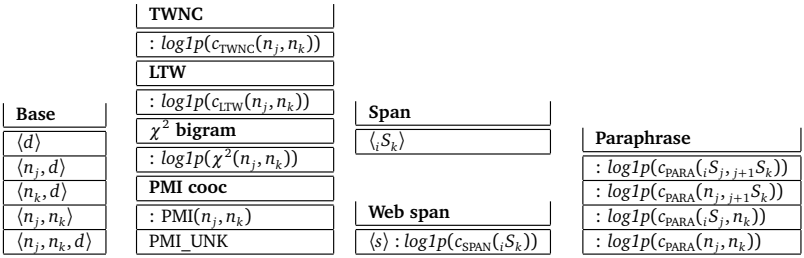

Table 1: Features used by our parser. We consider the combination of spans ${}_iS_j$ and ${}_{j+1}S_k$, and an edge is drawn between n_j and n_k. $\langle x \rangle$ denotes a template that is expanded into multiple features. The left-hand side of the colon is the feature's name. Omitted when obvious. The right-hand side is the feature's value. Binary-valued when omitted. (a) Base edge features. $d = k - j$ is the distance between n_j and n_k (1, 2, 3, 4 or ≥ 5). (b) Web-derived edge features. (c) Span features. $s = k - i + 1$ is the width of the span ${}_iS_k$ (2, 3, 4, 5 or ≥ 6). (d) Paraphrase features.

re-impelemt earlier models but, for comparison, incorporate them as features of our parser.

We begin with a first-order projective dependency model (Eisner, 1996; McDonald et al., 2005), which will be extended later. Specifically we use a high-dimensional linear classifier. The score of a dependency tree is defined as the sum of the score of all edges in the tree,

$$score(\boldsymbol{n}, \boldsymbol{t}) = \sum_{(j,k) \in edges(\boldsymbol{t})} \boldsymbol{w} \cdot \boldsymbol{\phi}(j,k)$$

where $edges(\boldsymbol{t})$ returns all edges in $\boldsymbol{t}$, $\boldsymbol{\phi}(j,k)$ gives a feature vector for the edge between n_j and n_k, and $\boldsymbol{w}$ is the corresponding weight vector that will be learned during training.

Table 1a shows features used by the initial parser, all of which are binary-valued. Unlike full-sentence parsing, noun compound analysis heavily relies on the edge distance d because an overwhelming majority of non-final words modify words to their immediate right. Also d helps the model capture some suffix-like words' tendency to being modified by their left-hand neighbors.

Given $\boldsymbol{w}$ and $\boldsymbol{n}$, we want to find $\boldsymbol{t}$ such that

$$\boldsymbol{t} = \operatorname*{argmax}_{\boldsymbol{t}'} score(\boldsymbol{n}, \boldsymbol{t}').$$

Following (McDonald et al., 2005), we adopt a lexicalized CKY chart parsing algorithm. Just like the one for context-free grammars, our algorithm uses bottom-up dynamic programming. For the word sequence $n_1, \cdots, n_L$, we consider a *span* ${}_iS_j = n_i, \cdots, n_j$ $(i \leq j)$, which holds a score. Our algorithm is simpler than that of McDonald et al. (2005) because we assume the head-final order. Thus whereas bidirectional parsing needs to keep 3 indices for each span, we only need one.

We begin with single-word spans, iteratively combine a pair of spans ${}_iS_j$ and ${}_{j+1}S_k$ to create a larger span ${}_iS_k$, and end up with ${}_1S_L$, the span for the whole word sequence. When ${}_iS_j$ and ${}_{j+1}S_k$ are combined, an edge is drawn between n_j and n_k. Given j, the score of ${}_iS_k$ is the sum of its own edge score and the scores of ${}_iS_j$ and ${}_{j+1}S_k$. To create ${}_iS_k$, we check every possible pair of subspans ${}_iS_j$ and ${}_{j+1}S_k$ by iterating over j and select the one best.

Algorithm 1 Passive-aggressive training (PA-I, prediction-based updates, weight averaging).

Input: training data $\mathcal{T} = \{(\boldsymbol{n}_i, \boldsymbol{t}_i)\}_{i=1}^{T}$

$\boldsymbol{w} = \mathbf{0}$; $\boldsymbol{v} = \mathbf{0}$
for $n = 1..N$ **do**
  shuffle $\mathcal{T}$
  for $(\boldsymbol{n}, \boldsymbol{t}) \in \mathcal{T}$ **do**
    predict $\hat{\boldsymbol{t}} = \text{argmax}_{\boldsymbol{t}}\ score(\boldsymbol{n}, \boldsymbol{t})$
    calculate cost ρ, the number of misidentified edges
    if $\rho > 0$ **then**
      loss $l = score(\boldsymbol{n}, \hat{\boldsymbol{t}}) - score(\boldsymbol{n}, \boldsymbol{t}) + \rho$
      $\tau = \min\{C, l/\|\Phi(\boldsymbol{n}, \boldsymbol{t}) - \Phi(\boldsymbol{n}, \hat{\boldsymbol{t}})\|^2\}$
      $\boldsymbol{w} = \boldsymbol{w} + \tau(\Phi(\boldsymbol{n}, \boldsymbol{t}) - \Phi(\boldsymbol{n}, \hat{\boldsymbol{t}}))$
      $\boldsymbol{v} = \boldsymbol{v} + \boldsymbol{w}$
    end if
  end for
end for
$\boldsymbol{w} = \boldsymbol{v}/(N * T)$

We use an online learning algorithm for training. We implement the online passive-aggressive algorithm (Crammer et al., 2006). Specifically we use the variant named PA-I, with prediction-based updates (Crammer et al., 2006) and weight averaging (Collins, 2002). Algorithm 1 gives the pseudo-code, in which $\Phi(\boldsymbol{n}, \boldsymbol{t}) = \sum_{(j,k) \in edges(\boldsymbol{t})} \boldsymbol{\phi}(j, k)$. We set C as 1.0.

3.3 Noun compound extraction

Next we extend the initial parser with web statistics. While previous studies relied on search engine hit counts (Lapata and Keller, 2004; Nakov and Hearst, 2005a) or n-grams (Bergsma et al., 2010; Pitler et al., 2010), we directly utilize an unannotated text corpus.

In preparation for calculating web statistics, we extract noun compounds from the web corpus. To do this, we first apply the morphological analyzer JUMAN[2] to each sentence to segment it into a word sequence. We then use the dependency parser KNP[3] to identify noun compounds. At a pre-processing step before dependency parsing, KNP chunks a given word sequence into *bunsetsu* phrases. We examine each nominal *bunsetsu* phrase, drop function words that follow content words, and extract sequences of noun and noun-like words. Extracted noun compounds are clean since word segmentation and phrase chunking can be done highly accurately. Note that extracted noun compounds include two-word ones.

3.4 Web-derived edge features

3.4.1 Two-word noun compounds (TWNC and LTW)

Using extracted noun compounds, we introduce web-derived edge features that measure the association between child n_j and head n_k. Following Lauer (1995), we begin with the simplest method of approximation, namely the use of counts from two-word noun compounds. Let $c_{\text{TWNC}}(n_j, n_k)$ be the number of two-word noun compounds that consist of n_j and n_k. We take the log of $c_{\text{TWNC}}(n_j, n_k)$ (to be precise, we use $log1p(x) = log(1 + x)$ to avoid zeros) and

[2] http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?JUMAN
[3] http://nlp.ist.i.kyoto-u.ac.jp/EN/index.php?KNP

add the result as one additional feature of the parser (**TWNC**, first of Table 1b). As usual, its corresponding weight is tuned using training data.

One advantage of this method is that the result is very clean because we only use a reliable portion of data. However, it has more chance of suffering from the problem of data sparseness than methods that exploit full data. Certain dependency relations might appear only in noun compounds with three or more words.

Alternatively, we focus on the last two words of every noun compound, which in our assumption always have a dependency relation. We take *log1p* of $c_{\text{LTW}}(n_j, n_k)$, the number of such word pairs (**LTW**, second of Table 1b).

3.4.2 Chi-squared bigram measure (χ^2 bigram)

Nakov and Hearst (2005a) used the bigram count $c(n_j, n_k)$, or the number of pages returned by a search engine in response to queries for the exact phrase "$n_j\ n_k$." Instead we collect all bigrams from noun compounds extracted from the web corpus. Either way, bigrams are not clean because they may not represent true dependency relations.

Nakov and Hearst (2005a) empirically showed that the χ^2 dependency measure performed better than other measures. The χ^2 measure is defined as follows:

$$\chi^2(n_j, n_k) = \frac{N(AD - BC)^2}{(A+C)(B+D)(A+B)(C+D)}$$

where $A = c(n_j, n_k)$, $B = c(n_j, \overline{n_k})$, $C = c(\overline{n_j}, n_k)$, $D = c(\overline{n_j}, \overline{n_k})$, and $N = A+B+C+D$ ($c(n_j, \overline{n_k})$ is the number of bigrams in which n_j is followed by a word other than n_k). Zero counts are replaced by 0.5. We take *log1p* of the χ^2 measure and add the result as one additional feature of the parser (χ^2 **bigram**, third of Table 1b).

3.4.3 PMI co-occurrence measure (PMI cooc)

Co-occurrences of n_j and n_k within noun compounds are yet another option although co-occurrences are also rough approximations of dependency relations. Since co-occurrence statistics require much larger space than successive bigrams, we only store pairs of words whose co-occurrence counts are greater than or equal to 10.

We follow Pitler et al. (2010) and use the pointwise mutual information (PMI)[4]

$$\text{PMI}(n_j, n_k) = log \frac{p_{\text{cooc}}(n_j, n_k)}{p_{\text{left}}(n_j) p_{\text{right}}(n_k)},$$

where $p_{\text{cooc}}(n_j, n_k)$ is the probability of the pair n_j, n_k appearing in the same noun compound in this order, $p_{\text{left}}(n_j)$ is the probability of n_j appearing in the left side of co-occurrence pairs, and $p_{\text{right}}(n_k)$ is defined in a similar manner.

We append $\text{PMI}(n_j, n_k)$ as a new feature. Another feature PMI_UNK is fired alternatively if $p_{\text{cooc}}(n_j, n_k) = 0$, $p_{\text{left}}(n_j) = 0$ or $p_{\text{right}}(n_k) = 0$ (**PMI cooc**, last of Table 1b).

[4]We could try any combination of (1) χ^2 and PMI, and (2) bigrams and co-occurrences. We did not investigate this further because experiments showed that simple log-counts performed very well.

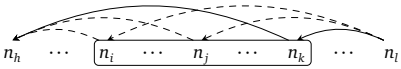

Figure 4: Span as constraints. The box denotes span ${}_iS_k$. The dashed edges are ruled out by the span while the solid ones are still possible.

3.5 Span features

The crux of our parsing model is the use of span features in addition to edge features. To do this, we first rewrite the score function in accordance with the parsing algorithm:

$$score(\boldsymbol{n}, \boldsymbol{t}) = \sum_{(i,j,k) \in spans(\boldsymbol{t})} \boldsymbol{w} \cdot \boldsymbol{\phi}(i, j, k)$$

where $spans(\boldsymbol{t})$ returns all spans with width ≥ 2, which we call non-trivial spans. Non-trivial spans correspond to non-leaf nodes in Figure 3d. The 3-tuple (i, j, k) represents each non-trivial span ${}_iS_k$ that consists of two subspans ${}_iS_j$ and ${}_{j+1}S_k$ ($i \leq j \leq k$). Edge features introduced in Sections 3.2 and 3.4 only use j (child) and k (head).

Now we introduce span features, which add a score to ${}_iS_k$. It is clear that even with this extension, we can still use the CKY algorithm for parsing. For each non-trivial span ${}_iS_k$, we add its span score only after selecting the best pair of subspans ${}_iS_j$ and ${}_{j+1}S_k$ by iterating over j because span features do not depend on j. The training algorithm is the same as before.

The selection of a span constrains multiple edges at once as illustrated in Figure 4. For span ${}_iS_k$, only n_k can interact with the outside of the span: n_k can be modified by n_h ($h < i$), and n_k can modify n_l ($k < l$). However, n_j ($i \leq j < k$) cannot be modified by n_h or cannot modify n_l. This property is useful when, for example, the widely used term "*jidou onsei ninshiki*" (automatic speech recognition) is followed by "*shisutemu*" (system). The selection of a span for the first three words rules out the edge between "*jidou*" (automatic) and "*shisutemu*" (system), and the edge between "*onsei*" (speech) and "*shisutemu*" (system) although both edges are plausible when context is ignored.

We employ two types of span features (**Span** and **Web span** in Table 1c). One is a set of binary features, each of which corresponds to a non-trivial span appearing in the training data. The other is a set of web-derived features, grouped by span width. We take *log1p* of $c_{\text{SPAN}}({}_iS_k)$, the number of times ${}_iS_k$ appears as the noun compound in the web corpus. For $c_{\text{SPAN}}({}_iS_k)$, we do not consider a noun compound nested in a longer noun compound because they cannot be identified confidently. Thus web-derived spans are clean even though we exploit the whole data.

Span features can be seen as a generalization of adjacency employed in early studies (Lauer, 1995). While adjacency is the measure of association between two successive words, span features cover not only two successive words but longer word sequences. As seen above, the parser can easily handle spans with arbitrary width. By contrast, combinations of edges can be handled with dynamic programming only if they are restricted to certain patterns such as consecutive siblings and grandparents (McDonald and Pereira, 2006; Koo and Collins, 2010).

3.6 Paraphrase features

In preliminary experiments, we discovered that many noun compounds took the form of predicate-argument pair. Such a predicate noun compound typically contains a *sahen* noun,

which functions as a verb when followed by light verbs such as *suru* (to do), *dekiru* (can do) and *sareru* (to be done). A nominal predicate-argument pair can be paraphrased by the combination of a noun phrase and a verbal phrase. For example, the noun compound "*sizen gengo shori*" (natural language processing) has corresponding explanatory expressions including

sizen gengo wo ‖ *shori suru*
nature language ACC processing do
to process natural language(s)

(‖ denotes a phrasal boundary). Conversely, this expression suggests the bracket structure "[[*sizen gengo*] *shori*]" ([[natural language] processing]).

We collect pairs of predicate and argument noun compounds from the web corpus and incorporate them as paraphrase features. We follow Kawahara and Kurohashi (2001) for extracting predicate-argument pairs. Although parsing errors are inevitable, we can circumvent this problem by exploiting the constraints of Japanese dependency structures: head-final and projective. The simplest example would be the second-to-last phrase of a sentence, which always depends on the last phrase. With such constraints, we can focus on syntactically unambiguous dependency pairs. For a newspaper corpus, 20.7% of dependency relations are extracted and their accuracy is 98.3% (Kawahara, 2012, p.c.).

For an argument noun phrase, we accept it only if it has the nominative (*ga*) or accusative (*wo*) case marker. For a predicate, we do not distinguish the type of light verbs ("to do," "can do", "to be done" and others). Note that predicate noun compounds may be longer than one word. The following examples are two-word noun compounds that can be used as predicates.

soshiki ka	*shouryou seisan*
organ -ization	little-volume production
organization (the act of organizing)	little-volume production

Paraphrase features conform with the three-argument feature function $\boldsymbol{\phi}(i, j, k)$ and can be used straightforwardly in dynamic programming. We employ four features as shown in Table 1d. The first feature takes *log1p* of $c_{\text{PARA}}({}_iS_j, {}_{j+1}S_k)$, the number of times span ${}_iS_j$ is used as an argument of a verbal phrase derived from span ${}_{j+1}S_k$. The second feature is based on $c_{\text{PARA}}(n_j, {}_{j+1}S_k)$, which resembles that of the first feature but uses the head word n_j instead of the span ${}_iS_j$. The third and fourth features are defined in similar manners. These features are mixtures of edges and spans.

Nakov and Hearst (2005a) incorporated hyphen, concatenation and other paraphrase-based cues into noun compound bracketing. For example, *cell-cycle* and *healthcare* reinforce the bracket structures "[[*cell cycle*] *analysis*]" and "[[*health care*] *reform*]" respectively. They have no Japanese counterpart, however. Other tasks of linguistic analysis in which simple paraphrase features are used include word segmentation (Kaji and Kitsuregawa, 2011) and PP attachment (Nakov and Hearst, 2005b; Bansal and Klein, 2011).

4 Experiments

4.1 Data

In-domain data We first built annotated data for both training and testing. We used the NTCIR1 TMREC test collection (Kageura et al., 1999).[5] It consisted of 1,870 Japanese paper

[5] We chose this test collection simply because it can also be used in future research on applications of noun compound analysis.

abstracts in the field of computer science. Gold-standard segmentation and POS tagging were provided.[6]

Following Nakagawa and Mori (2002), we extracted uninterrupted noun sequences as noun compounds. We discarded chunking errors, and single-word and two-word noun compounds. We randomly selected 3,100 noun compounds and manually annotated them with dependency relations.

Out-of-domain data We constructed two sets of annotated noun compounds for testing. We used J-STAGE,[7] an online collection of electronic journals. We collected Japanese papers in the fields of agriculture (**Out-of-domain 1**) and material science (**Out-of-domain 2**).

We extracted noun compounds through the procedure described in Section 3.3. We discarded segmentation and chunking errors, and two-word noun compounds. We randomly selected 1,000 noun compounds for each set and manually annotated them with dependency relations.

Web corpus The web corpus from which web statistics was calculated was compiled through procedures proposed by Kawahara and Kurohashi (2006). It consisted of about 70 million Japanese web pages.

4.2 Models

We trained and tested the parser with various combinations of features. For each model, we run 20 iterations for online learning. We conducted 5-fold cross-validation on the in-domain data. For out-of-domain data, we trained each model on the whole in-domain data.

For comparison, we also examined three baseline methods.
Left-branching Every non-final word modifies its immediate right neighbor.
Right-branching Every non-final word modifies the final word.
Random Choose a dependency tree at random.

4.3 Evaluation measures

We measured the performance of the parser with unlabeled attachment score (UAS). UAS is defined as the proportion of correctly identified dependency relations. Note that we did not exclude the second last word, which in our assumption always modified the last word. We allowed annotators to break the assumption although we found none. We used McNemar's test of significance to evaluate the degree of difference between a pair of model outputs.

4.4 Results

Table 2 shows unlabeled attachment scores. The left-branching baseline was strong because an overwhelming majority of non-final words modified their immediate right neighbors. The discriminative parser managed to beat the left-branching baseline even with the **Base** features alone.

Not surprisingly, porting to out-of-domain data resulted in drops in accuracy. These disparities can be explained by the fact that while for in-domain data, 64.6% of edges (word pairs, regardless of distance) in test data were observed at least once in training data, the number dropped drastically to 5.0% and 5.4% for out-of-domain data.

[6] Segmentations were sometimes inconsistent with those of the morphological analyzer JUMAN, which was used for building web statistics. This might have a slightly unfavorable impact on performance.

[7] `https://www.jstage.jst.go.jp/browse/`

Model	In-domain (7,717 edges)	Out-of-domain 1 (2,370 edges)	Out-of-domain 2 (2,389 edges)
Left-branching	88.32	86.20	86.40
Right-branching	49.03	53.54	52.66
Random	68.47	69.11	69.61
Base	94.27	88.44	88.32
+ TWNC	94.32	90.17**	92.42**
+ LTW	94.27	88.31	89.74**
+ χ^2 bigram	94.13	87.43	88.70
+ PMI cooc	94.30	87.93	88.91
+ Span	94.40	88.23	88.87*
+ Web span	94.35	88.86	90.41**
+ Span + Web span	94.43	88.86	90.83**
+ Paraphrase	94.08	88.06	88.74
+ Span + Web span + TWNC	94.54	90.13**	92.21**
+ Span + Web span + Paraphrase	94.46	89.49*	91.53**
+ Span + Web span + TWNC + Paraphrase	**94.64***	**90.30****	**93.01****

Table 2: Unlabeled attachment scores. * and ** mark statistically significant improvement over the **Base** model with $p < 0.05$ and $p < 0.01$ respectively.

Among the four types of web-derived edge features, the simplest **TWNC** feature performed best, consistently improving accuracy. The gains obtained for out-of-domain data were remarkable. Somewhat unexpectedly, the **LTW** feature performed much worse than **TWNC**. The χ^2 **bigram** and **PMI cooc** features were consistently beaten by **TWNC**.

For in-domain data, the **Span** features alone resulted in a performance gain slightly larger than **TWNC**. However, they seemed too domain-specific as they did not work well for out-of-domain data. By contrast, the **Web span** features brought consistent gains to both in- and out-of-domain data. Adding only the **Paraphrase** features to the **Base** model had a negative impact for in-domain data and out-of-domain 1.

The results indicate the complementary nature of the edge, span and paraphrase features. The combination of these features generally boosted performance. This was especially true for out-of-domain data. 0.63% and 0.70% gains were obtained when the **Paraphrase** features were added to the **Base** + **Span** + **Web span** model even though **Paraphrase** alone did not work well. **TWNC** alone worked well for out-of-domain data, but further gain was obtained when the **Span**, **Web span** and **Paraphrase** features were added. The highest scores were achieved by the **Base** + **Span** + **Web span** + **TWNC** + **Paraphrase** model (hereafter, the full model) for all datasets.

4.5 Discussion

We found that web span features were useful for complementing weak edges. In "[*fonon* [*jiyuu enerugī*]]" ([phonon [free energy]]), for example, the well-known term "*jiyuu enerugī*" (free energy) is modified ad hoc by "*fonon*" (phonon). The edge between "*fonon*" (phonon) and "*enerugī*" was so weak that in the **Base** model it was unable to override the strong preference for short-distance dependency. On the other hand, the web span feature strongly supported "*jiyuu enerugī*" (free energy). A powerful span means that non-head words within the span must not be modified from outside the span. For this reason, the edge between "*fonon*" (phonon) and "*jiyuu*" (free) was ruled out.

However, the span features sometimes had an adverse impact on parsing. Consider the following example.

[[*shinka gēmu*] *riron*]
evolution game theory
evolutionary game theory.

The full model wrongly output "[*shinka* [*gēmu riron*]]" ([evolutionary [game theory]]). This noun compound can be interpreted as a fusion of "*shinka gēmu*" (evolutionary game) and more prominent "*gēmu riron*" (game theory). In other words, the non-head word (game) of the latter is modified by the grafting of the former. However, our span features do not allow such an operation.

This inherent weakness of span might also explain the poor performance of paraphrase features. We investigated the weight vector of the full model. Somewhat surprisingly, we found that among four paraphrase features, only $c_{\text{PARA}}(n_j, {}_{j+1}S_k)$ (the argument's head word and the predicate's span) had a positive weight. In other words, the argument span ${}_iS_j$ was considered useless or even harmful by the model. One possible reason is the productivity of the argument. ${}_iS_j$ in paraphrase features imposes the condition that n_j must not be modified from outside the span. However, such a modification occurs very often. Even if the correct pair ${}_iS_j, {}_{j+1}S_k$ is covered by the web corpus, it is often blocked by another pair ${}_{i'}S_j, {}_{j+1}S_k$ $(i < i')$, which usually has larger counts.

While we use flat spans, the same is true of genuine tree models. Our span features show some similarity to adaptor grammars (Johnson et al., 2007), a generalization of probabilistic context-free grammars.[8] An adaptor grammar directly considers a distribution of subtrees rooted by a common non-terminal instead of decomposing them into derivation rules. A subtree is completely expanded into terminals. If subtrees are collapsed into terminal sequences, they become spans.

The adaptor grammar does not allow subtrees to be modified partially. This is unfavorable in general because "*parallel processing*" is productively modified by an adverb and transformed into "*massively parallel processing*" for example. To address this problem, we need to handle incompletely expanded trees that are to be completed by a *substitution* operator and/or we need to introduce an *insertion* operator (Shindo et al., 2011). For the semi-supervised setting of noun compound analysis, we may need collapsed versions of these operations.

4.6 Effect of corpus size

Finally, we investigated the effect of the size of the corpus from which we calculated web statistics. We reduced the number of web pages to 1/10, 1/100 and 1/1000. The models were trained and tested as before.

Figures 5(a)-(c) show UASs in relation to corpus size. In-domain data did not receive benefit from the increase of unannotated text. It seems that the Base and Span features, which were learned directly from annotated data, were too informative for the other features to work with.

For out-of-domain data, accuracy largely consistently improved with the corpus size except for the **Base** + **Paraphrase** model. The graphs indicate that further gain can be achieved by

[8] Adaptor grammars are not irrelevant to dependency parsing as dependency grammars can be transformed into context-free grammars (Johnson, 2007). The original adaptor grammars do not allow self-recursion, which is integral to dependency-derived CFGs, but this restriction was overcome by a variational inference scheme (Cohen et al., 2010).

simply enlarging the corpus. This is supported by Figure 5d, which depicts how many edges and spans in test data appear at least once in the web statistics. There is much room for improving coverage.

Conclusion

In this paper, we proposed a semi-supervised method for noun compound analysis that combined span features with edge features. Experiments show that span features improve accuracy and that further gain is obtained when they are combined with edge features.

Words within noun compounds are arranged in a rather fixed order, and adding a word in between appears to impair semantic coherence. The very fact that people often choose bracketing to denote the internal structure of a noun compound may be an intuitive justification of the use of spans since the bracket structure obscures dependency but shows spans more clearly.

Learning Effective and Interpretable Semantic Models using Non-Negative Sparse Embedding

Brian Murphy Partha Pratim Talukdar Tom Mitchell
Machine Learning Department
Carnegie Mellon University
{bmurphy,ppt,tom}@cs.cmu.edu

Abstract

In this paper, we introduce an application of matrix factorization to produce corpus-derived, distributional models of semantics that demonstrate cognitive plausibility. We find that word representations learned by Non-Negative Sparse Embedding (NNSE), a variant of matrix factorization, are sparse, effective, and highly interpretable. To the best of our knowledge, this is the first approach which yields semantic representation of words satisfying these three desirable properties. Though extensive experimental evaluations on multiple real-world tasks and datasets, we demonstrate the superiority of semantic models learned by NNSE over other state-of-the-art baselines.

Keywords: distributional semantics, sparse coding, neuro-semantics, vector-space models, interpretability, word embeddings.

Proceedings of COLING 2012: Technical Papers, pages 1933–1950,

1 Introduction

State-of-the-art distributional models of semantics, also termed vector-space models or word embeddings, derive word-representations in an unsupervised fashion from large corpora. They are primarily based on observed co-occurrence patterns, but are typically subsequently reduced in dimensionality using techniques such as Clustering, Latent Dirichlet Allocation (LDA) (Blei et al., 2003), or Singular Value Decomposition (SVD). They have proven effective as components of a wide range of NLP applications, and in the modelling of cognitive operations such as judgements of word similarity (Sahlgren, 2006; Turney and Pantel, 2010; Baroni and Lenci, 2010), and the brain activity elicited by particular concepts (Mitchell et al., 2008). However, with few exceptions (e.g. Baroni et al., 2010), the *representations* they derive from corpora are lacking in cognitive plausibility.

For instance, one of the SVD-based models described in this paper models similarity very successfully, revealing the set of words *mango, plum, cranberry, blueberry, melon* as the cosine-distance nearest neighbours of *pear*. However, the latent SVD dimension for which *pear* has its largest weighting is hard to interpret – its most strongly positively associated tokens are *action, records, government, record, search*, and negatively associated tokens are *sound, need, s, species, award*. In addition, the representation of *pear* is a dense vector of small positive or negative values on several hundred dimensions which are also active for words of all types and domains, whether semantically similar (e.g., other living things, and concrete objects) or dissimilar (e.g., abstract nominals, and function and content words of other parts-of-speech).

Certain cognitive arguments against such a representation are based on economy of storage (see Schunn, 1999; Murphy, 2004; Griffiths et al., 2007 for broader discussion on this point). A-priori it seems unlikely that the same compact set of features are sufficient and necessary to describe all semantic domains of a full adult vocabulary. Some very specific words may need more detailed descriptions (i.e., more properties) and generic words less. Properties are restricted to particular classes of concepts – limbs to animals, functions to manipulable artefacts, wheels to vehicles – and even within restricted semantic domains some features can be very specific to certain concepts, such as screens to electronic devices, antennae to insects and stripes to certain kinds of animal. It would also be uneconomical for people to store all negative properties of a concept, such as the fact that dogs do not have wheels, or that airplanes are not used for communication. And indeed in feature norming exercises (Garrard et al., 2001; McRae et al., 2005; Vinson and Vigliocco, 2008) where participants are asked to list the properties of a word, the aggregate descriptions are typically limited to approximately 10-20 characteristics for a given concrete concept, with limited overlap in features across semantic domain. So, for cognitive plausibility, we claim that a feature set should have three characteristics: it should only store positive facts; it should have a wide range of feature types, to cover all semantic domains in the typical mental lexicon; and only a small number of these should be active to describe each word/concept.

In the context of distributional models of semantics, these characteristics correspond to a non-negative and sparse embedding of lexical meaning. Of course, a raw co-occurrence matrix (whether based on local structural features, or document-region features) or certain derived measures such as positive pointwise mutual information (PPMI) will also be sparse and non-negative, but they lack the discovery of effective synonymy in the latent features of a dimensionality-reduced matrix. As a result, in this paper, we propose to apply sparse matrix factorization, with a constraint of non-negativity on the word-latent matrix.

In this paper, we introduce a new application of matrix factorization to produce a corpus-derived

distributional model of semantics with these desirable characteristics. We find that such word representations are effective in tasks of interest, are sparse, and are also interpretable, when learned by Non-Negative Sparse Embedding (NNSE) – a variation on Non-Negative Sparse Coding, which is a matrix factorization technique previously studied in the machine learning community (Hoyer, 2002; Mairal et al., 2010). To the best of our knowledge, this is the first approach whose output embeddings satisfy all these three desirable properties. We first compare its performance against a wide range of word-embedding methods (including LDA, SVD-based models, and Collobert & Weston's 2008 method) using a suite of behavioural benchmarks that are based on human judgements of lexical similarity. On these tasks the SVD and NNSE models have a decisive advantage, and we follow with an exploration of optimal dimensionality, also on a neurosemantics task (Mitchell et al., 2008). While both SVD and NNSE models have similar peak performance, their dependence on dimensionality is opposed: small numbers of features are optimal for SVD models, and large numbers of feature dimensions are optimal for NNSE models.

We then go on to explore the reasons for these differences, but examining the degree of sparsity seen in the SVD and NNSE models considered, and how easily each dimensional feature can be interpreted, using crowd-sourced judgements (Boyd-Graber et al., 2009). Here, the advantages of the NNSE models are very clear.

The paper is organized as follows: in Section 2, we breifly review the SVD and NNSE matrix factorization methods. Section 3 describes the main experiments, which evaluate various word embedding models in terms of felicity on human conceptual tasks, their degree of sparsity, and their ease of interpretability. In Section 4 we review related work, and then in Section 5, we conclude with a discussion of this new model's relation to other such models, and add some suggestions for further work.

2 Methods

Let $X = [\mathbf{x}_1, \mathbf{x}_2, \ldots \mathbf{x}_n] \in \mathbb{R}^{m \times n}$ be the input representation, where m is the number of words and n is the number of input dimensions (derived from corpus co-occurrence patterns). Each element $X_{i,j}$ represents the value of the j^{th} dimension for the i^{th} word. We are interested in embedding the m words in a k dimensional space, where $k < n$ usually. In other words, we are interested in estimating matrix $A \in \mathbb{R}^{m \times k}$, where the i^{th} row, $A_{i,:}$, represents the new embedding for the i^{th} word.

Although we compare many different word embedding techniques in our experiments, we describe below the two techniques, Singular Value Decomposition (SVD) and Non-Negative Sparse Embedding (NNSE), which we found to be most effective in our evaluation tasks (see, Section 3). In addition to task performance, we find that the embeddings learned by NNSE are also sparse and interpretable, two critical properties which are missing from the embeddings learned by SVD.

2.1 Singular Value Decomposition (SVD)

Singular Value Decomposition (SVD) is a matrix factorization technique which identifies the dimensions within each model with the greatest explanatory power, and which also has the effect of combining similar dimensions (such as synonyms, inflectional variants, topically similar documents) into common components, and discarding more noisy dimensions in the data. Given our input matrix $X \in \mathbb{R}^{m \times n}$, SVD performs the following decomposition:

$$X = USV^T \tag{1}$$

where $q = \min(m, n)$, $U \in \mathbb{R}^{m \times q}$, S is a $q \times q$ a diagonal matrix with sorted (largest to smallest) singular values on its diagonal, and $V \in \mathbb{R}^{n \times s}$. From this decomposition, we get our required embedding A as follows:

$$\begin{aligned} r &= \min(q, k) \\ A &= U(:, [1:r]) \end{aligned}$$

Please note that when X is centered, SVD and Principal Components Analysis (PCA) yield the same embedding. Latent Semantic Analysis (LSA) (Deerwester et al., 1990), a very popular technique used in Information Retrieval, performs SVD on a word by document matrix. We note that in our case, the matrix X is not restricted to be a word-document matrix.

In order to perform SVD on large and sparse X, we use the Implicitly Restarted Arnoldi method (Lehoucq et al., 1998; Jones et al., 2001). We refer the interested reader to these references for more details on the algorithm.

2.2 Non-Negative Sparse Embedding (NNSE)

In this section, we describe the Non-Negative Sparse Embedding (NNSE) method, a variation on Non-Negative Sparse Coding (NNSC), which is a matrix factorization technique previously studied in the machine learning community (Hoyer, 2002; Mairal et al., 2010). Given our input matrix X, NNSE returns a sparse embedding for the words in X (each word's input representation corresponds to a row in X). NNSE achieves this by solving the following optimization problem:

$$\begin{aligned} \arg \min_{A \in \mathbb{R}^{m \times k}, D \in \mathbb{R}^{k \times n}} \quad & \sum_{i=1}^{m} \left(||X_{i,:} - A_{i,:} \times D||^2 + \lambda ||A_{i,:}||_1 \right) \\ \text{where,} \quad & D_{i,:} D_{i,:}^T \leq 1, \ \forall 1 \leq i \leq k \\ & A_{i,j} \geq 0, \ \forall 1 \leq i \leq m, \ \forall 1 \leq j \leq k \end{aligned} \tag{2}$$

where $D \in \mathbb{R}^{k \times n}$ is a dictionary with k entries, $\lambda \in R$ is a hyperparameter, and $||A_{i,:}||_1 = \sum_{j=1}^{k} |A_{i,j}|$ is the l_1 regularization of the i^{th} row of A. The goal here is to decompose the input matrix X into two matrices, A and D, subject to the constraints that the length of the dictionary entries (rows of D) are upper bounded by 1, the rows of A are sparse, and that entries in A are all non-negative (i.e., $A_{i,j} \geq 0$). Unlike NNSC, NNSE does not impose a constraint of non-negativity on D.

Alternatively, this can also be thought of as a mixture model, with the A providing mixing proportion over the dictionary entries in D. This problem is also known as *basis pursuit* (Chen et al., 2001). The NNSE formulation can also be equivalently posed as a matrix factorization problem, and in this respect, both SVD and NNSE are different types of matrix decomposition algorithms.

We note that the NNSE objective is not convex with respect to the coefficients A and dictionary D. However, it is convex with respect to each variable when the others are kept fixed. We use the online algorithm in Mairal et al. (2010) to solve the NNSE optimization problem shown above. We refer the reader to Section 3 of Mairal et al. (2010) for details on the algorithm. The online algorithm is guaranteed to convergence, and it returns the non-negative sparse embedding matrix A (along with the dictionary D), whose i^{th} rows is the new embedding for the for the word whose input representation is given by the i^{th} row of matrix X. We note that overcomplete decomposition, i.e., $k > n$, is possible in case of NNSE. For all experiments in this paper, we set $\lambda = 0.05$ and implement NNSE using the SPAMS package[1].

3 Experiments

In this section we try to answer two main questions: what broad categories of word embedding methods are most effective in modelling cognition; and which of the well-performing models are more cognitively plausible. Several of the models evaluated were already available, and were adopted from Ratinov et al. (2010) (Collobert & Weston, HLBL), and from Řehůřek and Sojka (2010) (LDA topic model based on the English Wikipedia).

The SVD and sparse non-negative models on which we concentrate, were constructed from scratch, based on both LSA-style word-document co-occurrence counts (i.e., word-region features) and HAL-style word-dependency co-occurrence counts (i.e., word-collocate features). Counts were computed from a large English web-corpus, Clueweb (Callan and Hoy, 2009), over a fixed 40,000 word vocabulary. These were the most frequent word-forms found in the American National Corpus (Nancy Ide and Keith Suderman, 2006) summing to 97% of its token count, and should approximate the scale and composition of the vocabulary of a university-educated speaker of English (Nation and Waring, 1997).

The dependency counts were taken from a 16 billion word portion of Clueweb, extracted with the Malt parser, which achieves accuracies of 85% when deriving labelled dependencies on English text (Hall et al., 2007). The features extracted are pairs of dependency relation and lexeme, corresponding to each edge linked to a target word of interest (e.g., the word *coach* might have the dependency features *successful_adj, fires_obj, hires_subj*). This kind of model (Lin, 1998; Padó and Lapata, 2007; Baroni and Lenci, 2010) can be viewed as a more linguistically informed variant of flat window models (e.g., HAL, Lund et al., 1995) or directional models (Schütze and Pedersen, 1993; Bullinaria and Levy, 2007; Murphy et al., 2012). As is common with such models, a co-occurrence frequency cut-off (of 20 – see Bullinaria and Levy, 2007 for a systematic evaluation of this parameter) was used to reduce the dimensionality of the frequency matrix, and to discard noisy counts.

The document co-occurrence counts were taken from 10 million documents of Clueweb. The document model can be viewed as a variant of LSA (Deerwester et al., 1990; Landauer and Dumais, 1997), with differences in the frequency normalisation procedure. A frequency cut-off of 2 was used, so all counts of 1 were discarded (Bradford, 2008).

All models we constructed used positive pointwise-mutual-information (3,4) as an association measure to normalize the observed co-occurrence frequency $p(w,f)$ for the varying frequency of the target word $p(w)$ and its features $p(f)$. PPMI up-weights co-occurrences between rare words, yielding positive values for collocations that are more common than would be expected by chance, and discards negative values that represent patterns of co-occurrences that are *rarer* than one would expect by chance (i.e., if word distributions were independent). It has been shown to perform well generally, with both word- and document-level statistics, in raw and dimensionality reduced forms (Bullinaria and Levy, 2007; Turney and Pantel, 2010). The previous frequency cut-off is also important here, as PMI is positively biased towards hapax co-occurrences.

$$\mathrm{PPMI}_{wf} = \begin{cases} \mathrm{PMI}_{wf} & \text{if } \mathrm{PMI}_{wf} > 0 \\ 0 & \text{otherwise} \end{cases} \tag{3}$$

$$\mathrm{PMI}_{wf} = log\left(\frac{p(w,f)}{p(w)p(f)}\right) \tag{4}$$

The SVD matrix factorisation was first computed separately on the dependency co-occurrence matrix, and on the document co-occurrence matrix, with an output for each of 1000 latent dimensions. For

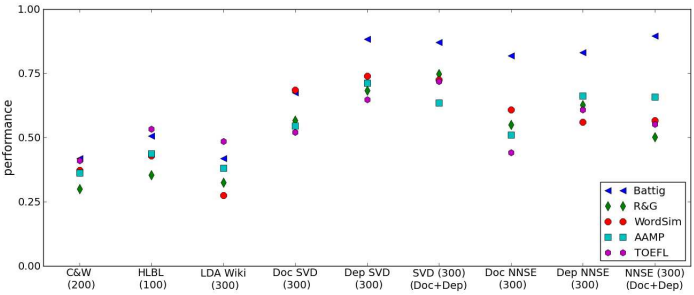

Figure 1: Behavioral evaluation of range of model types, with number of dimensions in parentheses (see Section 3.1.1 for more details).

this step we used Python/Scipy implementation of the Implicitly Restarted Arnoldi method (Lehoucq et al., 1998; Jones et al., 2001) which was coherent with the PPMI normalization used, since a zero value represented both negative target-feature associations, and those that were not observed or fell below the frequency cut-off. The combined SVD model was computed using conventional SVD on the 2000-dimensional concatenation of the output of the previous step – that is the two left singular vectors from the dependency and document models respectively.

While in principle it would be possible to produce the NNSE models directly on the co-occurrence data, here we chose to do this by using the SVD left-singular vectors as a stand-in for the full data. In other words, this is our input representation matrix $X \in \mathbb{R}^{m \times n}$ with $m = 35560$ words and $n = 2000$ input dimensions. Using these lower-noise approximate intermediate matrices reduces the computational task dramatically.

In the rest of this section, we evaluate the following. How effective are the different representations, and different dimensionalities, in various extrinsic evaluation tasks (Section 3.1)? How sparse are the SVD and NNSE representations (Section 3.2)? And how interpretable are these representations (Section 3.3)? All the NNSE representations used in the experiments in this section will be available at `http://www.cs.cmu.edu/~bmurphy/NNSE/`.

3.1 Evaluating Model Performance

3.1.1 Behavioral Experiments

The cognitive plausibility of computational models of word meaning has typically been tested using behavioural benchmarks, such as emulating elicited judgements of pairwise similarity or of category membership (Lund and Burgess, 1996; Rapp, 2003; Sahlgren, 2006).

Here we used five such tests. The two categorization tests were the Battig (Battig and Montague, 1969) test-set consisting of 82 nouns, each assigned to one of 10 concrete classes; and the AAMP (Almuhareb and Poesio, 2004) test-set containing 402 nouns in a range of 21 concrete and abstract classes from WordNet (Miller et al., 1990). Both these tests were performed with the Cluto clustering package (Karypis, 2003) and cosine distances, and success was measured as percentage purity over clusters based on their plurality class. Two sets of similarity judgements were used: the Rubenstein

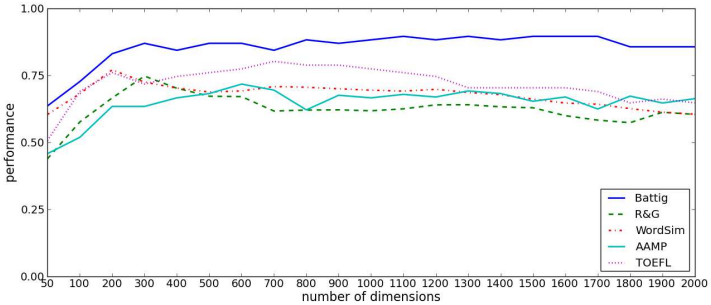

Figure 2: Behavioral evaluation of SVD models with range of dimensionality (see Section 3.1.1 for more details).

and Goodenough (1965) set of 65 concrete word pairs, and the strict-similarity subset of 203 pairs (Agirre et al., 2009) selected from the WordSim353 test-set (Finkelstein et al., 2002). Performance was evaluated with the Spearman correlation between the aggregate human judgements and pairwise cosine distances between word vectors in the model in question. Finally the TOEFL benchmark (Landauer and Dumais, 1997) consists of aggregate records from an examination task for learners of English, who have to identify a synonym among a set of distractors. Performance was measured as the percentage correct over 80 questions, if the cosine-distance of the target-synonym pair was smaller than the distance between the target and any of the distractor words.

For the NNSE and SVD models constructed here, an initial dimension setting of 300 was chosen, as this is in the middle range of those typically used in the literature. Where there was a choice with the other models we used the largest dimensionality available. For each of these two dimensionality reduction techniques, one model was constructed on the basis of document co-occurrences only (labelled "Doc" in the Figure 1), one using dependency co-occurrences only ("Dep"), and one using both sets of features combined ("Doc+Dep").

From Ratinov et al. (2010) we took both the Collobert & Weston model (200 unscaled dimensions) and the HLBL model (100 scaled dimensions).[2] The LDA model was the default implementation included with the Gensim package (Řehůřek and Sojka, 2010): an incremental algorithm based on Hoffman et al. (2010), over the English Wikipedia, using TF-IDF adjusted co-occurrences.

As in clear from Figure 1 the SVD and NNSE models out-perform the other embeddings, though we cannot exclude that these models would be competitive with other parameter settings than those available, such as with a larger source corpus, or a different number of explanatory dimensions. Among the SVD and NNSE models, those based on dependency and combined (dependency and document) co-occurrences perform similarly well, and seem to have some advantage over document co-occurrences alone. And at this dimensionality setting SVD and NNSE seem similarly successful. As a result, in the subsequent analyses we concentrate on the combined SVD and combined NNSE models.

[2]These proved most effective among the scaling/dimensionality settings available at http://metaoptimize.com/projects/wordreprs/.

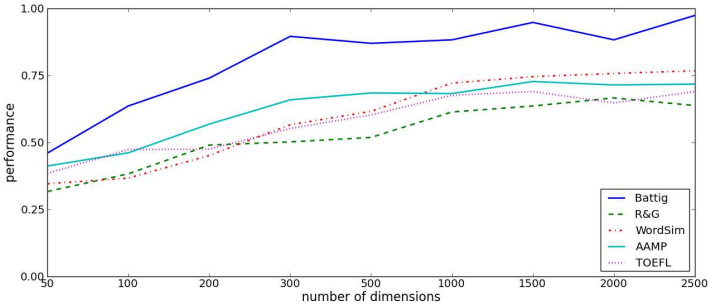

Figure 3: Behavioural evaluation of NNSE models with range of dimensionality (see Section 3.1.1 for more details).

We next examined how the choice of dimensionality affects the chosen SVD model (i.e., using both document and dependency co-occurrences) as evaluated with these behavioural tasks. As can be seen in Figure 2 performance peaks around the 200-300 dimension mark. In some tasks there is a fall-off in performance for higher dimensionalities, presumably as later dimensions are more noisy and/or irrelevant to these unsupervised tasks.

Finally we consider the effect of dimensionality for the NNSE models. In Figure 3 we see a very different pattern. For low dimensionalities it dramatically under-performs the SVD models, but at larger scales it continues to have an upward trend, peaking at similar levels.

In summary, these experiments demonstrate that NNSE and SVD models have similar peak performance, but with very different demands for dimensionality. NNSE needs at least 1000 dimensions to perform well, which may be understandable given that these dimensions must adequately describe all 40,000 words in the vocabulary used, and each word has on average 50 features active. The SVD model has very good performance at a dimensionality in the low hundreds, since it can pack information much more densely into a given number of features, and performance falls off as more noisy or irrelevant dimensions are added.

3.1.2 Neurosemantic Decoding Experiments

Mitchell et al. (2008) introduced a new task in *neurosemantic decoding* – using models of semantics to learn the mapping between concepts and the neural activity which they elicit during neuroimaging experiments. The dataset used here is that described in detail in Mitchell et al. (2008) and released publicly[3] in conjunction with the NAACL 2010 Workshop on Computational Neurolinguistics (Murphy et al., 2010). The Functional MRI (fMRI) data is from 9 participants while they performed a property generation task for each of 60 everyday concrete concepts: 5 exemplars of each of 12 semantic classes (mammals, body parts, buildings, building parts, clothes, furniture, insects, kitchen utensils, miscellaneous functional artifacts, work tools, vegetables, and vehicles). Each concept was presented six times and the resulting data-points were averaged to yield a single brain image for each concept, made up of approximately 20 thousand features (each a three-dimensional pixel, or "voxel").

[3] http://www.cs.cmu.edu/afs/cs/project/theo-73/www/science2008/data.html

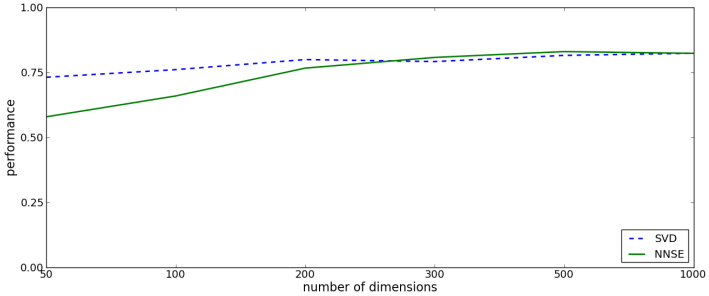

Figure 4: Neural activity test of NNSE and SVD models at range of dimensionalities (see Section 3.1.2 for details).

As in Mitchell et al. (2008), a linear regression model was used to learn the mapping from semantic features to brain activity levels. For each participant and selected fMRI feature we train a model to learn its activation as a regularised linear combination of the semantic features:

$$f = \mathbf{C}\beta + \lambda||\beta||^2 \tag{5}$$

where f is the vector of activations of a specific fMRI feature for different concepts, the matrix $\mathbf{C}$ contains the values of the semantic features for those concepts, β is the vector of weights we must learn for each of those (corpus-derived) features, and λ tunes the degree of regularisation.

The linear model was estimated with a least squared errors method and $L2$ regularisation, selecting the lambda parameter from the range 0.0001 to 5000 using Generalized Cross-Validation (see Hastie et al., 2011, p.244). The activation of each fMRI voxel in response to a new concept that was not in the training data was predicted by a β-weighted sum of the values on each semantic dimension, building a picture of expected the global neural activity response for an arbitrary concept. Again following Mitchell et al. (2008) we use a leave-2-out paradigm in which a linear model for each neural feature is trained in turn on all concepts minus 2, having selected the 500 most stable voxels in the training set using the same correlational measure across stimulus presentations. For each of the 2 left-out concepts, we predict the global neural activation pattern, as just described. We then try to correctly match the predicted and observed activations, by measuring the cosine distance between the model-generated estimate of fMRI activity and the that observed in the experiment. If the sum of the matched cosine distances is lower than the sum of the mismatched distances, we consider the prediction successful – otherwise as failed.

As can be seen in Figure 3.1.2 the peak performance of both combined SVD and combined NNSE models are close to identical. Again we see an upward trend for the NNSE model. However in the SVD model there is no fall-off for larger dimension sizes, which can be attributed to the supervised nature of this test – the feature selection and regularisation stages in the construction of the linear models should be able to ignore or down-weight noisy or irrelevant features. It should also be noted that the signal/noise ratio in brain data is quite low, and this test may be subject to a performance ceiling (see Levy and Bullinaria, 2012; Murphy et al., 2012).

	SVD_{300}	$NNSE_{50}$	$NNSE_{300}$	$NNSE_{1000}$
Sparsity level (% of zeros)	0	81.94	90.39	99.95
Average number of words per dimension	35560.0	6422.4	3418.5	1818.2
Average number of dimensions per word	300.0	9.0	28.8	51.1

Table 1: Comparison of sparsity level of SVD and NNSE models, the top 2 performing representations in Section 3.1. Compared to the dense (non-sparse) SVD representation, NNSE results in significantly sparser embeddings than SVD.

3.2 Evaluating Level of Sparsity

In this section, we evaluate the sparsity of NNSE relative to the dense representations of SVD. The degree of sparsity in these two top-performing representations (Section 3.1) are compared in Table 1, for SVD at $k = 300$, and for NNSE with $k = 50, 300, 1000$. Given one such representation $A \in \mathbb{R}^{n \times m}$, where $A_{i,:}$ is the new embedding for the i^{th} word, *sparsity level* measures the fraction of zero entries in this matrix out of the total $n \times m$ entries. *Average number of words per dimension* measures the average number of non-zero entries for each column of A, where each column corresponds to one dimension. *Average number of dimensions per word* computes the average number of non-zero entries for each row of A, where each row is a representation for one word, as already mentioned above. We note that since SVD is a dense representation, varying k in this case is not going to result in changes in the level of sparsity and values of the other two metrics compared in Table 1. Hence, in Table 1, we only present the results for SVD_{300} for reference.

From Table 1, based on the sparsity level measurements, we observe that NNSE results in significantly sparser representations compared to the dense representation learned by SVD. We observe that as k increases, NNSE estimates even sparser representations. This might possibly be due to the fact that with a small number of available dimensions (e.g., $k = 50$), each dimension is used to represent multiple latent concepts, resulting in non-zeros values for larger number of entries in each column and thereby in the full matrix A. In other words, each dimension acts as a mixture of latent concepts. However, we note that even at such settings (i.e., $k = 50$), NNSE achieves high sparsity levels (81.9%) compared to the dense SVD.

From Table 1, we observe that as k increases, the average number of words per dimension decreases, from 6422.4 with $k = 50$ to 1818.2 with $k = 1000$, i.e., each dimension becomes sparser as the number of available dimensions increases. This may be due to the fact, with smaller k (e.g., $k = 50$), NNSE has to compress the input data X into a smaller number of dimensions, resulting in coarser granularity for each dimension.

Finally, from Table 1, we observe that as k increases, NNSE uses a larger number of dimensions per word, but even then, the resulting embeddings are significantly sparser compared to SVD, where each word is represented using all available k dimensions.

3.3 Evaluating Interpretability

In the previous two sections, we evaluated performance of various word embeddings in different external tasks, and also the level of sparsity in these representations. Based on the performance evaluations, we found SVD and NNSE to be the most effective. In this section, we evaluate how interpretable these representations are. In other words, we would like to measure how coherent each of the dimensions of these representation are, i.e., given a representation A, we would like to

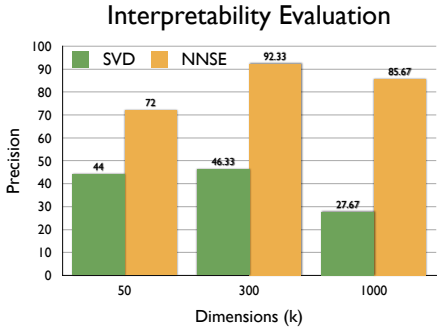

Figure 5: Comparison of interpretability of representations learned by SVD and NNSE for varying number of dimensions, k. Following (Boyd-Graber et al., 2009), word intrusion detection precision is used as the evaluation metric (higher precision implies higher interpretability). We observe that across all values of dimensions k, NNSE results in significantly more interpretable representations than SVD. See Section 3.3 for details.

determine how coherent each column (dimension) of A is.

Word Intrusion Detection Task: Following (Boyd-Graber et al., 2009), we use precision on a word intrusion detection task as the measure of coherence. The evaluation proceeds as follows: given a dimension (column) $A_{:,j}$, we first reverse-sort the words based on membership values of those words in the column (i.e., $A_{i,j},\ \forall 1 \leq i \leq n$). Next, we create a set consisting of the top 5 words from this ranked list, and also one word from the bottom half of this list, which is also present in the top 10th percentile of some other column in A. Thus, cardinality of this set is 6. The last word added from the bottom half is called an *intruder*. The goal is then to evaluate whether human subjects can identify this intruder word in a random ordering of the set. This process is repeated for each dimension, and the resulting precision is computed. This precision is used as the evaluation metric. Please note that we can compute precision in this setting as we know the true identity of the intruder word, it is just that this identity is hidden from the human evaluator. The idea behind this test is that if the current dimension is coherent, and thereby interpretable, then the human evaluator will be easily able to pick out the intruder word, thereby resulting in higher precision (higher is better). Example of such a set constructed from a dimension of the NNSE_{1000} is shown below,

{bathroom, closet, attic, balcony, quickly, toilet}

where *quickly* is the intruder, as the rest of the words form a coherent set listing different parts of a house. Following (Boyd-Graber et al., 2009), this evaluation scheme is also known as *reading tea leaves*, where it was used to measure coherence of probabilistic topic models.

We use Amazon Mechanical Turk (MTurk)[4] to get human judgements in the word intrusion detection task. Given an embedding matrix $A \in \mathbb{R}^{m \times k}$, we constructed n intruder sets as described above, one for each for the k dimensions. For $k > 300$, we randomly selected 300 dimensions for evaluation.

[4] http://mturk.amazon.com

Model	Top 5 Words (per dimension)
SVD_{300}	well, long, if, year, watch
	plan, engine, e, rock, very
	get, no, features, music, via
	features, by, links, free, down
	works, sound, video, building, section
$NNSE_{1000}$	inhibitor, inhibitors, antagonists, receptors, inhibition
	bristol, thames, southampton, brighton, poole
	delhi, india, bombay, chennai, madras
	pundits, forecasters, proponents, commentators, observers
	nosy, averse, leery, unsympathetic, snotty

Table 2: Examples of top 5 words for 5 randomly chosen dimensions from each of SVD_{300} and $NNSE_{1000}$. We observe that the dimensions in $NNSE_{1000}$ are much more semantically coherent (and thereby interpretable) compared to those in SVD_{300}.

Detecting the intruding word in each such set was presented as a separate decision point, called Human Intelligence Task (HIT). Each HIT was evaluated by 3 different workers (turkers), and a compensation of $0.01 was provided for each feedback. Majority voting over the three responses was used as the final decision on a given set (HIT).

Discussion: Experimental results comparing precision of the SVD and NNSE representations on the word intrusion task for different value of k are presented in Figure 5. From this figure, we observe that, for all values of k, representations learned by NNSE are considerably more interpretable compared to those estimated by SVD. We find that interpretability for both of them peak at $k = 300$.

For qualitative comparison, top 5 words from 5 randomly selected dimensions each of SVD_{300} and $NNSE_{1000}$ are presented in Table 2. From this, we get further anecdotal evidence about the higher interpretability of NNSE compared to SVD.

4 Related Work

Corpus-derived models of semantics have been extensively studied in the NLP and machine learning communities (Collobert and Weston, 2008; Ratinov et al., 2010; Turney and Pantel, 2010; Socher et al., 2011; Huang et al., 2012). Additionally, dimensionality reduction techniques such as SVD, and topic distributions learned by probabilistic topic models such LDA (Blei et al., 2003) can also be used to induce word embeddings. Although the embeddings learned by these methods have many overlapping properties, to the best of our knowledge, none of these previous proposals satisfy the three desirable properties: effective in practice, sparse, and interpretable. We find that Non-Negative Sparse Encoding (NNSE), a variation on a matrix factorization technique previously studied in the machine learning community, can result in semantic models which satisfy all three properties listed above.

In terms of interpretability, the NNSE is dramatically more effective than equivalent SVD models, and is comparable with LDA models evaluated in Boyd-Graber et al. (2009). In this context, it is interesting to compare it to another sparse interpretable model based on corpus co-occurrences, such as Strudel (Baroni et al., 2010). One major difference is that Strudel explicitly extracts descriptive properties, and that it does not involve a latent dimension discovery step. This has the advantage that

Weight	Top Words (per weighted dimension)
0.69	bike, mtb, bikes, harley, motorcycle, davidson, bicycle, cycling, biker, giro
0.35	canoe, raft, scooter, kayak, skateboard, bicycle, tractor, lawnmower, wheelchair
0.15	sedan, dealership, dealerships, dealer, convertible, camry, minivan, pickup, corolla
0.10	attorney, malpractice, lawyer, attorneys, lawyers, wrongful, litigation, injury, accident
0.08	earnhardt, speedway, irl, indy, racing, schumacher, mclaren, nascar, roush, race

Table 3: Examples of top 5 weighted dimensions in NNSE for the token *motorbike*, where each dimension is characterised by its top words.

Weight	Top Words (per weighted dimension)
0.84	raspberry, peach, pear, mango, melon, strawberry, banana, berry, cranberry, citrus
0.25	peaches, apricots, pears, cherries, blueberries, figs, oranges, plums, raspberries
0.10	birch, fir, spruce, pine, elm, mahogany, aspen, cypress, willow, cedar
0.08	kreme, pillsbury, falafel, brownie, pretzel, pesto, horseradish, oreo, guacamole, pita
0.07	patties, slices, cubes, tacos, wedges, chunks, enchiladas, burritos, fajitas, tortillas

Table 4: Examples of top 5 weighted dimensions in NNSE for the token *pear*, where each dimension is characterised by its top words.

it can model human tasks that directly involve properties and their types, such as the feature norming exercises mentioned earlier (which our NNSE model is not capable of currently). Conversely, it has a disadvantage in that it does not address the ubiquitous synonymy and polysemy among property labels. For example, the Strudel representation for *motorbike* has the properties (ordered by their strength of association): *ride, rider, sidecar, park, road, helmet, collision, vehicle, car, moped*.

The corresponding representation in NNSE is dominated by the five dimensions listed in Table 3. For each dimension we show the words that characterize its meaning, and the magnitude of its contribution to *motorbike*. These seem to describe the following respective classes which may correspond to topical usages of the word: (motor)cycling; leisure vehicles; vehicle sales; accidents and litigation; and racing. The corresponding listing for *pear* in Table 4, also exhibits some different senses of the word, covering *fruit*, *food* more generally, and *trees*.

Overall, we find that NNSE model is an alternative coding of the information stored in the SVD model. These models differ however in how that information is distributed across dimensions. The SVD model, as expected, is maximally compact, compressing as much information as possible into the minimum number of dimensions, but yielding individual dimensions that are very hard to interpret. The NNSE model is equally effective in modeling human judgements and brain activity elicited during lexical semantic tasks, but has a sparse structure which closely matches some common assumptions in cognitive science about conceptual representations.

5 Conclusion

In this paper, we propose the novel application of Non-Negative Sparse Embedding (NNSE), a variation on a constrained matrix factorization technique previously studied in the machine learning community (Hoyer, 2002; Mairal et al., 2010), to learn corpus-derived semantic models (word embeddings). To the best of our knowledge, this is the first approach which learns embeddings

which are effective in practice, sparse, and interpretable – a desirable list of properties which was not achievable by previously proposed methods.

There are still many ways in which we can extend and improve this new embedding method. First of all, we would like to test it as a component of core NLP tasks, such as chunking, named-entity-recognition, and parsing. We also plan to compare the individual NNSE dimensions to other benchmarks that explicitly cover categories and properties, such as feature norms, WordNet, and other collections of human judgements such as the 20Q data (Palatucci et al., 2009). Finally, we plan to look more closely at the relative contributions of different sources of input representations, such as dependency and document co-occurrences that underlie the current model, to examine the relationship between topical and attributional meanings that they correspond to.

Acknowledgments

We are thankful to Khaled El-Arini (CMU) and Min Xu (CMU) for many useful discussions on sparse coding. We thank Justin Betteridge (CMU) for his help with parsing the corpus, and Yahoo! for providing the M45 cluster over which the parsing was done. We also thank Marco Baroni (University of Trento) and Seshadri Sridharan (CMU) for assistance in preparing the behavioural benchmarks. We thank CMU's Parallel Data Laboratory (PDL) for making the OpenCloud cluster available. We are thankful to the anonymous reviewers for their constructive comments. ABSTRACT
The paper presents results of clustering terms extracted from economic articles in Polish Wikipedia. First, we describe the method of automatic term extraction supported by linguistic knowledge. Then, we define different types of term similarities used in the clustering experiment. Term similarities are based on Polish Wordnet and morphosyntactic analysis of data. The latter takes into account: term contexts, coordinated sequences of terms, syntactic patterns in which terms appear and words that are parts of terms (such as their heads and modifiers). Then we performed several experiments with hierarchical clustering of the 400 most frequent terms. We present the results of clustering when different groups of similarity coefficients are applied. Finally, we present an evaluation that compares the results with manually obtained groups. Our results prove that morphosyntactic information can help or even serve themselves for initial clustering of terms in semantically coherent groups.

KEYWORDS: terminology extraction, terminology clustering, Polish.

Proceedings of COLING 2012: Technical Papers, pages 1951–1962,
COLING 2012, Mumbai, December 2012.

1 Introduction

Many NLP applications, like text indexing, information extraction or question answering, rely on sets of predefined concepts which can be identified within texts, on a given subject. Such concepts form either hierarchical ontologies or flat terminology lists. Although there are already very many works aimed at making these kinds of resources available, still, the existing data is very limited with regard to the chosen application/knowledge domain as well as natural language addressed. An overview of existing approaches to automatic terminology extraction is included in (Pazienza et al., 2005) while problems with ontology creation are described, among others, in (Cimiano, 2006).

For some NLP purposes flat terminology lists are sufficient, but for others, like IE, ontologies representing relations between particular terms are more adequate. Unfortunately, domain ontologies' availability is very limited and what is even more crucial – they are rarely adequate for the purpose at hand. They are either too specific or too general, or do not cover the appropriate domain, or they are outdated. Ontology reuse and projection is still a very difficult and unresolved issue. As a result, when general ontologies like SUMO (Pease and Niles, 2001) are insufficient, or are not available in a particular language, a new dedicated ontology has to be created. In such a case, a list of concepts to be included in the ontology can be prepared manually by a domain expert, or can be (at least initially) extracted from texts similar to those which are to be processed.

In this paper we address the problem of finding interesting concepts in Polish economic texts and organizing them in coherent groups which can be further analyzed more easily than a long unstructured term list. The identified sets of terms will be used for developing a domain model which will constitute the base of an information extraction system. The basic idea is to facilitate the construction of IE systems by automation of the initial stage of domain model creation, i.e. defining concepts which can be addressed in the selected type of texts, and relate them to particular language expressions. The same method may be used later on to gather new concepts which appear in time and relate them to the already existing ones on the basis of the contexts of their occurrences.

As a test domain we have chosen economy, in particular, economic articles of Polish Wikipedia. In the paper we present the process of selecting term candidates, their ordering according to the defined importance measure and clustering. To make the approach usable for many domains we assume that only general language resources like a morphological tagger and Wordnet are used.

2 Data

The experiment was conducted on the economic articles taken from the Polish Wikipedia. Only textual content of these articles was taken into account. The data was collected in 2011 and contains 1219 articles that have economics related headings and articles linked to them. The data contains about 456,000 tokens. An initial linguistic analysis of the plain texts was performed. It consisted of the following steps:

- Segmentation into tokens. We distinguish words (365,042), numbers (14,906) and punctuation marks (76,239).
- Morphological annotation. To each word we assign: its base form, part of speech and complete morphological characterization. The annotation is based on the results obtained

by the publicly available Polish POS tagger Pantera (Acedański, 2010) that cooperates with a general-purpose morphological analyzer of Polish Morfeusz SGJP (Woliński, 2006). The Pantera tagger allows us to define a separate dictionary in which we can describe unknown tokens. So we defined an additional domain dictionary containing 741 entries of word-forms (not recognized by the Morfeusz analyzer). Many of them have more than one morphological characterization, e.g. *podsektor* 'subsector' that represents a noun in the nominative or accusative case. In case of adjectives there are usually more possible interpretations, for example the word-form *proekologiczne* 'proecological' has 7 different characterizations in the additional dictionary. Our dictionary does not describe all unknown tokens as we decided not to analyze foreign words and proper names that are not present in Morfeusz. In the data, many notions are translated into foreign languages, e.g. *Spółdzielnia europejska* 'European Cooperative Society' has in the data its Latin equivalent 'Societas Cooperativa Europaea', and all three tokens are annotated with *ign* tag that indicates an unknown word. So still 10,796 tokens have no morphological characterization.

- Improving tagger results. We defined 84 rules in Spejd (Przepiórkowski, 2008) (a cascade of regular grammars) in order to correct Pantera decisions, and to extend some descriptions. The advantage of using this method is the possibility of taking contexts into account. Spejd rules are particularly helpful in correcting some regular tagging errors in frequently occurring phrases. They corrected or extended over 4,000 token descriptions. The changes in the tagset consisted in the introduction of the *number* tag assigned to Arabic as well as Roman numerals, and extending descriptions of abbreviations (*brev* POS). In Morfeusz, an abbreviation is characterised only by a specification whether it has to be followed by a full stop. We extended its description with information about the type of word or phrase it abbreviates to allow for constructing correct grammatical phrases containing the abbreviation.

- Removing improperly recognized sentence endings after abbreviations.

3 Terms identification

The very first problem while doing terminology extraction is to define what a domain term really is. Unfortunately, there exists no strict definition of this concept and usually only pragmatical approaches are taken. For the purpose of this work we defined a term as a noun phrase which occurs more frequently in domain specific texts than in the general language. Thus, we decided not to follow the approach in which linguistic information is neglected (like (Wermter and Hahn, 2005)), but to use morphological information at the stage of candidate selection. We also use this information while defining similarity coefficients.

For term candidates we choose noun phrases of a limited internal complexity, i.e. we assume that they are built according to one of the following syntactic schemata of which the first four are very frequent and the last one is much less common. In particular, we do not allow for prepositional phrases to occur within the terms (compare the results of the terminology extraction task described in (Marciniak and Mykowiecka, 2012)).

- a single noun or an abbreviation, e.g. *bank* 'bank', *EC* 'European Commission';
- a noun followed (or, more rarely, preceded or surrounded) by an adjective, e.g. $administracja_{n}\ publiczna_{adj}$ 'public administration', $wysoki_{adj}\ dochód_{n}$ 'high income', $ogólna_{adj}\ sytuacja_{n}\ gospodarcza_{adj}$ 'general economic situation';

- a noun followed by another noun in genitive, e.g. $kurs_{n,nom}$ $walut_{n,gen}$ 'exchange rate';
- a combination of the last two structures, e.g. $walne_{adj,nom}$ $zgromadzenie_{n,nom}$ $akcjonariuszy_{n,gen}$ 'general meeting of shareholders',
- a noun preceded by an adjectival phrase, e.g. *wschodnia i południowa Afryka* 'East and South Africa'.

For recognizing the selected types of nominal phrases, a cascade of six simple shallow grammars was created. Its rules operate on the results of morphological analysis described in section 2. The gradual phrase creation starts with adjective modifiers and then genitive modifiers are added.

To make our data a little more coherent (domain related) we eliminated time related expressions (names of months, nouns like 'hour', 'minute', adjectives like 'late') which are studied separately. We also excluded selected sets of nouns and adjectives which can be thought of as a kind of 'stop words' for the terminology extraction task, that is words which can be used in very many contexts and which themselves do not constitute terms elements. These are adjectives like *dany* 'given' or pronouns. The list was built up in our previous terminology extraction experiment (Mykowiecka and Marciniak, 2012) and supplemented with new elements in the current one. The list which contains 65 words is used only additionally, many such phrases can be eliminated at the later stage of ordering term candidates.

Applying the adopted set of rules to the data resulted in obtaining 80,212 types of phrases in which there are 45,144 top level types occurring 104,576 times. The longest (non overlapping) phrases which can be built starting from subsequent text positions were extracted. Their internal structure was annotated by markers showing subphrase boundaries. For the resulting set of phrases, we performed an analysis similar to that proposed in (Frantzi et al., 2000). In this approach both the entire high-level phrases and the internal nominal subphrases are taken into account, e.g. in the phrase *rzecznik dyscypliny finansów publicznych* 'advocate for public finance discipline' we also encounter the subphrases *dyscyplina finansów publicznych* 'public finance discipline' and *finanse publiczne* 'public finance'. Taking subphrases into account is important, as for example, the following phrases: *kapitał obrotowy* 'working capital' *system emerytalny* 'pension system' and *akt notarialny* 'notarial deed' did not occur in isolation in the data.

As Polish is an inflectional language, phrases which are identified within the text are of different forms (e.g. $\text{kurs}_{n,acc}$ $\text{walut}_{n,gen}$, $\text{kursie}_{n,loc}$ $\text{walut}_{n,gen}$ 'exchange rate') so the usual processing stages like counting phrase frequencies and preparing a list of phrase types became difficult. To overcome this problem we produce an artificial base form of every identified phrase occurrence, by taking base forms assigned by the tagger to its elements, i.e. $\text{kurs}_{n,nom}$ $\text{waluta}_{n,nom}$.

All extracted phrases are ranked according to the value of a specially defined coefficient (C-value) which is calculated basing on the occurrences of the phrase in the text as a stand alone phrase and its occurrences within other phrases from the list. This allows us to identify terms which never (or very rarely) occur in isolation, and to some extent, to filter out erroneous phrases (those which are recognized by a shallow grammar as one phrase but in fact are incomplete although grammatically sound) or are built up of more than one phrase (like *zamieszkania właściwość różnych organów* 'living jurisdiction of different authorities' which resulted from *podlegają z uwagi na swe miejsce zamieszkania właściwości różnych organów* 'fall under jurisdiction of different authorities depending on their place of living').

We used a slightly modified definition of C-value which is given below. p – is a phrase under consideration, LP – is a set of phrases containing p, and P(LP) – the number of types of phrases

differing in elements which are adjacent to p, that is the sum of different direct left and right one-word contexts counted separately (e.g. if the phrase *angielski bank* 'English bank' occurs in three types of longer phrases: *angielski bank inwestycyjny* 'English investment bank', *najstarszy angielski bank inwestycyjny* 'the oldest English investment bank' and *bankructwo najstarszego angielskiego banku inwestycyjnego* 'bankruptcy of the oldest English investment bank' , P(LP) is set to 2).

$$C-value(p) = \begin{cases} lc(p) * freq(p) - \frac{1}{P(LP)} \sum_{lp \in LP} freq(lp), & if\ P(LP) > 0, \\ lc(p) * freq(p), & if\ P(LP) = 0 \end{cases}$$

where $lc(p) = log_2(length(p))$ if $length(p) > 1$ and 0.1 otherwise;

To eliminate phrases which are not from the economy domain, but occur in all types of texts similarly often, we compared the list of phrases obtained for Wikipedia economic texts with phrases obtained form the balanced one million word subcorpus of NKJP (the corpus of general Polish (Przepiórkowski et al., 2012)) using the same processing schema. Table 1 shows how many terms are recognized in both corpora and how many of them have a grater C-value in each data set. Less than 10% of terms recognized in economic texts are also recognized in NKJP data — the longest common phrases have 5 words.

Table 1: Comparison with general corpus

Terms	common	C-value greater in econom.	C-value greater in NKJP
1-word	4089	767	3322
2-words	2558	1133	1425
3-5-words	201	98	103
Total	7848	1998	4850

There are a number of phrases with a greater C-value for NKJP subcorpus and relevant to the economic domain, e.g. *skarb państwa* 'state treasury', *urząd skarbowy* 'treasury office', *ustawa budżetowa* 'budget act'. So we decided that phrases which have a greater C-value counted in the context of general texts than that counted for economic data, should be manually inspected.

For the clustering experiment, the first 400 terms from the list, ranked according to the C-value coefficient, were chosen. On the bases of the comparison with NKJP terms, from the original list we removed one-word terms like: *grupa* 'group', *przyklad* 'example', *funkcja* 'function'; and a few multi-word terms, e.g: *wszcząć postępowanie* 'initiation of proceedings', *różny rodzaj* 'different types'. Removed terms were substituted with the subsequent terms from the list. Choosing a relatively small number of terms was motivated by the need for manual checking of the results.

4 Defining similarity features

At the next stage of domain model creation, a list of terms is organized into clusters which group elements addressing similar concepts. This is most frequently done manually by domain experts, but manual processing of a long list of names is time consuming and prone to errors. To perform this task automatically it is necessary to decide how to represent term similarity. In our approach we decided to use morphosyntactic information (in this case we follow the ideas presented in (Nenadić et al., 2004)), as well as information included in Polish Wordnet.

4.1 Contextual similarity

Contextual similarity is based on the contexts in which terms appear. We consider left and right contexts of terms separately. Contexts are not allowed to cross sentence or paragraph boundaries. We decided to consider the following types of context patterns:

- POS contexts. In this case patterns are strings of part of speech tags. We took into account patterns of 2 to 4 elements. If sentence boundaries are encountered, the context is shorter.
- The base form of the token preceding and following the term (separately).
- The base form of the nearest verb. If there are no verbs encountered within the sentence boundaries, the context is set to the null context.
- The base form of the nearest noun type token (e.g. nouns, gerunds).
- The nearest preposition.

In the case of the last two contexts, if there are no prepositions or nouns between the term and a verb, the context is set to the null context.

4.2 Coordination

Co-occurrence of terms in coordinated sequences is the next type of information we take into account when finding similar terms. We find sequences of terms connected by conjunctions or commas. All terms should be in the same grammatical case, and can be preceded by a preposition. The following example of a coordinated sequence: *<akcje>, <obligacje> i <instrumenty pochodne>* '<shares>, <bonds> and <derivatives>' joins terms denoting various financial instruments. We also consider coordination of prepositional phrases that consist of a preposition and a term, where terms are in the same grammatical case. See an example of such a phrase: *dla <osoby prywatnej> i dla <jednostki organizacyjnej>* 'for <a private person> or for an <organization unit>'. We do not check the wordforms of prepositions in coordinated sequences, but the grammatical case of terms has to be the same. This is a rough method of coordinated terms recognition and needs further refinements. For example, it will not recognize the following coordination: *eksportowane do Niemiec*$_{gen}$ *i na Litwę*$_{acc}$ 'exported to Germany and to Lithuania'. However, it excludes the majority of cases where two terms preceded by prepositions are separated by a comma and they belong to two different parts of a sentence, e.g: *W <Polsce>*$_{loc}$*, mimo <wpisania pojęcia konsumenta>*$_{gen}$ *do konstytucji ...* 'In [Poland], despite of [entering the notion of a consumer] into the constitution ...'.

In our data we detected 5,885 coordinated sequences of terms, which join 9,807 different pairs of terms. The vast majority of them occurred only a few times, only 9 pairs of terms occurred in coordinated sequences more than 10 times. The most frequent pair of terms *<towar>* 'product' and *<usługa>* 'service' occurred 74 times. For the selected 400 terms, 157 coordination pairs were found within the texts.

4.3 Syntactic patterns

Besides the coordination sequences we recognize several syntactic patterns that indicate similarity between terms. These patterns contain the following Polish phrases/words: *taki jak* 'such as', *czyli* 'or, that is', *na przykład* 'for example', *to jest* 'that is' and *zarówno...jak i* 'both...and also' and their equivalents. The first four patterns have the following construction:

<term1> [key phrase] <list of terms>

while the last one has slightly different form:

[key phrase 1] <term1> [key phrase 2] <list of terms>.

In the above patterns <list of terms> is the coordination of terms with limitations and internal similarity measures described in 4.2. These constructions recognize similarity between pairs built up from <term1> and all terms in the <list of terms>. Let us consider the following example:

wiele cech <oferty rynkowej> takich jak <cena>, <jakość> i <forma płatności>

'many features of <market offer> such as <price>, <quality> and <form of payment>'

The above phrase indicates that following 3 pairs of terms are similar:

- *<oferty rynkowej>* 'market offer' and *<cena>* 'price'
- *<oferty rynkowej>* 'market offer' and *<jakość>* 'quality'
- *<oferty rynkowej>* 'market offer' and *<forma płatności>* 'form of payment'

In the data we detected 545 pairs of similar terms recognized by the above lexical patterns from which 85 are used in the clustering experiment of 400 terms.

4.4 Lexical Similarity

Terms that have the same head element usually describe related concepts, for example *kurs obcej waluty* 'foreign currency exchange rate' and *kurs dolara* 'dollar exchange rate' have the same head element *kurs* 'exchange rate', and describe similar notions. In the task we promote terms with the same head. If the heads of two terms are the same, then the head similarity coefficient for these phrases is set to 1. We do not consider different meanings of heads so the following phrases: *klasa robotnicza* 'working class' and *klasa szkolna* 'classroom' are set to 1.

Terms that have common words are also more related than those without any common words. Counting them we exclude common heads. For example the common adjective *budżetowy* 'budgetary' indicates that the following terms are to a certain degree similar: *dotacja budżetowa* 'budget subsidy' *wydatek budżetowy* 'budget expenditure' and *założenia budżetowe* 'budget assumption' To establish these types of similarities for all term pairs we counted how many common words they have (except common head elements). The similarity between two terms is equal to the number of common modifiers divided by the number of modifiers of the longer term.

4.5 Wordnet similarity

Polish Wordnet (PlWordNet, (Piasecki et al., 2009)) is one of the biggest resources of the type introduced by Princeton Wordnet (Miller, 1995), but it mainly describes general language and it contains mostly one word items. Domain terminology usually contains a prevalence of multiword expressions. On our list, among 400 terms, 130 are one word expressions and 270 are longer. All one word terms have at least one sense defined in PlWordNet. For multiword expressions the situation is drastically different: 52 phrases are defined in PlWordNet while 218 phrases are not. For 3 of them their head elements are also not described: *Brytania* 'Britain, *środki* 'resources', *Adam* 'Adam' (two of them are proper names, for the word 'resources' only the singular form is defined which has different meanings).

The above statistics show that in order to utilize information given in PlWordnet, operating only on information in the phrases which appear within the data, is insufficient. Thus, we decided

to calculate the similarity between terms on the basis of information given both on the terms themselves and on their head elements. The schema of calculating similarity between terms A and B was defined in two steps. In the first one an initial similarity value is set to:

- if both terms appear in PlWordNet and share at least one synset — 1/minimum of synsets defined for A and B;
- otherwise, if A appears in PlwordNet and belongs to the same synset as one of the B hiper- or hiponims – 0.5/number of synsets of A;
- otherwise, if B appears in PlwordNet and belongs to the same synset as one of the B hiper- or hiponims – 0.5/number of synsets of B;

In the second step, when at least one of the terms is longer than one word, the similarity value is assigned to a minimum from the number resulting from the following additions and 1:

- if A is a multiword term:
  - if A's head belongs to at least one synset to which B also belongs: +0.25;
  - otherwise, if A's head belongs to at least one synset to which the head of a multiword A also belongs: +0.1;
  - if B belongs to the same synset as a hiper- or hiponim of A's head: +0.15
- if B is a multiword term
  - if B's head belongs to at least one synset to which any hiper- or hiponim of B also belongs: +0.05
  - if (oneword) A belongs to the same synset as the head of B: +0.2
  - if (oneword) A belongs to the same synset as a hiper- or hiponim of B: +0.1

This process resulted in 298 nonzero coefficients. 19 pairs were judged to be equivalent (similarity 1), e.g. *<dochód>-<zysk>* 'income-gain', *<prawo>-<zasada>* 'law-rule. One example was incorrect: *<model>-<klient>* 'model-customer'.

4.6 Overall Similarity

All similarity tables were rescaled in such a way that the highest coefficient for each measure is equal 1. In all experiments described below, an overall similarity of a pair of terms was calculated as a weighted sum of up to 19 coefficients:

- neighboring left/right form (lf, rf),
- left/right POS contexts of length 2/3/4 (c2l, c3l, c4l, c2r,c3r,c4r),
- first left/right verb, noun, preposition (l_v, l_n, l_p, r_v, r_v, r_p),
- coordination coefficient (crd),
- syntactic patterns coefficient (syn)
- common head coeff. (head),
- common modifiers coeff. (mod),
- wordnet similarity (wdnet).

5 Clustering

Automatic clustering was done using MultiDendrograms (Fernández and Gómez, 2008) performing hierarchical clustering. From several options, the unweighted average of similarity coefficient values was selected on the basis of the results of the preliminary tests.

As no resource which can be used as a reference set exists, to enable the evaluation of the results, a manually prepared version of the partition of 400 terms was created. The only instruction given to a person doing this task was to group similar elements even if they cannot be treated as subtypes of one concept. The result, which was verified by the second annotator, comprises 127 group, of which 30 contain only one element. The maximal group size is 14.

In the experiments, different weighting schemata of the coefficients used to calculate the overall similarity measure were tested. The exact values of the weights assigned for some selected models are given in Table 2. To check the impact of morphosyntactic features on the result obtained while using only PlWordNet data, automatic clustering was done for the models belonging to the three groups described below.

- only Wordnet similarity (as defined above) has nonzero (i.e. 1) weight – model W1,
- all weights are non zero — models W4, W5 and W6,
- Wordnet similarity is assigned 0, its weight is distributed among other weights which are initially set as in W4 – W2.

Table 2: The selected models characterization

	fl	fr	syn	c2l	c2r	c3l	c3r	c4l	c4r	crd	mod	head	r_v	r_n	r_p	l_v	l_p	l_n	wdnet
w2	.11	.11	.058	.058	.058	.033	.033	.013	.013	.058	.058	.108	.058	.058	.018	.058	.043	.053	.00
w4	.10	.10	.050	.050	.050	.025	.025	.005	.005	.050	.050	.100	.050	.050	.010	.050	.035	.045	.15
w5	.13	.13	.100	.015	.020	.010	.010	.003	.002	.050	.050	.080	.040	.050	.050	.100	.030	.030	.10
w6	.10	.10	.050	.050	.050	.025	.020	.001	.001	.050	.050	.100	.020	.050	.010	.123	.040	.040	.13

The results of clustering were compared using the B-cubed measure (Bagga and Baldwin, 1998) positively evaluated in different experiments, e.g. (Amigó et al., 2009). This measure counts precision for every group element so it is sensitive to both – presence and absence of the elements of groups. The results presented in Tab. 3 show some of the tested system configurations. Rows correspond to the combinations of weights given in Tab. 2. Each cell of the table contains precision, recall and F-measure results obtained when comparing the models to the manual clustering (rescaled into the 0-100 range).

Table 3: Model comparisons with manual grouping.

	127 groups	best F-value	nb of groups
W1	64.2/74.1/68,8	84.9/71/77.4	175
W2	62.4/60.9/61.7	82,5/56,9/68,2	205
W4	74.3/73.9/74.1	94.9/69.6/80.3	190
W5	76.8/73.6/75.1	90.6/69.6/78,7	175
W6	76.4/73.0/73.8	94.4/68.8/79.6	191

By adjusting the weights used in the definition of the similarity measure, we obtained an enhancement of the clusters matching which did not vary much (for reasonable weight distribution). For all these models the results were about 5% better than those obtained using only Wordnet data. Using morphosyntactic information alone also gave usable results at the level of about 62%.

Conclusions

In the paper we presented the results of the process of detecting coherent groups within terminological phrases extracted from real texts from the economy domian. The obtained results show that in the case where semantic information is lacking, morphosyntactic description of the contexts of term occurrences can help in a terminology clustering task. Even when only morphosyntactic features are available, the results achieved can make further manual clustering much easier. However, adding other sources of information, like Wordnet relation for phrase head elements, improves the results.

The F-measure of about 75% achieved when comparing the automatically obtained clusters to manually obtained groups is not high, but in the case of this task, which also proved difficult for well trained annotators, can be seen as good enough to be utilized in further domain ontology development. The presented method can be used for texts in any domain or language but the quality of the results highly depends on the quality of lexical tools used for preprocessing. Our results of the lexical preprocessing stages showed that the quality and coverage of Polish taggers are not very good when dealing with more specific texts. In such cases even a small additional dictionary might be necessary to obtain good results. On the other hand, a big common part which economic texts have with general language used in newspapers make the terminology selection stage less precise.

ABSTRACT
One of the main issues in a word alignment task is the difficulty of handling function words that do not have direct translations which we call unique function words. They are often aligned to some words in the other language incorrectly. This is prominent in language pairs with very different sentence structures. In this paper, we propose a novel approach for handling unique function words. The proposed model *monolingually derives* unique function words from bilingually generated treelet pairs. The monolingual derivation prevents incorrect alignments for unique function words. The derivation probabilities are estimated from a large monolingual corpus, which is much easier to acquire than a parallel corpus. Also, the proposed alignment model uses semantic-head dependency trees where dependency relations between words become similar in each language. Experimental results on an English-Japanese corpus show that the proposed model achieves better alignment and translation quality compared with the baseline models.

TITLE AND ABSTRACT IN JAPANESE

二言語の生成と単言語の派生によるアライメント

単語アライメントタスクにおける主な問題の一つは、機能語の中でも相手言語に対応する語が存在しない機能語の扱いの困難さである。我々はこのような語を孤立機能語と呼ぶ。孤立機能語は、相手言語の何らかの単語に不適切に対応付けられることが多く、これは特に文構造が大きく異なる言語対において顕著である。本論文では、孤立機能語を扱うための新しい手法を提案する。提案モデルは、二言語で生成された部分木ペアから、孤立機能語をそれぞれ単言語で派生することにより、孤立機能語が誤って対応付けられることを防ぐ。派生確率は、対訳コーパスに比べて入手が容易である大規模単言語コーパスから推定する。また提案モデルは、単語同士の依存関係が各言語で近くなるように、意味主辞依存構造木を用いる。英日コーパスでの実験結果から、提案モデルはベースラインモデルと比べてより良いアライメントおよび翻訳精度を実現した。

1 Introduction

Alignment accuracy is crucial for providing high quality corpus-based machine translation systems because translation knowledge is acquired from an aligned training corpus. For similar language pairs, alignment accuracy is high. Less than 10% alignment error rate (AER) for French-English has been achieved by the conventional word alignment tool GIZA++, an implementation of the alignment models called the IBM models (Brown et al., 1993), with some heuristic symmetrization rules. However, for distant language pairs such as English-Japanese, the conventional alignment method is quite inadequate (achieving an AER of about 20%).

There are two main issues in a word alignment task for distant language pairs: one is the word order difference, while the other relates to function words. The word order issue has to some extent been solved by using word dependency trees in the alignment model (Nakazawa and Kurohashi, 2011). Most of the remaining alignment errors are related to function words such as English articles and Japanese case markers (Wu et al., 2011) because they do not have counterparts in the other language. As an example, most of the errors in Figure 1 are related to function words: "has" and "は (*topic-marker*)" in example (A), and "although", "は (*topic-marker*)", "を (*ACC*)" and "が (*but*)" in example (B).

Several previous works focused on alignment errors of function words. Isozaki et al. (2010) inserted pseudo nodes in English sentences for Japanese function words. Wu et al. (2011) removed the alignment of some function words to effectively acquire translation rules using the underlying word alignment by GIZA++. Nevertheless, these methods for dealing with function words are ad-hoc and based on hand-crafted rules.

In this paper, we propose a novel approach for handling function words. If there is a direct translation for a function word, these words should be aligned with each other. For function words that do not have any counterparts, the conventional model is supposed to align them to NULL, but it does not always work well. They are often aligned to some words incorrectly. In contrast with the conventional model, our model *derives* such function words from content words in their own language. The derivation probabilities used in our proposed model are estimated from a large monolingual corpus for each language. Thus, we do not require a large parallel corpus. With this derivation model, we can reduce alignment errors for function words, which leads to a better translation resources such as a phrase table, which is acquired from a word-aligned parallel corpus. In the remainder of this paper, we use English-Japanese language pairs for explanation. However, it should be noted that the proposed model is completely language independent.

2 Semantic-head dependency tree

The proposed model utilizes word dependency trees on both the source and target sides. Dependency trees are effective for language pairs with very different word orders, such as English-Japanese, to achieve high quality alignment by absorbing the difference (Nakazawa and Kurohashi, 2011). There are two types of word dependency trees: syntactic-head and semantic-head. Our model adopts the latter. This section discusses the difference between syntactic-head and semantic-head, and the reason why we choose the semantic-head dependency tree.

The syntactic-head dependency tree has two main drawbacks. One is that distances between content words are excessively large for agglutinative languages such as Japanese. The other is that dependency relations differ because of the difference in head word definitions in each

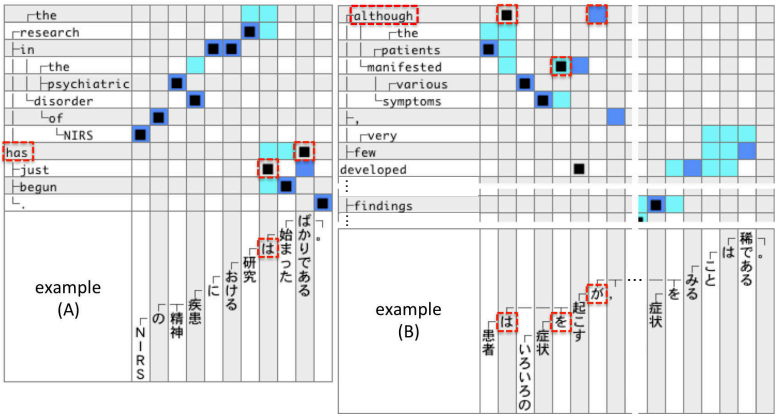

Figure 1: Alignment results of Nakazawa and Kurohashi (2011). Black boxes depict the system output, while dark blue (Sure) and light blue (Possible) cells denote gold-standard alignments. Cells demarcated by dotted lines are alignment errors related to function words.

language. On the other hand, in semantic-head dependency trees, function words giving additional information to content words are placed as children of the content words, thus it preserves the dependency relations between words over languages. In the semantic-head dependency tree (on the right of Figure 2), "medical treatment ↔ 治療", "may ↔ かも しれない", "not ↔ ない" and "weight ↔ 体重" are all children of "change ↔ 変化", while the relations are not preserved in the syntactic-head dependency tree (on the left of Figure 2). Because of these advantages, our model uses semantic-head dependency trees.

In this paper, English sentences are first parsed by nlparser (Charniak and Johnson, 2005) which outputs phrase structures that are then converted into word dependency trees by defining the head word for phrases. The conversion rules follow Collins' head percolation table (Collins, 1999) with some modifications for acquiring semantic-head dependency trees. The following head-specifying rules are examples in which the syntactic head (underlined) and the semantic head (double underlined) is different.

- VP → MD VB (ex. "may change" in Figure 2)
- VP → VBZ JJ (ex. "is large")

Japanese sentences are usually parsed based on a unit called a *basic phrase*, which consists of one content word followed by zero or more function words. In syntactic-head word dependency trees, on the left of Figure 2, the head word is the last function word (or the content word if there is no function word in a basic phrase), and other words depend on their following words (Hajič et al., 2009). In semantic-head dependency trees, while function words showing a relationship between content words such as case markers are placed as parents of content words, other function words are placed as children. We obtain semantic-head dependency trees by modifying the rule file of the Japanese dependency analyzer KNP (Kawahara and Kurohashi, 2006b).

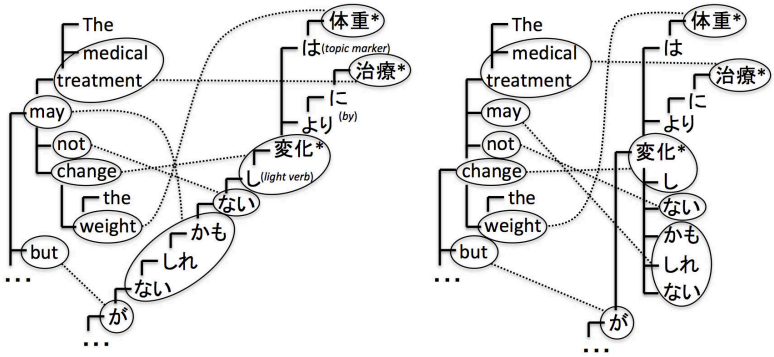

Figure 2: Examples of syntactic-head (left) and semantic-head (right) dependency trees. The root of the tree is at the extreme left and words are placed from top to bottom. Japanese content words are indicated by "*".

Several related studies use the semantic-head dependency trees in machine translation (Hong et al., 2009; Xu et al., 2009). They use English-side semantic-head dependency trees for pre-reordering of English sentences in order to make the word order closer to that of Subject-Object-Verb language sentences. The closer the word order is, the easier it is to train the model. However, certain hand-crafted rules are needed for reordering, and pseudo words are used to take care of function words. Compared with these studies, our proposed model uses semantic-head dependency trees on both sides and does not reorder sentences, and therefore it does not require any hand-crafted rules or pseudo words.

3 Handling function words

Although each language has a closed set of function words, the variety of function words differs between languages. For example, in Figure 2, some function words have direct translations in the other language ("may ↔ かも しれ ない", "not ↔ ない" and "but ↔ が"), while others do not ("the", "は (*topic marker*)" and "に より (*by*)"). The first case is less problematic, and any alignment model can correctly detect the link. The second case represents the issue addressed in this paper. We call function words that do not have direct translations *unique function words*.

One solution, adopted by almost all the existing alignment models, is to align unique function words to NULL. However, it is difficult to judge whether a unique function word has to be NULL-aligned or not, and often causes alignment errors as shown in Figure 1. Also, the NULL-aligned words behave as gaps between aligned words, making it harder to capture relations between aligned words. In Figure 2, "に より (*by*)" is a gap between "治療 (*medical treatment*)" and "変化 し (*change*)" whereas counterparts have a direct parent-child relation.

Another solution is to enhance the alignment model so as to handle a larger unit than a word, and include the unique function words in neighboring alignments. For example, "weight ↔ 体重" can include the Japanese "は (*topic marker*)" and become "weight ↔ 体重 は". However, this solution can lead to a less appropriate parameter estimation for an alignment model because "weight ↔ 体重" and "weight ↔ 体重 は" are treated as different alignment patterns

while the two patterns have essentially no difference.

The novel solution to this problem proposed in this paper is to *derive* unique function words from neighboring words monolingually. In the monolingual derivation model, "は (*topic marker*)" can be derived from "体重 (*weight*)" without changing the original treelet pair "weight ⟷ 体重", and therefore the model achieves good estimation of parameters. Note that it is also possible to derive "は (*topic marker*)" from "変化 し (*change*)" because they are contiguous in the tree structure. Another advantage of the monolingual derivation model is that it can reduce the gaps between alignments, and preserve the dependency relations between treelets over languages. For example, the model can derive "に より (*by*)" from "変化 し (*change*)" or "治療 (*medical treatment*)" and let the dependency relation between "変化 し (*change*)" and "治療 (*medical treatment*)" be direct parent-child like their English counterparts. This is effective for estimating the dependency relation probability described in Section 4.3.

4 Model overview

The proposed model is an extension of that proposed by Nakazawa and Kurohashi (2011). This earlier model was overcoming the long-distance reordering issue by incorporating dependency trees. However, it was suffering from alignment errors for function words, which our new model solves by incorporating a *monolingual derivation model*. First we describe the generative story for the joint alignment model in the same manner as in previous work (Marcu and Wong, 2002; DeNero et al., 2008; Nakazawa and Kurohashi, 2011).

1. Generate ℓ concepts from which bilingual treelet pairs are generated independently.
2. For each treelet pair, derive zero or more treelets monolingually from each treelet in the treelet pair.
3. Combine the treelets in each language so as to create parallel sentences.

The number of concepts ℓ (> 0) is parameterized using a geometric distribution

$$P(\ell) = p_\$ \cdot (1 - p_\$)^{\ell - 1} \tag{1}$$

where $p_\$$ is a constant. Each concept generates a bilingual treelet pair from an unknown distribution θ_T. We call the treelet pair the *core alignment* denoting it as $\langle e_C, f_C \rangle$. Either one of the treelets in a treelet pair can be NULL, which represents an unaligned treelet. Unaligned treelets must be composed of exactly one word (NULL-alignment restriction).

Each treelet e_C and f_C derives sets of treelets $\{d_{e_C}\}$ and $\{d_{f_C}\}$ monolingually which basically consist of unique function words. The numbers of monolingual derivations $|\{d_{e_C}\}|$ and $|\{d_{f_C}\}|$ (≥ 0) are parameterized using a geometric distribution

$$P(|\{d_{e_C}\}|) = p_d \cdot (1 - p_d)^{|\{d_{e_C}\}|}, \quad P(|\{d_{f_C}\}|) = p_d \cdot (1 - p_d)^{|\{d_{f_C}\}|} \tag{2}$$

where p_d is a constant. Each derivation is drawn from a known multinomial distribution ϕ_{e_C} and ϕ_{f_C}, as explained in Section 4.2. We use the notation e to represent the combination of e_C and $\{d_{e_C}\}$, and f for f_C and $\{d_{f_C}\}$. Thus $\langle e, f \rangle$ contains $\langle e_C, f_C \rangle$, $\{d_{e_C}\}$ and $\{d_{f_C}\}$.

Finally, the treelet pairs are combined in each language. We denote the relation of treelets on the e-side as $D_E = \{(j \rightarrow k)\}$, where $(j \rightarrow k)$ denotes that treelet e_j depends on treelet e_k, and on the f-side as D_F. D refers to D_E and D_F as a whole. With these notations, the joint

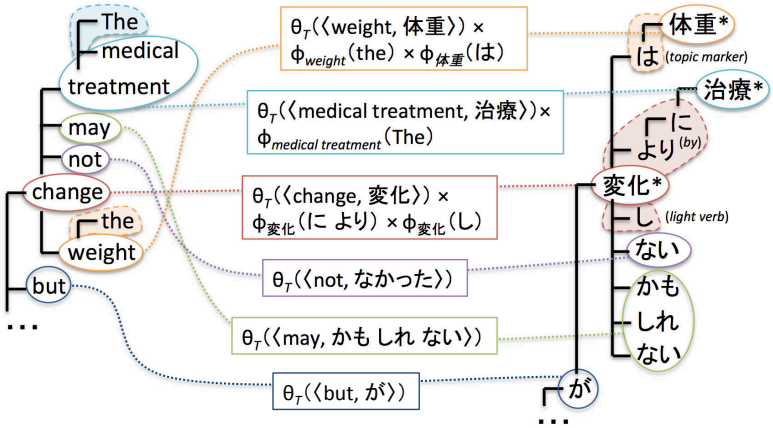

Figure 3: Example showing the calculation of the bilingual generation probability and monolingual derivation probability.

probability for an aligned sentence pair is defined as:

$$P(\ell, \{\langle e, f\rangle\}, D) = P(\ell) \cdot P(D|\{\langle e, f\rangle\}) \cdot \prod_{\langle e,f\rangle} \left(\theta_T(\langle e_C, f_C\rangle) \cdot P(|\{d_{e_C}\}|) \cdot \prod_{d_{e_C}} \phi_{e_C}(d_{e_C}) \cdot P(|\{d_{f_C}\}|) \cdot \prod_{d_{f_C}} \phi_f(d_{f_C}) \right). \tag{3}$$

In Figure 3, we show an example of the calculation of bilingual generation probability and monolingual derivation probability for each treelet pair (ignoring $P(|\{d_{e_C}\}|)$ and $P(|\{d_{f_C}\}|)$ for ease of understanding). For the core alignment ⟨not, ない⟩, there is no derivation, and only bilingual generation probability $\theta_T(\langle not, \text{なかった}\rangle)$ is used. For ⟨change, 変化⟩, there are two derivations from "変化 (*change*)"; "に より (*by*)" and "し (*light verb*)". Therefore, we need to calculate two monolingual derivation probabilities in addition to the bilingual generation probability.

The remainder of this section gives the details of the bilingual generation probability θ_T, monolingual derivation probability ϕ and dependency relation probability $P(D)$.

4.1 Bilingual generation probability

When generating bilingual treelets, we first need to decide whether to generate an unaligned treelet (with probability p_N) or an aligned treelet pair (with probability $1-p_N$). Aligned treelet pairs are generated from an unknown probability distribution θ_A, which obeys the Dirichlet process (DP):

$$\theta_A(\langle e_C, f_C\rangle) \quad \sim \quad DP(M_A, \alpha_A), \tag{4}$$

where M_A is the base distribution and α_A is a concentration parameter. The base distribution is defined as:

$$M_A(\langle e_C, f_C\rangle) = [P_e(e_C)P_{WA}(f_C|e_C) \cdot P_f(f_C)P_{WA}(e_C|f_C)]^{\frac{1}{2}}$$
$$P_e(e_C) = p_t \cdot (1-p_t)^{|e|-1} \cdot \left(\frac{1}{n_e}\right)^{|e_C|} \quad P_f(f_C) = p_t \cdot (1-p_t)^{|f|-1} \cdot \left(\frac{1}{n_f}\right)^{|f_C|}, \tag{5}$$

where P_{WA} is the translation probability computed by IBM model1 (Brown et al., 1993), and n_e and n_f are the numbers of word types in each language. θ_A does not give a weight to an unaligned treelet.

Unaligned treelets are generated from another unknown probability distribution θ_N:

$$\begin{aligned} \theta_N(\langle e_C, f_C\rangle) &\sim DP(M_N, \alpha_N) \\ M_N(\langle e_C, f_C\rangle) &= \begin{cases} P_{WA}(e_C|\text{NULL}) & \text{if } f_C = \text{NULL} \\ P_{WA}(f_C|\text{NULL}) & \text{if } e_C = \text{NULL} \end{cases}. \end{aligned} \tag{6}$$

θ_N does not give a weight to an aligned treelet pair. Note that an unaligned treelet is always composed of only one word in our model. Finally, θ_T can be decomposed as:

$$\theta_T(\langle e_C, f_C\rangle) = p_N\theta_N(\langle e_C, f_C\rangle) + (1-p_N)\theta_A(\langle e_C, f_C\rangle). \tag{7}$$

The earlier study (Nakazawa and Kurohashi, 2011) only considered treelets as alignment units. However, this is inadequate for semantic-head dependency trees, since a set of sibling function words is often considered as an alignment unit. In Figure 2, for example, sibling "かも しれ ない (*may*)" in Japanese should be aligned to the English "may". Therefore, our model allows siblings to be a core alignment unit when the siblings are contiguous in the word sequence. We suppose the term "treelet" includes siblings in this paper.

4.2 Monolingual derivation probability

We only explain the *e*-side derivations in this section, since the *f*-side is the same. We calculate the monolingual derivation probability using a large monolingual corpus. Derivations d_{e_C} are conditioned on the treelet e_C from which they were derived:

$$\phi_e(d_{e_C}) = p(d_{e_C}|e_C). \tag{8}$$

For example, $\phi_{medical\ treatment}(\text{the}) = p(\text{the}|\text{medical treatment})$. However, using a treelet as a condition is vulnerable to the data sparseness problem. We use an *anchor word* in e_C as the condition instead of e_C. The derivation is connected to the anchor word in the word dependency tree:

$$p(d_{e_C}|e_C) \approx p(d_{e_C}|A(e_C, d_{e_C})). \tag{9}$$

The function $A(e_C, d_{e_C})$ returns the anchor word in e_C for d_{e_C}. For example, $A(\text{medical treatment, the})$ is "treatment".

$p(d_{e_C}|A(e_C, d_{e_C}))$ are calculated as follows:

$$p(d_{e_C}|A(e_C, d_{e_C})) = \frac{Count(d_{e_C}, A(e_C, d_{e_C}))}{\sum_d Count(d, A(e_C, d_{e_C}))}. \tag{10}$$

Table 1: The English derivations (left) and Japanese derivations (right) acquired from the sentences in Figure 3. 'P', 'L' and 'R' denote, respectively, Parent, pre-child (dependent from the Left), and post-child (dependent from the Right).

$Count(d_{e_C}, A(e_C, d_{e_C}))$ denotes the frequency with which d_{e_C} is connected to $A(e_C, d_{e_C})$ in the monolingual corpus. Taking each sentence in Figure 3 as an example sentence in the monolingual corpus, we can enumerate the derivations shown in Table 1 from the sentences. A derivation must be contiguous as a tree, and we do not consider sibling derivations. We distinguish three types of derivations: parent, pre-child (dependent from the left) and post-child (dependent from the right).

This lexicalized derivation is excessively specific. For example, the highest probability derivations from "Ph.D." acquired from the English Web corpus (Kawahara and Kurohashi, 2006a) are "a", "student", "thesis" in order. Consequently, using only lexicalized derivation can cause many derivation errors. We consider not only the lexicalized derivation probability, but also another probability using part-of-speech (POS) is used as the condition. Using the notation $A_{pos}(e_C, d_{e_C})$ for the POS of the anchor word, the monolingual derivation probability is defined as:

$$p(d_{e_C}|e_C) = [p(d_{e_C}|A(e_C, d_{e_C})) \cdot p(d_{e_C}|A_{pos}(e_C, d_{e_C}))]^{\frac{1}{2}}. \quad (11)$$

$p(d_{e_C}|A_{pos}(e_C, d_{e_C}))$ is also acquired from the large monolingual corpus in the same manner as $p(d_{e_C}|A(e_C, d_{e_C}))$. We take the geometric mean of the two probabilities because this eliminates noisy derivations of lexicalized probabilities while keeping the derivation preferences for each word.

Note that we do not need to discriminate between content words and function words in the enumeration of derivations and the calculation of derivation probabilities. Generally, the neighboring words of function words are content words. The vocabulary size of content words is much larger than that of function words. Therefore, the number of derivation patterns from function words is quite large, causing their probabilities to be very small. The probabilities naturally prefer deriving function words from content words than deriving content words from function words.

4.3 Dependency Relation Probability

Our model considers dependency relations between treelets and assigns a weight to each relation following the previous work (Nakazawa and Kurohashi, 2011). Here, each treelet includes both core and derivation treelets, and treelets in a treelet pair have the same index, for example, the counterpart of e_j is f_j.

The dependency relations are considered on each e and f side in the same manner, thus we only explain the e-side. First, we find the nearest aligned parent treelet, which we call relational parent, for each treelet in e-side. The relational parent is searched by ascending the dependency tree to the root node until an aligned treelet is found. The number of unaligned treelets on the path to relational parent from e_j is denoted as $N(e_j)$. $N(e_j) = 0$ if the relational parent is the direct parent of e_j. We consider an imaginary root as the relational parent for the root treelet of a sentence.

Suppose the relational parent treelet of e_j is e_k. Then, we consider where their counterparts, f_j and f_k respectively, are on the dependency tree of the other side. We can assume that f_j tends to depend on f_k because the dependencies between concepts hold across languages. The dependency relation probability reflects this tendency. We define the function $rel(e_j, e_k)$ which returns a dependency relation between the counterparts of the two arguments, in other words, dependency relation between f_j and f_k. We express a dependency relation as the shortest path from f_j to f_k. For simplicity, we indicate the path with a pair of non-negative integers, where the first is the number of steps going up (Up) the dependency tree and the other is the number going down ($Down$). For example, in Figure 3, traveling from "medical treatment" to "weight" requires 1 step going up (to reach "change") and 1 step going down, so the dependency relation is $(Up, Down) = (1, 1)$.

Finally, we assign the dependency relation probability to a triplet of non-negative integers $R_f = (N, Up, Down)$. The dependency relation probabilities for the e-side are drawn from an unknown probability distribution θ_{ef} and for the f-side from θ_{fe}, with both obeying the DP:

$$\begin{array}{rclcrcl} \theta_{ef}(R_e) & \sim & DP(M_{ef}, \alpha_{ef}) & & M_{ef}(R_e) & = & p_{ef} \cdot (1-p_{ef})^{N+Up+Down-1} \\ \theta_{fe}(R_f) & \sim & DP(M_{fe}, \alpha_{fe}) & & M_{fe}(R_f) & = & p_{fe} \cdot (1-p_{fe})^{N+Up+Down-1}. \end{array} \tag{12}$$

Using the notations and definitions above, the dependency tree-based reordering model $P(D|\{\langle e, f\rangle\})$ is decomposed as:

$$P(D|\{\langle e, f\rangle\}) = \prod_{\langle e,f\rangle} \theta_{ef}(R_e) \cdot \theta_{fe}(R_f). \tag{13}$$

5 Model training

We train the model by means of a collapsed Gibbs sampling, which has been used in some recent NLP works (Nakazawa and Kurohashi, 2011; DeNero et al., 2008). In a Gibbs sampling, we first need to initialize the states of the training data, such as the boundaries between treelets and their alignments, and also initialize the latent variables according to the initial states of the data. Starting with the initial state, we generate many samples sequentially from the last state by changing a small local point. Normalizing the counts in the samples yields the parameter estimations.

5.1 Initialization

We initialize the states of the training data by heuristically merging bi-directional alignment results of the standard word alignment tool GIZA++. Many machine translation studies use heuristics to combine the two alignment results, one of which is called grow-diag-final-and (Koehn et al., 2007). Our heuristic is similar to this, but the difference is that we combine the two results based on dependency trees, and not on word sequences. The initialization is carried out by the following steps:

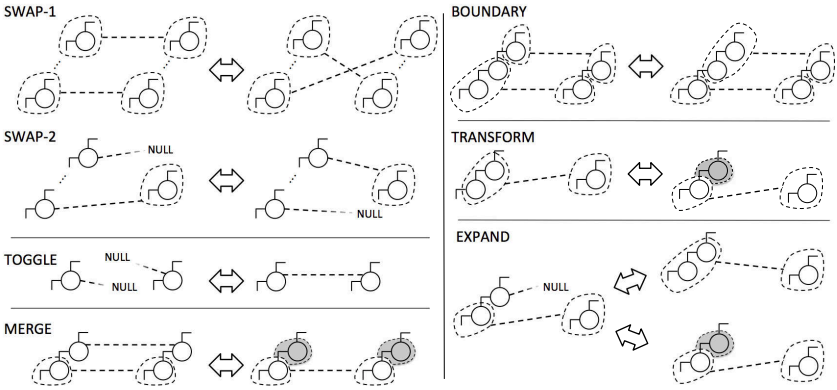

Figure 4: Illustration of the sampling operators. A solid circle represents a single word, while a treelet is depicted surrounded by a broken line. A gray treelet represents a derivation. A link directly connected to a word denotes that the treelet must consist of exactly one word, whereas other treelets can consist of one or more words including derivations.

1. Take the intersection of the two results.
2. In the union of the two results, accept alignment points connected to at least one accepted point in terms of the dependency tree (corresponds to grow-diag).
3. In the union of the two results, accept alignment points between two unaligned words (corresponds to final-and).

Initial boundaries of treelets and their alignments, and also the counts of treelet pairs and dependency relations are thus acquired. Note that there is no derivations after the initialization step.

5.2 Sampling operators

Our sampler repeatedly uses the six operators illustrated in Figure 4, to generate samples. Each application of an operator generates one new sample. We could, of course, use all the generated samples. However, since successive samples are almost the same, except for one local part, it is futile keeping all the samples. Thus, for each iteration, we keep only one sample, which is the final outcome after applying all the operators to all the possible points in all the sentence pairs in the training corpus.

SWAP
The SWAP operator exchanges the counterparts of two treelets, which may have derivations. There are two cases: [SWAP-1] both treelets are aligned, and [SWAP-2] one of the two treelets is unaligned and the other consists of exactly one word.

TOGGLE
The TOGGLE operator adds or removes an alignment. If f_j and e_k are both unaligned treelets, TOGGLE links the two treelets. Alternatively, if f_j and e_j are aligned, TOGGLE cuts the link

and makes each of the treelets unaligned. Because of the NULL-alignment restriction, f_j and e_j must consist of exactly one word.

MERGE
The MERGE operator combines a one-to-one alignment with the neighboring alignment as derivations from each treelet, or separates derivations from each treelet as an independent alignment.

BOUNDARY
The BOUNDARY operator moves the boundary between two treelets by one word. This operator does not change the type (core or derivation) of the boundary word.

TRANSFORM
The TRANSFORM operator changes the type of a word from core to derivation or vice versa.

EXPAND
The EXPAND operator expands or contracts an aligned treelet. If an unaligned treelet is next to an aligned one, EXPAND merges the unaligned and aligned treelets, either as a part of core treelet or derivation treelet. As the opposite direction, it excludes a marginal node from a treelet, and to make the excluded node unaligned.

6 Alignment experiments

We conducted alignment experiments on the English-Japanese corpus to show the effectiveness of the proposed model.

6.1 Settings

For the experiments, we used the JST[1] paper abstract corpus. This corpus was created by NICT[2] from JST's 2M English-Japanese paper abstract corpus using the method of Utiyama and Isahara (2007). This corpus consists of 996K parallel sentences: 24.7M words in English and 27.5M words in Japanese. Unfortunately, this corpus is not publicly available now, but they will become available in the near future.

As gold-standard data, 500 sentence pairs were annotated by hand using two types of annotations: sure (S) alignments and possible (P) alignments (Och and Ney, 2003). The unit of evaluation was the word. We used precision, recall, and alignment error rate (AER) as evaluation criteria. All the experiments were run on the original forms of words. The hyper parameters for our model used in the experiments are as follows: $p_\$ = 0.1$, $p_d = 0.9$, $p_N = 0.1$, $p_t = 0.8$, $\alpha_A = 100$, $\alpha_N = 100$, $\alpha_{fe} = 100$, $\alpha_{ef} = 100$, $p_{fe} = 0.5$, $p_{ef} = 0.5$. They are borrowed from the previous work (DeNero et al., 2008; Nakazawa and Kurohashi, 2011) and changed a little. The training time was about 1 day using 200 CPU cores. It is much slower than the word-sequence-based models because considering tree structures is computationally more complex.

The derivation probabilities were calculated from English and Japanese Web corpora each consisting of 550M sentences (Kawahara and Kurohashi, 2006a). We limited the maximum size of a derivation treelet to three words. We only consider top-20 frequent derivations for each word and POS.

[1] http://www.jst.go.jp/
[2] http://www.nict.go.jp/

English sentences were converted into phrase structures using Charniak's nlparser (Charniak and Johnson, 2005), and then they were transformed into dependency structures by rules defining head words for phrases (Collins, 1999). Japanese sentences were converted into dependency structures using the morphological analyzer JUMAN (Kurohashi et al., 1994) and the dependency analyzer KNP (Kawahara and Kurohashi, 2006b).

For comparison, we used GIZA++ (Och and Ney, 2003), which implements the well-known word-based statistical alignment model of the IBM Models. We conducted word alignment bidirectionally with the default parameters and merged them using the grow-diag-final-and heuristics (Koehn et al., 2003). We also tested the BerkeleyAligner[3] (DeNero and Klein, 2007) in the unsupervised training mode with default settings.

6.2 Experimental result and discussion

The experimental results are given in Table 2. "Syntactic-head" is the alignment accuracy of the baseline system by Nakazawa and Kurohashi (2011), while "Semantic-head w/o derivation" is the result of using the baseline model on semantic-head dependency trees. The results of incorporating the monolingual derivation are given in the bottom two rows, where "all" means that we evaluated all the alignments including derivations, while "core" means that we only evaluated the core alignments.

As mentioned in Section 1, the baseline model has already shown much better alignment accuracy than the conventional models, GIZA++ and BerkeleyAligner. There was a slight improvement using semantic-head dependency trees (0.36% absolute AER reduction).

The proposed model further improved the alignment accuracy. Compared with the baseline model, we achieved 0.6% and 1.34% improvement in absolute AER by evaluating all the alignments and only the core alignments respectively. The relative error reduction in AER is about 10% for the core alignment, which can be considered as a significant improvement. The reason of the further AER decrease when using only the core alignments is as follows: although the monolingual derivation can prevent from incorrect alignments for unique function words, it sometimes causes over derivations. This is discussed in detail later.

Figure 5 shows the alignment results by the proposed model for sentences in Figure 1. The proposed model reduced the alignment errors for unique function words by deriving them monolingually, and found correct alignments which the baseline system failed to find.

There are two main causes of alignment errors in the proposed model. One is the granularity of the derivation probability. We used the product of the two probabilities, lexicalized and POS-based, to take advantage of them, but this is insufficient. For example, in the sentence fragment "the possibility that ...", the proposed model failed to derive the unique word "that" from "possibility". In another fragment "the patient who ...", the proposed model failed to derive "who" from "patient". The reason for these failures is the low probability in the POS-based derivation. The possible solution for the granularity problem is to use word classes where each word class contains the words which have similar derivation distribution. For example, some abstract nouns such as "possibility" and "fact" tend to derive appositive "that", and person-category nouns tend to derive a relative "who".

The other cause of alignment errors is the over derivation typically created by the noise in a parallel sentence and parsing error. On the left of Figure 6, the fragment of the Japanese

sentence “音 列 の (*of tone sequence*)” has no corresponding part in the English sentence. “音 列 (*tone sequence*)” is correctly aligned to NULL, but the function word “の (*of*)” is incorrectly derived from “法 (*method*)”. On the right of Figure 6, the Japanese “HDMI は” should not depend on “異なる (*different*)”, but on “使用 (*use*)”. Because of this parsing error, the topic marker “は” is incorrectly derived from “異なる (*different*)”. One possible short-term solution for the parsing problem is to use the n-best parsing results in the model. An alternative solution was proposed by Burkett et al. (2010), who described a joint parsing and alignment model that exchanges useful information between the parser and aligner.

7 Translation experiments

We conducted English-to-Japanese and Japanese-to-English translation experiments on the same corpus used in the alignment experiments. We translated 500 paper abstract sentences from the JST corpus. Note that these sentences were not included in the training corpus. We use Joshua[4], a Java-based opensource implementation of the hierarchical decoder, version 4.0 (Ganitkevitch et al., 2012) with default settings. It was tuned using another 500 development sentence pairs.

Table 3 shows the BLEU (Papineni et al., 2002) scores for the translations. The proposed

Alignment model	En → Ja	Ja → En
GIZA++ & grow-diag-final-and	23.84	17.75
Syntactic-head (baseline)	24.16	17.83
Semantic-head w/o derivation	24.11	18.06
Semantic-head w/ derivation (all)	**24.55**†	**18.46**†‡
Semantic-head w/ derivation (core)	24.45	17.76

Table 3: BLEU scores for English-to-Japanese and Japanese-to-English translation experiments. † and ‡ marks indicate significant difference by bootstrap resampling (Koehn, 2004) from the decoder using GIZA++ & grow-diag-final-and alignment and baseline alignment respectively ($p < 0.05$).

model using all the alignments including derivations achieved the best translation quality. We believe this improvement is due to the reduction in function word alignment errors. The BLEU score decreased when only core alignments were used. This is because the exclusion of the derivations increased the ambiguity of the translation rules.

Conclusion and future work

In this paper, we proposed a novel approach for handling unique function words based on semantic-head dependency trees. The proposed model monolingually derives unique function words from bilingually generated treelet pairs. The derivation probabilities are acquired from a large monolingual corpus for each language. We showed that semantic-head dependency trees are more effective than syntactic-head dependency trees for high quality alignment, and that the treelet derivation model can reduce alignment errors for function words resulting in better translation quality.

To further validate the effectiveness of the proposed model, we need to apply our model to other language pairs, including the Korean language, which is also an agglutinative language. In addition, we need to resolve the issues discussed in Section 6.2.

Optimizing for Sentence-Level BLEU+1 Yields Short Translations

Preslav NAKOV Francisco GUZMÁN Stephan VOGEL

ABSTRACT
We study a problem with *pairwise ranking optimization* (*PRO*): that it tends to yield too short translations. We find that this is partially due to the inadequate smoothing in PRO's BLEU+1, which boosts the precision component of BLEU but leaves the brevity penalty unchanged, thus destroying the balance between the two, compared to BLEU. It is also partially due to PRO optimizing for a sentence-level score without a global view on the overall length, which introducing a bias towards short translations; we show that letting PRO optimize a *corpus-level* BLEU yields a perfect length. Finally, we find some residual bias due to the interaction of PRO with BLEU+1: such a bias does not exist for a version of MIRA with sentence-level BLEU+1. We propose several ways to fix the length problem of PRO, including smoothing the brevity penalty, scaling the effective reference length, grounding the precision component, and unclipping the brevity penalty, which yield sizable improvements in test BLEU on two Arabic-English datasets: IWSLT (+0.65) and NIST (+0.37).

1 Introduction

Early work on statistical machine translation (SMT) has relied on generative training using maximum likelihood parameter estimation. This was inspired by the noisy channel model (Brown et al., 1993), which asked for calculating the product of two components, a language model and a translation model, giving them equal weights. As mainstream research has moved towards combining multiple scores, the field has switched to discriminative tuning in a log-linear fashion. The standard approach has been to maximize BLEU (Papineni et al., 2002) on a tuning dataset using a coordinate descent optimization algorithm known as *minimum error rate training* (*MERT*), as proposed by Och (2003).

MERT has dominated the SMT field for years, until the number of parameters in the log-linear model has gradually increased, in some cases to hundreds and even to hundreds of thousands of scores, which has called for new tuning algorithms since MERT was unable to scale beyond just a handful of parameters. Many alternatives to MERT have been proposed over the years, but it is only recently that some of them have gained popularity in the community, most notably, the *margin infused relaxed algorithm* (MIRA) (Chiang et al., 2008) and *pairwise ranking optimization* (*PRO*) (Hopkins and May, 2011).

While the number of parameters that an optimizer can handle has become a major concern recently, there are many other important aspects that researchers have paid attention to, e.g., the performance of parameters when translating unseen test data, the speed of convergence, the stability across multiple reruns, the objective function being optimized (e.g., BLEU vs. an approximation of BLEU), the mode of learning (e.g., online vs. batch).

Here we study a different, and so far neglected, aspect: the characteristics of the translations generated using weights found by different optimizers. More specifically, we focus on the length with respect to the reference translations. It has been observed that while optimizers like MERT and MIRA typically yield translation hypotheses with the right level of verbosity, other optimizers such as PRO tend to generate translations that are too short.[1] This phenomenon has not been analyzed in sufficient detail so far; yet, it is important since generating short translation hypotheses is penalized by BLEU, which could mean missed opportunities for better BLEU scores. Our contributions can be summarized as follows:

- We analyze the length issue with PRO in detail, we explore possible reasons, and we propose several fixes. We achieve small but consistent improvements in BLEU for fixes that yield longer hypotheses: up to 0.65 BLEU points absolute. We also find that the better a fix approximates the target length, the higher the testing BLEU score.
- We find that the core of the problem is the function being optimized: sentence-level BLEU+1 yields short translations, while corpus-level BLEU yields the right verbosity.
- We demonstrate that what matters is the objective function, not the optimization algorithm. We show that similar translations – in terms of BLEU score and length – can be generated using weights from different optimizers, e.g., PRO vs. MIRA, when they are given the same objective function, e.g., sentence-level vs. corpus-level BLEU.

The remainder of this paper is organized as follows: Section 2 describes related work, Section 3 explains the length issue with PRO and several methods we propose to fix it, Section 4 describes our experiments and evaluation results, and Section 5 offers a more general analysis and discussion. Finally, Section 6 concludes with directions for future work.

[1] That is why the Moses toolkit has an option to run a few iterations of MERT after PRO – to get the length right.

2 Related Work

The dominant approach for parameters optimization in SMT is to use MERT (Och, 2003), a batch tuning algorithm that iterates between two modes: (i) generating a k-best list of translation hypotheses using the current parameters values, and (ii) parameter optimization using the k-best lists from all previous iterations. MERT optimizes expected BLEU. It works well for a small number of parameters, but suffers from scalability and stability issues (Foster and Kuhn, 2009). Most importantly for our discussion, it tends not to have length biases; this is also confirmed by our own experiments (see Table 4).

Various alternatives to MERT have been proposed, motivated primarily by scalability considerations. One popular alternative is MIRA (Watanabe et al., 2007; Chiang et al., 2008, 2009), which is a perceptron-like online tuning algorithm with passive-aggressive updates. It uses an approximation to BLEU, where a sentence is scored in the context of a pseudo-document formed from the n-gram statistics for the last few updates. MIRA can scale to thousands of parameters and generally has no length bias (see Table 4).

Another recent, but already popular alternative to MERT is PRO (Hopkins and May, 2011), which models parameter tuning as pairwise ranking optimization. This is a batch tuning algorithm, which iterates between translation and optimization, just like MERT, but scales to thousands of parameters. It uses an add-one smoothed sentence-level version of BLEU, known as BLEU+1 (Lin and Och, 2004), and suffers from a length bias: the parameters it finds yield translations that are too short compared to the references (see Table 4). Exploring the reasons for this bias and proposing ways to solve it is the main focus of this paper.

There are many other tuning strategies, which fall outside of the scope of the current study, but to many of which some of our general finding and conclusions should apply. This includes improved versions of some of the above-mentioned algorithms, e.g., a batch version of MIRA (Cherry and Foster, 2012), or a linear regression version of PRO (Bazrafshan et al., 2012), but also many original algorithms that use a variety of machine learning methods and loss functions. We refer the interested reader to some excellent recent overviews: (McAllester and Keshet, 2011; Cherry and Foster, 2012; Gimpel and Smith, 2012).

To the best of our knowledge, no prior work has tried to study the reasons for the length bias of optimizers like PRO. However, researchers have previously expressed concerns about sentence-level BLEU+1, and some have proposed improvements, e.g., He and Deng (2012) used different smoothing for higher-order n-grams, unclipped brevity penalty, and scaled reference length. However, this was not done for the purpose of studying the length bias of PRO; moreover, as we will see below, the use of BLEU+1 is not the only reason for this bias.

3 The Length Bias with PRO

We explore the following hypotheses about the length bias with PRO:

- **PRO's optimization:** The bias could be due to the optimization mechanism of PRO.
- **BLEU+1:** PRO uses BLEU+1, where the add-one smoothing is applied to the precision component but does not touch the brevity penalty, which introduces an imbalance.
- **Sentence-level optimization:** PRO uses a (smoothed) sentence-level BLEU instead of corpus-level BLEU, which could make it hard to get the global corpus length right.

3.1 Possible Reason 1: The Optimization Mechanism of PRO

PRO is a batch optimizer that iterates between (i) *translation*: using the current parameter values, generate k-best translations, and (ii) *optimization*: using the translations from all previous iterations, find new parameter values. The optimization step has four substeps:

1. **Sampling:** For each sentence, sample uniformly at random $\Gamma = 5000$ pairs from the set of all candidate translations for that sentence from all previous iterations.
2. **Selection:** From these sampled pairs, select those for which the absolute difference in their BLEU+1 scores is higher than $\alpha = 0.05$.
3. **Acceptance:** For each sentence, accept the $\Xi = 50$ selected pairs with the highest absolute difference in their BLEU+1 scores.
4. **Learning:** Assemble the accepted pairs for all sentences into a single set and use it to train a ranker to prefer the higher-scoring sentence in each pair.

While sampling is unlikely to introduce a bias, selection and acceptance could do so.

Selection could filter too many pairs for some of the sentences, leaving for them less than Ξ pairs for the acceptance step; such sentences would be under-represented compared to those for which there are Ξ pairs accepted. If these under-represented sentences are generally longer then their references, this could yield a bias towards shorter translations.

Similarly, by focusing on the pairs with the highest differentials, the acceptance step would over-represent pairs with big differences in sentence lengths, e.g., a sentence that is extremely long/short compared to the reference would have a very low BLEU+1 score, and thus it will have a high differential when paired with any other sentence. If at some iteration, the k-best list is populated with overly long sentences, they would keep getting accepted in subsequent iterations of PRO, and thus the classifier will keep learning that being shorter is better.

Given the above discussion, we propose the following experiments with PRO:

- **PRO, no threshold.** At the selection step, keep everything, i.e., no selection step.
- **PRO, random accept.** At the acceptance step, accept the pairs at random, as opposed to accepting those with the highest differentials in BLEU+1, i.e., no acceptance step.
- **PRO, no threshold, random accept.** Combination of the previous two.

3.2 Possible Reason 2: BLEU+1

The other possible reasons are related to BLEU; thus, we should have a look at its definition:

$$\text{BLEU} = BP \cdot \left(\prod_{n=1}^{N} p_n \right)^{\frac{1}{N}} \tag{1}$$

BLEU has two components: (1) brevity penalty (BP), and (2) precision component (PC), the geometric mean of n-gram precisions p_n, $1 \leq n \leq N$. The BP is defined as follows:

$$BP = \begin{cases} 1 & \text{if } c > r \\ \exp\left(1 - \frac{r}{c}\right) & \text{if } c \leq r \end{cases} \tag{2}$$

where c is the length of the candidate, and r is the effective reference corpus length.

BLEU is defined at the corpus-level, and p_n, r and c are sums over all corpus sentences:

- $p_n = \frac{\sum_i m_{in}}{\sum_i h_{in}}$, where m_{in} is the number of n-gram matches between a translation and the references for sentence i, and h_{in} is the number of n-grams in the hypothesis;[2]
- $c = \sum_i c_i$, where c_i is the length of the candidate translation for sentence i;
- $r = \sum_i r_i$, where r_i is the reference length for sentence i; in case of multiple reference translations, this is the closest reference sentence length.

While BLEU is defined at the corpus level, PRO works at the sentence level and thus needs to optimize sentence-level BLEU for each sentence i. Such a version of BLEU can be obtained by redefining p_n, r and c to look at sentence i only: $p_n = \frac{m_{in}}{h_{in}}$, $c = c_i$, and $r = r_i$.

Using such a sentence-level version of BLEU is problematic though since it can easily become zero. This is because of the product of n-gram precisions in the geometric mean of the precision component of BLEU: if some p_n is zero, the whole product will be zero. In particular, it is easy to see that BLEU will be zero for any hypothesis without 4-gram matches. This is undesirable for optimization purposes since it does not allow to distinguish (a) a hypothesis translation that has no matches at all from (b) one that has unigram, bigram and trigram matches but no 4-gram matches; intuitively, the latter should be preferred over the former.

A popular strategy to solve the problem, which is also adopted by PRO, is to use an add-one smoothed version of BLEU, called BLEU+1, where p_n is redefined as follows: $p_n = \frac{m_{in}+1}{h_{in}+1}$.

There are two observations we can make about BLEU+1: (i) while it alters the precision component, it leaves the brevity penalty unchanged, and (ii) it is strictly positive.[3]

Let us start with the first observation. Adding one to m_{in} implies the need to add an extra n-gram to the reference translation – an n-gram that matches the candidate translation. This can be seen in the extreme case of a perfect match between the hypothesis and the reference: then, the additional match between the hypothesis and the reference, which is accounted for in m_{in}, would also require an additional word in the reference. However, the brevity penalty is not altered to account for this additional n-gram. Consider the special case of unigrams: if we assume that the reference contains an extra unigram, then it should be longer by one word. And vice versa, adding one extra word to the reference would increase the number of n-grams it contains by one for each n, $1 \leq n \leq N$, which is exactly what BLEU+1 assumes in its precision smoothing.

Let us try to analyze the impact of BLEU+1 on the hypothesis length. We have seen that BLEU+1 sees the precision component of a longer reference, but it pays the brevity penalty with respect to a shorter one. Because BLEU+1 boosts the precision component while leaving the BP intact, the relative weight of BP decreases compared to the original BLEU. This means that there could be potential gain from staying shorter if this can boost precision even further: the BP price to be paid for this would be relatively lower than it was in BLEU. Thus, high-scoring shorter hypotheses are more likely with BLEU+1 than with BLEU.

[2] More precisely, let g_n be an arbitrary n-gram, and let $\#_c(i, g_n)$ be the number of times g_n occurs in the candidate translation for sentence i. Let also $\#_r(i, g_n)$ be the maximum number of occurrences of g_n in any reference translation for sentence i. Then, we can define $m_{in} = \sum_{g_n} \min\left(\#_c(i, g_n), \#_r(i, g_n)\right)$ and $h_{in} = \sum_{g_n} \#_c(i, g_n)$.

[3] While BLEU+1 in PRO is strictly positive, there are definitions in the literature that allow it to become zero, e.g., Lin and Och (2004) do not smooth the unigram counts, which makes BLEU+1 zero in case of no matches at all. Experimenting with their version of BLEU+1 is left for future work; it would still need a fix for BP though.

Let us now consider the second observation: that BLEU+1 is strictly positive. While there is nothing wrong with this per se, it suggests a different way to restore the balance between BP and PC: by "grounding" BLEU+1 so that it is zero when there are no matches at all. This can be achieved by subtracting from the precision component of BLEU+1 the score for that component when there are no matches. Thus, the "grounded" precision component of BLEU+1 changes from $PC = \left(\prod_{n=1}^{N} \frac{m_{in}+1}{h_{in}+1}\right)^{\frac{1}{N}}$ to $PC = \left(\prod_{n=1}^{N} \frac{m_{in}+1}{h_{in}+1}\right)^{\frac{1}{N}} - \left(\prod_{n=1}^{N} \frac{1}{h_{in}+1}\right)^{\frac{1}{N}}$.

Given the above discussion, we propose the following fixes for the sentence-level BLEU+1:

- **BLEU, PC-unsmoothed**. Just use BLEU. The idea is that if add-one smoothing in BLEU+1 is causing length problems, they should go away if unsmoothed BLEU is used instead. While unsmoothed BLEU will make many pairs of hypotheses indistinguishable, both having a score of zero, many other pairs with at least one non-zero-score hypothesis will still remain, and they should be enough to train the classifier of PRO.
- **BLEU+1, grounded.** "Ground" the PC of BLEU+1 by subtracting from it its value when there are no matches. Given the asymmetry of add-one smoothing in BLEU+1, which boosts the PC for shorter sentences more than for longer ones for the same number of matches, "grounded" BLEU is slightly more biased towards longer sentences.
- **BLEU+1, BP-smoothed.** Use add-one smoothing not only for the precision component but also for the length of the reference translation, i.e., use $r = r_i + 1$, in addition to $p_n = \frac{m_{in}+1}{h_{in}+1}$. The idea here is to smooth the PC and the BP consistently, thus maintaining the balance between them: if we assume an extra n-gram in the reference, then we should also assume that the reference contains an extra word.
- **BLEU+1, BP-smoothed, grounded.** Combination of the previous two: smooth the reference length in BP and also ground the precision component of BLEU+1 .

3.3 Possible Reason 3: Sentence-Level Optimization

Another possible reason for the length issue with PRO could be a bias due to a sentence-level version of BLEU being optimized as opposed to using a corpus-level BLEU. If, for whatever reason, being a bit shorter than the reference is preferable to being a bit longer, e.g., because sentence-level BLEU+1 penalizes longer sentences more than shorter ones, then the candidate translation for each sentence will try to stay on the short side as opposed to getting longer than the reference translation. These length differences might be minimal at the sentence level, but they would accumulate and would eventually yield a larger difference at the corpus level. The crucial observation is that if each and every sentence looks at its length in isolation, it would be reluctant to getting longer than its reference (since this would harm its sentence-level BLEU), even if this could improve corpus-level BLEU.

One possible way to address the problem is to introduce in the sentence-level brevity penalty information about the ratio of the corpus-level length and the effective reference corpus length from the previous iteration of PRO. For example, if the corpus length was shorter than the effective reference corpus length, then we could scale the sentence-level reference lengths r_i on the current iteration accordingly, so that proportionally higher brevity penalty be paid for being too short; and vice versa, if on the previous iteration the corpus length was too long, we could scale the reference length so that no penalty be paid for staying proportionally shorter; this idea was previously explored by He and Deng (2012).

Another possibility is to unclip the brevity penalty, as proposed by He and Deng (2012), by allowing it to get bigger than 1, thus effectively becoming a "bonus" for longer sentences. If there is a bias in sentence-level BLEU+1 towards shorter translations, i.e., longer hypotheses are penalized by the precision component more heavily than shorter hypotheses are penalized by BP, then turning the brevity penalty into a bonus for longer hypothesis should encourage them; note, however, that they will still be discouraged by the decrease in the score for the precision component, which should act as a counter-balance.

Finally, if optimizing sentence-level BLEU causes problems, we could just get rid of it and use some kind of corpus-level BLEU instead. This is what MIRA does (Chiang et al., 2008): even though it is an online algorithm and makes updates on a per-sentence basis, it does not use a sentence-level BLEU, but instead it calculates the BLEU score for the current sentence in the context of a pseudo-corpus that tracks the n-gram statistics of the model-best derivations from the last few updates. We could adopt a similar strategy here as well.

Given the above, we propose the following fixes/substitutes for the sentence-level BLEU+1:

- **BLEU+1, unclipped.** Use an unclipped brevity penalty: $BP = \exp\left(1 - \frac{r}{c}\right)$.
- **BLEU+1, scaled.** Scale the reference length with the inverse length ratio (ILR) from the previous iteration of PRO, i.e., define $r = r_i \cdot ILR$, where $ILR = c'/r' = \sum_i c'_i / \sum_i r'_i$, where c' and r' are the corpus-level candidate and reference lengths from the previous iteration, respectively; we define $LR = 1$ for the first iteration of PRO.
- **BLEU+1, unclipped, scaled.** Combination of the previous two: BLEU+1 with unclipped brevity penalty and also with scaled reference length. This combination is advocated by He and Deng (2012).[4]
- **Corpus-level BLEU, MIRA-style.** This is BLEU calculated using a background pseudo-corpus, similar to the way this is done in MIRA. In our case, this pseudo-corpus is initialized with an exponentially decaying sum over the sufficient statistics for the one-best hypotheses from all previous iterations of PRO: taken with a weight of 0.9 for the last iteration,[5] with a weight of 0.9^2 for the iteration before it, etc. Then, the BLEU score for a candidate sentence is calculated by adding its sufficient statistics to the sufficient statistics for the background pseudo-corpus. Each time PRO samples, selects, and accepts a pair of hypotheses to use for training its classifier, we immediately update the pseudo-corpus by adding to it the sufficient statistics for the higher-scoring sentence, i.e., the positive example, in the pair. Thus, while the pseudo-corpus is initialized with the statistics from previous iterations, it soon gets dominated by statistics for the positive examples that are being accepted as training sentence pairs at the current iteration, since there are more of them than there are one-best hypotheses from previous iterations.[6] As in MIRA, our pseudo-document is time-dependent and thus can adjust dynamically to changing sentence lengths by encouraging or discouraging longer translations depending on what kinds of sentences have been accepted already.

[4] He and Deng (2012) further add to the combination a sophisticated smoothing for the precision component; however, in our experiments, the combination of all three changes to BLEU of theirs did not work well with PRO, yielding extremely long translations and an absolute loss of seven BLEU points on the NIST datasets.

[5] The value of 0.9 was found to work well in general, but many other values yielded a similar result since the BLEU score gets dominated by examples from the current iteration very quickly, making this value irrelevant.

[6] We only allow up to 25 iterations, which means there could be up to 24 accumulated one-best hypotheses per sentence, while we accept up to $\Xi = 50$ pairs per sentence.

4 Experiments and Evaluation

We compare variations of three parameter optimization algorithms: MERT, PRO, and MIRA. In all experiments, we use the phrase-based SMT model (Koehn et al., 2003) as implemented in the Moses toolkit (Koehn et al., 2007), and we report evaluation results over two datasets: NIST, which has four reference translations, and IWSLT, with a single reference translation.

In order to be able to directly compare the candidate/reference length ratios on the development and on the testing datasets, we need to make sure that we use the same tokenization when calculating BLEU on tuning and on testing. Such differences can arise because many standard scoring tools, e.g., those of NIST, work on detokenized text, which they retokenize again internally; this retokenization typically differs from the one used by the SMT system. As a result, the optimizer and the final scorer would most certainly see different tokenizations, and more crucially, this could affect the length ratios and thus the brevity penalty. Thus, we report BLEU scores calculated using the *multi-bleu* scoring tool, which uses the supplied tokenization and does no retokenization; we supplied it with references that were tokenized and truecased using the same models that were used for training and tuning.[7]

Finally, in order to avoid stability issues, we report results averaged over three runs.

4.1 Experimental Setup

Preprocessing: We tokenized the English side of all bi-texts and the monolingual data for language modeling using the standard tokenizer of Moses. We further truecased this data by changing the casing of each sentence-initial word to its most frequent casing in the training corpus; for lines containing ALL CAPS, we did this for each word. We segmented the words on the Arabic side using the ATB segmentation scheme: we used MADA (Roth et al., 2008) for NIST, and the Stanford word segmenter (Green and DeNero, 2012) for IWSLT.

Training. We built separate directed word alignments using IBM model 4 (Brown et al., 1993), we symmetrized them with the *grow-diag-final-and* heuristic of Moses, and we extracted phrase pairs of length up to seven. We scored these pairs using maximum likelihood with Kneser-Ney smoothing, to build a phrase table with five standard scores: forward and reverse phrase translation probabilities, forward and reverse lexical translation probabilities, and phrase penalty. We also built a lexicalized reordering model (Koehn et al., 2005): *msd-bidirectional-fe*. For language modeling, we trained a separate 5-gram Kneser-Ney smoothed model on each corpus (target side of a training bi-text or monolingual dataset); we then interpolated these models minimizing the perplexity on the target side of the tuning dataset. Finally, we built a log-linear model including the language model probability, the word penalty, and the parameters from the phrase and the reordering tables.

Tuning. We tuned the weights in the log-linear model by optimizing BLEU (Papineni et al., 2002) on the tuning dataset, using MERT, PRO, or MIRA. We allowed optimizers to run for up to 25 iterations, and we allowed them to extract 1000-best lists for each iteration.

Decoding. On tuning and testing, we dropped unknown words (this has yielded slightly shorter translations) and we used monotone-at-punctuation decoding (this had no impact on the translation length). On testing, we further used cube pruning and minimum Bayes Risk decoding (the latter yielded slightly longer translations).

[7] Still, for comparison purposes, we also report BLEU calculated with respect of the original references using NIST v13a, after detokenization and recasing of the system's output (shown in small script in the tables).

4.2 Datasets

We experimented with the Arabic-English datasets from two machine translation evaluation campaigns: (1) the NIST 2012 Open Machine Translation Evaluation[8], and (2) the IWSLT 2011 Evaluation Campaign on Automatic Talk Translation (Federico et al., 2012).

1. NIST: We trained the phrase and the reordering tables on all training datasets from NIST 2012 (except for UN), we tuned on MT06 and tested on MT09. For language modeling, we built a separate LM from the English side of each training dataset, and from each year of the English GigaWord; we then interpolated them into a single LM.
2. IWSLT: We trained the phrase and the reordering tables on the TED training dataset, we tuned on dev2010, and we tested on tst2010. Since there was a small mismatch in the source/reference length ratios between dev2010 and tst2010, we also experimented with reversed tuning/testing, tuning on tst2010 and testing on dev2010; this is to see the impact of the test set length ratio being a bit longer and also being a bit shorter than the tuning dataset ratio. We used two LMs: one trained on the English side of TED, and another one that is an interpolation of Europarl and WMT11 News.

4.3 Evaluation Results

We experimented with MERT, MIRA, PRO, and the various fixes thereof that were introduced in Section 3. The results of these experiments are shown in Tables 1, 2, 3, and 4. In these tables, the first column describes the method, followed by (1) the BLEU scores and (2) the length ratio of the candidate corpus-level translation to the effective reference corpus length, which are calculated (i) for the tuning dataset using multi-bleu,[9] (ii) for the test dataset using multi-bleu, and (iii) for the test dataset using the NIST scoring tool v13a.

The most important column in these tables is column three, which reports the candidate/reference length ratio for the tuning dataset as calculated using multi-bleu. We will be observing the impact of the various fixes we propose on this ratio: the closer it gets to 1.0, the better the fix should be; this will be verified by the value in the following column four, which shows the BLEU score on the test dataset calculated using multi-bleu.

4.3.1 Testing Possible Reason 1: The Optimization Mechanism of PRO

Table 1 explores possible reason 1 from Section 3, i.e., that there may be a bias in the optimization mechanism of PRO. It compares the original PRO to (a) PRO with no threshold for the selection step (default: filter pairs whose difference in BLEU+1 is less than a threshold: $\alpha = 0.05$), (b) PRO with random acceptance for the acceptance step (default: accept the pairs with the highest absolute difference in BLEU+1), and (c) combination of (a) and (b).

We can see in Table 1 that the length ratio in column three stays relatively stable for the different versions of PRO for all testing datasets. Note, however, the notable exception of IWSLT for (c), which exhibits a large increase in the length ratio: from 0.958 to 0.967.

[8] `http://www.nist.gov/itl/iad/mig/openmt12.cfm`

[9] Note that the results for the tuning dataset are obtained not using the BLEU score for the last iteration of the respective optimizer, but by translating the development set one more time – using the weights that the tuning algorithm has found. This is because, for some of the optimizers, the final tuning weight calculation might use weights from previous iterations, e.g., PRO accumulates and interpolates weights, while our version of MIRA, Batch-MIRA (Cherry and Foster, 2012), returns the weights from the iteration that yielded the highest BLEU score (using this option was suggested by the authors of Batch-MIRA; we found that it also worked best for our datasets).

Method	Tune: multi-bleu BLEU	Tune: multi-bleu len ratio	Test: multi-bleu BLEU	Test: multi-bleu len ratio	Test: NIST v13a BLEU	Test: NIST v13a len ratio

PRO, accept random	26.11	**0.953**	$26.48_{(+0.03)}$	0.946	25.46	0.949
PRO, no threshold, accept random	26.06	**0.954**	$26.36_{(-0.09)}$	0.946	25.35	0.948

Table 1: Testing possible reason 1: bias in the optimization mechanism of PRO.

These results are inconclusive but they show that, at least for one dataset, the length bias in PRO was influenced by its selection and acceptance steps.[10] Overall, multi-bleu in column 4 stays stable, with a slight degradation in some cases, which is not surprising and can be attributed to PRO training its classifier on less reliable examples in these cases – ones with smaller BLEU+1 differentials, which risks focusing on tiny, unimportant distinctions.

4.3.2 Testing possible Reason 2: Bias in the Smoothing of BLEU+1

Table 2 explores possible reason 2 from Section 3, i.e., that the length issue may be caused by the smoothing in BLEU+1; see also Section 3.2 for more detail. It compares the results for the original PRO to a version (a) without smoothing of the precision component, (b) with grounding of the precision component, (c) with smoothing of the brevity penalty, and (d) with both BP-smoothing and PC-grounding.

Several interesting observations can be made about this table. First, we can see that using unsmoothed BLEU instead of BLEU+1 yields consistent improvements of the length ratio for all datasets; it also improves multi-bleu and NIST v13a scores. This suggests that the smoothing in BLEU+1 could indeed be one of the causes for the length problem. A similar trend can be seen for grounded BLEU+1, which performs slightly better, both in terms of length ratio and in terms of multi-bleu and NIST v13a scores. This suggests that part of the problem could be the balance between the precision component and the brevity penalty in BLEU+1: grounding reduces the absolute value of the precision component, which was inflated by BLEU+1, and thus helps restore a balance between the two components that is closer to that in BLEU. Moreover, grounded BLEU+1 has the advantage of assigning a non-zero value to any sentence with at least one unigram match, while unsmoothed BLEU assigns a zero score to many sentences, which could leave PRO with less training examples.

[10] However, there could be other reasons, e.g., the kind of classifier PRO uses, the fact that it samples from all previous steps, etc.; exploring these possibilities is left for future work.

Method	Tune: multi-bleu BLEU	len ratio	Test: multi-bleu BLEU	len ratio	Test: NIST v13a BLEU	len ratio

PRO, BP-smoothed, PC-grounded	26.41	**1.003**	$27.07_{(+0.62)}$	0.995	26.04	0.994

Table 2: Testing possible reason 2: bias in the smoothing of BLEU+1.

Using add-one smoothing for the brevity penalty of BLEU+1 yields even better results on NIST and IWSLT-reversed: for IWSLT-reversed, the length ratio jumps from 0.952 to 0.991, and multi-bleu on the test dataset gains +0.65 absolute. The improvements in the length ratio are comparable for IWSLT-forward (from 0.958 to 0.987), and are more modest for NIST (from 0.981 to 0.988), where there is less room for improvement because of the higher baseline and because of the multiple reference translations. Overall, BP-smoothing works better than grounding, which suggests that smoothing with add-one both the precision component and the brevity penalty is a good way to restore the balance between them.

Finally, the combination of BP-smoothing and grounding yields even further improvements in the length ratios: 0.992 for NIST, 0.996 for IWSLT, and 1.003 for IWSLT-reversed. This adds +0.14 additional multi-bleu points to NIST, but slightly hurts IWSLT in both directions. This suggests that while grounding helps improve the balance between the precision component and ultimately the brevity penalty even further, it does this at the cost of deteriorating the estimates for the precision component, and thus the result in terms of multi-bleu is mixed.

Overall, as the length ratio gets closer to 1 on tuning, it does so on testing as well; this typically also yields an improvement in both multi-bleu and NIST v13a – we have achieved absolute multi-bleu improvements of up to +0.34 for NIST and +0.65 for IWSLT-reversed.

4.3.3 Testing Possible Reason 3: Sentence-Level Optimization

Table 3 explores possible reason 3 from Section 3, i.e., that the length issue may be due to sentence-level optimization. It compares the results for the original PRO to a version that (a) scales the reference length with the inverse document-level length ratio from the previous iteration of PRO, (b) unclips the brevity penalty, and (c) a combination thereof.

Method	Tune: multi-bleu BLEU	len ratio	Test: multi-bleu BLEU	len ratio	Test: NIST v13a BLEU	len ratio
NIST dataset (tune: MT06, eval: MT09)						
PRO	45.65	**0.981**	48.45	0.976	47.80	0.978
PRO, scaled	45.72	**0.984**	$48.50_{(+0.05)}$	0.979	47.87	0.981
PRO, unclipped	45.78	**0.992**	$48.81_{(+0.36)}$	0.990	48.18	0.992
PRO, unclipped, scaled	45.83	**0.993**	$48.82_{(+0.37)}$	0.991	48.19	0.993
IWSLT dataset (tune: dev2010, eval: tst2010)						
PRO	26.96	**0.958**	26.34	0.965	25.30	0.973
PRO, scaled	27.07	**0.975**	$26.39_{(+0.05)}$	0.984	25.31	0.991
PRO, unclipped	26.54	**1.024**	$25.63_{(-0.71)}$	1.035	24.34	1.040
PRO, unclipped, scaled	26.38	**1.030**	$25.43_{(-0.92)}$	1.042	24.14	1.046
IWSLT dataset – reversed (tune: tst2010, eval: dev2010)						
PRO	26.08	**0.952**	26.45	0.945	25.43	0.946
PRO, scaled	26.29	**0.972**	$26.75_{(+0.30)}$	0.962	25.73	0.963
PRO, unclipped	25.65	**1.033**	$26.40_{(-0.05)}$	1.021	25.34	1.021
PRO, unclipped, scaled	25.53	**1.037**	$26.09_{(-0.36)}$	1.028	25.02	1.028

Table 3: Testing possible reason 3: sentence-level optimization.

We can see that scaling does a great job at improving the length ratio, especially for IWSLT (in both directions), where it improves from 0.958/0.952 to 0.975/0.972; the effect is more limited for NIST – from 0.981 to 0.984, probably because of the higher baseline and due to the multiple reference translations. Scaling also yields small but consistent improvements in the multi-bleu/NIST-v13a scores on the tuning and the test datasets: up to +0.30 multi-bleu for IWSLT-reversed (but only +0.05 on the other two datasets).

We can further see that unclipping the brevity penalty in BLEU+1 yields a much larger increase in the length ratio, but this has mixed effect on the multi-bleu score: for NIST, the length ratio improves from 0.981 to 0.992, which yields a gain of +0.36 multi-bleu points absolute, but for IWSLT, the ratio jumps over 1, which yields a drop in the multi-bleu score.

The combination of unclipping and scaling yields an even higher length ratio, which helps NIST a bit, but hurts IWSLT even further as its length increases even more over 1.

Next, we experimented with sentence-level vs. corpus-level BLEU for PRO. The results are shown in Table 4. We can see that switching to corpus-level BLEU (calculated with respect to a pseudo-document, similarly to MIRA; see Section 3) yields a perfect length ratio of 1 on all tuning datasets, which is on par with the length ratios of MIRA and MERT, which also optimize corpus-level BLEU. This also improves the tuning multi-bleu for all datasets, and the testing multi-bleu by +0.14 for NIST and by +0.29 for IWSLT-reverse; however, there is a drop of -0.14 for IWSLT-forward because of a test length ratio that goes over 1 – due to a difference in the source/target length ratios between the tuning and the test sets for IWSLT.

We further tested the impact of doing the reverse: plugging a sentence-level BLEU+1 score as an objective in a corpus-level optimizer that generally has no length bias – MIRA. The results are shown in Table 4. We can see that MIRA with sentence-level BLEU+1 yields short reference translations just like PRO. This suggests that optimizing for sentence-level BLEU+1 yields short translations, regardless of the optimizer that is being used.

Method	Tune: multi-bleu BLEU	len ratio	Test: multi-bleu BLEU	len ratio	Test: NIST v13a BLEU	len ratio	*Avg. sent-BLEU tune*	*test*

Table 4: Sentence-level vs. corpus-level BLEU: experiments with PRO, MIRA, and MERT.

Note, however, that the length ratio with sentence-level MIRA does not drop all the way down to that of PRO, which also uses sentence-level optimization; this suggests once again that part of the bias may be coming from the optimization mechanism of PRO (which we have explored above as possible reason 1). This difference is larger for IWSLT than for NIST, which means that this bias is less pronounced with multiple reference translations.

The last two columns in Table 4 show the average sentence-level BLEU score, calculated for the tuning and the testing datasets. We can see that, on the tuning dataset, sentence-level optimizers score consistently higher than corpus-based ones on sent-BLEU, but they are not very competitive on corpus-BLEU; this suggests a mismatch of objectives. Note, also the relatively big difference between corpus-BLEU (i.e., multi-bleu – columns 2 and 4) and sent-BLEU (which uses no smoothing – columns 8 and 9) for IWSLT (about 4-5 BLEU points absolute), and the much smaller difference for NIST (0-1 BLEU points). One possible explanation is that with multiple references, average sent-BLEU approximates corpus-BLEU better; this is yet another possible reason for the length issue with PRO being less pronounced with NIST compared to IWSLT.

5 Discussion

Our experiments suggest that the length issue of PRO is due primarily to optimizing for sentence-level BLEU+1, which (i) cannot "see" the global length ratio, and (ii) uses a biased smoothing in BLEU+1, which boosts the precision part of the score, but leaves the brevity penalty intact, thus destroying the balance between the two. This is confirmed by an experiment where we plugged sentence-level BLEU+1 in MIRA. We have also found that part of the bias may be coming from the optimization mechanism of PRO.

We have proposed a number of ways to fix the length ratio of PRO by fixing BLEU+1, some of which have worked fairly well, e.g., smoothing the brevity penalty and scaling the effective reference length. Other fixes such as grounding the precision component and unclipping the brevity penalty were less helpful. Moreover, some combinations thereof have yielded too long length ratios, which had a negative impact on multi-bleu for IWSLT, but not for NIST.

Given our experimental results, we cannot make a universal recommendation about which fixes would work best for all datasets, but, in practical terms, we would recommend trying different fixes and choosing the one for which the length ratio is closest to 1 on the tuning dataset. Following this advice for Tables 2 and 3, we would select BLEU+1 with unclipped BP and scaled reference length for NIST (tuning length ratio of 0.993), and BLEU+1 with BP-smoothing and PC-grounding for IWSLT (tuning length ratio of 1.003), yielding +0.37 multi-bleu for NIST and +0.62 for IWSLT-reversed on the test dataset.

Coming back to our title: optimizing for sentence-level BLEU+1 yields short translations. This is true for the tuning dataset that the optimizer sees, but we can make no claims about the lengths of the test-time translations. This is because they can differ from the tuning set a lot in terms of verbosity, and the optimizer has no control over this.[11] However, if the tuning and the testing datasets have similar source/reference ratios (which is the best guess in the absence of other information), we expect that the claim would also hold for the test set.[12]

6 Conclusion and Future Work

We hope that the present study will be useful for those who want to use optimizers such as PRO and MIRA, which can handle many features, but feel frustrated that certain idiosyncrasies cause MERT to still yield the best test BLEU scores in certain cases. Here we have pointed out that one cause for this are poor length ratios in the resulting translations, which we have attributed to the use of sentence-level BLEU+1 as an objective function. We have thus suggested a number of simple modifications, which do improve the length ratio in practice, ultimately yielding better BLEU scores, while also preserving the sentence-level nature of BLEU+1, which makes optimizers simpler conceptually and implementation-wise.

In future work, we plan a more systematic study of the relationship between optimizers and objective functions with respect to the target/reference length ratio, which would be extended with other optimizers such as TER (Snover et al., 2006) and METEOR (Lavie and Denkowski, 2009). Overall, we see two promising general directions in which the present study can be extended. First, explore the relationship between sentence-level and corpus-level optimization and the possibility to combine them. Second, study the characteristics of translations generated using weights from different optimizers: while here we have only touched length, we believe there are many other important aspects that are worth exploring.

Acknowledgments

We thank the anonymous reviewers for their comments, which helped us improve the paper.

[11] For example, the average source/reference length ratio for our NIST tuning dataset MT06 is 1.248, which is very close to that for MT09, which is 1.252, and thus translation/reference length ratios are very close as well; however, this is not so for MT05, where the source/reference ratio is only 1.183; thus, tuning on MT06 and testing on MT05 yields translations that are too long even for standard PRO. There is also some imbalance in the source/reference length ratios of dev2010 vs. tst2010 for IWSLT, and thus we experimented with reversing them.

[12] The internal scoring tool segmentation and the recasing have an influence as well; though, we have seen in columns 6-7 of all tables that (1) the length ratios are quite close, and (2) the relative improvements in terms of BLEU are quite correlated for multi-bleu and for the NIST scoring tool v13a.

Grammarless Parsing for Joint Inference

Abstract

Many NLP tasks interact with syntax. The presence of a named entity span, for example, is often a clear indicator of a noun phrase in the parse tree, while a span in the syntax can help indicate the lack of a named entity in the spans that cross it. For these types of problems joint inference offers a better solution than a pipelined approach, and yet large joint models are rarely pursued. In this paper we argue this is due in part to the absence of a general framework for joint inference which can efficiently represent syntactic structure.

We propose an alternative and novel method in which constituency parse constraints are imposed on the model via combinatorial factors in a Markov random field, guaranteeing that a variable configuration forms a valid tree. We apply this approach to jointly predicting parse and named entity structure, for which we introduce a zero-order semi-CRF named entity recognizer which also relies on a combinatorial factor. At the junction between these two models, soft constraints coordinate between syntactic constituents and named entity spans, providing an additional layer of flexibility on how these models interact. With this architecture we achieve the best-reported results on both CRF-based parsing and named entity recognition on sections of the OntoNotes corpus, and outperform state-of-the-art parsers on an NP-identification task, while remaining asymptotically faster than traditional grammar-based parsers.

1 Introduction

Research in statistical parsing has made significant progress on recovering the kinds of annotations found in treebank-annotated corpora (Collins, 2003; Petrov et al., 2006), but in practice parsing is rarely an end in itself. Instead, parsing must be integrated with other forms of markup (part-of-speech tagging, named-entity recognition, coreference resolution) in order to perform complete end-to-end tasks like question answering. Historically, independent pursuit of these tasks has often been accompanied by the belief that improvements on a measure intrinsic to parsing (for our domain, often F1 on the test section of the Wall Street Journal) will accurately reflect improvements on an end task when incorporated into a complete system.

Nevertheless, errors propagate in NLP pipelines, and the need for a consistent analysis across several layers of linguistic structure has motivated the development of joint models in which uncertainty is shared between individual model components. Previous work has applied joint inference to parsing and named-entity recognition (NER), the task pursued in this paper, by augmenting the grammar with specialized non-terminals which couple syntactic and NER labels to represent an analysis over both domains (Finkel and Manning, 2009). This coupling proved to be beneficial to both tasks, increasing parsing performance by 0.47 F1 and NER performance by 3.27 F1 on average over the independently-trained models.

Proceedings of COLING 2012: Technical Papers, pages 1995–2010,
COLING 2012, Mumbai, December 2012.

Yet there are many reasons one might be concerned with this approach. First, it is a problem-specific formulation of a joint problem, and not necessarily extensible to problems that require a looser or more flexible coupling between the two problem domains. For instance, the presence of an NER span indicates the presence of a noun phrase in the corresponding syntax. NER spans are therefore a subset of syntactic constituent spans, and the two problems can be represented with a single tree-structured derivation. However, a joint model of prosody and parsing would be difficult to capture with this approach, as boundaries of prosodic and syntactic spans are not required to overlap (Selkirk, 1984; Jackendoff, 2002, Ch. 5, p. 118-123).

Second, formulating joint inference as context-free parsing also imposes a computational burden at a particularly susceptible point in the algorithm. Consider the CKY algorithm's complexity of $O(|G|n^3)$, where $|G|$ is the size of the grammar and n the length of the sentence. While algorithms are generally compared in terms of their asymptotic complexity (here the property of being a cubic-time algorithm), in many natural language problems the grammar constant is by far the most computationally expensive component. In the grammar augmentation approach to joint inference, the grammar constant increases as the product of the different domains' label sets.

Perhaps the most limiting aspect of this approach is that it makes assumptions over what types of structures are permissible, which may force the model structure of one problem into less intuitive designs based on the structure of another. For instance, named entity recognizers have traditionally been developed using sequence models, but some of the sequential model structure is lost when conforming to a grammar-based notion of joint inference.[1]

All of the aforementioned criticisms will only become more pertinent when joint inference in NLP begins to scale toward coupling the three or more problems in larger end-to-end systems. We therefore present in this paper a more generalized approach to joint inference via combinatorial factor constraints in factor graphs. In particular we describe a special-purpose combinatorial factor for constraining syntactic variables to a valid constituent bracketing, providing an efficient and flexible method for representing constituent syntax in graphical models. We first demonstrate that on its own this simple parser setup is competitive in accuracy with more complex models at the standard task of recovering treebank annotation. Then, we demonstrate the composability of the factor graph approach by coupling the syntactic representation to a semi-Markov NER model and performing inference jointly.

2 Parsing without a Grammar

While the dominant approaches to constituency parsing almost always depend on an explicit grammar, efficiently representing grammatical parsing in frameworks as general as factor graphs is very difficult. In this section we will discuss methods for representing constituency-style parsing constraints in a factor graph. This general-purpose syntactic representation can then be flexibly coupled to other tasks, and trained based upon common inference and learning methods.

A factor graph is a type of graphical model represented as a bipartite graph composed of variables, whose values represent the state of the world, and factors, which specify potentials over the belief of a particular state. For learning methods that require the marginal beliefs to compute a gradient, factor graphs provide an efficient way of computing such marginals via message passing inference algorithms.

[1] In this particular case, one could compose the context-free grammar with the finite-state model—causing the grammar to grow even more. Similar problems arise in combining syntactic machine translation models with n-gram language models (Vaswani et al., 2011).

The difficulty in representing grammars with factor graphs is that the complexity of inference in such a graph scales exponentially in the size of the largest clique. Naively representing a weighted grammar in Chomsky normal form requires variables to be densely connected with ternary factors [2] to represent the application of a weighted grammar rule. This is not only computationally problematic (on a per-iteration of inference basis), but could also further complicate convergence when performing belief propagation, an efficient message passing inference algorithm (Pearl, 1988), in the now exceedingly loopy graph.

If we were to back off from a desire to represent grammatical parsing in a factor graph, we could impose a constraint which prohibits crossing brackets by examining variables in a pairwise manner and assigning zero probability to configurations in which two conflicting variables were both on, and this would be possible with a quartic number of constraining factors. But while both approaches would capture the gist of a useful constraint, they are both computationally inefficient and will still fail to prohibit all structures that are not valid trees.

Instead we introduce a special-purpose combinatorial factor, CKYTree. It was observed previously (Smith and Eisner, 2008) that the outgoing messages from such combinatorial factors to a variable could be computed from the factor's posterior beliefs about that variable, thus defining an interface for inserting special purpose logic within the standard inference algorithm. Instead of representing a tree constraint externally in the structure of the model, we can encapsulate similar logic in this factor where the computation can be done more efficiently with variants of standard dynamic programming algorithms (Figure 1). Previous work has applied this technique to non-projective and projective dependency parsing (Smith and Eisner, 2008; Naradowsky et al., 2012), and a similar belief propagation approach has been used to enforce well-formed productions in CCG parsing (Auli and Lopez, 2011).

More specifically, inputs to this algorithm are the span weights $u(i,j)$. As in earlier dependency parsing work, these weights are derived from the ratio of messages coming in from the $Span$ variables:

$$u(i,j) = \frac{m_{Span(i,j)\rightarrow \text{CKYTree}}(\text{true})}{m_{Span(i,j)\rightarrow \text{CKYTree}}(\text{false})}$$

After running this inside-outside algorithm in $O(n^3)$ time, we calculate the $O(n^2)$ outgoing messages from CKYTree:

$$m_{\text{CKYTree}\rightarrow Span(i,j)}(\text{true}) = g(i,j)$$
$$m_{\text{CKYTree}\rightarrow Span(i,j)}(\text{false}) = 1 - u(i,j) \cdot g(i,j)$$

Here $g(i,j)$ is the gradient of the sum of the weights of all trees with respect to the input weight $u(i,j)$. Using the familiar inside β and outside α quantities, we can write this as:

$$g(i,j) \stackrel{\text{def}}{=} \frac{\partial \beta(0,n)}{\partial u(i,j)} = \frac{\alpha(i,j)}{\beta(0,n)}$$

[2] Ternary factors connect three variables, in this case a parent span variable and two contained and adjacent child span variables.

Algorithm 1 Bracket inside algorithm

function Inside(u, n)
  for $w \leftarrow 2..n$ **do**
    for $i \leftarrow 0..(n-w)$ **do**
      $k \leftarrow i + w$
      $s \leftarrow \mathbf{0}$
      for $j \leftarrow (i+1)..(k-1)$ **do**
        $s \overset{\oplus}{\leftarrow} \beta(i,j) \otimes \beta(j,k)$
      end for
      $\beta(i,k) \leftarrow s \oplus u(i,k)$
    end for
  end for
  return β
end function

Algorithm 2 Bracket outside algorithm

function Outside(u, β, n)
  for $w \leftarrow n..2$ **do**
    for $i \leftarrow 0..(n-w)$ **do**
      $k \leftarrow i + w$
      for $j \leftarrow (i+1)..(k-1)$ **do**
        $\alpha(i,j) \overset{\oplus}{\leftarrow} \alpha(i,k) \otimes \beta(j,k) \otimes u(i,k)$
        $\alpha(j,k) \overset{\oplus}{\leftarrow} \alpha(i,k) \otimes \beta(i,j) \otimes u(i,k)$
        $g(i,k) \overset{\oplus}{\leftarrow} \alpha(i,k) \otimes \beta(i,j) \otimes \beta(j,k)$
      end for
    end for
  end for
  return g
end function

Figure 1: Bracket inference algorithms are special cases of the familiar inside and outside algorithms for PCFGs (Baker, 1979) with a different "grammar-rule" weight $u(i,j)$ for each span.

2.1 Bracket Model

Having introduced the necessary computational framework, we can now present our most basic model of syntax: a factor graph for predicting unlabeled, projective binary constituency trees without any representation of a grammar. We model the possible parses of an n-word sentence with the following factor graph:[3]

- Let $\{Span(i,j) : 0 \leq i < j \leq n\}$ be $O(n^2)$ boolean variables such that $Span(i,j) = \textsf{true}$ iff there is a bracket spanning i to j.[4]
- Let $\{\text{Brack}(i,j) : 0 \leq i < j \leq n\}$ be $O(n^2)$ unary factors, each attached to the corresponding variable $Span(i,j)$. These factors score the independent suitability of each span to appear in an unlabeled constituency tree.
- Let CKYTree be a global combinatorial factor attached to all the $Span(i,j)$ variables. This factor contributes a factor of 1 to the model's score if the span variables collectively form a legal, binary bracketing and a factor of 0 otherwise. It enforces, therefore, a hard constraint on the variables. All outgoing messages from this factor are computed simultaneously by the outside algorithm described above in §2.

This comprises the core of our parsing model, which couples local span-oriented factors with rich features to a combinatorial factor that guarantees the global structure is a valid constituent tree. Though it is lightweight, with a complexity of $O(n^3 + n^2)$ in comparison to $O(|G|n^3)$ of a traditional CKY parser, it is not possible to identify which predicted spans are introduced through binarization (because constituents are not labeled), and thus limits the validity of parser comparison. Instead of evaluating this model in isolation, we immediately augment it with factors and variables to model *labeled* constituency trees.

[3] Variables are denoted by italicized names, factors by small capitals.

[4] In practice, we do not need to include variables for spans of width 1 or n, since they will always be true.

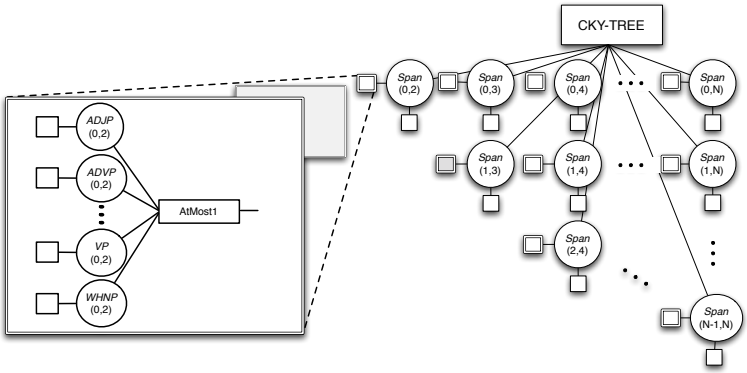

Figure 2: A graphical depiction of Bracket Model and Labeled Bracket Model. The components of the Bracket Model – *Span(i,j)* variables, corresponding Brack(i,j) factors (shown as single-bound rectangles), and the constraining tree factor – are represented on the right. The Labeled Bracket Model extensions include the AtMost1 factors on each span variable (shown as double-bound rectangles), which coordinate to select just one label from the set of nonterminals (illustrated left).

2.2 Labeled Bracket Model (LBM)

Extending the bracket model to incorporate a set of labels L is as simple as connecting each $Span(i, j)$ variable to a set of $Label$ variables via a factor that ensures at most one label is present:

- Let $\{Label(i, j, \lambda) : \lambda \in L$, and $0 \leq i < j \leq n\}$ be $O(|L|n^2)$ boolean variables such that $Label(i, j, \lambda) = \text{true}$ iff there is a bracket spanning i to j with constituent label λ.

- Let $\{\text{AtMost1}(i, j) : 0 \leq i < j \leq n\}$ be $O(n^2)$ factors, each coordinating the set L of possible nonterminal variables to the $Span$ variable at each i, j tuple, allowing a label variable to be true iff all other label variables are false and $Span(i, j) = \text{true}$.

One contribution of this paper is the exploitation of logical factors to proxy multinomial distributions. In this case the AtMost1 factors coordinate sets of label variables with a boolean indicator variable, capturing the same semantics as the multinomial while, most importantly, partitioning the values themselves into separate boolean variables. This is a necessary design choice for easily extending the model with grammatical rules as discussed in Section §6.

Asymptotically this is still an advantageous decomposition, yielding a complexity of $O(n^3 + |L|n^2)$, though the label set must also include a separate nonterminal for labels introduced through binarization of the original grammar, so predicted spans labeled with these binarized symbols can be removed when constructing the final parse tree. While there is some freedom in this choice and a traditional CNF transformation often introduces a binarized variant of each constituent, we find no appreciable benefit from having more than one binary symbol.

2.3 Inference

With the exception of combinatorial factors, which have their own specialized propagators as described above, inference is performed using the standard sum-product algorithm (Pearl, 1988), also known as *belief propagation* (BP). Each node in the graph sends and receives messages of two types:

A message from a variable node v to a factor node u is the product of all the messages from the factor nodes connected to v excluding u itself.

$$m_{v \to u}(x_v) = \prod_{u* \in N(v)/u} m_{u* \to v}(x_v)$$

Similarly, a message from a factor node u to a variable node v is the product of the factor and all of the messages from neighboring variables, marginalizing over all neighboring variables with the exception of x_v.

$$m_{u \to v}(x_v) = \sum_{x'_u : x'_v = x_v} f_u(X'_u) \prod_{v* \in N(u)/v} m_{v* \to u}(x'_{v*})$$

In cases where u is a combinatorial factor, its own combinatorial algorithm is executed instead of the standard update, but inference otherwise continues without change.

Both the bracket and label models form non-loopy graphs and, in a manner analogous to the forward-backward algorithm on chains, converge in two iterations of message passing. The robustness of this approach to joint inference with syntax is that regardless of the model structure that may be created for other tasks or couplings, the inference algorithm can remain the same. If loops arise in the graph then the convergence guarantee is lost, but in practice we find that loopy BP, which is fundamentally the same algorithm run on cyclic graphs, often converges within several iterations for joint parsing and NER tasks.

2.4 Unary Re-writes

While our motivation here is to present a syntactic representation which can be used to the benefit of a separate NLP end task, we also assess the performance of the parser independently, and must therefore address the rather tangential issue of unary rewrites. In a context-free grammar, internal unary productions—nonterminals with a single nonterminal child—fall out naturally from the recursive definition of the model, but in our span-factored formulation they must be handled separately. Similar work in conditional random field parsing (Finkel et al., 2008) collapses unary rewrite chains to single augmented rules while prohibiting multiple rewrites from occupying the same span, but this comes at the cost of additional complexity during decoding. Other work has attempted to separately predict leaf-level unary rewrites, albeit for the purpose of improving decoding speed (Bodenstab et al., 2011).

We follow the latter approach, pruning unary rewrites from the data entirely (replacing them with their parent constituent) and training a separate log-linear classifier for reinserting unary rewrites into the trees produced by the parser. Because the distribution of unary rewrites is so overwhelmingly concentrated in the nodes immediately governing the leaves of the tree, we focus our efforts solely on predicting these unary rewrites, accepting the performance hit of not predicting any which may appear in the body of the tree (comprising between 11% and 15% of all unary spans newswire sections of OntoNotes).

3 Named Entity Model

To demonstrate the usefulness of this syntactic representation in joint inference tasks, we choose to evaluate primarily on the end task of named entity extraction. In contrast to previous work, we avoid augmenting the grammar with special non-terminals and construct the model once again within the context of a factor graph. This choice allows us to emphasize the sequential information that historically has produced state-of-the-art performance.

As with parsing, however, incorporating some state-of-the-art models is not a trivial task. Consider for instance a semi-Markov conditional random field (semi-CRF) model (Sarawagi and Cohen, 2004). The context-rich nature of these models is very difficult to capture within the top-down derivations of a tree-based decoder for joint inference. Even in the general framework of a factor graph, representing these structures efficiently in a manner compatible with the rest of the joint architecture presents a challenge. However, we can once again encapsulate this logic within one combinatorial factor and connect it in a global fashion to all variables corresponding to NER spans. First, we assume a named entity variable set analogous to the LBM (denoted $NER\text{-}Span$ and $NER\text{-}Label$ and behaving similarly).

- Let Semi-CRF be a combinatorial constraint connected to all $NER\text{-}Span(i, j)$ variables. The factor implements a weighted Semi-CRF with a maximum span width μ, as described in (Sarawagi and Cohen, 2004), over the log-odds of each span variable's boolean values. Unlike the valid-bracketing constraint imposed by the CKYTree factor, this effect can be achieved with a polynomial number of binary factors. The $O(\mu^2 n^2)$ such factors would lead to inefficient inference in a very loopy factor graph. In all experiments $\mu = 10$.

4 Joint NER and Parsing

Perhaps the main advantage of casting constituency parsing in terms of a factor graph is the ease with which the model can be extended to improve separate but related task. To illustrate this, we couple our LBM constituency parser to the span-based model of named-entity recognition with an additional type of specialized factor:

- Let $\{\text{NER-Nand}(i, j) : 0 \leq i < j \leq n; 1 < j - i \leq \mu\}$ be a set of at most $O(n^2)$ factors coordinating syntactic $Span(i, j)$ and named entity span variable $NER\text{-}Span(i, j)$, multiplying in 1 unless both variables are on, in which case it multiplies a connective potential $\phi(i, j)$ derived from its features. Intuitively the joint model might learn features weights such that $\phi(i, j) > 1$, i.e., constituents and NER spans are more likely to be coterminous. The number of these coordinating factors is constrained to the number of NER span variables, subject to the maximum span-width $\mu = 10$.

These special purpose factors allow the model to learn how to best coordinate the sub-problems, adding an additional layer of flexibility to the joint architecture. For this particular domain, features that are useful for distinguishing noun phrase spans from other spans are good candidates, as essentially all named entities correspond to noun phrases in the syntax.

5 Experiments

We have presented an argument for why the combinatorial factor graph approach to joint inference can be considered a very general and principled framework for representing and reasoning over

joint models. In this section we aim to demonstrate that these benefits are not merely conceptual or aesthetic in nature, but translate to practical performance improvements in the model. In the following sections we first demonstrate that parsers based on this architecture outperform previous CRF parsers, and that they provide both an asymptotic advantage over state-of-the-art parsers in decoding speed and an attractive compromise between speed and performance. We then show that the semi-CRF NER model is a comparable baseline to previous standalone models, and that it improves upon previous results when trained jointly.

5.1 Data

We primarily evaluate all of our model configurations on the same data set: a selection of six corpora drawn from the English broadcast news section of the OntoNotes 2.0 dataset (Hovy et al., 2006). The data are partitioned to achieve an approximately 3:1 ratio between training and test sets. This is an exact reproduction of the partitioning found in (Finkel and Manning, 2009), where detailed corpus statistics may be found. As in that work, we remove empty leaf nodes, coarsen nonterminal labels (NP, not NP-PRD), and filter out sentences longer than 40 words. In supplementary parsing experiments we make us of the OntoNotes Wall Street Journal Corpus distribution, using the standard train/test split and sentences with between 3 and 40 words.

5.2 Features

For each of the models presented here, every boolean variable mentioned has a corresponding unary factor representing its likelihood of being true. This leads to a wide-variety of features, depending on the variable's semantics.

For parsing we rely on features comparable to those used in edge-factored dependency parsing (McDonald et al., 2005), consisting of combinations of unigram features (word, part-of-speech, capitalization, and presence of punctuation) between the tokens at or near the span boundaries, including tokens immediately outside and inside of the span. This allows us to capture very strong lexical indications of a span, such as the presence of a comma immediately outside the start and end of the indices. We also look for the occurrence of particular tags anywhere within the span, which might signify that a constituent should not span those indices unless it is sufficiently large. A previous generative model of span-based grammar induction (Klein and Manning, 2002) considered the probability of a span to depend on the part-of-speech tags of the two words immediately outside of it, and on the conjunction of the tags within it. For spans that are sufficiently small (here $w < 10$),

the part-of-speech tags of all words inside of the span are concatenated. Examples of these feature sets are provided in Table 1. The reliance on part-of-speech tags as features is afforded through the use of an existing maxent part-of-speech tagger (Toutanvoa and Manning, 2000) which allows us to treat part-of-speech tags as observed while maintaining a fair comparison to other systems which also do not utilize gold part-of-speech tags.

Features for the unary classifier portion of the model also consist of the same unigram features (word, tag, capitalization, etc.), but are taken over 5-word windows from the tokens of the sentence.[5]

Features for NER spans are generally identical to those used for syntactic spans, while the feature sets specifying span labels are much more lexically-oriented. In addition to a small set of contextually-directed information we look primarily at word shape; character n-grams (windows of 2 to 5); capitalization; normalization; regular expressions for initials, numerics, times, and Roman numerals; and membership in a set of lexicons for ordinals, days of the week, months, scientific units, common names, honorifics, and stop words.

5.3 Parsing Results

We present the results of the LBM on labeled parsing, largely in comparison to similar work using CRF parsing with chart decoding (F&M'09). The LBM significantly outperforms the previous standalone approach in all data sets, yielding improvements of up to over nine points in F1 over this model (Table 2). Though the models are generally quite similar, the large performance discrepancy does raise the question of whether or not this could be due solely due to the unique hybrid approach to parsing represented by the LBM over traditional methods, where local factors observe much more information than can be traditionally utilized while still having strong top-down structural constraints at play. It is possible that some of this gap is merely due to different feature sets, but the feature set used here is by no means an exhaustive or fine-tuned set, comparable in size to the features often used by graph-based dependency parsers.

In comparison to other widely available parsers, which are constructed using a vertical and horizontal Markov window of 1 where applicable, the LBM does not achieve absolute state-of-the-art, but still compares favorably to these established models on this data set, outperforming both configurations of the Stanford Parser. It is important to note that these factor graph representations of syntax are still extensible enough to incorporate non-terminal or grammar refinement, or reranking, to further improve their performance. Our purpose in this section is simply to present them as a suitable alternative to existing parsers and prove that the syntactic predictions upon which other tasks can be jointly modeled are themselves quite accurate.

5.4 Decoding Efficiency

We compare against reference implementations of the PCFG parser (Klein and Manning, 2003) and lexicalized parser included in the Stanford Parser distribution[6], and train up comparable grammars for all models from sections 2–21 of the Wall Street Journal Treebank corpus (Marcus et al., 1993).

Efficiency of the LBM is quite competitive with these models (Figure 3). When evaluated in its standard configuration, with a full nonterminal set for each span, the LBM edges out the PCFG

[5] It is also possible to derive features from the parse tree, using the constituent labels collected by traversing the tree along the root-to-leaf path. This results in an average of 4.63% F1 improvement on the unary prediction task over linear features, but requires that the tree be decoded prior to generating unary productions. For convenience we predict the tree and its unary productions simultaneously.

Table 2: Labeled model performance. The feature-rich Labeled Bracket Model (LBM) provides significant gains over previously published CRF parsing scores. Unlabeled parsing was evaluated against the true, non-binarized bracketings. The +Rules model refers to the grammar-enhanced version of the model described in Section §6. As in previous work, we find that in the joint setting we find only marginal improvements in parsing F1, and abstain from providing them for the sake of clarity.

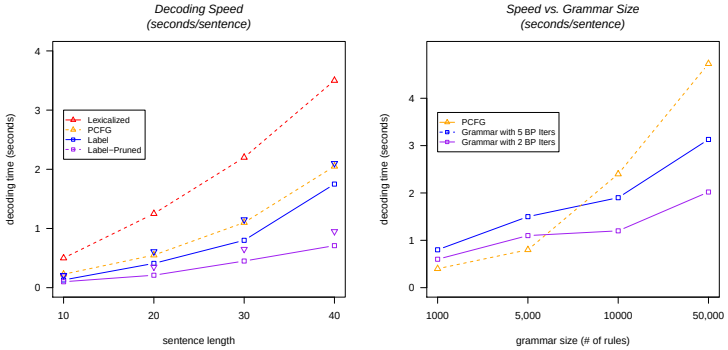

Figure 3: Decoding speeds. Comparing the performance of the labeled model, in both its standard and pruned configuration, with standard PCFG and lexicalized parsing baselines (left), the factor graph models generally decode faster than their counterparts. While featurization cost (inverted triangle annotation) hinder the standard configuration, the pruned model is quite fast. When comparing the grammar model to the PCFG model, and increasing the size of the grammar (right), the additive grammar term provides a clear and substantial benefit as the grammar size increases.

model, the faster of the two baseline systems, but only marginally so. Additionally we indicate the contribution that feature extraction time makes to overall decoding time by the carets above the factor graph parser points. In the case of the standard LBM this removes any performance benefit provided by the factor graph implementation over the PCFG. However, when combined with pruning and reducing the binarized nonterminal set to use one, the LBM becomes a very attractive choice, decoding almost twice as fast on 40-word sentences as the PCFG, and three times faster than the lexicalized model.

The bracket model cannot offer competitive accuracy when compared to the other models and has limited application given its output is only a set of projective spans. However, coupled with an appropriate task it does offer exceptional parsing speed, decoding length 40 sentences at more than 10 per second on our test system, and may be useful as a component in select joint modeling tasks.

5.5 NER Results

We again evaluate on the OntoNotes corpus, which contains both syntactic and named entity annotation, training our model with 10 iterations of stochastic gradient descent (SGD), each with 5 iterations of BP, evaluating on the more difficult full 16-entity label set. Results are presented in Table 3.

Both baseline systems, trained without any syntactic information, perform comparably on average. This is somewhat surprising given the sequential constraints of our NER model, but likely also due in part to the less difficult 4-label NER task reported in previous results. However, we see stronger than average gains by coupling the models and using joint inference. For instance, the factor graph model outperforms the previous best results on four of the six data sets, but improves over it by a much larger margin than the F&M system does on the two data sets it performs best in.

		Prec	Recall	F1	F&M '09
ABC	NER Only	76.4	67.8	72.13	74.51
	NER Joint	76.5	71.3	73.93	**74.91**
CNN	NER Only	75.2	75.0	75.07	75.78
	NER Joint	79.2	79.9	**79.56**	78.70
MNB	NER Only	68.9	70.1	69.50	62.21
	NER Joint	72.7	71.3	**72.02**	66.49

	NER Joint	86.4	88.1	87.23	**88.18**

Table 3: NER baseline and joint model performance. Decoding jointly consistently improves the NER results across all corpora, providing the largest gains on corpora with the most data and best parser performance. In comparison to F&M '09, our joint model outperforms in all but two of the corpora.

6 Grammar Rules as Factors

Our final extension, the incorporation of grammar rules into the model, requires only the addition of rule factors that connect triples of labeled span variables:

- Let $\{\text{Rule}(i,j,k,X,Y,Z) : 0 \leq i < j < k \leq n; X,Y,Z \in L\}$, be a sparsely-applied set of ternary factors which coordinate across the $Label$ variables at spans (i,j), (j,k), and (i,k).

The difficulty in constructing a rule-based augmentation is not as much structural as it is about finding an efficient way to add rules to the model. It is easy to enumerate the $O(|L|n^2)$ potentials necessary for the LBM, but it becomes prohibitive to work with the $O(|L|^3 n^3)$ potentials that represent a complete grammar.

Figure 4 illustrates a rule factor constraining three $Label$ variables. Grammar rules don't function in the traditional way, where rules guide a set of allowable derivations. Instead, a Rule factor may be instantiated across any triplet of nonterminals to alter the local $Span$ and $Label$ beliefs. Each rule has a single primary feature: its string representation ($\mathsf{NP} \rightarrow \mathsf{NP\ VP}$), though we do also incorporate back-off features for smoother statistics ($\mathsf{X} \rightarrow \mathsf{NP\ VP}$, $\mathsf{NP} \rightarrow \mathsf{X\ VP}$). The ease with which the LBM can be augmented with rules is due to the factorization of the $Label$ variables into large sets of binary variables, instead of one high-dimensional multinomial, for each span.

To learn a sparse set of grammar rules, we used perceptron updates. After decoding a set of training sentences, we computed the difference between the rule applications in the hypothesized and true trees, and updated the weights of those productions accordingly. This creates grammars of roughly 1200 productions on both OntoNotes and WSJ and significantly outperforms the LBM results (Table 2).

Figure 3 illustrates the performance of the grammar model in comparison to a PCFG as we artificially increase the size of the grammar (sentences were fixed at length 40). Our model is unlexicalized and coarse-grained, so simply constructing a grammar by reading off the productions found in the WSJ treebank yields only 2751 rules. While the intent of developing this model is specifically for fast joint inference, lexicalizing the grammar or refining it via a split-merge procedure to bring

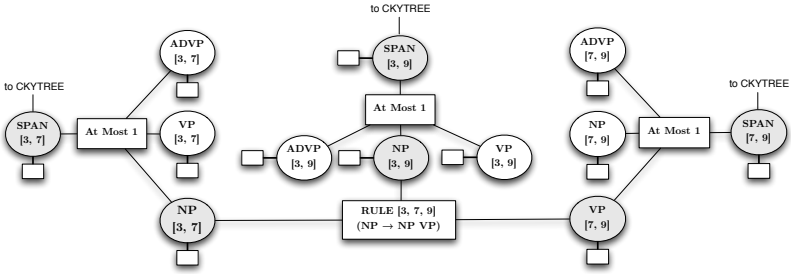

Figure 4: A Rule factor constraining three $Label$ variables. Not every span or constituent label must participate in a rule; the number of rules added on top of the labeled bracket model may be quite small. Rules act only to fix up small ungrammatical or dispreferred configurations that are more probable when looking solely at local span information.

performance to state-of-the-art levels solely on parsing increases the grammar size, often producing grammars comprising millions of rules in the latter case. In these cases our model provides clear asymptotic benefits. As depicted in Figure 3 (right), even by 50,000 rules the grammar model has begun to decode significantly faster than the PCFG, with a strong asymptotic advantage with grammars in excess of 10k rules.

All our grammar model performance experiments use five iterations of BP (less if the model converges faster), but for comparison we also present decoding times if we ran the parser as if it were exact inference, and required only two.

6.1 Comparisons to Established Parsers

How do these models handle parsing on larger, more traditionally-sized corpora? On our modified WSJ data set (Table 2, bottom) the LBM performs surprisingly well in comparison to the widely used Stanford and Berkeley parsers (Finkel et al., 2008; Petrov and Klein, 2007), achieving an F1 of 82.54% despite having no representation of a grammar. Augmenting this model with 15 iterations of rule induction yields our largest improvement over the label model, increasing F1 by 1.78% to 84.32% and brings performance in line with state-of-the-art parsers.

Another consideration is our reliance on local potentials, and predictions made primarily based on the rich sources of information at, around, and within span boundaries. While joint tasks may at some point leverage more sophisticated tree annotations, many systems, such as named-entity recognizers, rely primarily on accurately identifying NP spans. Despite having lower labeled F1 than one of the three widely-used constituency parsers we evaluated, the LBM outperforms them all on NP detection (Table 4), making it unlikely that further NER improvements will be had by leveraging these much more sophisticated, but slower, models.

7 Conclusions and Future Work

We have shown how to decompose and represent constituency parsing in terms of variables in a dynamic Markov random field, decoding with general inference algorithms: belief propagation in the exact case for both labeled and unlabeled parsing without a grammar, and loopy BP when augmented with rules or coupled with an NER model. We have demonstrated the convenience

Model	NP-P	NP-R	NP-F1
LBM	90.07	90.02	90.42
+Rules	90.15	91.07	**90.60**
Stanford-PCFG	83.88	85.74	84.80
Stanford-Factored	85.07	87.83	86.43
Berkeley	89.17	90.96	90.06

Table 4: NP prediction results. While some established parsers outperform LBM in general parsing F1 (82.54 LBM vs. 86.21 Berkeley), LBM outperforms all evaluated parsers on a measure more reflective of its potential to many joint modeling scenarios, while remaining asymptotically faster.

and effectiveness of using these combinatorial syntactic representations in joint inference tasks, generally improving performance on named entity recognition over the previous state-of-the-art.

As a standalone parser, both the LBM and rule model provide some decoding efficiency benefit over PCFG and lexicalized baselines, while providing parsing results comparable with the best coarse-grammar, unlexicalized parsers. We also showed how labeling spans via a set of boolean label variables allows ternary factors to function as grammatical rules, not specifying an entire derivation but instead fixing up trees in situations where the LBM would otherwise err.

One natural extension to the parser portion of this work is to port over useful advances from the parsing literature, lexicalizing the grammar or refining the nonterminal set. However, it is also possible to exploit other aspects of the factor graph representation. Most pertinent to parsing performance, a factor graph allows for arbitrary constraints between variables—a potentially promising avenue for incorporating additional linguistic information (headedness, lexicalization, agreement) in unique and powerful ways. This approach would be particularly interesting for languages whose dependencies are hard to capture with the traditional independence assumptions made by PCFGs. The more inherently distributed structure of this model would also make it a good choice for parallelization.

Error Mining with Suspicion Trees: Seeing the Forest for the Trees

Shashi Narayan[1] Claire Gardent[2]
(1) Université de Lorraine/LORIA, Nancy, France

shashi.narayan@loria.fr, claire.gardent@loria.fr

Abstract

In recent years, error mining approaches have been proposed to identify the most likely sources of errors in symbolic parsers and generators. However the techniques used generate a flat list of suspicious forms ranked by decreasing order of suspicion. We introduce a novel algorithm that structures the output of error mining into a tree (called, suspicion tree) highlighting the relationships between suspicious forms. We illustrate the impact of our approach by applying it to detect and analyse the most likely sources of failure in surface realisation; and we show how the suspicion tree built by our algorithm helps presenting the errors identified by error mining in a linguistically meaningful way thus providing better support for error analysis. The right frontier of the tree highlights the relative importance of the main error cases while the subtrees of a node indicate how a given error case divides into smaller more specific cases.

COLING 2012, Mumbai, December 2012.

1 Introduction

In recent years, error mining approaches have been proposed to identify the most likely sources of errors (called, *Suspicious Forms*) in symbolic parsers and generators. (van Noord, 2004) initiated error mining on parsing results with a very simple approach computing the parsability rate of each n-grams in a very large corpus. The parsability rate of an n-gram $w_i \dots w_n$ is the ratio $P(w_i \dots w_n) = \frac{C(w_i \dots w_n | OK)}{C(w_i \dots w_n)}$ where $C(w_i \dots w_n)$ is the number of sentences in which the n-gram $w_i \dots w_n$ occurs and $C(w_i \dots w_n \mid OK)$, the number of sentences containing $w_i \dots w_n$ which could be parsed. In other words, the parsability rate of an n-gram is the proportion of sentences in which this n-gram occurs and for which parsing succeeds. An n-gram then, is a suspicious form if it has a low parsability rate.

(van Noord, 2004)'s approach was extended and refined in (Sagot and de la Clergerie, 2006), (de Kok et al., 2009) and (Gardent and Narayan, 2012) as follows. (Sagot and de la Clergerie, 2006) defines a suspicion rate for n-grams which takes into account the number of occurrences of a given word form and iteratively defines the suspicion rate of each word form in a sentence based on the suspicion rate of this word form in the corpus. Further, (de Kok et al., 2009) extends this iterative error mining to n-grams of words and POS tags of arbitrary length. And (Gardent and Narayan, 2012) extends (van Noord, 2004)'s approach to mine for suspicious subtrees rather than n-grams.

An important limitation shared by all these error mining approaches is that their output is a flat list of suspicious forms ranked by decreasing order of suspicion. There is no clear overview of how the various suspicious forms interact and as a result, the linguist must "hop" from one error case to another instead of focusing on improving sets of related error cases. In short, the output of these error mining approaches lacks structure thereby making it difficult to handle errors in a linguistically meaningful way.

To overcome this shortcoming, we propose an algorithm which structures the output of error mining into a *suspicion tree* making explicit both the ranking of the main distinct error cases and their subcases. The suspicion tree is a binary tree structure whose internal nodes are labelled with suspicious forms and whose leaf nodes represent the clusters of error mined data grouped according to the suspicious forms characterizing their elements. Like in a decision tree, each cluster in the suspicion tree is characterized by the set of attributes (suspicious forms) labelling its ancestors; and the tree itself represents a disjunction of mutually exclusive error cases.

We illustrate the impact of our error mining algorithm on error analysis by applying it to detect and analyse the most likely sources of failure in a surface realiser developed to participate in the Surface Realisation Shared Task (Belz et al., 2011); and we show how this error mining algorithm permits improving the surface realiser.

The paper is structured as follows. We start (Section 2) by introducing our error mining algorithm. In essence, this algorithm adapts (Quinlan, 1986)'s ID3 algorithm to build a suspicion tree such that the clusters obtained group together sets of input data that share similar sources of failure (called *suspicious forms*); and the attributes labelling these clusters are the suspicious forms indicating which are these most likely causes of failure. In Section 3, we show how this error mining algorithm helps improving a surface realiser executed on the input dependency trees provided by the Surface Realisation (SR) Task challenge. Section 4 concludes with pointers for further research.

2 Building Suspicion Trees

In this section, we introduce the *suspicion tree algorithm* and discuss its complexity.

2.1 The Suspicion Tree Algorithm

As mentioned above, our error mining algorithm resembles (Quinlan, 1986)'s ID3 decision tree learning algorithm, in that it recursively partitions the data by first, selecting the attribute (here, a suspicious form) that best divides the data into more homogeneous subsets (*attribute selection*) and second, using this attribute to split the data into two subsets, a subset containing that attribute and a subset excluding that attribute (*dataset division*).

In what follows, we define the metric used to recursively select a suspicious form and partition the data, namely the *Suspicion Score* metric. We specify the termination conditions. We illustrate by means of examples how suspicion trees help structure the output of error mining. And we contrast the suspicion tree algorithm with (Quinlan, 1986)'s ID3 decision tree learning algorithm.

The Suspicion Score Metrics. Let $\mathbb{D}$ be the dataset to be error mined and $\mathbb{F}$ be the set of attributes used to partition the data. Here, $\mathbb{D}$ is a set of dependency trees provided for the Surface Realisation Task by the Generation Challenge; and $\mathbb{F}$ is the set of subtrees of $\mathbb{D}$ whose frequency is above a given threshold. Following (Gardent and Narayan, 2012), we use a complete and efficient Hybrid Tree Miner algorithm (Chi et al., 2004), to compute the set of subtrees that are present in $\mathbb{D}$.

Let $\mathbb{D}$ be divided into two disjoint sets: PASS (*P*) is the set of instances $t^P \in \mathbb{D}$ for which the processing system (e.g., a parser or a generator) succeeds; and FAIL (*F*) is the set of instances $t^F \in \mathbb{D}$ for which the system fails. Given these two sets, the **suspicion score** $S_{score}(f)$ of a form $f \in \mathbb{F}$ is then defined as follows:

$$S_{score}(f) = \frac{1}{2}(\text{Fail}(f) * \ln count(f) + \text{Pass}(\neg f) * \ln count(\neg f))$$

Intuitively, this metric captures the degree to which a form is associated with failure: it is high whenever a form f is often present in data associated with failure (high *F(ail)-Suspicion*, Fail(f)) and/or when it is often absent in data associated with success (high *P(ass)-Suspicion*, Pass($\neg f$)).

The **F-Suspicion rate of** f is defined as the proportion of cases where f occurs in an instance t for which the processing system fails:

$$\text{Fail}(f) = \frac{count(f|\text{FAIL})}{count(f)}$$

$count(f)$ is the number of instances containing f and $count(f|\text{FAIL})$ is the number of instances containing f for which processing failed.

Conversely, the **P-Suspicion rate of a form** f is defined as the proportion of cases not containing f and for which processing succeeds ($count(\neg f)$ is the number of instances where f is absent and $count(\neg f|\text{PASS})$ is the number of instances not containing f for which processing succeeds):

$$\text{Pass}(\neg f) = \frac{count(\neg f|\text{PASS})}{count(\neg f)}$$

Attribute Selection, Dataset Division and Termination. The suspicion tree algorithm selects at each step of the tree building process, the form f with highest suspicion score i.e. the form such that, in the current dataset, most instances that contain f fail to be processed; and most instances that excludes f lead to successful processing.

Based on this selected f, the current dataset is divided into two subsets: the set of instances which contain f and the set of instances which exclude f.

The form selection and dataset division process are called recursively on the new subsets until (i) the obtained set of instances is fully homogeneous (all instances in that set lead to either successful or unsuccessful processing); (ii) all forms have been processed; or (iii) the depth upper bound is reached (see below).

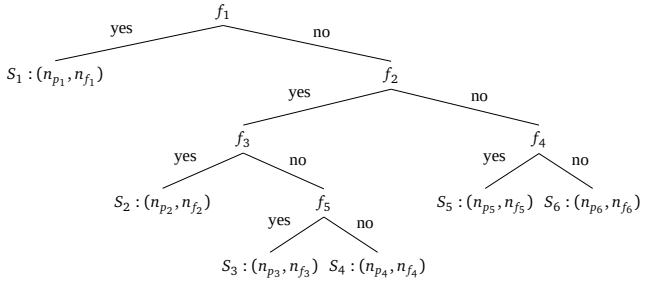

Figure 1: An example *Suspicion Tree*. Internal nodes are labeled with suspicious forms and leaves indicate the number of instances in the current data set S_i for which processing succeeds (n_{p_i}); and for which processing fails (n_{f_i}). When the sources of errors are clearly identifiable, n_{p_i} will be low, n_{f_i} will be high and the rightmost leaf (f_4) will have a low n_{f_i}.

Example. Figure 1 shows an abstract suspicion tree which illustrates how suspicion trees help structuring the output of error mining. The right frontier highlights the relative importance of the main distinct error cases while subtrees indicate how a given error case divides into smaller more specific cases. The branches of the tree also indicate the combinations of forms that frequently cooccur in failure cases.

More specifically, the root f_1 of this *suspicion tree* is the most suspicious form present in the corpus $\mathbb{D}$. Starting from the root, following the edges with label "no" (the *right-frontier* of the tree i.e., f_1, f_2 and f_4) yields the ranked list of suspicious forms present in $\mathbb{D}$ by decreasing order of suspicion. Following branches yields datasets labeled with sets (conjunctions) of suspicious forms. For example, the set S_2 with n_{p_2} of pass instances and n_{f_2} of failed instances has f_2 and f_3 as their top ranked suspicious forms. The *suspicion tree* also displays the relative ranking of the suspicious forms. For example, the set $(S_2 \cup S_3 \cup S_4)$ has f_2 as its most suspicious form, and f_3, f_5 as its next two most suspicious forms. Moreover, most of the instances in S_1, S_4 and S_5 fail because of a single form namely, f_1, f_2 and f_4 respectively.

Suspicion tree algorithm vs. ID3 algorithm. There are two main differences between (Quinlan, 1986)'s ID3 decision tree learning algorithm and the suspicion tree construction algorithm.

First, the suspicion tree construction algorithm allows for stronger pruning and termination conditions – in this way, only the most relevant suspicious forms are displayed thereby facilitating error analysis.

Second, attribute selection is determined not by the information gain (IG) but by the suspicion score

(SS) metrics. Recall that the information gain[1] metrics aims to identify the attributes which lead to more homogeneous classes. In the present case, the classes are either PASS (the inputs for which generation succeeds) or FAIL (the inputs for which generation fails). Thus the IG metrics will indifferently seek to identify attributes which predominantly associate either with a FAIL or with a PASS. There is no preference for either the FAIL or the PASS class. For error mining however, what is needed is to identify attributes which predominantly associate with the FAIL class. That is, we need a metric which permits identifying attributes which leads to classes that are homogeneous in terms of FAIL instances rather than homogeneous in terms of either FAIL or PASS instances. The example shown in Figure 2 illustrates the difference.

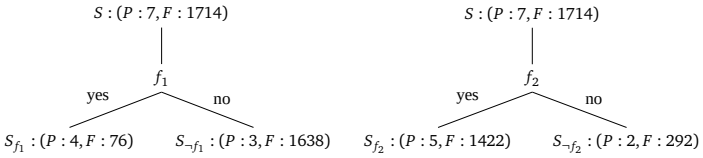

Figure 2: Attribute Selection using Information Gain (Left) and Suspicion Score (Right). While IG selects f_1, an attribute which associate 76 times with generation failure, SS selects f_2, an attribute which associates 1422 times with generation failure.

In this example, we apply the IG and the SS metrics to the same input data, a set containing 7 inputs associated with generation success and 1714 inputs associated with generation failure. While SS selects f_2, an attribute which associates 1422 times with generation failure, IG selects f_1, an attribute which associate only 76 times with generation failure. In this case, the information gain metrics incorrectly select f_1 because its absence from the input, yields a numerically very homogeneous class in terms of generation failure. Indeed, the information gain of f_1 is close to but higher than the information gain of f_2 because the resultant subsets S_{f_i} and $S_{\neg f_i}$ are treated equally while computing the information gain.

2.2 Complexity Analysis and Extensions

Let n and m be the size of the dataset $\mathbb{D}$ and of the form set $\mathbb{F}$ respectively. Then, in the worst case, the suspicion tree will be of depth $O(log\ n)$ with $O(n)$ nodes. Each node chooses a suspicious form out of $O(m)$ forms. Thus the worst computational complexity for building the suspicion tree is $O(m\ n\ log\ n)$. But on average, the algorithm described in Section 2.1 performs much faster than this. The worst case happens when the forms used to classify the corpus into PASS and FAIL are not very discriminant i.e., when all suspicious forms are equally probable.

The algorithm for building the suspicion tree is directly proportional to the size of the set $\mathbb{F}$. Since $|\mathbb{F}|$ can be very large, this can be problematic. Indeed, in the error mining on sentences for parsing systems proposed in (Sagot and de la Clergerie, 2006), the authors indicate that, in order to remain computationally tractable, the approach must be restricted to n-grams of smaller size (unigrams and bigrams). The problem is accrued of course when considering tree shaped suspicious forms (Gardent and Narayan, 2012). To abate this issue we propose two extensions to prune the suspicion tree.

[1]Information gain (IG) is defined as $IG = H(S) - ((|S_{f_i}|/|S|) * H(S_{f_i}) + (|S_{\neg f_i}|/|S|) * H(S_{\neg f_i}))$ where $H(X)$ is the entropy of set X. (Quinlan, 1986)

First, we reduce the form space $\mathbb{F}$. Following a suggestion from (de Kok et al., 2009), instead of considering all possible forms, we only consider those forms whose frequency is above a given threshold. We also account for *suspicion sharing* (i.e., the sharing of suspicion by several overlapping forms) by only considering a larger suspicious form if its suspicion rate is larger than the suspicion rate of all smaller forms it contains. These two extensions reduce the form space significantly and allow for an efficient building of the suspicion tree. To enumerate with these extensions, we use a complete and efficient algorithm described in (Gardent and Narayan, 2012).

Second, we constrain the depth of the suspicion tree. Because error mining is a cyclic process, building the complete suspicion tree is usually unnecessary. The quantity of information processed in each cycle depends on the user but in general, the linguist will focus on the top suspicious forms, use these to improve the generator and rerun error mining on the improved results. The faster the error mining step is, the better this is for this development cycle. Considering this, we added an extra constraint over the depth of the suspicion tree. This depth limit permits pruning the suspicion tree and a faster improvement cycle. In our experiments, we used a depth limit of 10.

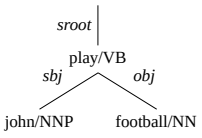
With these extensions, the enumeration process of suspicious forms takes 10-15 minutes for a dataset consisting of 123,523 trees. Building a suspicion tree for the same dataset takes about one minute.

3 Applying the Suspicion Tree Algorithm to Generation Data

We now report on an experiment we did using the suspicion tree algorithm described in the preceding section to detect and classify the most likely causes of failure when running a surface realiser on the Surface Realisation (SR) Task data. We first describe the experimental setup (Section 3.1). We then illustrate by means of examples, how suspicion trees better support error analysis than ranked lists proposed by previous error mining approaches (Section 3.2). Finally (Section 3.3), we discuss the improvements in surface realisation obtained by fixing the errors identified using error mining.

3.1 Experimental Setup

Dataset The dataset to be error mined is the set of shallow dependency trees (Figure 3) provided by the SR Task organisers and used as input for surface realisation. These trees are unordered syntactic dependency trees whose edges are labelled with dependency relations and whose nodes are labelled with lemmas and part of speech (POS) categories. In this paper, we represent these trees by an n-tuple with the root node of the tree as its first element followed by $(n-1)$ elements representing its dependent subtrees. Dependency relations are lowered to the corresponding daughter node.



word (play, (john), (football))
POS (VB, (NNP), (NN))
dep (*sroot*, (*sbj*), (*obj*))
word/**POS** (play/VB, (john/NNP), (football/NN))
***dep*-POS** (*sroot*-VB, (*sbj*-NNP), (*obj*-NN))

Figure 3: An example shallow dependency tree from the SR Task and the corresponding representations used in this paper. Our error mining algorithm considers as suspicious forms, subtrees labelled with arbitrary conjunctions of lemmas (word), part-of-speech tags (POS), dependency relations (*dep*).

To facilitate error mining, we proceed in an incremental way and examine dependency trees in the SR data that correspond to NP and Sentences of increasing size. Here we report on error mining performed on NP-type dependency trees of sizes 4 (NP-4), 6 (NP-6) and all (NP-ALL), and S-type dependency trees of sizes 6 (S-6), 8 (S-8) and all (S-ALL) (where the size refer to the number of nodes/lemmas in the tree). The data used for generation is preprocessed whereby named entities and hyphenated words are grouped into a single word and punctuation is removed so as to first focus on lexical and grammatical issues.

Attributes The attributes used to partition the SR data are suspicious trees i.e., subtrees of the SR dependency trees whose frequency is above a given threshold. Following (Gardent and Narayan, 2012), we allow for various views on errors by mining for forms labelled with lemmas only (word); with parts of speech (POS); with dependency relations (*dep*); with lemmas and parts of speech (word/POS); and with dependency relations and parts of speech (*dep*-POS) (cf. Figure 3).

Generation System The system to be tested is the symbolic Surface Realiser described in (Narayan and Gardent, 2012). We ran this surface realiser on the SR input data and separately stored the input dependency trees for which generation succeeded (PASS) and the input dependency trees for which generation failed (FAIL). We then removed from the failed data, those cases where generation failed either because a word was missing in the lexicon or because a grammar rule was missing but required by the lexicon and the input data. These cases can easily be detected using the generation system and thus do not need to be handled by error mining.

Error Mining We iterate several times between error mining and performance improvement and applied the suspicion tree algorithm to both the NP and the S data[2].

3.2 Error Analysis using Suspicion Trees

We now show by means of examples how the suspicion tree algorithm helps support error analysis. We start by showing how the overall structure of the suspicion tree (right frontier and subtrees) improves upon ranked lists when analysing the data. We then go on to show how subtrees in the suspicion tree permit differentiating between forms that are suspicious in all contexts and require a single correction; forms that are suspicious in all contexts but require several corrections; and forms that are suspicious in some but not all contexts.

3.2.1 Suspicion Trees vs. Ranked Lists

Figure 4 shows a top fragment of the suspicion tree obtained by error mining on NP-4. The node labels in this tree describe suspicious forms with part-of-speech information only.

In that tree, the right frontier indicates that the main distinct suspicious forms are, in that order:

1. Possessive NPs (POSS is the part of speech tag assigned to possessive *'s*[3])
The suspicious form (POSS) points to a mismatch between the representation of genitive NPs (e.g., *Oakland's thief*) in the SR Task data and in the grammar. While our generator expects the representation of '*Oakland's thief*' to be (thief/NN, ('s/POSS, (oakland/NNP))), the structure provided by the SR Task is (thief/NN, (oakland/NNP, ('s/POSS))). Hence whenever a possessive appears in the input data, generation fails. This is in line with (Rajkumar et al., 2011)'s finding that the logical

[2]Iteration stops either when the results are perfect (perfect coverage and perfect BLEU score) or when the trees fail to be discriminative enough (low number of FAIL instances associated with the suspicion tree leaves). So far, the latter situation did not occur and we are still using the suspicion tree to identify the main sources of errors for the remaining error cases.

[3]In fact, the part of speech tag assigned to possessive *'s* in the SR data is POS not POSS. We renamed it to avoid confusion with POS as an abbreviation for part-of-speech.

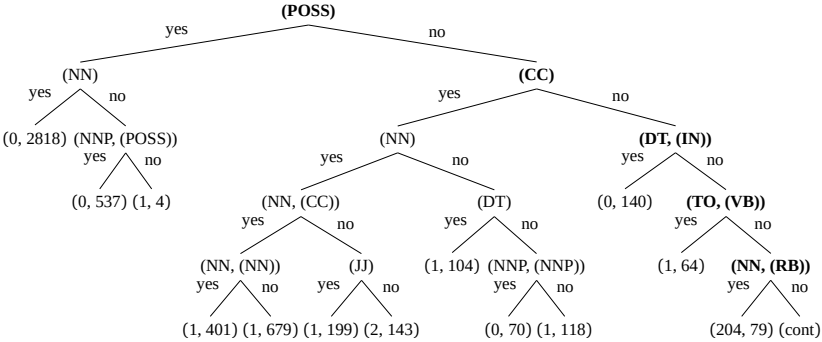


Figure 4: Suspicion Tree for Generation from the NP-4 data. Nodes are labelled with dependency subtrees with POS information. The leaves (p, f) represent the cluster with PASS (p) and FAIL (f) instances.

forms expected by their system for possessives differed from the shared task inputs. To correct these cases, we implemented a rewrite rule that converts the SR representation of possessive NPs to conform with the format expected by our realiser.

2. NPs with coordination (CC with daughter node NN)

The second top right frontier node unveils a bug (conflicting feature values) in the grammar trees associated with NP conjunction (e.g., *Europe and the U.S.*) which made all sentences containing an NP conjunction fail.

3. Determiners (DT) dominating a preposition (IN)

As we shall see below, this points to a discrepancy between the SR part of speech tag assigned to words like '*some*' in '*some of the audience*' and the part of speech tag expected by our generator. While in the SR data, such occurrences are labelled as determiners (DT), our generator expects these to be tagged as pronouns (PRP).

4. The complementizer *to* (TO) dominating a verb (VB)

As discussed below, this points to cases where the infinitival verb is a noun modifier and the input structure provided by the SR Task differs from that expected by our realiser.

5. Nouns (NN) dominating an adverb (RB)

This points to a discrepancy between the SR part of speech tag assigned to words like 'alone' in '*real estate alone*' and the part of speech tag expected by our generator. While in the SR data, such occurrences are labelled as adverbs (RB), our generator expects these to be tagged as adjectives (JJ).

In addition, for each node n on the right frontier, the subtree dominated by the yes-branch of n gives further information about the more specific forms that are subcases of the suspicious form labelling n.

The suspicion tree gives a structured view of how the various suspicious forms relate. In comparison, the ranked lists produced by previous work are flat structures which may fail to adequately display these information. For instance, applying (Gardent and Narayan, 2012)'s error mining algorithm to the data used to produce the tree shown in Figure 4 yields the list shown in Figure 5. Contrary to the suspicion tree shown in Figure 4, this list fails to highlight the main culprits and

Figure 5: Ranked list of suspicious forms for Generation from the NP-4 data.

the relations between the various suspicious forms. Thus the 5 main distinct suspects identified by the right frontier of the suspicion tree appears as 1st, 3rd, 15th, 19th and 28th in the ranked list. Furthermore, while subcases of the main suspects are grouped in the yes-branch of these suspects in the suspicion tree, in the ranked list, they appear freely interspersed throughout. For example, suspicious forms involving the two main suspects in the suspicion tree approach (POSS and CC part-of-speech tags) are scattered throughout the list rather than grouped under the first two right frontier nodes respectively.

Also the stronger pruning conditions used for building the suspicion tree restrict the branch exploration as soon as homogeneous clusters are achieved. For a given dataset, it only explores those suspicious forms which are good enough to identify the problems causing the failure in that dataset. For example the data containing the suspicious form (POSS) is explored with 3 suspicious forms (POSS), (NN) and (NNP, (POSS)) in the suspicion tree shown in Figure 4 whereas in the ranked list shown in Figure 5, there are 11 suspicious forms associated with (POSS). In general, the number of forms displayed by the suspicion tree algorithm is much less than that of the ranked list ones thereby giving a clearer picture of the main culprits and of their subcases at each stage in the error mining/grammar debugging cycle.

3.2.2 Reading error types off the tree structure

For each node n labelled with suspicious form f_n in a suspicion tree, the subtree dominated by n gives detailed information about the possible contexts/causes for f_n. In what follows, we show how the suspicion tree algorithm permits distinguishing between three main types of suspicious forms namely, forms that are suspicious in all contexts and require a single correction; forms that are suspicious in all contexts but require several corrections; and forms that are suspicious in some but not all contexts.

Forms that are suspicious independently of context and require a single correction. When a suspicious form always leads to failure, the node labelled with that suspicious form has no subtree thereby indicating that all configurations including that suspicious form lead to generation failure independent of context.

Such cases are illustrated in Figure 6 which show two views (one with part of speech tag only, the other with words and parts of speech tags) of the suspicion tree obtained after addressing the two main causes of errors identified in the previous section. That is, a rewrite rule was applied to convert the SR representation of possessive NPs to conform with the format expected by our

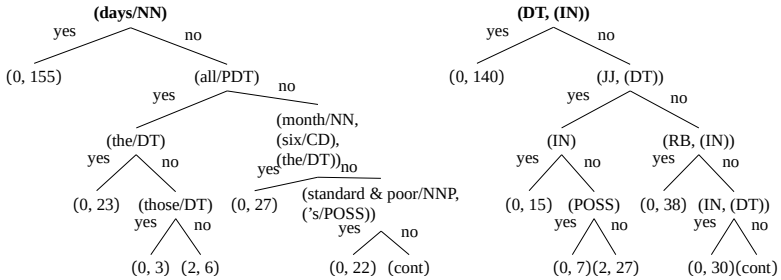

Figure 6: Suspicion Tree for (word/POS) (left) and (POS) (right) for Generation from the NP-4 data (after fixing genitive and coordination cases).

realiser ((POSS) suspicious form); and the grammar was corrected to generate for NP coordination ((CC) suspicious form).

In each of these two trees, the yes-branch of the root node has no subtree indicating that all input trees containing either the word form '*days*' with part of speech tag NN (days/NN); or a determiner dominating a preposition ((DT,(IN))) lead to generation failure.

The root node (days/NN) of the suspicion tree shown on the left of Figure 6 points to a problem in the lexicon. Although days/NN is present in the lexicon, it is not associated with the correct TAG family. We modified the entries corresponding to (days/NN) in the lexicon to solve this problem.

As mentioned above, the root node (DT, (IN)) of the suspicion tree shown on the right in Figure 6 points to a part-of-speech tagging problem in the SR Data. Words like '*some*' or '*all*' followed by a preposition (e.g., *some of the audience*, *all of fiscal 1990*, *those in other industries*) are assigned the determiner part of speech tag (DT) where our generator expects a pronoun (PRP) part-of-speech tag. To correct these cases, we implemented a rewrite rule that maps DT to PRP in the above specified context.

As these two examples illustrate, using different views (forms labelled with part of speech tags only *vs.* forms labelled with words and parts of speech) on the same data may help identifying problems at different levels. Both suspicion trees in Figure 6 are built for generation from same NP-4 dataset. The leftmost tree (suspicious forms labelled with both lemma and part of speech information) helps identifying problems in the lexicon whereas the rightmost tree (suspicious forms labelled with parts of speech only) points to problems in the input data.

Forms that are suspicious independent of context but require several corrections. It may be that a given form is almost always suspicious but that it occurs in different linguistic contexts requiring different corrections. In such cases, the suspicion tree will highlight these contexts. The root of the tree shown in Figure 7 is a case in point. The suspicious form (*im*-VB) describes subtrees whose head is related to a verb by the *im* dependency relation i.e., *infinitival verbs*. The subtrees (of the yes-branch) of that root further describe several syntactic configurations which are suspect and contain an infinitival verb. The node labelled with (*oprd*-TO) points to subcases where the infinitival verb is the complement of a control (1a[i]) or a raising verb (1a[ii]). The node labelled with (*im*-VB, (*prd*-JJ)) points to a subcase of that case namely that of an infinitival verb which is

the complement of a control or a raising verb and subcategories for an adjectival complement e.g., (1b). Finally, the node labelled with (*nmod*-TO, (*im*-VB)) points to cases where the infinitival verb is a noun modifier (1c).

Although all of these cases are due to a mismatch between the SR Task dependency trees and the input expected by our realiser, they point to different input configurations requiring different modifications (rewritings) to ensure compatibility with the realiser. The structured information given by the suspicion tree provides a clear description of the main tree configurations that need to be rewritten to correct generation failures induced by infinitival verbs. We used these information to implement the rewrite rules required to resolve the identified mismatches.

Forms that are suspicious in some but not all contexts. The suspicion tree can also highlight forms that are suspicious in some but not all contexts. For instance, the right frontier of the suspicion tree in Figure 8 shows that the CD (cardinals) part of speech occurs in several suspicious forms namely, (IN, (CD)) (a preposition dominating a cardinal), (CD, (IN)) (a cardinal dominating a preposition), (CD, (CD)) (a cardinal dominating a cardinal), (CD, (DT)) (a cardinal dominating a determiner) and (CD, (RB)) (a cardinal dominating an adverb). Examples for these configurations and their subcases are given in (2).

Noticeably, the suspicious form (CD) does not appear in the suspicion tree. In other words, the tree highlights the fact that cardinals lead to generation failure in the contexts shown but not in all contexts. Indeed, in this case, all suspicious forms points to a single cause of failure namely, a mis-

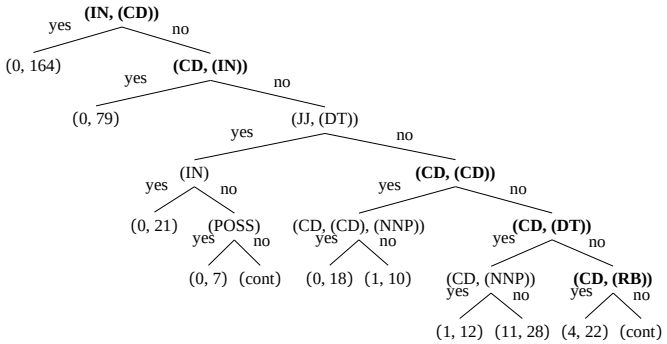

Figure 8: Suspicion Tree (POS) for Generation from the NP-6 data (after fixing genitive, coordination and determiner cases).

match between grammar and lexicon. In the TAG grammar used, the constructions illustrated in (2) all expect cardinals to be categorised as nouns. In the lexicon however, cardinals are categorised as determiners. We modified the lexicon to categorise cardinals as determiners, nouns and adjectives and rerun the generator on the input. In the newly built suspicion trees, cardinals no longer induce high generation failure rates. The fact that cardinals are not always associated with failure can be traced back to the fact that they are often used as determiners and that for this context, the lexicon contains the appropriate information.

3.3 Using Error Mining to Improve Generation Results

We now briefly report on how the suspicion tree algorithm can help improve a generation system by showing the impact of corrections on undergeneration.

Generating NPs. Table 1 summarises a run with 6 iterations between error mining and error correction on the NP data. The corrections involve rewriting the SR data to the format expected by our realiser, grammar corrections and lexicon enrichment. Each time a correction is applied, the suspicion tree is recomputed thereby highlighting the next most likely sources of errors. G(Coord) indicates a fix in the grammar for coordination (discussed in Section 3.2.1). R(Gen) involves rewriting dependency trees for genitive NPs (e.g., *Oakland 's thief*) (Section 3.2.1) and R(Dt) rewriting dependency trees with determiners to map its part-of speech from determiner (DT) to pronoun (PRP) (Section 3.2.2) and to noun (NN) (nominal positions, e.g., *That's good*). L(days) involves updating the lexicon with correct days/NN to TAG families mapping (Section 3.2.2). R(Adv) involves rewriting dependency trees with adverbs to map its part-of speech from adverb (RB) to adjective (JJ) (e.g., *real estate alone*) (Section 3.2.1).

As the table shows, error mining permits decreasing undergeneration by 22.6, 25.6 and 8.7 points for NPs of size 4, 6 and ALL respectively. This suggests that simple NPs can be generated but that bigger NPs still cause undergeneration (8.2% and 13% of the cases respectively for NP-6 and NP-ALL) presumably because of more complex modifiers such as relative clauses, PPs and multiple determiners. Since in particular, relative clauses also appear in sentences, we proceeded to error mine the sentence data so as to provide more data for the error mining algorithm and therefore get a more global picture of the most important causes of failure.

	Input Data	Init Fail	G(Coord)	R(Gen)	R(Dt)	L(days)	R(Adv)
NP-4	23468	5939 (*25.3*)	4246 (*18.1*)	999 (*4.3*)	833 (*3.6*)	678 (*2.9*)	649 (*2.7*)
NP-6	10520	3560 (*33.8*)	2166 (*20.6*)	956 (*9.1*)	881 (*8.4*)	876 (*8.3*)	865 (*8.2*)
NP-ALL	123523	26769 (*21.7*)	21525	16702	16263	16094	16028 (*13*)

Table 1: Diminishing the number of errors using information from error mining on NP data. The first column indicates the type of NP chunks to be processed, the second (*Input Data*) the number of NP chunks to be processed, the third (*Init Fail*) the number of input on which generation initially fails and the last 5 ones the decrease in errors (the number of failed cases with the *percentage failure*) after fixing error cases identified by the suspicion tree. R(X) indicates that the correction is obtained by rewriting the input for phenomena X, G(X) indicates corrections in the grammar and L(X) indicates corrections in the lexicon.

Generating Sentences. Tables 2 show the impact of corrections on generation for sentences. For this data, we start with all the improvements made during error mining on the NP data. Table 2 represents this step as *NP-Final* summarizing generation results after all improvements from Table 1. During error mining on the S data, *infinitival verbs* (discussed in Section 3.2.2) and *auxiliary verbs* appear as prominent mismatches between the SR dependency trees and the input expected by our generator. R(Inf) in Table 2 involves 3 different rewriting rules corresponding to dependency relations *im*, *oprd* and *prd* for rewriting dependency trees with infinitival verbs. R(Aux) indicates rewriting for dependency trees with Verb/Auxiliary nuclei (e.g., *the whole process might be reversed*).

	Input Data	NP-Final	R(Inf)	R(Aux)
S-6	3877	1707 (*44.0*)	753 (*19.4*)	398 (*10.3*)
S-8	3583	1749 (*48.8*)	936 (*26.1*)	576 (*16.1*)
S-ALL	26725	19280 (*72.1*)	17862 (*66.8*)	16445 (*61.5*)

Table 2: Diminishing the number of errors using information from error mining on S data. The first column indicates the type of sentences to be processed, the second (*Input Data*) the number of sentences to be processed, the third (*NP-Final*) the number of input (processed with all improvements from Table 1) on which generation fails and, the fourth and the fifth error rates after rewriting dependency trees for infinitival cases and auxiliary verb cases respectively.

Finally, Table 3 summarises results from Table 1 and Table 2 adding an extra final improvement step (*Final*) consisting of minor grammar improvement (trees for pre-determiner PDT added, e.g., *all these millions*), lexicon enrichment (mapping to TAG families corrected) and rewriting rule (mapping part-of-speech from conjunction CC to determiner DT, e.g., *neither/CC the Bush administration nor arms-control experts*). The "Final" row in this Table shows the impact of S error reduction on NP error reduction. As can be seen reducing S-errors positively impact NP errors throughout.

In total we defined 11 rewrite rules (Gen-1, Dt-4, Adv-1, Inf-3, Aux-1 and Final-1), made 2 grammar corrections and performed a few lexicon updates.

Coverage and accuracy. As the tables show, the corrections carried out after a few cycle of error mining and error correction helps achieve a large improvement in coverage for smaller dependency trees; we notice a large drop of 23.2 points (from 25.3% to 2.1%) in error rates for NP-4, 28.3 points for NP-6, 34.5 points for S-4 and 33.6 points for S-6. For larger dependency trees however, improvement is more limited and other error cases becomes visible. Thus, the failure rate is reduced

by 10.4 points for NP-ALL (NPs from minimum size 1 to maximum size 91 with the average size 4); and by 10.9 points for S-ALL (sentences from minimum size 1 to maximum size 134 with the average size 22). The suspicion tree built after the *Final* step shows that coordination cases appear as most suspicious forms. Although the corrections made for coordination in the grammar G(Coord) permit generating simple coordinations (e.g., *John and Mary likes beans.*, *We played on the roof and in the garden.*, *I cooked beans and she ate it.*), the grammar still fails to generate for more complex coordination phenomenon (e.g., verb coordination *I cooked and ate beans.*, gapping phenomenon *John eat fish and Harry chips.*, *I liked beans that Harry cooked and which Mary ate.*) (Sarkar and Joshi, 1996). Other top suspicious forms are multiword expressions (e.g., *at least*, *so far*) and foreign words (part-of-speech FW) (e.g., *the naczelnik*, *perestroika*, *product de jour*).

	NP-4	NP-6	NP-ALL	S-6	S-8	S-ALL
Input Data	23468	10520	123523	3877	3583	26725
Init Fail	5939 (*25.3*)	3560 (*33.8*)	26769 (*21.7*)	-	-	-
NP-Final	649 (*2.7*)	865 (*8.2*)	16028 (*13.0*)	1707 (*44.0*)	1749 (*48.8*)	19280 (*72.1*)
S-Final	-	-	-	398 (*10.3*)	576 (*16.1*)	16445 (*61.5*)
Final	503 (*2.1*)	584 (*5.5*)	13967 (*11.3*)	371 (*9.5*)	545 (*15.2*)	16374 (*61.2*)

Table 3: Overall impact of error mining on generation from different types of dependency trees. The first row indicates the type of dependency data to be processed and the second (*Input Data*) the number of data to be processed. The rows named (*Init Fail*), (*NP-Final*), (*S-Final*) and (*Final*) are initial error rates, errors after applying improvements from Table 1, errors after applying improvements from Table 2 and errors after final improvements respectively.

To assess the precision of the surface realiser after error mining, we computed the BLEU score for the covered sentence data and obtained a score of 0.835 for S-6, 0.80 for S-8 and 0.675 for S-ALL[4].

4 Conclusion

We introduced an error mining algorithm that takes inspiration from (Quinlan, 1986)'s ID3 algorithm to structure the output of error mining in a way that supports a linguistically meaningful error analysis. We demonstrated its workings by applying it to the analysis of undergeneration in a grammar based surface realisation algorithm. And we show that it permits quickly identifying the main sources of errors while providing a detailed description of the various subcases of these sources if any.

The approach is generic in that permits mining trees and strings for suspicious forms of arbitrary size and arbitrary conjunctions of labelling. It could be used for instance to detect and structure the n-grams that frequently induce parsing errors; or to identify subtrees that frequently occur in agrammatical output produced by a generator.

We are currently working on further improving the generator using the suspicion tree algorithm. In future work, we plan to use our error mining algorithm to detect the most likely sources of over-generation based on the output of a surface realiser; and to investigate whether the approach can be useful in automatically detecting treebank and parse errors (Boyd et al., 2008; Dickinson and Smith, 2011).

Acknowledgments The research presented in this paper was partially supported by the European Fund for Regional Development within the framework of the INTERREG IV A Allegro Project.

[4]The BLEU score before error mining and correction is not reported here since it has low coverage due to the mismatches between the structures provided by the SR task and those expected by the realiser.

Abstract
We present a novel algorithm for surface realisation with lexicalist grammars. In this algorithm, the structure of the input is used both top-down to constrain the selection of applicable rules and bottom-up to filter the initial search space associated with local input trees. In addition, parallelism is used to recursively pursue the realisation of each daughter node in the input tree. We evaluate the algorithm on the input data provided by the Generation Challenge Surface Realisation Task and show that it drastically reduce processing time when compared with a simpler, top-down driven, lexicalist approach.

1 Introduction

Depending on the type of semantic representation encoded by the grammar, two main types of algorithms have been proposed for generating sentences with bi-directional, unification-based grammars such as CCG (Combinatory Categorial Grammar, (Espinosa et al., 2010)), HPSG (Head-Driven Phrase Structure Grammar, (Carroll et al., 1999)) and TAG (Tree Adjoining Grammar, (Gardent and Kow, 2005)).

For recursive semantic representations such as first-order logic formulae, head-driven algorithms (Shieber et al., 1990) have been argued to be best because they restrict the combinatorics inherent to bottom-up search; they avoid non termination by using lexical items to guide the search ; and they allow for semantically nonmonotonic grammars (i.e., grammars where the semantics of a rule at the left hand side need not be subsumed by the semantics of the rule at the right hand side). One main issue with this approach however is the so-called logical form equivalence problem (Shieber, 1993). A logic formula may have several logically equivalent but syntactically distinct formulae. For instance $p \wedge q$ is logically equivalent to $q \wedge p$. In general though, a grammar will associate with natural language expressions only one of these logically equivalent formula. Hence a generator will be able to produce the natural language expression E only when given the formula ϕ associated by the grammar with E. For all other formulae logically equivalent to ϕ, it will fail. Since, the problem of computing logical equivalence for first order logic is undecidable, the problem is quite deep.

For flat semantic representations such as MRSs (Minimal Recursion Semantics, (Copestake et al., 2001)) on the other hand, lexicalist approaches (Espinosa et al., 2010; Carroll and Oepen, 2005; Gardent and Kow, 2005) have extensively been used because (i) they impose few constraints on the grammar thereby making it easier to maintain bi-directional grammars that can be used both for parsing and for generation; and (ii) the approach eschews the logical form equivalence problem – Since the semantic representations are unstructured, there is no requirement on the generator to mirror a semantic structure. One known drawback of lexicalist approaches however is that they generally lack efficiency. Indeed, previous work has shown that the high combinatorics of lexicalist approaches stem from (i) strong lexical ambiguity (each input element is usually associated with a large number of grammatical structures thereby inducing a very large initial search space); (ii) the lack of order information in the input (as opposed to parsing where the order of words in the input string restricts the number of combinations to be explored); and (iii) intersective modifiers (given n modifiers applying to the same constituent, there are $n!$ ways to combine these together).

In this paper, we present an algorithm for surface realisation that combines techniques and ideas from the head-driven and the lexicalist approach. On the one hand, rule selection is guided, as in the lexicalist approach, by the elementary units present in the input rather than by its structure – In this way, the logical form equivalence issue is avoided. On the other hand, the structure of the input is used to provide top-down guidance for the search and thereby restrict the combinatorics.

To further improve efficiency, the algorithm integrates three additional optimisation techniques. From the lexicalist approach, it adapts two techniques designed to prune the search space, namely a so-called polarity filter on local input trees (Bonfante et al., 2004); and the use of a language model to prune competing intermediate substructures. In addition, the algorithm is parallelised to explore the possible completions of the top-down predictions simultaneously rather than sequentially.

The algorithm was implemented using a Feature-Based Lexicalised Tree Adjoining Grammar for English and tested on the Generation Challenge Surface Realisation task data (Belz et al., 2011). We compare our algorithm with a baseline lexicalist approach which processes the input tree top

down. The results show that the algorithm we propose drastically improves on the baseline, reducing generation time for sentences longer than 6 words w.r.t. this baseline.

This paper is structured as follows. Section 2 situates our approach with respect to related work. Section 3 introduces the input data provided by the Generation Challenge Surface Realisation task and used for the evaluation. Section 4 introduces the tree adjoining grammar used by the algorithm. Section 5 presents the surface realisation algorithm we developed. Section 6 describes the evaluation setup and the results obtained. Section 7 concludes with pointers for further research.

2 Related Work

Most of the recent proposals on optimising surface realisation with unification grammars focuses on lexicalist approaches, they place minimal requirements on the grammar and eschew the logical form equivalence problem. We now review the optimisation techniques used in these approaches. We also briefly review recent work on statistical approaches to surface realisation.

For HPSG, (Carroll and Oepen, 2005) present a bottom-up, lexicalist, surface realiser which uses a chart based strategy, subsumption-based local ambiguity factoring and a procedure to selectively unpack the generation forest according to a probability distribution given by a conditional, discriminative model. The algorithm is evaluated on the *hike* treebank, a collection of 330 sentences of instructional text taken from Norwegian tourism brochures with an average length of 12.8 words. Practical generation times average below or around one second for outputs of 15 words.

For TAG, (Gardent and Kow, 2007) propose a three step surface realisation algorithm for FB-LTAG (Feature-Based Lexicalised Tree-Adjoining Grammar) where first, a so-called polarity filter is used to prune the initial search space second, substitution is applied to combine trees together and third, adjunction is applied.

In essence, polarity filtering filters out combinations of FB-LTAG elementary trees which cover the input semantics but cannot yield a valid parse tree either because a syntactic requirement cannot be satisfied or because a syntactic resource cannot be used. In this way, the exponential impact of lexical ambiguity can be reduced. Furthermore applying substitution before adjunction means that first a skeleton sentence is built before modifiers are adjoined. This permits reducing the combinatorics introduced by intersective modifiers as the multiple intermediate structures they may license do not propagate to the rest of the sentence tree. In practice however, evaluation is restricted to short input and the algorithm fails to scale up (Gardent and Perez-Beltrachini, 2010).

(Koller and Striegnitz, 2002) present a surface realisation algorithm where (i) the XTAG FB-LTAG grammar (The XTAG Research Group, 2001) is converted to a dependency grammar capturing the derivation trees of XTAG and (ii) a constraint-based dependency parser is used to construct derivation trees from semantic representations. The parser used was specifically developed for the efficient parsing of free word order languages and is shown to efficiently handle both the lexical ambiguity and the lack of order information in the input that are characteristic of surface realisation from a flat semantics. The evaluation however is restricted to a few hand constructed example inputs; and the grammar conversion ignores feature structure information.

To address these shortcomings, (Gardent and Perez-Beltrachini, 2010) present an approach which makes use of the procedure for converting an FB-LTAG to a Feature-Based Regular Tree Grammar (FB-RTG) described in (Schmitz and Roux, 2008). Like in (Koller and Striegnitz, 2002), the initial FB-LTAG is converted to a grammar of its derivation trees. However in this case, the grammar conversion and the resulting feature-based RTGs accurately translates the full range of unification

mechanisms employed in the initial FB-LTAG. An Earley, bottom-up algorithm is developed and the approach is tested on a large benchmark of artificially constructed examples illustrating different levels of linguistic complexity (different input lengths, different numbers of clauses and of modifiers). The approach is shown to outperform the algorithm presented in (Gardent and Kow, 2007) in terms of space. Speed is not evaluated however and the algorithm is not evaluated on the real life data.

Probabilistic techniques have also been proposed to improve e.g., lexical selection, the handling of intersective modifiers and the selection of the best output. For instance, (Bangalore and Rambow, 2000) uses a tree model to produce a single most probable lexical selection while in CCG based White's system (White, 2004), the best paraphrase is determined on the basis of n-gram scores. To address the fact that there are $n!$ ways to combine any n modifiers with a single constituent, (White, 2004) proposes to use a language model to prune the chart of identical edges representing different modifier permutations, e.g., to choose between *fierce black cat* and *black fierce cat*. Similarly, (Bangalore and Rambow, 2000) assumes a single derivation tree that encodes a word lattice (*a {fierce black, black fierce} cat*), and uses statistical knowledge to select the best linearisation. Recently, (Espinosa et al., 2008) adapted the supertagging techniques first proposed for parsing (Bangalore and Joshi, 1999) to surface realisation. Given a treebank in the appropriate format, this technique permits filtering the initial search space by using a model trained on that treebank. Supertagging was shown to improve the performance of symbolic parsers and generators significantly. However, it requires the existence of a treebank in a format appropriate to generate the supertagging model.

In sum, various symbolic and statistical techniques have been developed to improve the efficiency of grammar-based surface realisation. However, statistical systems using supertagging require the existence of a treebank in an appropriate format while the purely symbolic systems described in (Carroll and Oepen, 2005; Gardent and Kow, 2005; Koller and Striegnitz, 2002; Gardent and Perez-Beltrachini, 2010) have not been evaluated on large corpora of arbitrarily long sentences such as provided by the surface realisation (SR) task (Belz et al., 2011).

Recently, (Guo et al., 2011; Bohnet et al., 2011; Stent, 2011) have developed statistical dependency realisers that do not make use of an explicit grammar but use cascaded classifiers and n-gram models to map in SR input data to sentences. They obtain the best results in the SR task partly because, for grammar based systems, converting the provided input into the format expected by the grammar proved to be extremely difficult.

The algorithm we propose departs from these approaches in that it is a grammar-based approach; it is optimised by combining parallel processing, top-down prediction and local bottom-up polarity filtering; and it was evaluated on a large scale using the input data provided by Generation Challenge SR Task.

3 Input Representations

Recently, the Generation Challenge has promoted a Surface Realisation (SR) task (Belz et al., 2011) where the input provided to test and compare surface realisers are (deep or shallow) dependency structures. Here we assume as input to surface realisation, the shallow dependency structures provided by this task namely, unordered trees whose edges are labelled with syntactic functions and whose nodes are labelled with lemmas, part of speech tags, partial morphosyntactic information such as tense and number and, in some cases, a sense tag identifier. All words of the original sentence are represented by a node in the tree. An example of the shallow dependency trees used

for the SR task is given in Figure 1.

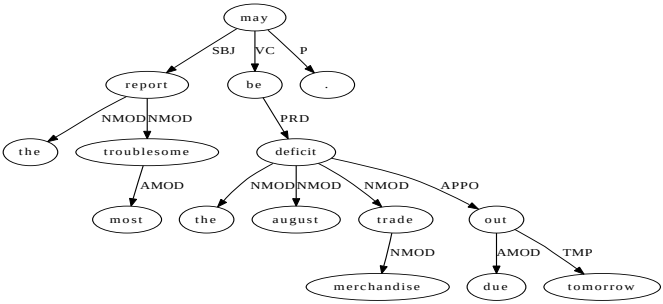

Figure 1: Input shallow dependency tree from the Generation Challenge Surface Realisation Task for the sentence "*The most troublesome report may be the August merchandise trade deficit due out tomorrow .*"

Note that contrary to the flat semantic representations often used by surface realisers, the SR data has a clear tree structure. Thus the combinatorics induced by the lack of order in flat semantic representations is less in this task. Indeed, the algorithm we present exploits this structure to minimize the combinatorics. Similarly, (White, 2006) applies chunking constraints to the graph structure of flat semantic representation to constrain the generation of coordinate structures and address the issue of semantically incomplete phrases.

4 Grammar

Following (Gardent and Perez-Beltrachini, 2010), we perform surface realisation using a Feature-Based Regular Tree Grammar (FB-RTG) describing the derivation trees of a Feature-Based Lexicalised Tree Adjoining Grammar (FB-LTAG, (Joshi and Schabes, 1996)) rather than the FB-LTAG itself. In what follows, we briefly introduce FB-LTAG and the derived FB-RTG used for generation.

4.1 FB-LTAG

The grammar underlying the surface realisation algorithm presented in the next section is an FB-LTAG for English consisting of roughly 1000 trees and whose coverage is similar to XTAG (The XTAG Research Group, 2001).

Figure 2 shows an example FB-LTAG. Briefly, an FB-LTAG consists of a set of elementary trees which can be either initial or auxiliary. Initial trees are trees whose leaves are labeled with substitution nodes (marked with a down-arrow) or terminal categories. Auxiliary trees are distinguished by a foot node (marked with a star) whose category must be the same as that of the root node. In addition, in an FB-LTAG, each elementary tree is anchored by a lexical item (lexicalisation) and the nodes in the elementary trees are decorated with two feature structures called *top* and *bottom* which are unified during derivation. Two tree-composition operations are used to combine trees: substitution and adjunction. Substitution inserts a tree onto a substitution node of some other tree while adjunction inserts an auxiliary tree into a tree. Derivation in an FB-LTAG yields two trees: a *derived tree* which is, like for context free grammars, the tree produced by combining the grammar rules (here, the elementary trees) licensed by the input; and a *derivation tree* which indicates how

the derived tree was built i.e., which elementary trees were used and how they were combined. Figure 3 show the derived and derivation trees associated by the grammar shown in Figure 2 with the sentence "*Which fruit has John eaten?*". For a detailed presentation of the FB-LTAG formalism, the reader is referred to (Vijay-Shanker and Joshi, 1988).

4.2 FB-RTG

As shown in (Koller and Striegnitz, 2002; Gardent and Perez-Beltrachini, 2010), processing the derivation trees of a given FB-LTAG rather than its derived trees is more efficient. Following (Gardent and Perez-Beltrachini, 2010), we therefore use not the initial FB-LTAG described in the previous section, but the FB-RTG grammar of derivation trees that can be derived from it. That is, the surface realisation algorithm first builds a derivation tree. The generated sentence is then extracted from the derived tree[1] which can be reconstructed from this derivation tree using the original FB-LTAG.

Figure 2 shows an example FB-LTAG and the corresponding FB-RTG. The conversion from FB-LTAG to FB-RTG is described in detail in (Schmitz and Roux, 2008). Intuitively, the FB-RTG representation of an FB-LTAG elementary tree t, is a rule whose left hand side (LHS) describes the syntactic requirement satisfied by t (e.g., S_S for an initial tree rooted in S and VP_A for an auxiliary tree rooted in VP) and whose right hand side (RHS) describes its requirements. Adjunction is handled as an optional requirement which can be satisfied by the adjunction of an empty string and subscripts indicates the nature of the requirement (S for a substitution and A for adjunction). For instance, the rule **r8** in Figure 2 repeated below for convenience, describes the contribution of the elementary tree **t8** lexicalised with the lemma *eat* to a derivation tree as follows: **t8** can satisfy a requirement for a substitution on a node labelled with the S category (LHS with the category S_S) and requires one substitution on a node labelled with the NP category (NP_S on the RHS) and two optional adjunctions of category S and VP respectively (S_A, VP_A on the RHS).

$$S_S^{[t:T,b:B]} \rightarrow eat(S_A^{[t:T,b:B]}\ NP_S^{[t:[wh:-]]}\ VP_A)$$

The derivation process in FB-RTG produces trees that are almost identical to the FB-LTAG derivation trees. Figure 3 shows the FB-LTAG derived, FB-LTAG derivation and FB-RTG derived tree for the sentence "*Which fruit has John eaten?*". When abstracting away from the categorial nodes, the FB-RTG derivation tree mirrors the derivation tree of the original FB-LTAG. The *A* and *S* subscripts indicate which operation was used for combining; and the nodes at which each FB-LTAG elementary tree adjoins or substitutes is encoded by features in these trees: for instance, the subject node of **t9** will have the feature *subject* while its object node will have the feature *object*. By comparing the dependency relations present in the input tree with the feature values given by the grammar, it is thus possible to determine on which nodes of the mother tree in the derivation tree, its daughter trees should combine.

Note that the FB-RTG tree is unordered. During generation, the appropriate linearisation of the lexical items is obtained by constructing the FB-LTAG derived tree from the FB-RTG derivation tree. Morphological realisation is carried out in a post-processing step from the list of lemmas and feature structures decorating the yield of the FB-LTAG derived tree.

[1] in FB-LTAG, the mapping from derivation tree to derived tree is one-to-one.

Figure 2: A toy FB-LTAG and the corresponding FB-RTG. For the sake of clarity, feature structures are abbreviated. **r11** (not present in the original FB-LTAG) implements optional adjunction for arbitrary categories with X, a variable ranging over all syntactic categories.

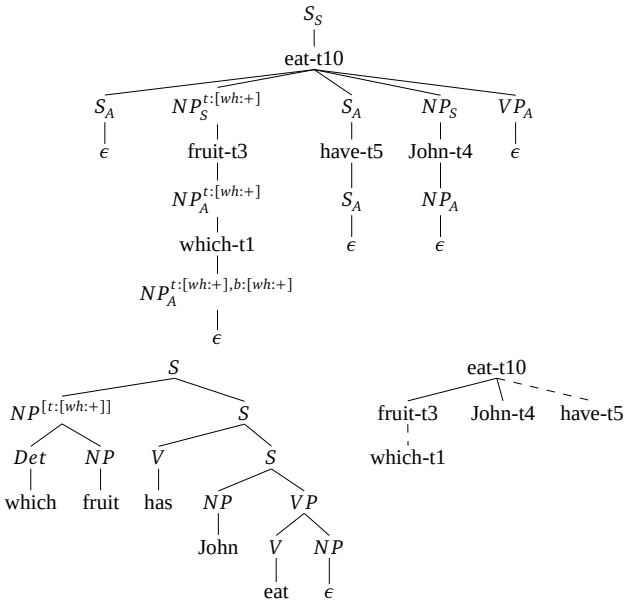

Figure 3: The FB-RTG derivation for "*Which fruit has John eaten*" and the corresponding FB-LTAG derived and derivation trees. In the derivation tree, the nodes are labelled with a lemma/FB-LTAG tree name pair; dashed lines indicate adjunction and solid lines substitution. Adjunction and substitution sites have been omitted.

5 The Surface Realisation Algorithm

Surface realisation starts from the root node of the input tree and processes all children nodes in parallel by spreading the lexical selection constraints top-down and completing the FB-RTG rules bottom-up. Figure 4 shows the architecture of the surface realiser. The controller provides the interface to our surface realization system. It takes a shallow dependency tree as input and produces a ranked list of sentences as output. More specifically, the controller defines a process pool such that each process present in this pool represents a node (a lemma) in the input dependency tree and the communication scheme among processes reflects the dependency relations among nodes in the input dependency tree. In this way, generation is guided by the structure of the input dependency tree.

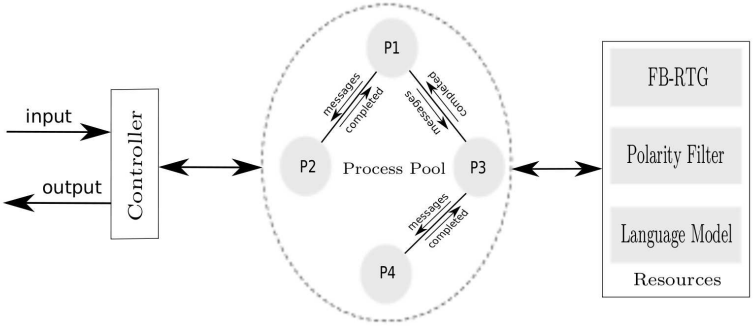

Figure 4: A Parallel Architecture for Surface Realisation

The algorithm proceeds in five major steps as follows.

Top-Down Rule selection and Filtering. Starting from the root node, the input dependency tree is traversed top-down to associate each node in the input tree with a set of grammar rules (from the FB-RTG). This step corresponds to the lexical lookup phase of lexicalist approaches whereby each literal in the input selects the grammar rules whose semantics subsumes this literal. Our approach differs from existing lexicalist approaches however in that it uses the top-down information given by the structure of the input to filter out some possibilities that cannot possibly lead to a valid output. More precisely, for each input node n with lemma w, only those rules are selected which are associated with w in the lexicon. In addition, the left-hand side (LHS) category of each selected rule must occur at least once in the right-hand side (RHS) of the rules selected by the parent node.

For instance, given the input dependency tree shown in Figure 5 for the sentence "*Which fruit has John eaten?*", and the grammar given in Figure 2, all rules **r8**, **r9** and **r10** associated with the lemma '*eat*' will be selected because all of them corresponds to the S[2] rooted initial trees[3].

[2]The controller triggers the root process "eat" with the initial lexical selection constraint (S_S, S rooted initial trees) to generate complete sentences.

[3]The grammar is lexicalised with lemmas rather than forms. The appropriate forms are generated at the end of the generation process based on the lemmas and on the feature structures decorating the yield of the trees output by the generator.

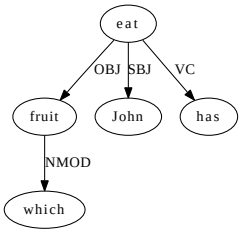

Figure 5: Dependency Tree for "*Which fruit has John eaten*"

$$\begin{array}{lllll} \surd & \textbf{r8} & S_S^{[t:T,b:B]} & \rightarrow & eat(S_A^{[t:T,b:B]}\ NP_S^{[t:[wh:-]]}\ VP_A) \\ \surd & \textbf{r9} & S_S^{[t:T,b:B]} & \rightarrow & eat(S_A^{[t:T,b:B]}\ NP_S^{[t:[wh:-]]}\ VP_A\ NP_S) \\ \surd & \textbf{r10} & S_S^{[t:T,b:B]} & \rightarrow & eat(S_A^{[t:T,b:B]}\ NP_S^{[t:[wh:+]]}\ S_A\ NP_S\ VP_A) \end{array}$$

The parent process creates a new lexical selection constraint message consisting of its RHS requirements in selected RTG rules and passes it to its children processes. In Figure 5, the process associated with the node '*eat*' will send a message consisting of S_A, NP_S and VP_A (RHS requirements of rules **r8**, **r9** and **r10**) to its children processes associated with '*fruit*', '*John*' and '*have*'.

Starting from the trigger initiated by the *controller*, the process of message spreading happens in recursive and parallel manner throughout the process pool reflecting the input dependency tree in a top-down fashion. It eliminates all RTG rules which cannot possibly lead to a valid output well before carrying out any substitution and adjoining operation on the RTG rules.

For instance, the rule **r7** for '*have*' will not be selected because its left-hand side is S_S which does not satisfy the lexical selection constraints (S_A, NP_S and VP_A) sent by its parent '*eat*'.

$$\begin{array}{lllll} \surd & \textbf{r5} & S_A^{[t:T]} & \rightarrow & have(S_A^{[t:T]}) \\ \surd & \textbf{r6} & VP_A^{[t:T]} & \rightarrow & have(VP_A^{[t:T]}) \\ \times & \textbf{r7} & S_S^{[t:T,b:B]} & \rightarrow & have(S_A^{[t:T,b:B]}\ NP_S^{[t:[wh:-]]}\ VP_A\ NP_S) \end{array}$$

Leaf closure. When reaching the leaf nodes of the input tree, the top and bottom feature structures of the rules selected by these leaf nodes are unified. The completed rules of a leaf node are sent back to its parent.

Local Polarity filtering. As mentioned in Section 2, polarity filtering (Gardent and Kow, 2005) eliminates from the search space those sets of rules which cover the input but cannot possibly lead to a valid derivation either because a substitution node cannot be filled or because a root node fails to have a matching substitution site[4] While (Gardent and Kow, 2005) applies polarity filtering to the initial search space (the set of rules selected by all literals in the input), we apply polarity filtering to each local tree while going up the input tree. Thus, this filtering will weed out all combinations

[4]Since it only eliminates combinations that cannot possibly lead to a valid parse, polarity filtering does not affect completeness. Nor does it place any particular constraint in the grammar. All that is required is that the grammar encodes a notion of resources and requirements i.e., of items that cancel each other out. Typically, grammar rules support this constraint in that e.g., the left-hand side of a rule and one category in the right-hand side of another rule can be viewed as canceling each other out if they match.

of mother rules and completed immediate daughter rules which cannot possibly yield a complete tree either because some daughter rule cannot be used or because some requirement of the mother rule cannot be satisfied. For instance, after processing the daughters of the '*eat*' node in the input dependency tree shown in Figure 5, all combinations of **r8** (intransitive '*eat*') with the daughter trees will be excluded. This is because at this stage of processing, the trees built bottom up for '*which fruit*', '*John*' and '*have*' includes two NPs with LHS category NP_S (Figure 6) while the **r8** rule only requires one such NP. That is, for this rule, the completed daughter rule for *which fruit* will show up as a superfluous syntactic resource.

$$\begin{array}{lll} \times & \textbf{r8} & S_S^{[t:T,b:B]} \rightarrow eat(S_A^{[t:T,b:B]}\ NP_S^{[t:[wh:-]]}\ VP_A) \\ \surd & \textbf{r9} & S_S^{[t:T,b:B]} \rightarrow eat(S_A^{[t:T,b:B]}\ NP_S^{[t:[wh:-]]}\ VP_A\ NP_S) \\ \surd & \textbf{r10} & S_S^{[t:T,b:B]} \rightarrow eat(S_A^{[t:T,b:B]}\ NP_S^{[t:[wh:+]]}\ S_A\ NP_S\ VP_A) \end{array}$$

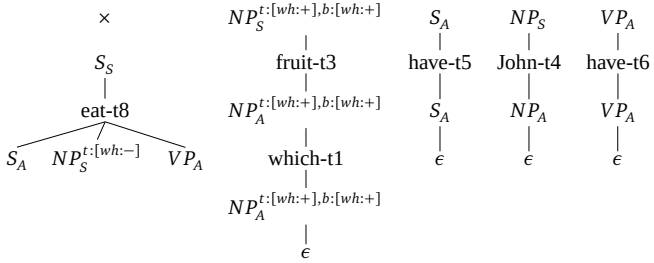

Figure 6: Polarity Filtering will filter out the **r8** rule for '*eat*' since one of trees '*which fruit*' or '*John*' would then appear as a superfluous syntactic resource as illustrated by the above derivation.

By restricting polarity filtering to local input trees, we avoid the computation of the very large automaton required when filtering the global initial search space as done in (Gardent and Kow, 2005).

As noted by one of our reviewers, supertagging models can probably approximate local polarity filtering. For instance, a supertagger model might learn that an intransitive category is very unlikely whenever the input dependency tree contains one or more core arguments.

The combined effect of top-down filtering and local polarity filtering avoids considering most of RTG rules which can never lead to valid output well before carrying out any substitution and adjoining operation on the RTG rules to try to complete them. The Earley, bottom-up algorithm (Gardent and Perez-Beltrachini, 2010) also achieves some amount of top-down filtering during its prediction stage but the lexical selection constraint is limited to the top of the RHS requirements of the RTG rule being processed, hence it may try completing the RTG rules which cannot possibly lead to a valid output whereas in our proposed approach all RHS requirements of the selected RTG rules are available as the lexical selection constraint information during both top-down filtering and local polarity filtering steps.

Bottom-Up generation. For each local tree in the input, the rule sets passing the local polarity filter are tried out for combination. The completed daughter RTG rules are combined to the local

initialized RTG rule using substitution and adjoining operations. The local initialized RTG rule fails to complete if any feature conflicts are found.

Note that for each rule set let through by polarity filtering, the category and the number of daughter trees exactly match the requirement of the associated mother rule. For instance, as explained above, the rule **r8** representing an intransitive use of the verb '*eat*' is ruled out by polarity filtering since it does not permit "consuming" the NP_S resource provided by one of NPs '*which fruit*' or '*John*'. Conversely, given an input tree of the form `eat(john, has)`, the rules **r9** and **r10** representing a transitive use of the verb '*eat*' would be filtered out by polarity filtering. As a result, the intermediate structure shown below will not be computed. That is, while the global polarity filtering used in (Gardent and Kow, 2005) permits weeding out global combination of trees that are invalid, local polarity filtering additionally permits reducing the number of intermediate structures built first, because there is no need for prediction i.e., for active chart items and second, because intermediate structures that cannot possibly lead to a valid derivation are not built.

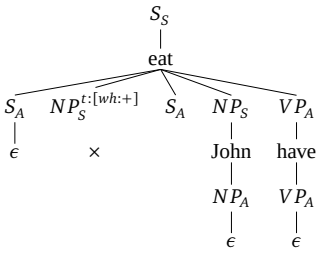

Figure 7: Given the input tree `eat(john, has)`, local polarity filtering filters out this intermediate structure because it cannot be completed given the input

N-gram filtering using a Language Model. To further prune the search space and to appropriately handle word order, the SR algorithm also integrates a language model and can be parametrized for the number of best scoring n-grams let through after each bottom-up generation step. In this way, not all possible orderings of intersective modifiers are produced, only those that are most probable according to the language model.

6 Empirical Evaluation

We now report on the results obtained when running the algorithm and the grammar described above on the shallow input data provided by the Generation Challenge Surface Realisation Task. Because we are presenting an algorithm for surface realisation rather than a surface realiser, the main focus of the evaluation is on speed (not coverage or accuracy). Nevertheless, we also report coverage and BLEU score as an indication of the capabilities of the surface realiser i.e., the algorithm combined with the grammar and the lexicon.

6.1 Runtimes

The SR data on which we evaluate our surface realisation algorithm are the shallow dependency trees described in Section 3.

We use as a baseline the FB-RTG based lexicalist approach (**B**ASELINE) described in (Narayan, 2011). In this approach, FB-RTG rules are selected top-down following the structure of the input dependency tree and all FB-RTG rules selected for a given local input tree are tried out for combination using a chart-based approach. This baseline thus permits observing the impact of the various optimisations described below. In future work, it would be interesting to obtain time information from the systems participating in the SR challenge and to compare them with those of our system.

TDBU-PAR (top-down, bottom-up and parallelised) is the algorithm presented here running on a 4 core system. To evaluate the impact of parallelism on runtimes, we also computed runtimes for a sequential version of the same algorithm (**T**DBU-SEQ). In **T**DBU-SEQ, daughter subtrees (processes) of the input dependency tree are processed sequentially.

Table 1 shows the runtimes for the three surface realisation algorithms **B**ASELINE, **T**DBU-SEQ and **T**DBU-PAR with varying sizes of sentences. For the TDBU algorithms, the n-gram filtering is set to 10 that is, for each local input tree, the 10 best n-grams are passed on. We split the data into 4 sets according to the input length where the input length is the number of nodes (or words) in the input dependency tree. The average number of words in a sentence in the first set $S(0-5)$ is 4, in the second set $S(6-10)$, 7, in the third set $S(11-20)$, 15, and in the final set $S(All)$ (all lengths), 17. The maximum length of a sentence in the final set $S(All)$ is 74. To make comparisons between **B**ASELINE, **T**DBU-SEQ and **T**DBU-PAR possible, the maximum arity of words present in the input dependency trees is set to 3 (because BASELINE mostly fails on input containing nodes with higher arity).

Algorithm	Sentences (Length L)							
	$S(0-5)$		$S(6-10)$		$S(11-20)$		$S(All)$	
	Total	Succ	Total	Succ	Total	Succ	Total	Succ
	1084	985	2232	1477	5705	520	13661	2744
BASELINE	0.85	0.87	10.90	10.76	110.07	97.52	–	–
TDBU-SEQ	1.49	1.63	2.84	3.64	4.36	6.03	4.52	3.18
TDBU-PAR	1.53	1.66	2.56	3.28	2.66	4.14	2.57	2.78

Table 1: Comparison between generation times (seconds)

BASELINE turns out to be faster than **T**DBU-PAR and **T**DBU-SEQ for sentences of smaller length (≤ 5). It can be explained because of the parallelism and the multiprocessing overhead. But **T**DBU-PAR and **T**DBU-SEQ leaves behind **B**ASELINE for longer sentences. For input longer than 10, the simple **B**ASELINE algorithm times out whereas **T**DBU-PAR remains stable. For $S(All)$, **T**DBU-PAR achieves a reasonable average of 2.57 seconds for all sentences (Total) and 2.78 seconds for successful sentences (Succ).

Table 1 does not show a big difference in performance between **T**DBU-PAR and **T**DBU-SEQ because the maximum arity of the input dependency trees is kept low (maximum 3). In Table 2, we split the data by arity whereby the dataset $S(i)$ consists of input dependency trees with maximum arity i. As can be seen, the difference between the two algorithms steadily increases with the arity of the input thereby demonstrating the impact of parallelism.

6.2 Coverage and Accuracy

The grammar and lexicon used to test the surface realisation algorithm presented in this paper are under development so that coverage and accuracy are still low. Table 3 shows the coverage and

Algorithm	Sentences (Arity)											
	$S(1)$		$S(2)$		$S(3)$		$S(4)$		$S(5)$		$S(6)$	
	Total	Succ	Total	Succ	Total	Succ	Total	Succ	Total	Succ	Total	Succ
	190	178	1218	964	3619	1039	5320	605	2910	137	1093	18
TDBU-SEQ	0.89	0.94	2.52	2.63	3.65	3.39	5.07	4.54	5.24	4.62	8.20	7.29
TDBU-PAR	0.97	1.03	2.35	2.50	2.63	3.10	2.91	3.77	2.86	3.88	3.09	4.76

Table 2: Comparison between generation times (seconds) with varying arities.

accuracy (on the covered sentences) results obtained for sentences of size 6 (S-6), 8 (S-8) and all (S-All). The dataset S-All differs from the dataset $S(All)$ discussed in previous section. S-All considers all sentences without any restriction over the maximum arity in the input dependency trees. S-All consists of 26725 sentences with the average length of 22 and the maximum length of 134. The maximum arity in these sentences varies from 1 to 18 with an average of 4.

Data Type	Total	Coverage (#)		Coverage (%)	BLEU Score
		Covered	Uncovered		
S-6	3877	3506	371	90.43	0.835
S-8	3583	3038	545	84.79	0.800
S-All	26725	10351	16374	38.73	0.675

Table 3: Coverage and Bleu Scores for covered sentences.

As can be seen coverage markedly decreases for longer sentences. Error mining on this data indicates that failure to generate is due mostly to complex sentence coordinations (e.g., verb coordination, gapping phenomenon) (Sarkar and Joshi, 1996) which could be very common in sentences of average length 22 in S-All. Other failure causes are inadequate treatments of multiword expressions and foreign words.

7 Conclusion

We presented a novel algorithm for surface realisation with lexicalised grammar which takes advantage of the input structure (a tree) to filter the initial search space both top-down and bottom up; and to parallelise processes. We evaluated this algorithm on large scale data and showed that it drastically reduces runtimes on this data when compared to a simple lexicalist approach which explores the whole search space.

As mentioned in section 3, the input data provided by the SR task differs from the flat semantic representations assumed by most existing surface realisers in that it displays a clear tree structure. The algorithm presented here makes use of that structure to optimize performance. In future work, we plan to investigate whether the hybrid top-down, bottom-up approach we developed to guide the SR search can be generalised to the graph structure of semantic representations.

Acknowledgments We would like to thank Laura Perez-Beltrachini for useful discussion on generation using the FB-RTG. We are grateful to the Generation Challenge SR Task organisers for providing us with the SR data and to Anja Belz and Mike White for providing us with the task evaluation scripts. The research presented in this paper was partially supported by the European Fund for Regional Development within the framework of the INTERREG IV A Allegro Project.

A Comparison of Syntactic Reordering Methods for English-German Machine Translation

Jiří Navrátil Karthik Visweswariah Ananthakrishnan Ramanathan
IBM Research
jiri@us.ibm.com, v-karthik@in.ibm.com, aramana2@in.ibm.com

ABSTRACT
We describe two methods for syntactic source reordering developed for English-German SMT. Both methods learn from bilingual data accompanied by automatic word alignments to reorder the source such that it resembles that of the target. While the first method is an extension of a parse-based algorithm and accommodates contextual triggers in the parse, the second method uses a linear feature-based cost model along with a Traveling Salesman Problem (TSP) solver to perform the reordering. Our results indicate that both methods lead to improvements in BLEU scores in both directions, English→German and German→English. Significant gains in human translation quality assessment are observed for German→English, however, no significant changes are observed in the human assessment for English→German.

KEYWORDS: Parse-based reordering, TSP, English-German SMT.

Proceedings of COLING 2012: Technical Papers, pages 2043–2058,
COLING 2012, Mumbai, December 2012.

1 Introduction

Language-specific word order differences have presented a long-standing challenge in the development of statistical machine translation (SMT) systems. Most mainstream SMT approaches do incorporate word order information, either implicitly (e.g., as part of word phrases), or explicitly, e.g., by means of lexicalized distortion models. However, challenges remain, particularly in modeling long-range word movement. Furthermore, certain language pairs, more than others, exhibit particularly demanding reordering patterns. One such pair is English-German - the focus of this work. With its long-range verb movement and its use of separated verb prefixes, German and English word ordering can induce movements spanning an entire sentence. Section 1.1 describes some of these phenomena more in detail.

Recent improvements in phrase-based SMT algorithms have included source word reordering so as to resemble its target word order. A reordering typically uses rules obtained either manually, e.g., (Niessen and Ney, 2001; Collins et al., 2005), or derived from data by automatic means, e.g., (Xia and McCord, 2004; Rottmann and Vogel, 2007; Zhang et al., 2007; Crego and Habash, 2008; Niehues and Kolss, 2009).

In this paper we further develop two methods first introduced in (Visweswariah et al., 2010, 2011) with the aim to address specific issues arising in English↔German SMT. In particular, we extend the parse-based reordering introduced for a variety of language pairs in (Visweswariah et al., 2010) by creating rules capable of capturing essential contextual triggers in the parse tree hierarchy. For the second method we describe refinements of the feature-based reordering (Visweswariah et al., 2011), which corresponds to solving a Traveling Salesman Problem (TSP). While the method described in (Visweswariah et al., 2011) carries over and performs well for German→English, for English→German we propose a method to integrate the English parse into the reordering model focusing on the issues in English→German reordering. We compare the performance of both methods against various baselines and across multiple evaluation domains for both English→German and German→English directions. Our results indicate that both methods achieve significant improvements in translation quality, as measured by automatic metrics, and some improvements when judged by human reviewers.

Following the description of the methods and refinements in Section 2 we discuss related work in Section 3. Experimental evaluation, results, and discussion are presented in Section 4.

1.1 German Word Order

Despite their common heritage, German and English word order can differ rather dramatically. Most frequently such differences relate to verbs, particularly to verb groups, including auxiliary, main verbs, and their participles. Verb movements tend to span large portions of the sentence, thus presenting a considerable challenge to basic reordering models in standard SMT systems.

Word ordering can often be identical to that in English, as shown in an example in Figure 1. At the same time, an addition of a modal verb in the same example sentence triggers a movement of the main verb to the end of the clause, as shown in Figure 2. Similarly distant verb movements also occur in subordinate clauses. Besides verb movement, word order may vary in other parts of the sentence, including negation, adverbial phrases, etc.

2 Data-Driven Syntactic Reordering

We use data-driven syntactic reordering to mitigate some of the differences in word order mentioned above. Specifically, we investigate two methods of syntax-based reordering: (1) an

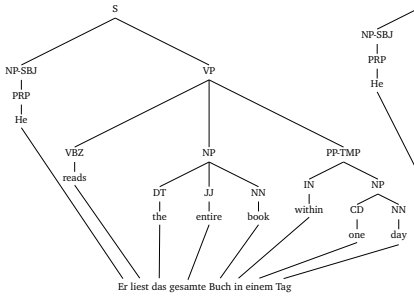

Figure 1: A single verb sentence with monotone ordering pattern

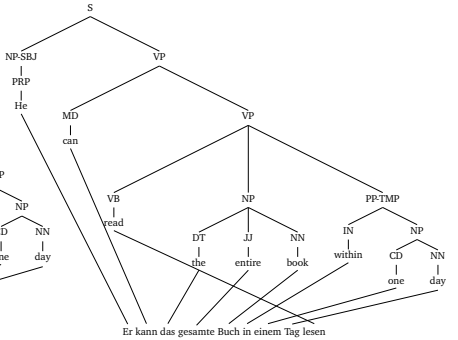

Figure 2: A modal verb triggering a reordering pattern

extension of the parse-based word reordering introduced in (Visweswariah et al., 2010), and (2) feature-based reordering model described in (Visweswariah et al., 2011). Both methods use a bilingual corpus, automatic word alignments, and some source syntax information (parse tree in the first case, POS in the second) to train a reordering model. In both cases the objective is to minimize a measure of an overall distortion observed in the word alignments. We apply the reordering to source sentences in both the training and the test of the system as part of preprocessing.

2.1 Parse-Based Reordering

Visweswariah et al. (Visweswariah et al., 2010) described reordering of each sentence using a set of rules applied to the parse tree of the source sentence. The goal of these rules is to make the source word order resemble the expected target order. Given automatic word alignments and source parses, the rules are inferred from a training corpus.

The parse-based model is probabilistic in nature. Given a source constituency tree, S, it aims to assign the highest probability $P(T|S)$, among all possible reordered trees T, to a tree with its constituents reordered so as to reflect the expected target word order. The model restricts itself to trees that can be obtained only by permuting child nodes of any of its non-terminal constituents, and it makes a simplifying assumption that the children of a node are permuted independently of any other node in the tree. Thus, the overall probability simplifies to a product of constituent-level permutations:

$$P(T|S) = \prod_{n \in I(S)} P(\pi(d_n)|d_n) \quad (1)$$

where n denotes a node, $I(S)$ the set of all non-terminal (interior) nodes of the tree, d_n are the children of the node n, and π is the permutation function. Given the word alignment information, each node in d_n, is permuted based on the individual average *target* position. The average target position is calculated using the alignments $a(w)$ as follows:

$$tpos(n) = \frac{1}{|D(n)|} \sum_{w \in D(n)} a(w) \quad (2)$$

whereby $D(n)$ denotes the set of all descendant leaves (words) of a node n, and $a(w)$ is a function returning the position index of a source word w in the target translation. Each such permutation is recorded over the entire training corpus $\mathscr{C}$ and its permutation probabilities are then estimated to maximize the likelihood $\prod_{S \in \mathscr{C}} P(T|S)$:

$$P(\pi(d_n)|d_n) = \frac{count(\pi(d_n))}{count(d_n)} \tag{3}$$

As already pointed out in (Visweswariah et al., 2010), the above model bears several weaknesses. Besides generic issues regarding parser and alignments accuracy, the assumed independence of a permutation from other nodes (context) can be harmful. This turns out to be particularly true for German. As in the example in Figure 2, a full verb following a modal verb is typically parsed as a VP child node of a VP modal node. In this example the main verb should be placed at the end of the clause due to the presence of the modal, while in the absence thereof typically no reordering occurs (Figure 1). The lack of such distinction in the simplified $\pi(d_n)$ renders extracted rules indiscriminative. The authors reported improvements in translation quality for several languages (French, Spanish, Hindi) with the exception of German where no gains over an unreordered baseline were observed highlighting this weakness as a probable cause.

We propose extending the permutation probability function to include contextual information from S. In this extension each permutation probability is now a function of the permutation node set d_n and a context node subset $\phi_n \in S$:

$$P(T|S) = \prod_{n \in I(S)} P(\pi(d_n)|d_n, \phi_n) \tag{4}$$

Although the subset ϕ can be arbitrary we choose ϕ_n to constitute subtrees of S that are related to d_n via its parental lineage as well as its siblings. For instance, in the Figure 2 this relation would be the subtree including the non-terminals (top-down): S, VP, MD, VP, VB, NP, and PP-TMP. More specifically, in our experiments we investigated ϕ to include the parent of d_n, i.e n, siblings of n (both to its left and right), as well as k levels of grand parents (with k varying between 1 and 5). We relaxed the subtree matching by assuming "wildcards" between any of the siblings. This increases the rule recall for parses with minor variations from the observed patterns (in other words, we apply a *tree grep* instead of a strict tree match).

The probability of a permutation is estimated as in Eq. (3) with observation counts now collected with respect to the context ϕ of each observed permutation. A permutation rule pruning is performed based on an absolute observation count (in our case any rule with less than 20 observations) as well as a significance threshold (count must be 20% higher relative to the next competing permutation). We only retain the best permutation (in the maximum likelihood sense) for a unique pattern (ϕ, d_n), thus, a final rule now consists of a left- and right-hand side: $(\phi, d_n) \rightarrow \pi(\phi, d_n)$. Reusing the example in Figure 2 the best applicable rule actually extracted from the training corpus is:

```
[S [VP MD [VP VB NP PP-TMP VP] VP] S] --> 1 2 0
```

which enacts a move of the verb "read" (VB) to the end of the sentence and resolves the crossing alignment shown in Figure 2.

Given a parse tree all matching rules are applied recursively (matched always against the original parse) to create a new reordered tree.

2.2 TSP-Based Reordering

In (Visweswariah et al., 2011) a reordering model was proposed that does not require a parser, and learns to reorder words based on reference reorderings derived from hand alignments. The model assigns pairwise costs $c(m,n)$ for word w_m immediately preceding word w_n. The cost of a reordering permutation π for a sentence $\mathbf{w}$ is the sum of these pairwise costs:

$$C(\pi|\mathbf{w}) = \sum_i c(\pi_i, \pi_{i-1}).$$
